Abstract: The direct conversion of fibroblasts to induced dopaminergic (iDA) neurons and other cell types demonstrates the plasticity of cell fate. The low efficiency of these relatively fast conversions suggests that kinetic barriers exist to safeguard cell type identity. Here we show that suppression of p53, in conjunction with cell cycle arrest at G1 and appropriate extracellular environment, markedly increase the efficiency in the transdifferentiation of human fibroblasts to iDA neurons by Ascl1, Nurr1, Lmx1a and miR124. The conversion is dependent on Tet1, as G1 arrest, p53 knockdown or expression of the reprogramming factors induces Tet1 synergistically. Tet1 knockdown abolishes the transdifferentiation while its overexpression enhances the conversion. The iDA neurons express markers for midbrain DA neurons, support dopaminergic transmission, and extend arborization and synaptic connections when grafted in rat brains. Our results suggest that overcoming these kinetic barriers may enable highly efficient epigenetic reprogramming in general and will generate patient-specific midbrain DA neurons for Parkinson's disease research and therapy.

Title: Highly efficient derivation of human midbrain neuroepithelial stem cells and dopaminergic neurons from pluripotent stem cells by mimicking embryonic midbrain development

Authors: *K. HEMMER, J. C. SCHWAMBORN;
Developmental and Cell. Biol., Luxembourg Ctr. For Systems Biomedicine, Belvaux, Luxembourg

Abstract: Parkinson´s disease (PD) is the second most common neurodegenerative disorder characterised by non-motor symptoms like hyposmia or depression, and motor symptoms like resting tremor, bradykinesia, akinesia, rigidity and postural instability. The progressive loss of midbrain dopaminergic neurons (mDANs) of the substantia nigra pars compacta is the main pathology causing these motor symptoms. Conventional therapies only achieve temporary symptomatic relief. However, no neuroprotective treatment exists yet that halts or even counteracts the progression of the disease. Consensus is growing that this failure of bench-to-bedside translation can be attributed to the lack of appropriate preclinical PD models. The generation of patient-specific mDANs offers an attractive tool to model PD *in vitro*. This novel model can be used to further understand disease processes, and to screen for compounds for neuroprotective therapies. For such approaches it is a requirement that *in vitro*-derived mDANs are as similar as possible to their *in vivo* counterparts. This similarity includes the expression of midbrain specific markers, electrophysiological functionality, morphology, and dopamine production. During embryonic development, the patterning of mDANs is a carefully balanced process that is defined by a precise timing of inhibiting or inductive cues produced by organising centres. In the here described project, we established a novel highly efficient mDANs differentiation protocol by modulating developmentally regulated pathways, similar to the *in vivo* mDANs differentiation process. In our novel protocol human induced pluripotent stem cells

(iPSCs) are regionalized toward a midbrain neuroepithelial stem cell (mNESCs) fate by mimicking sonic hedgehog (SHH) signalling, wingless-type MMTV integration site (WNT) signalling and the fibroblast growth factor (FGF) pathway. This derivation process is conducted under hypoxic conditions. The thereby obtained mNESCs are able to self-renew and can be efficiently differentiated into tyrosine hydroxylase (TH) positive dopaminergic neurons. Moreover, immunostainings of differentiated neurons reveal the expression of the midbrain markers forkhead box A2 (FOXA2), LIM homeobox transcription factor 1 (LMX1), nuclear receptor subfamily 4 group A member 2 (NR4A2, also known as NURR1), and engrailed 1 (EN1). We conclude that our novel protocol for *in vitro* derivation of midbrain specific dopaminergic neurons mimics the according *in vivo* developmental process. This new protocol represents an attractive starting point for the utilization of patient-specific cells for *in vitro* modelling of PD.

Title: Developing iPSC-derived neurons for studying the regulation of SNCA expression by miRNAs in relation to Parkinson's and Dementia with Lewy body diseases.

Authors: *L. TAGLIAFIERRO, M. W. LUTZ, O.-C. GLENN, O. CHIBA-FALEK; Neurol., Duke Univ. Hlth. Syst., Durham, NC

Abstract: Synucleinopathies are a group of neurodegenerative diseases that share a common pathological lesion of intracellular aggregates, named Lewy Bodies, composed mainly of α-synuclein protein encoded by the *SNCA* gene. Genetic studies have implicated *SNCA* in the etiology of these diseases. This study focuses on two diseases in this group: Parkinson's Disease (PD) and Dementia with Lewy Bodies (DLB). Both are characterized by α-synuclein aggregates in the neurons, however they have distinct characteristics with respect to the cell type containing the aggregates and the predominantly affected brain region. Specifically, dopaminergic neurons are primarily affected in PD whereas DLB is defined by aggregates in cholinergic neurons. Our goal is to explore common and distinct regulatory mechanisms of *SNCA* gene expression in the

context of these pathologies. It has been suggested that *SNCA* expression levels are critical for the development of synucleinopathies. Gene expression levels are affected by different factors: genetic, epigenetic, environment, gender, and age. Our lab aims to explore the genetic regulatory mechanisms underlying *SNCA* expression levels that include *cis* and *trans*-acting factors. This work focuses on the regulation of SNCA by microRNAs (miRNA). Towards this goal, we established a model system of induced Pluripotent Stem Cell (iPSC)-derived neurons from a subject with normal Karyotype and from a patient with *SNCA*-triplication. These two iPSC lines were differentiated into dopaminergic and cholinergic neurons to model PD and DLB, respectively, and the analysis of miRNAs was performed for each neuronal type at four differentiation stages: iPSCs, Neural Precursor Cells, final neurons, and aged neurons. miRNA are known to regulate gene expression via interactions with Untranslated Regions (UTRs). A computational analysis using TargetScan identified five miRNA binding sites in *SNCA* 3'UTR. Evaluation of the miRNA expression profiles revealed distinctive pattern between the dopaminergic and the cholinergic neurons and along the differentiation stages of each neuronal type. *SNCA* mRNA levels have been measured at all differentiation points of the dopaminergic and cholinergic neurons, and were correlated with the miRNA profiles. Experiments of genome editing using CRISPR/Cas9 technology are underway to evaluate how *cis*-variants modulate *SNCA* expression via their interactions with the *trans*-acting factors. In conclusion, we developed an isogenic iPSC-based model system to better understand the *cis* and *trans* acting factors that contribute to the regulation of *SNCA* expression in the context of PD and DLB.

Title: Multielectrode array platform to study long-term potentiation in human induced pluripotent stem cell-derived neuronal networks

Authors: *S. BIESMANS, S. HINCKLEY, A. BANG;
CPCCG Screening Ctr., Sanford Burnham Prebys Med. Discovery Inst., LA Jolla, CA

Abstract: Numerous neurological conditions including neurodegenerative and psychiatric disorders such as Alzheimer's disease and clinical depression are characterized by synaptic dysfunction and cognitive impairment. Long-term potentiation (LTP) is a persistent

strengthening of synapses between neurons that is considered to be one of the major cellular mechanisms underlying memory and learning. Disease modeling and drug discovery approaches would benefit tremendously from human cell-based platforms to study LTP in disease. Human induced pluripotent stem cells (hiPSC) offer such a system in that they circumvent issues of species specificity, are scalable, and can carry complex genetic backgrounds, which is especially important for modeling diseases with high heritability. Here we present a platform to study LTP in neuronal networks comprised of hiPSC-derived neurons. Using either iCell® DopaNeurons or in-house generated hiPSC-derived cortical neurons co-cultured with human primary astrocytes, we developed a procedure that supports neuronal network formation on 48-well multielectrode arrays. Analysis of spontaneous electrical activity shows that an initial phase of primarily single spike firing is followed by synchronized bursting indicating development of functional neuronal networks. At 4 weeks after plating, 84% of the electrodes recorded spontaneous synchronized bursting events wherein most of the neurons in the network spiked together. At this point, the cultures were exposed to forskolin and rolipram to trigger LTP by increasing intracellular cyclic adenosine monophosphate levels, resulting in a significant increase in the number of network bursts that lasted up to 7 days after washing off the drugs. Long-lasting maintenance of LTP requires *de novo* gene expression and protein synthesis. Ongoing studies include expression analyses of transcription factors and signaling molecules that regulate enduring LTP. In conclusion, we have developed a robust, medium-throughput platform to study LTP in hiPSC-derived neuronal networks. This technology will allow for disease modeling and drug screening of disease-relevant cell types on patient-specific genetic backgrounds.

Title: Survival and development of different subtypes of neural progenitor cells transplanted into jaundiced and non-jaundiced rat brain

Authors: ***F.-C. YANG**[1], S. M. RIORDAN[4], M. WINTER[2], L. GAN[1], J. L. VIVIAN[3], J. A. STANFORD[1,2], S. M. SHAPIRO[4];

Abstract: Neonatal hyperbilirubinemia targets specific brain nuclei and can lead to kernicterus. One of the most vulnerable brain regions is basal ganglia, especially the globus pallidus (GP). A debilitating symptom of kernicterus associated with GP damage is dystonia. Stem cell transplantation has been suggested to effectively improve motor function in basal ganglia-related diseases such as Parkinson's disease and Huntington's disease. We believe that targeting affected brain regions with neuronal stem cells is a promising therapeutic approach for treating dystonia in kernicterus. It is unknown, however, how elevated bilirubin levels in the brain will affect neural progenitor cell survival and functional development. In this study, we injected different subtypes of neural progenitor cells (resemble excitatory spinal cord interneurons or inhibitory basal ganglia neurons) into the basal ganglia of jaundiced (jj) Gunn rats and their nonjaundiced (Nj) littermates and compared cell survival, fiber outgrowth, and cell properties. Each animal received 10,000 neural progenitor cells (2.5µl) injected unilaterally at P20. Animals were perfused at P43 and 30 µm of brain sections through the injection site and the GP were collected for immunohistochemical (IHC) analyses for STEM121 (human cells), Ku80 (human cell nucleus), and hSYP (human-specific synaptophysin) expression. Our preliminary results indicated, 3 weeks after transplantation, neural precursor cells survived and migrated outside the injection sites in the striatum of both jj and Nj rats. Grafted neurons frequently formed abundant neurites. Some neurites extended toward the GP or cerebral cortex. Very long fibers traveling along the corpus callosum were also observed. However, there were only low levels of hSYP-ir staining identified on/nearby the outgrowth fibers of both jj and Nj brains, suggesting that synaptogenesis is impaired or still developing. We conclude that neural precursor cells not only survive within the basal ganglia of jaundiced rats, but they also form neurites. These results support the feasibility of neural stem cell injections for the treatment of kernicterus. Future investigation into the use of these cells as a possible treatment of dystonia due to kernicterus will focus on alternative stem cells lines with larger percentages of GABAergic and cholinergic neurons to more closely mimic the major cell types of the GP.

Title: Direct induction of human motor neuron progenitors from peripheral blood of patients with primary lateral sclerosis

Authors: *T. WANG, M. MEDYNETS, M. K. FLOETER, A. NATH;
NINDS/NIH, Bethesda, MD

Abstract: Primary lateral sclerosis (PLS) is a neuromuscular disorder characterized by progressive weakness of voluntary muscles caused by the chronic degeneration of upper motor neurons in the central nervous system. The pathogenesis of PLS is largely unknown and its study is hindered by the lack of access of patient specific motor neurons which is pivotal for constructing in vitro disease models. Recent developments in the field of cell transformation make it possible to derive neurons from induced pluripotent stem cells which can be generated by transfecting other somatic cells with Yamanaka factors. However, generating iPSC is a time and labor demanding process and requires expertise in the field. We recently reported generating neural stem cells directly using peripheral blood cells which are clinical available. Here we aimed to directly generating motor neuron progenitor cells from clinical blood samples which can provide a large quantity of motor neurons for the in vitro study of motor neuron disorders. By transfecting enriched CD34+ cells from patient blood samples with Sendai virus containing Yamanaka factors (Oct4, Sox2, C-Myc and Klf4), we collected cells after five days of culture and transferred them to motor neuron progenitor cells media for another two weeks to make neural spheres. For motor neuron differentiation, the resulting spheres were then cultured on matrigel coated plates in motor neuron differentiation media for another 10 days. The resulting spheres and neurons were further immunostained for neural progenitor and motor neuron markers such as Nestin, HB9, ISL-1 and ChAT. We found that nestin-positive neural spheres were formed as early as one week after the neural induction and HB9 and ISL-1 positive spheres were formed two weeks after. These neurospheres were differentiated into ChAT positive motor neurons when cultured in motor neuron differentiation media. The whole process takes about a month and we believe this is a convenient and the fastest technique to generate motor neurons directly form clinical blood samples. The generated motor neuron progenitors could be very useful for in vitro modeling of motor neuron diseases such as PLS and potentially for developing neural transplantation therapies.

Title: Increased susceptibility of machado joseph disease patient-specific neurons to stress

Authors: *J. JATHO-GRÖGER, K. KLEINSIMLINGHAUS, D. POPPE, J. LADEWIG, P. KOCH;
Inst. of Reconstructive Neurobio., Bonn, Germany

Abstract: Machado Joseph Disease (MJD)/ Spinocerebellar Ataxia Type 3 (SCA3) belongs to the group of polyglutamine (polyQ) expansion disorders and is the most prevalent autosomal dominantly inherited cerebellar ataxia worldwide. The cause of this progressive neurodegenerative disease is an expansion of a CAG trinucleotide repeat in exon 10 of the MJD1 gene leading to an extended tract of repeated glutamines (polyQ) in the resulting Ataxin3 protein (ATXN3). Recent data suggest that either conformational changes of the expanded ATXN3 protein and/or a loss of free available ATXN3 due to recruitment of ATXN3 into aggregates leads to the dysregulation of multiple cellular pathways such as ubiquitination or transcriptional regulation. Here we used induced pluripotent stem cells (iPSCs) to study the influence of expanded and/or lost ATXN3 on gene expression in patient-specific neurons. To that end we generated isogenic iPSC-derived neural stem cell lines, expressing either the normal (ATXN3cont), the expanded (ATXN3exp) or no ATXN3 (ATXN3ko) using CRISPR/Cas9-mediated gene editing. By transcriptional profiling of neurons generated from these lines we identified several genes, which were dysregulated in ATXN3exp and ATXN3ko neurons. Among those we identified a cluster of genes, which was significantly downregulated in ATXN3exp and ATXN3ko neurons compared to their isogenic controls. Functionally, these genes are important regulators of cell homeostasis and participate in an array of protective stress responses. Consequently, we found that ATXN3exp and ATXN3ko neurons are more susceptible to several types of cellular stress. Our findings support that ATXN3 has an important role in regulating the cellular stress response and that an increased susceptibility towards stress contributes to the pathogenesis of Machado Joseph Disease.

Title: Identification of therapeutic targets and pathogenic mechanisms for C9orf72 ALS using phenotypic chemical screening

Authors: *J. ICHIDA, Y. SHI, S. LIN, Y. LI, K. STAATS, E. SON;
USC, Los Angeles, CA

Abstract: Expansion of a GGGGCC repeat in *C9orf72* recently emerged as the most common cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD), making it a key therapeutic target. However, the neurodegenerative mechanisms underlying *C9orf72* ALS/FTD are unclear, limiting the identification of therapeutic strategies. To identify potential therapeutic targets and delineate pathogenic mechanisms, we established a model of *C9orf72* ALS using induced motor neurons (iMNs) generated by transcription factor-based reprogramming and performed a chemical genetic screen using neuron survival as a readout. *C9orf72* patient iMNs, but not induced dopaminergic neurons, undergo accelerated degeneration (3 patients, 3 controls, p=.002) and possess the hallmark pathology of *C9orf72* ALS. Removing the repeat expansion CRISPR/Cas9 editing fully rescues iMN survival. Thus, *C9orf72* iMNs faithfully model ALS disease processes. From a screen of 1000 bioannotated small molecules, we identified three classes of molecules that rescue *C9orf72* patient iMN survival without affecting the survival of controls, as well as one class that specifically accelerates *C9orf72* iMN degeneration. We find that at least one class of therapeutic compounds rescues *C9orf72* iMN survival by reversing a defect in endocytosis that causes aberrant upregulation of glutamate receptors on iMNs. By restoring proper glutamate receptor homeostasis, which is maintained in neurons through endocytosis, this class of molecules prevent *C9orf72* iMN degeneration by excitotoxicity, which we find to be the major cause of neurodegeneration in our model. Verifying the relevance of these findings to patients, glutamate receptors are significantly upregulated on motor neurons in postmortem tissue from both patients and *C9orf72* mutant mice, and neurons in *C9orf72* mice undergo hyperactivation when exposed to glutamate *in vivo*. Thus, our results highlight the importance of early endosomal trafficking in *C9orf72* ALS pathogenesis, and identify several potential therapeutic targets.

Title: Single-cell detection of secreted Aß and sAPPα secreted from human iPSC-derived neurons and astrocytes

Authors: ***M.-C. LIAO**[1,2], C. MURATORE[2], T. GIERAHN[3], S. SULLIVAN[2], P. SRIKANTH[2], P. DE JAGER[2], J. LOVE[3], T. YOUNG-PEARSE[2];

Abstract: Secreted factors play a central role in normal and pathological processes in every tissue in the body. The brain is composed of a highly complex milieu of different cell types, and few methods exist that can identify which individual cells in a complex mixture are secreting specific analytes. By identifying which cells are responsible, we can better understand neural physiology and pathophysiology, more readily identify the underlying pathways responsible for analyte production, and ultimately use this information to guide the development of novel therapeutic strategies that target the cell types of relevance. We present here a method for detecting analytes secreted from single human iPSC-derived neural cells, and have applied the method to measure Aβ and sAPPα, analytes central to Alzheimer's disease pathogenesis. Through these studies, we have uncovered the dynamic range of secretion profiles of these analytes from single iPSC-derived neuronal and glial cells, and have molecularly characterized subpopulations of these cells through immunostaining and gene expression analyses. In examining Aβ and sAPPα secretion from single cells, we were able to identify previously unappreciated complexities in the biology of APP cleavage that could not otherwise have been found by studying average responses over pools of cells. This technique can be readily adapted to the detection of other analytes secreted by neural cells, which would have the potential to open new perspectives into human CNS development and dysfunction.

Title: Transcriptional comparisons of motor neuron cellular models reveal gene networks associated with maturation, age, and ALS

Authors: *R. HO, S. SANCES, C. N. SVENDSEN;
Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Modeling Amyotrophic Lateral Sclerosis (ALS) with human induced pluripotent stem cells (iPSCs) or with transgenic mice aims to reenact embryogenesis, maturation, and aging of motor neurons (MNs) *in vitro*. Studies have identified molecular pathways affected by ALS conditions in both model systems as well as in post-mortem human MNs. However, the extent to which mouse ALS models faithfully recapitulate pathways observed in human MNs has not been closely examined. Additionally, the maturity of MNs grown *in vitro* compared to MNs *in vivo* remains largely unaddressed; therefore, it is unclear to what extent this *in vitro* system captures critical aspects of MN development and molecular signatures associated with ALS. We compared transcriptomes among human iPSCs, iPSC-derived MNs (iMNs), fetal MNs, and adult MNs, as well as orthologous tissues from mice. Principal component analysis produced a maturation scale revealing that iMNs were more similar to fetal tissue than to adult MNs. Additionally, we resolved gene networks and pathways associated with MN maturation and aging. During maturation, expression increased for axonogenesis, myelination, synaptic transmission, and immune response pathway genes and expression decreased for translation, mitochondrial electron transport, and DNA repair pathway genes. During aging, expression increased for proteasomal genes and, interestingly, expression decreased for immune response and amyloid catabolism genes. These networks enriched for familial ALS genetic variants and were also affected in familial as well as sporadic ALS MNs. Based on these principal component and gene co-expression network analyses, we developed a panel of twenty key genes that can accurately assess either the maturation or disease state of cell or tissue samples. Genetic and

epigenetic analysis of regulatory features associated with co-expression networks revealed candidate pre- and post-transcriptional regulators of co-expressed genes that could be targeted to affect MN development, maturation, and disease. Lastly, we demonstrate that the global expression of orthologous genes involved in spinal cord MN fetal development and maturation are largely parallel between human and mouse systems, and gene co-expression networks associated with maturation are well-conserved between the two species. This analysis thus provides a more sensitive interrogation of gene-to-gene expression relationships underlying human and mouse spinal cord MN physiology. Altogether, our findings suggest that developing strategies to further mature and age iPSC-derived MNs will provide more effective iPSC models of ALS.

Title: C9orf72 als patient and control ipsc line-derived cortical neurons and astrocytes reveal diminished network activity when co-cultured with c9orf72 patient-derived astrocytes

Authors: *V. J. GARCIA, G. M. THOMSEN, D. RUSHTON, K. WU, R. H. BALOH, C. N. SVENDSEN;
Cedars-Sinai, West Hollywood, CA

Abstract: Amyotrophic lateral sclerosis (ALS) is characterized by the loss of neurons in the cortex, brain stem and spinal cord, and also by the malfunction of astrocytes. Only ~10% of ALS diagnoses are attributed to a genetic mutation. A recently discovered mutation on chromosome 9 open reading frame 72 (C9orf72) has been connected to approximately 40% of familial ALS and 9% of sporadic ALS disease instances. This novel mutation provides a valuable opportunity to investigate ALS disease mechanisms. Here, we explored the physiology of astrocyte and cortical neuron co-cultures that were differentiated from C9orf72 patient-derived induced pluripotent stem cell (iPSC) lines or from control iPSC lines. Using microelectrode array, we evaluated combinations of disease or control astrocyte and neuron co-cultures, and found that astrocytes derived from control iPSC lines promote healthier network activity in both control and C9orf72-derived neurons, when compared to diseased astrocytes or neurons alone. Using patch-clamp, we

describe intrinsic, physiological properties of diseased astrocytes and cortical neurons. Further, we use two C9orf72 isogenic lines to evaluate the rescue of disease phenotypes.

Title: Functional maturation and *In vitro* disease modeling of human pluripotent stem cell-derived retinal ganglion cells

Authors: ***J. S. MEYER**[1], S. K. OHLEMACHER[2], C. M. FLIGOR[2], A. SRIDHAR[2], Y. XIAO[3], T. R. CUMMINS[4];
[1]Dept. of Biol., [2]Biol., IUPUI, Indianapolis, IN; [3]Stark Neurosciences Res. Inst., [4]Pharmacol. and Toxicology, Indiana Univ., Indianapolis, IN

Abstract: Retinal ganglion cells (RGCs) play an essential role in transmitting visual information from the eye to the visual thalamus in the brain. They are also the primary cell type affected in traumatic retinal injuries as well as optic neuropathies. Human pluripotent stem cells (hPSCs) provide an attractive source of cells that can be used for patient-specific cell replacement therapies, drug screening, and disease modeling. However, little is known about the functional maturation of these hPSC-derived RGCs. As such, the development of these neurons from hPSCs was evaluated over time, and methods in which to influence their maturation and functionality were tested. hPSCs were differentiated toward a neural lineage in a stepwise fashion as previously described, yielding highly enriched populations of optic vesicle-like neurospheres. Within 40 days of differentiation, presumptive RGCs differentiated in a temporally-appropriate manner and expressed a compliment of RGC-associated features as well as proper morphological features. In prolonged culture, subtypes of RGCs emerged over time, including melanopsin-expressing intrinsically photosensitive RGCs. The maturation of hPSC-derived RGCs in extended cultures was observed by extensive neurite outgrowth, and the development of synaptic-like structures was further examined by microscopy and

electrophysiology. Additionally, induced pluripotent stem cells (iPSCs) were generated from a glaucoma patient exhibiting an E50K mutation in the Optineurin (OPTN) gene, associated with degeneration of RGCs leading to normal tension primary open angle glaucoma. These cells were differentiated to an RGC fate and assayed for phenotypic differences compared to a wild type line of iPSCs. These results will facilitate the use of hPSC-derived RGCs to study the progression of neuronal development and degeneration, the development of drug therapeutics and the use of hPSC-derived RGCs for cell replacement therapies.

Title: Human iPSC-derived cortical neuron model of Huntington's Disease

Authors: ***V. B. MATTIS**[1], D. RUSHTON, 90048[2], S. YOUNESI[2], C. TOM[2];
[1]Cedars-Sinai, West Hollywood, CA; [2]Cedars-Sinai, Los Angeles, CA

Abstract: Induced pluripotent stem cell (iPSC) models of Huntington's disease (HD) provide an opportunity to study the mechanisms underlying disease pathology in patient tissues relevant to disease. These human-based studies are critical, due to inherent differences in cortical development and timing between humans and mice. The most prominent cell loss in HD patients occurs in cerebral cortex and striatum. In transgenic HD mice, the electrophysiological signaling has been shown to be altered even before behavioral phenotypes are present. We therefore differentiated HD and non-diseased iPSCs into functional cortical neurons by recapitulating developmental events. The HD iPSC-derived cortical neurons display key electrophysiological and immunocytochemical phenotypes as compared to their non-diseased counterparts.

Title: Infiltrating T lymphocytes reduce myeloid phagocytosis activity in synucleinopathy model

Authors: *A. SOMMER[1], T. FADLER[1], E. DORFMEISTER[1], A.-C. HOFFMANN[2], W. XIANG[2], B. WINNER[1], I. PROTS[1];
[1]IZKF Junior Res. Group 3, [2]Inst. of Biochem., FAU Erlangen Nuremberg, Erlangen, Germany

Abstract: Synucleinopathies comprise a group of neurodegenerative diseases associated with abnormal accumulation of α-synuclein, among them Parkinson´s Disease (PD) is the most prominent. One of the key factors contributing to the progression of synucleinopathies is neuroinflammation. Besides activation of the innate immune cells (CNS myeloid cells), adaptive immune cells are also thought to be involved in the immune response. However, the role of the adaptive immune system, especially lymphocytes, in synucleinopathies like PD remains largely unclear. To investigate how lymphocytes impact synucleinopathies, human wild type α-synuclein (WTS) transgenic mice were crossed with mice lacking mature lymphocytes ($Rag2^{-/-}$) to answer the question. Using this *in vivo* model, we determined α-synuclein aggregation as well as numbers of the innate and adaptive immune cells in the midbrain of the central nervous system (CNS). Compared to WTS^{+} $Rag2^{+/+}$ mice, where T but not B lymphocytes infiltrated the CNS, decreased amounts of α-synuclein aggregates were found in WTS^{+} $Rag2^{-/-}$ mice lacking mature lymphocytes. Besides, the number of $Iba1^{+}$ CNS myeloid cells was not altered in presence of T lymphocytes, but we found increased frequencies of the $CD11b^{+}$ $CD45^{hi}$ population in the CNS, indicative of an increased number of infiltrated myeloid cells. Subsequently, the CNS myeloid cells were further classified according to their activation phenotype (M1 vs. M2) by gene and protein expression analysis. Interestingly, genes associated with the M1 myeloid phenotype were higher expressed in WTS^{+} $Rag2^{+/+}$ mice, whereas in the absence of lymphocytes in WTS^{+} $Rag2^{-/-}$ mice genes associated with anti-inflammatory M2 myeloid phenotype were upregulated. M1 myeloid cells are also known to perform less phagocytosis activity compared to the M2 phenotype. To proof, whether the presence of T or B lymphocytes might influence the phagocytic activity of the CNS myeloid cells, BV2 microglia were cultured with aggregated α-synuclein in presence or absence of T or B lymphocytes *in vitro.* In the presence of T but not B lymphocytes, significantly less α-synuclein was phagocytosed by BV2 microglia, further supporting the prevalence of the M1 phenotype in the presence of T lymphocytes. In conclusion, T lymphocytes strongly contribute to increased α-

synuclein pathology via modulation of the CNS myeloid cell function. In the presence of T lymphocytes, microglia phagocytosis of aggregated α-synuclein is reduced, which increases the severity of synucleinopathy.

Title: Creation of neural cell models of Gaucher disease type 2 from patient derived iPSC to study mechanisms of pathology.

Authors: *C. E. MCKINNEY, K. BAUMGARNER;
Genetics/Stem Cell Lab., Edward Via Col. of Osteo. Mediine, Spartanburg, SC

Abstract: More than half a century has passed since the enzymatic defect underlying Gaucher disease was appreciated. Yet, major questions regarding disease mechanisms driving pathogenesis remain. This is especially true for the neuropathic form where there are currently no effective therapies. The ability to reprogram human cells (for example; blood PBMCs and fibroblasts) to create human induced pluripotent stem cells (hiPSC) pioneered by Yamanaka has profound implications for studies of neurodegenerative disease and for applications in regenerative medicine. Here we describe neural cells derived from patient hiPSC to investigate pathologic mechanisms involved in neuronopathic Gaucher disease (GD2). This neural source material previously unavailable for study addresses the unmet, critical need to understand molecular mechanisms involved in driving neurodegeneration in Gaucher cells.
We obtained GD2 fibroblasts (Coriell Institute) where cell lines are L444P homozygotes or L444P compound heterozygotes. BJ control fibroblasts (ATCC) and control PBMCs from blood were also obtained. We created hiPSC lines from these sources by reprogramming with Yamanaka factors using a non-integrating Sendai virus carrier. Characterization of these hiPSC included mycoplasma screening, karyotyping and immunocytochemistry for pluripotent markers. *In vitro* differentiation shows these lines are capable of generating endoderm, mesoderm and ectoderm tissues. Digital droplet PCR (ddPCR) using cDNA from each GD2 and control line shows the original GD2 fibroblasts lines have decreased GBA1 (lysosomal glucocerebrosidase)

expression and a moderate increase in GBA2 (non-lysosomal glucocerebrosidase) expression when compared to controls. Using the novel GD2 and control hiPSC lines, we derived neural progenitor cells (NPCs) expressing the neuro-markers, SOX2, nestin and hSynapsin-EGFP. NPCs from each line were transformed into neurons by a defined growth medium containing supplements to drive differentiation. Endpoint PCR confirmed expression of neural biomarkers (e.g., NeuN, MAP2, β-tubulin III,) and ddPCR tracked the expression of non-lysosomal GBA2, lysosomal GBA1 and other lysosomal genes. Western blots and enzyme assays define the reduction of glucocerebrosidase presence and activity. Neural exosomes isolated from conditioned medium were characterized for exoproteins. We are beginning to investigate RNA cargo profiles in the neural exosomes. Using these neurons, we anticipate more clearly defining the pathogenesis of GD2 and creating a model to test therapeutic strategies for this inborn error of metabolism.

Title: Generation and characterization of retinal ganglion cells derived from human induced pluripotent stem cells

Authors: *J. C. HADERSPECK, K. ACHBERGER, S. LIEBAU;
Inst. of Neuroanatomy and Developmental Biol., Eberhard Karls Univ. Tübingen, Tübingen, Germany

Abstract: Visual impairments are a major health issue in people across all age groups and throughout the globe. Among these, retinal disorders are a leading cause for blindness, affecting mainly photoreceptors as the photosensitive layer of the eye, as well as retinal ganglion cells (RGCs) that form the optic nerve and transmit visual information from the retina to the brain. RGCs can be disrupted for a variety of different reasons, including inflammatory, traumatic, ischemic or hereditary reasons, resulting in partial or total loss of vision.Induced pluripotent stem (iPS) cells provide exciting new opportunities in the field of regenerative and personalized medicine. The capacity of iPS cells for unlimited self-renewal and their potential to differentiate into virtually every cell type of the human body has led to a steadily increasing number of protocols published that describe the molecular requirements for the respective differentiation processes. Although the human eye is a complex organ, with the retina alone consisting of at

least 5 main classes of neurons, it was shown that the development of this organ can now be recapitulated *in vitro.* Our group has successfully generated retinal organoids from human iPS cells, resembling an early developmental stage of optic vesicle-like structures and expressing markers for different retinal cell types. In addition, using a combined floating and adhesion protocol, we have generated RGCs with long axons from human iPS cells. RGC maturation and morphology are analyzed with the help of RGC-specific promoter constructs and by expression analysis of markers for RGCs at different stages. This source of RGCs can now be used to further investigate the development and maturation of the human retina and the optic nerve, as well as for disease modeling of retinal disorders. Using patient-derived somatic cells as starting material for reprogramming and subsequent differentiation into RGCs, we aim to use this model to elucidate RGC-associated disease phenotypes *in vitro*.

Title: Establishing phenotypes in human-IPSCs for stem cell therapy after white matter stroke

Authors: *J. A. MAZZITELLI[1], I. L. LLORENTE[1], J. CINKORNPUMIN[2], W. E. LOWRY[2], S. T. CARMICHAEL[1];
[1]Neurol., [2]Molecular, Cell, Developmental Biol., UCLA, Los Angeles, CA

Abstract: Approximately one quarter of all strokes in humans occur in white matter, and the progressive nature of white matter lesions often results in severe physical and mental disability. WMS is characterized by a significant loss of axons and oligodendrocytes, as well as a migration of astrocytes to the outside of the infarct area. This specific structural disruption and cell loss suggests potential targets for WMS therapies. Two human induced pluripotent stem cell (iPSC) lines were recently introduced as appealing cell sources for cell transplantation to repair neuronal networks disrupted by ischemic stroke: iPSC-neural precursor cells (NPCs) and iPSC-glial enriched progenitor cells (GEPs). iPSCs were derived from human dermal fibroblasts through ectopic expression of the transcription factors KLF4, OCT4, SOX2, and C-MYC. NPC differentiation was induced via addition of all-trans retinoic acid to iPSCs. GEP differentiation was induced by treating NPC cultures with an iron chelator (deferoxamine), resulting in activation of hypoxia inducible factor (HIF) and enhanced gliogenesis. In order to assess the phenotype of these iPSCs and thus determine their potential for cell transplantation therapy in

WMS, iPSC-NPCs and iPSC-GEPs were cultured in the presence of growth factors and in growth factor withdrawal and then stained for known neuronal and astrocytic markers at 15 days, 2 months, and 4 months. Cells were also stained for proliferation and pluripotency markers at 15 days, 2 months, and 4 months. Immunofluorescent staining at 15 days showed increased expression of the immature neuronal marker Doublecortin in iPSC-NPCs and immature astrocytic marker GFAP in iPSC-GEPs. Proliferation and pluripotency markers (Ki67, Pax6, Sox2) also showed increased expression in iPSC-NPCs and iPSC-GEPs at 15 days. At 4 months, iPSC-NPCs and iPSC-GEPs showed increased expression of mature neuronal (NeuN) and astrocytic (S100 Beta) markers, respectively. Both cell lines showed significant downregulation of proliferation and pluripotency markers (Pax6, Sox2) after 4 months. iPSC-NPCs and iPSC-GEPs display proper differentiation and determined neuronal and astrocytic fates, respectively, indicating their potential role in phenotype-specific cell transplantation therapies in WMS.

Title: Modeling Huntington's disease with medium spiny neurons directly reprogrammed from patient fibroblasts

Authors: *M. B. VICTOR, M. RICHNER, A. S. YOO;
Developmental Biol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Huntington's disease (HD) is an inherited neurological disorder that typically manifests in midlife and is characterized by two cellular hallmarks, the presence of misfolded and aggregated protein inclusions, and massive degeneration of striatal medium spiny neurons (MSNs). Human neurons derived from HD patient induced pluripotent stem cells (iPSCs) demonstrate lower resilience to cellular stressors, but do not exhibit mutant huntingtin protein aggregates. Here we show the capability of neurogenic microRNAs, miR-9/9* and miR-124, in

combination with striatum-enriched transcription factors, to efficiently convert fibroblasts from multiple patients with HD into MSNs that bear inclusion bodies (IBs) rich in amyloid-like filaments as detected by immunoelectron microscopy. Moreover, MSNs reprogrammed from HD patients also exhibit lower survivability in culture in comparison to cells reprogrammed from age- and gender-matched healthy controls. Interestingly, HD fibroblasts directly reprogrammed into cortical neurons instead of MSNs still exhibit IBs, yet with sustained survivability in culture. Our results suggest that contrary to neurons derived from induced pluripotent stem cells, directly reprogrammed neurons may be better suited for modeling late-onset diseases and that the faithful acquisition of specific neuronal-subtype identities is critical for disease modeling. Our microRNA-mediated approach to model neuronal subtype-specific vulnerabilities in HD may also prove to be advantageous in modeling other neurodegenerative disorders.

Title: Epigenetic profiling of *In vitro* generated midbrain dopamine neurons to study the role of mobile genetic elements in Parkinson's disease

Authors: N. L. HARING[1], M. P. SMIDT[1], *F. M. JACOBS[2];
[1]Swammerdam Inst. for Life Sci., [2]Swammerdam Inst. for Life Sciences, Fac. of Sci., Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: The multifactorial ethiology of Parkinson's disease (PD) and other neurodegenerative diseases implies the existence of master regulators that control the expression of gene groups involved in pathogenesis. There is an increasing body of evidence that put forward retrotransposons as potential key players in gene-regulatory pathways associated with neural development, aging, and disease. Retrotransposons are parasitic DNA sequences that shaped our genome over the course of evolution via their copy-and-paste strategy. Besides the mutagenic effects of retrotransposition events through insertion into coding sequences, mobile genetic elements can function as enhancers for nearby genes. Their activity is regulated via epigenetic repression recruited by KRAB zinc-finger proteins. Reduction of repressive histone marks and DNA methylation during aging could release the repression of retrotransposons, potentially

leading to abberant activation of genetic cascades underlying PD pathology.
In this study we profile the epigenetic landscape of human embryonic stem cell (hESC)-derived midbrain dopamine (mDA) neurons to unveil the epigenetic regulation of retrotransposons in the cell type that is specifically affected in PD. Subsequently, we model the epigenetic landscape of PD by chemically inducing DNA hypomethylation in hESC-derived mDA neurons to study the effects on retrotransposons activity and the genes in their close vicinity.
At the time of submission the study was still ongoing, results and conclusions will be presented at the poster.

Title: Multiparametric measurements of the effects of neural stem cells on mild and moderate traumatic brain injuries in mice using longitudinal magnetic resonance imaging

Authors: *R. C. BOGGS[1,2], L. WATTS[2], P. FOX[2], G. CLARKE[2], M. M. DAADI[1,2];
[1]Texas Biomed. Res. Inst., San Antonio, TX; [2]Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Traumatic brain injury (TBI) is a major cause of morbidity and mortality worldwide. In the general population, TBI poses a greater risk in athletes and military personnel making these groups particularly susceptible to TBI related ailments. Cognitive and functional deficits following TBI are often life altering and severely limits the quality of life in TBI patients. Direct mechanical damage causes neuronal and vasculature alterations that can lead to functional and structural changes in the blood vessels, gray and white matter that manifest as functional impairments like motor deficits, memory impairment, depression and anxiety. A prospect in reversing functional deficits associated with TBI is neural stem cell (NSC) transplantation, which has been used as a method of promoting brain repair by replenishing the damaged cell pool in several neurological disease models. NSCs have been shown to engraft with host tissue in animal models of brain injury and to promote plasticity and functional recovery. However, further studies are needed to bring these therapeutic approaches to the clinic. We have developed a TBI animal model for transplantation of NSCs to test neural repair of axonal injury, cerebral blood flow (CBF), reduction of lesion volumes and behavioral improvements. We used a controlled

cortical impact device to induce mild and moderate TBI in the left hemisphere of the cortex in adult CB57BL/6 mice. Magnetic resonance imaging (MRI) scans used are Diffusion Tensor Imaging (DTI) for Fractional Anisotropy (FA) and Apparent Diffusion Coefficient (ADC) maps, Arterial Spin Labeling CBF and Rapid Acquisition with Relaxation Enhancement (RARE) T_2 scans. ADC is used for early detection of ischemic brain injury and FA to evaluate damage to the white matter. RARE T_2 scans and T_2 maps can show the anatomy and size of the lesion, respectively, and CBF changes are predictive of the future progression of lesion volume. We used a battery of behavioral tests to assess motor and cognitive deficits and recovery. Behavioral data show increased anxiety, depression, and decreased motor coordination in TBI mice as seen using Light-Dark Box, Forced Swimming, Beam Walking, Cylinder, and Foot Fault Tests, respectively. MRI scans confirmed severity and location of lesion, diffusion and blood flow deficits using RARE-T_2, FA and ADC maps, and ASL scans, respectively. Our TBI model does increase anxiety and depressive behavior as compared to baseline with a reduction in motor coordination likely from hindering the right forepaw. ADC scans show a wider area of injury than T_2 while FA shows evidence of white matter damage.

Title: MRI guided delivery of neural stem cells into the CNS of nonhuman primates

Authors: K. MALLOY[1], G. CHOUDHURY[1], J. LI[2], A. TORRES[1], S. GUPTA[3], C. KANTORAK[3], T. GOBBLE[3], P. FOX[2], G. CLARKE[2], *M. DAADI[1];
[1]Texas Biomed, Southwest Natl. Primate Res., San Antonio, TX; [2]Univ. of Texas Hlth. Sci. Ctr. at San Antonio,, San Antonio, TX; [3]3MRI-Interventions, Irvine, CA

Abstract: Optimizing neural stem cell (NSC) delivery procedures is critical to the success of cell therapy. Unlike small molecules and growth or neurotrophic factors, cells are sensitive to their host microenvironment. Cell injection variables, such as flow rate, needle diameter, cell density, tissue porosity and mechanics, affect the penetration and dispersion of the cells into the target tissue and therefore, may compromise efficacy. In this study, we used magnetic resonance

imaging (MRI) to guide and accurately transplant NSCs into specific structures of the central nervous system (CNS). NSCs were labeled with the contrast agent Super Paramagnetic Iron Oxide (SPIO) nanoparticles, which visualizes the NSC grafts as hypointense regions on MRI. The injection parameter infusion speed and cannula diameter were initially established using a brain surrogate phantom gel model. The SPIO-labeled NSCs were injected into 0.6% agarose gel phantoms under real-time MRI to monitor the dispersion of the NSCs. The selected optimal injection parameters were used for the ClearPoint^{TM} MRI-guided delivery system into the putamen of baboon. A whole-brain 3D MRI series with ClearPoint Software established a 3D coordinate system. A cannula trajectory guide (SmartFrame^{TM}) with four MRI-sensitive fiducial markers was attached to the skull. The fiducial markers allowed the software to segment the SmartFrame^{TM} and determine the trajectory of the cannula. Iterative imaging was used to align the cannula trajectory with the target until there was less than 1 mm error between the desired target and cannula trajectory. Once the cannula trajectory was finalized, a burr hole was drilled at this location and the cannula loaded with SPIO-labeled NSCs was inserted through the guide into the brain. The injection was then initiated at 1μL/min and recorded in real-time with a TurboFlash series. A whole-brain 3D image series was acquired post-injection to visualize the graft. The post-injection MRI images confirmed that NSCs were successfully delivered to the putamen. The evidence suggests MRI guidance offers a safe, accurate and minimally invasive procedure to deliver cells to the CNS.

Title: Differentiation and transplantation of dopaminergic neurons derived from IPSC-LRKK2 in nonhuman primate.

Authors: *G. ROY CHOUDHURY[1], A. TORRES[1], G. YANG[1], M. M. DAADI[1,2];
[1]Texas Biomed. Res. Inst., San Antonio, TX; [2]Departments of Cell. & Structural Biol., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Parkinson's disease (PD) is a chronic progressive neurodegenerative disorder caused by the death of dopaminergic neurons in the substantia nigra pars compacta (SNc). The loss of dopaminergic neurons in the SNc results in a range of debilitating movement disorders, such as bradykinesia, tremor, rigidity and postural instability in the affected patients. Pluripotent stem cells (PSCs) are specialized cells that can be differentiated into the three germ layers and serve as a valuable source for cell-based replacement therapies. Evidence indicates that stem cell derived dopaminergic neurons are a promising avenue in the search for a viable long-term treatment in PD patients. Here, we report the isolation of self-renewable neural stem cells (NSCs) from human induced pluripotent stem cells (iPSCs) derived from Parkinson's disease patients with LRRK2 (G2019S) mutation. The NSCs demonstrated the ability to proliferate in response to epidermal growth factor (EGF) and basic fibroblast growth factor (FGF2). The isolated NSCs were further differentiated in glial conditioned media (GCM) with FGF2 into neurons of dopaminergic lineage. Following differentiation, immunohistochemistry analysis revealed the presence of β-tubulin positive neurons that co-localized with the dopaminergic neuron marker tyrosine hydroxylase. Quantitative analysis of the immunohistochemistry staining demonstrated that the number of dopaminergic neurons from NSCs differentiated in GCM was significantly higher on days 1, 2 and 7 in vitro compared to control-treated NSCs. In the next step, the differentiated cells were transplanted into the putamen of a nonhuman primate (Callithrix jacchus) and the animal was monitored for a period of 1 month. The object retrieval task, with barrier detour and activity analysis, was validated as a behavioral test for evaluating motor and cognitive functions. In conclusion, we have isolated of NSCs from human iPSCs that can be differentiated into dopaminergic neurons using glial conditioned media and growth factors. Furthermore, we have successfully transplanted the differentiated dopaminergic neurons into the putamen of a nonhuman primate.

Abstract: The Leucine-Rich Repeat Kinase (LRRK2) G2019S gain of function gene mutation is one of the most prevalent mutations contributing to Parkinson's disease (PD) pathogenesis. The increased kinase activity alters mitochondrial health, axon outgrowth, intracellular trafficking and autophagy. We have previously shown that human LRRK2 G2019S iPS-derived neurons exhibit increased vulnerability to PD associated cell stressors and modify mitochondrial dynamics, which can be rescued by LRRK2 inhibitors (Cooper et al., 2012, Sci Transl Med. 2012, 4;4(141):141ra90.). Human iPS-derived neurons carrying LRRK2 G2019S mutation and challenged with the endoplasmic reticulum (ER) calcium (Ca^{2+}) uptake blocker thapsigargin (THP) show significantly decreased ER stress responses accompanied by neurite collapse when compared with healthy subject controls. As THP blocks ER Ca^{2+} influx via sarco/endoplasmic reticulum Ca^{2+} -ATPase (SERCA) and induces ER stress, this indicates that iPS neurons carrying LRRK2 G2019S mutation exhibit an altered capacity to regulate Ca^{2+} homeostasis. Indeed, we further discovered that after THP-induced SERCA block human iPS-derived neurons carrying the LRRK2 G2019S mutation exhibit an increase in depolarization-induced calcium influx in to the cell and modified calcium decay (interpreted as buffering capacity), when compared to healthy subject control neurons. This phenotype is diminished by treatment with antisense oligonucleotides targeting LRRK2 G2019S mutation. These data indicate that the LRRK2 G2019S mutation alters intracellular calcium homeostasis and ER stress response, phenotypes that could contribute to PD neuronal dysfunction.

Abstract: The ability to generate neurons derived from induced pluripotent stem cells (iPSCs) from normal individuals and patients promises to fill a critical gap between human and animal studies, and will provide new insight into the pathogenesis of neurological disorders such as Alzheimer's disease. Here, we established a multistep protocol to generate individual-specific cortical neurons with astrocytes in vitro from human iPSCs. First, iPSCs are directly induced into a neuronal lineage by dual inhibition of SMAD signaling. The induced cells are positive for neural progenitor cell markers nestin and Sox2. Second, the neural progenitor cells go through an extended period of neurogenesis and terminal neuronal differentiation, as evidenced by ubiquitous Tuj1- and MAP2-positive neurons. Astrocytes are generated towards the end of neurogenesis. Finally, the differentiated neurons mature, developing dendritic spines and acquiring electrophysiological properties. We are currently using this model to investigate the biochemical and synaptic dysfunction exhibited by neurons derived from healthy donors and Alzheimer's disease patients with pathogenic mutations.

Title: Resolving the neuronal and glial component of tauopathies with human induced pluripotent stem cells.

Authors: *S. AGATHOU[1], M. IOVINO[2], M. SPILLANTINI[2], R. KARADOTTIR[2];
[1]Wellcome-Trust MRC Stem Cell institute, Univ. of Cambridge, Cambridge, United Kingdom;
[2]John van Geest Ctr. for Brain Repair, Univ. of Cambridge, CAMBRIDGE, United Kingdom

Abstract: Frontotemporal Dementia with Parkinsonism linked to Chromosome 17 (FTDP-17T) comprises 50% of all dementia cases under the age of 60 and involves the aggregation of the microtubule-associated protein tau. Studies of tauopathies have mainly based on transgenic animals, whereby over-expression of human-specific tau is engineered. However, neurodegenerative diseases are mainly restricted to humans, and tau isoform expression differs greatly between species. Moreover, accumulating evidence indicates a contributory role for oligodendrocytes (OLs) in tauopathies. Alongside neuronal tangles, glial tangles have been observed in FTDP-17T and *in vivo* OL tau expression is sufficient to induce tauopathy. Our aim was to overcome the above limitations and to investigate the glial contribution to tauopathies by generating and characterising human neurons and OLs from induced pluripotent stem cells (iPSCs) of patients with FTDP-17T tau mutations. Whole-cell patch clamp recordings, calcium imaging and molecular biology techniques were used to examine the effects of the N279K and P301L tau mutations on membrane properties, ion-channel composition, neurotransmitter signalling and tau isoform expression in both human neurons and OLs. We demonstrated that hiPSC-derived FTDP-17T neurons recapitulate tau pathology *in vitro* and thus provide a good tool for investigating human neurodegeneration. We discovered that tau mutations accelerate neuronal maturation and increase the excitability of human iPSC-derived cortical glutamatergic neurons. Moreover, FTDP-17T human neurons have mitochondrial trafficking deficiencies and mutation-specific morphological and molecular phenotypes. We generated oligodendrocyte precursor cells from FTDP-17T and control hiPSCs, both of which matured into myelin-producing axon-interacting OLs. We showed that human and rodent OLs express tau in culture and we investigated the effect of the N279K-tau mutation on basic membrane properties, ion-channel expression and neurotransmitter signalling in human OLs. We are currently investigating the effect of mutant tau on the myelinating potential of human OLs by generating a human myelinating co-culture *in vitro*, with hiPSC-derived neurons and OLs. In summary, we showed that pathologic tau mutations affect the excitability of human neurons and that human OLs express tau although its role and the effect of tau mutations are still unclear The outcomes of this study have increased our understanding of the pathological mechanisms governing human tauopathies.

Title: C9ORF72 ALS patient motor neuron cultures exhibit protein-level dysregulation in mitochondrial cristae organization complexes

Authors: ***P. DURVASULA**, A. KAUS, B. MANDEFRO, A. GROSS, A. KERL, W. YANG, D. SAREEN;
Advanced Hlth. Sci. Pavilion, Room 8405, Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease affecting upper and lower motor neurons (MNs). While ALS is largely sporadic, intronic G_4C_2 repeats in *C9ORF72* (C9-ALS) have been identified in a significant subset of familial and sporadic patients. Proposed mechanisms of degeneration include oxidative stress, aberrant axonal transport, protein aggregation and bioenergetics failure. Interestingly, mitochondrial dysfunction may possess a role in many of these mechanisms.
We identified dysregulated mitochondrial proteins in multiple C9-ALS patient induced pluripotent stem cell (iPSC)-derived MN (iMN) cultures via quantitative tandem mass tag (TMT) proteomic analysis in comparison to a healthy control group. Among the 5,433 protein groups analyzed, 208 displayed significant differences in C9-ALS mutant iMN cultures, with 89 of those being mitochondrial protein groups. Bioinformatics pathway analysis revealed that aside from oxidative phosphorylation, TCA cycle, and tRNA charging pathways, imbalances in proteins critical for cristae organization and stability were a major contributor. This is particularly relevant due to the recent discovery of a missense mutation in the CHCHD10 gene, which has been implicated as a cause of familial ALS. Specifically, CHCHD10 encodes a mitochondrial protein that is enriched at cristae junctions in the intermembrane space, and has been shown to interact with several members of the mitochondrial contact site and cristae organizing system (MICOS) complex. The MICOS complex proteins are associated with the formation and maintenance of mitochondrial cristae. Together with components of the mitochondrial intermembrane space bridging complex (MIB) and the translocases of the outer (TOM) and inner (TIM) membranes, MICOS proteins are crucial for maintaining the characteristic architecture of mitochondria. As determined by our quantitative proteomics data, at

least 10 of the MICOS-MIB-TOM complex components were dramatically up-regulated in C9-ALS iMN cultures. Evidence exists, which shows that overexpression of at least one of the members of the MICOS complex leads to a considerable extension and deformation of cristae membranes and junctions. We hypothesize that disruption of mitochondrial membrane architecture and cristae junction integrity contributes to neural cell dysfunction in ALS.
In conclusion, our results suggest protein-level molecular signs of impaired mitochondrial functioning in C9-ALS patient cultures. Identifying dysregulated elements of mitochondrial biology will expand our knowledge of ALS disease onset and progression.

Abstract: Tuberous sclerosis complex (TSC) is an autosomal dominant disorder caused by the mutation of either *TSC1* or *TSC2* genes. A large proportion of patients with TSC exhibit neurological symptoms including epilepsy and intellectual disability. A further 50% meet the diagnostic criteria for Autism. However, the appearance of this broad spectrum of neurologic manifestations does not always correlate with the neuroanatomical defects common to TSC,

suggesting the possibility of underlying functional defects affecting neural development of TSC patients. To investigate cellular and molecular phenotypes in TSC we generated multiple patient and sibling control-derived induced pluripotent stem cell (iPSCs) lines. Patient lines carry de novo heterozygous *TSC2* mutations. We then generated neural progenitor cells (NPCs) capable of fully differentiating into neurons, and investigated in detail their proliferation and differentiation properties. We observed that patient NPCs exhibit a consistent growth delay. Next we investigated molecular mechanisms that underlie this phenotype, and discovered specific abnormalities in the activity of the PI3K-Akt-mTOR signaling pathway that were not previously reported in heterozygous rodent models. Our findings elucidate disease mechanisms that may impact brain development and cognition in TSC.

Title: Corneal Diabetes: The development of the first innervated *In vitro* model

Authors: *S. PRIYADARSINI[1], D. KARAMICHOS[2];
[1]Ophthalmology, Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK; [2]Ophthalmology & Cell Biol., Univ. of Oklahoma Hlth. Sci., Oklahoma City, OK

Abstract: Purpose: Diabetes (DM) is a leading cause of blindness in adults worldwide. Today, 284 million people are severely visually impaired worldwide, of which 39 million are completely blind. In ocular health, diabetes severely affects all ocular tissues including the cornea. To-date, studies on the diabetic cornea are limited and mainly focused around the epithelium and nerves. Several animal models have been developed however, in many occasions, the strategies and treatments that were successful in rodents failed in humans. The development of a model more relevant to the patient population is absolutely necessary. In this study we developed a 3D self-assembled corneal tissue substitute that mirrors the basic anatomical and physiological of the corneal tissue *in vivo* and can be used as a tool for investigating the defects in the human diabetic cornea as well as screening the efficacy of various agents before animal testing. **Methods:** Human corneal stromal cells from healthy (HCF), Type I (T1DM), and Type 2 (T2DM) diabetic donors. Cells were seeded on polycarbonate membrane inserts at 1million cells/well with Vitamin C stimulation to promote collagen assembly. Human corneal nerve cells (HCNs) were

obtained and seeded on top of the constructs at the 3 weeks' time point and differentiated. At week 4, all constructs were processed for RT PCR and WB. Results were analyzed using Graph Pad Prism 6. **Results:** Our study results showed upregulated nerve markers (βIII tubulin and Nestin) expression in HCNs co-cultured with T2DM (3 fold increase, $p \leq 0.001$) whereas T1DM co-cultures showed downregulated expression(1 fold, $p \leq 0.05$) for both the nerve cell markers when compared to our healthy controls. We also witnessed increased Col I (4 fold, $p \leq 0.0001$) and Col V (2.5 fold, $p \leq 0.001$) expression in T2DM which correlates with significant increase in ECM assembly and deposition. **Conclusion:** In this study we have successfully developed a novel 3D corneal substitute that helps better understanding of the crucial parameters that often gets altered during hyperglycemic conditions and are essential for the normal corneal environment maintenance. Targeting these parameters would pave the way for developing therapeutic measures in treating corneal DM complications.

Title: Integrating microRNA and mRNA expression profiles of spinal motor neuron progenitors from human embryonic stem cell

Authors: *H. CHEN[1], J. XI[4], L. HOU[2], Z. MAO[3];
[1]Tongji Hosp., Hupei, China; [2]Dept. of Rehabil., [3]Dept. of Neurol., Tongji Hosp., Wuhan, China; [4]Tongji Univ., Shanghai, China

Abstract: Spinal motor neuron progenitors play a vital role in the development of motor neuron. However, the molecular mechanisms controlling this important process are largely unknown. MicroRNAs (miRs) can control mRNA expression, protein production and cell function by silencing translation or by destabilization of target mRNAs. Many studies suggested that microRNA can regulate the neural system development. In the present study, to identify the individual microRNAs (miRNAs) and mRNAs that may regulate the differentiation from human embryonic stem cell (hESCs) to spinal motor neuron progenitor, the expression profiles of motor neuron progenitors were analyzed. Microarray analyses revealed the up-regulated or down-regulated miRNAs and mRNAs in these neuronal progenitors during motor neuron development, and we found hsa-miR-9-3p, hsa-miR-551a, hsa-miR-30e-3p, hsa-miR-181d-5p, hsa-miR-200b-3p, hsa-miR-564, hsa-miR-125a-3p played important role in the motor neuron progenitor, and

also their target genes including HOXB4, HOXB9, NKX6-1, PHOX2B, TUBB3, DBX1and PTEN. These data support a crucial role for miRNAs and facilitate a potential regulatory network regulated by the genes and miRNAs during the spinal cord motor neuron differentiation.

Title: Extracellular environment & neural differentiation

Authors: *S. C. PANDANABOINA[1], A. ALDRIDGE[2], M. SRIVATSAN, 72401[2];
[1]Biol. Sci., Arkansas State Univ., State University, AR; [2]Biol. Sci., Arkansas State Univ., Jonesboro, AR

Abstract: A constant interaction between the developing neural progenitor cells (NPC) and their immediate extracellular environment influences the process of differentiation and cell fate. Cell culture studies are crucial contributors to deciphering those interactions. Mimicking the immediate extracellular environment with strategies such as using different growth factors, scaffolds/matrices, co-cultures with other cell types for neural differentiation are approaches increasingly being used because neural cells, differentiated in significant numbers with specific phenotypes, can help transplantations in the future for functional recovery from brain/spinal cord injuries. Since vascular endothelial cells in the brain develop along with neural progenitor cells and exosomes secreted by cells are being identified as effective cell to cell communicators we tested their influence on neural differentiation. Rat NPCs (Invitrogen) were maintained in culture in Neurobasal medium with B27 supplement (Gibco) with the addition of 1% whole fetal bovine serum (FBS+Exosome) and exosome depleted FBS(FBS-Exosome). In a second set of experiments they were co-cultured with vascular endothelial cells (hCMEC/D3 cells, EMD Millipore). Immunocytochemistry using neuronal and glial markers (primary antibodies for Nestin (undifferentiated cells), NueN (for neurons) and GFAP (for astroglial cells) followed by Alexa Fluor conjugated secondary antibodies and phase contrast and fluorescence microscopy

showed that NPCs cultured for 10 days that were exposed to FBS+Exosome showed the maximum differentiation potential either into glia (13%) or neurons (29.5%) while NPCs cultured in the presence of vascular endothelial cells showed the least differentiation as 96.5% of the cells remained undifferentiated after 10 days in culture. The addition of the conditioned medium from the vascular endothelial cells still affected differentiation (89% remained undifferentiated) , however not as much as when they were co-cultured. These results suggest that exosomes in serum play an important role in differentiation while presence of vascular endothelial cells may retard differentiation. The mechanism of action of these different environments for their influence on neural differentiation is under investigation.

Abstract: Dysregulated expression of miR-219, a brain-specific microRNA, has been observed in neurodevelopmental disorders, such as schizophrenia (SCZ). However, its role in normal mammalian neural stem cells (NSCs) and neurons and in SCZ pathogenesis remains unknown. We show here that microRNA miR-219 suppresses mouse NSC proliferation downstream of the nuclear receptor TLX. Moreover, we demonstrate up-regulation of miR-219 expression and down-regulation of TLX expression in NSCs derived from SCZ patient iPSCs and *DISC1*-mutant isogenic iPSCs. SCZ iPSC-derived NSCs exhibit reduced cell proliferation. Overexpression of TLX or inhibition of miR-219 action rescues the proliferative defect in SCZ NSCs. Moreover,

using deep sequencing analysis, we have identified a list of genes that are dysregulated in neurons derived from SCZ iPSCs and found that a set of these genes are potential miR-219 downstream targets. How elevated expression of miR-219 contributes to neuronal pathology in SCZ through regulating its downstream target genes is under investigation.

Title: A human cell repository for neurological disease research

Authors: ***M. L. SUTHERLAND**[1], J. A. TISCHFIELD[2], J. C. MOORE[2], S. SACCONE[3], M. SHELDON[2];
[1]NINDS/NIH, Rockville, MD; [2]Dept. of Genet. and The Human Genet. Inst. of New Jersey, Rutgers, The State Univ. of New Jersey, Piscataway, NJ; [3]Psychiatry, Washington Univ., St Louis, MO

Abstract: The National Institute of Neurological Disorders and Stroke (NINDS) Human Cell and Data Repository (NHCDR) was established in 2015 through a grant to RUCDR Infinite Biologics at Rutgers University. The NHCDR has 169 fibroblast and 72 induced pluripotent stem cell (iPSC) lines for Alzheimer's Disease (AD), Amyotrophic Lateral Sclerosis (ALS), Ataxia-telangiectasia, Frontotemporal Lobar Degeneration (FTD), Huntington's Disease (HD), Parkinson's Disease (PD), and healthy controls. These human cell lines are available to both academic and industry investigators for research purposes and can be ordered through the online NHCDR catalog (https://stemcells.nindsgenetics.org/). All iPSC lines have a certificate of analysis that summarizes the quality control assessment completed on the distribution lot. New iPSC lines will be added in 2016 and include PD iPSC lines carrying a synuclein SNCA A53T mutation, a PTEN induced putative kinase 1 PINK1 (ILE368ASN) mutation, a Parkin PARK2 (ARG275TRP) or (ARG42PRO) mutation, or a glucocerebrosidase GBA (GLU326LYS) mutation and FTD iPSC cell lines carrying a Progranulin PGRN (M1L) mutation or a Tau MAPT (P301L) mutation. The NHCDR also plans to generate isogenic lines for several of the

iPSC mutation carrying lines.
In 2016, NINDS will also add iPSC lines used by NeuroLINCS, where extensive omics data is available at www.neuorlincs.org. NeuroLINCS is one of six data and signature generating centers comprising the National Institute of Health (NIH) Library of Integrate-Network Signatures (LINCS) Common Fund program. The goal of NeuroLINCS is to establish cellular signatures for ALS and SMA, wherein the cell signatures are studied in the presence or absence of perturbants. Through a collaboration with NINDS, ten Target ALS Foundation iPSC lines can be ordered through the NHCDR catalog.
Established in 1998, RUCDR Infinite Biologics (www.rucdr.org) is the world's largest university-based integrated cell and DNA repository, assisting researchers throughout the world by providing the highest quality biomaterials, technical consultation, and logistical support. Its services include sample collection and bioprocessing (i.e., blood fractionation, nucleic-acid extraction, cell-line creation, etc.) and analytical services such as gene expression, sequencing, and genotyping. The RUCDR Infinite Biologics Stem Cell Center (RSCC) offers comprehensive services that include the reprogramming of source cells such as skin fibroblasts and blood cells to yield iPSC cells. In addition, RSCC performs a complete range of assays to characterize iPSCs to assess their quality, pluripotency and genomic stability.

Title: Idiopathic autism patient-derived neural stem cells exhibit patient-specific proliferation defects in comparison to sibling control

Authors: *M. WILLIAMS[1,2], S. PREM[2], C. PINTO[3], X. ZHOU[2], P. YEUNG[2], C.-W. LUI[2], Z. PANG[2], L. BRZUSTOWICZ[4], P. MATTESON[2], J. MILLONIG[2], E. DICICCO-BLOOM[2]; [1]Neurosci., Rutgers Univ. Dept. of Cell Biol. and Neurosci., Piscataway, NJ; [2]Neurosci., Rutgers University, Robert Wood Johnson Med. Sch., Piscataway, NJ; [3]Neurosci., [4]Biol., Rutgers Univ., Piscataway, NJ

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder defined by abnormalities in social interactions and stereotyped/restrictive behavior. Study of ASD has been hindered by disease heterogeneity and difficulties in creating representative mouse models. To define neurodevelopmental deficits in idiopathic autism, we (NJ Autism Center of Excellence; PI Millonig) generated induced pluripotent stem cells (iPSC) from 8 severely affected males and their unaffected brothers (Sib) and derived neural stem cells (NSCs). Here we focus on proliferation of ASD and Sib NSCs. To address possible variability, studies are performed blind, and all measures are assessed in multiple NSCs obtained from 2-3 independent iPSC clones for each subject. To define effects, cells were grown at high density (50K cells/cm^2) and labeled at 48h with tritiated thymidine to assess DNA synthesis and EdU for S-phase entry. In parallel, single cell analyses were conducted at 48h by acutely dissociating high-density cultures, and performing innumostaining on at low density (10K/cm^2) cultures fixed at 2h. Further, sister cultures were dissociated at 2, 4 and 6 days to quantify live cell numbers via hemocytometer. To measure protein levels, NSCs ($5x10^4$ cells/cm^2) are plated in 35 mm dishes and harvested at 48h for immunoblotting. ASD NSCs from a single-family comparison exhibit a robust and reproducible proliferation defect. In over 20 experiments utilizing NSCs derived from multiple clones per individual (2 for Sib, 3 for ASD), ASD NSCS display a 65% reduction in DNA synthesis. Additionally, ASD NSCs exhibit a 33% reduction in the proportion of cells in S-Phase as well as a 60% reduction in cell numbers after 6 days in culture. FGF, a known regulator of neurogenesis, reverses this proliferation defect in ASD NSCs by increasing cell numbers at 6 days in culture to that of Sib NSCs. Furthermore, in preliminary studies of cell cycle regulators, ASD NSCs exhibit a 65% increase in levels of cyclin-dependent kinase inhibitor p27, a negative regulator of the cell cycle. In contrast, preliminary studies of another ASD-Sib pair reveal no evidence of a proliferation defect, though the NSCs exhibit a differential response to FGF. Thus proliferation defects may be idiopathic autism patient-specific, supporting the concept of personalized medicine. In aggregate, our observations suggest we are able to discover differences in ASD-implicated biological processes and as well as potential underlying mechanisms. In comparison of an ASD-sibling pair this toolset has begun to uncover patient-specific differences in cellular phenotypes, as might be expected in idiopathic ASD.

Title: Disrupted neuronal maturation in Angelman syndrome using patient-specific induced pluripotent stem cells

Authors: *J. J. FINK[1], T. M. ROBINSON[2], E. S. LEVINE[2];
[1]Neurosci., [2]Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstract: Maternal deletion of chromosome 15q11-q13 results in a neurodevelopmental disorder known as Angelman syndrome (AS). Interestingly, individuals with a duplication of this region have a related neurodevelopmental disorder called 15q duplication syndrome (Dup15q), which in some cases is associated with autism. These syndromes are also associated with overlapping phenotypes including intellectual disability, impairments in language, and seizures. The gene believed to be responsible for AS encodes the ubiquitin ligase UBE3A. For Dup15q, it is believed that UBE3A also plays an important role, but it is likely that other genes also contribute. In both syndromes, alterations in synaptic signaling and plasticity appear to contribute to the disease phenotype, at least in mouse models, but the relevant downstream targets of UBE3A and their functional roles are unknown. Moreover, the seizure phenotype associated with these syndromes suggests the presence of an excitatory/inhibitory imbalance and/or neuronal hyperexcitability. Overall, it is clear that UBE3A is an important role-player in normal brain development and plays essential roles in excitability and synaptic function and plasticity.
In this study, we are using electrophysiological approaches and calcium imaging to examine neuronal excitability, synaptic activity, and plasticity of induced pluripotent stem cell-derived (iPSC) neurons from AS, Dup15q, and control subjects. Depolarized resting membrane potentials (RMP) were observed in both control and AS neurons early in development. Neurons derived from control subjects show a progressive hyperpolarization in RMP over development that is lacking in neurons derived from AS subjects. Similarly, control neurons show a developmental increase in spontaneous synaptic activity that is not observed in AS neurons, suggesting a genotypic difference in synapse number and/or release probability. These cellular phenotypes seem to be caused by loss of UBE3A as knockdown of this protein in control neurons and reestablishing UBE3A in AS neurons is able to mimic and rescue, respectively, these phenotypes. These iPSC-derived neurons also show spontaneous action potential firing and synchronous activity and we are currently exploring synaptic plasticity differences in these cultures using single cell recordings and multi-cell calcium imaging. Overall, these approaches may prove useful for identifying novel targets for drug discovery and for screening potential

therapeutics aimed at reversing the seizures, movement disorders, and language and cognitive impairments in AS and Dup15q.

Title: Differentiation and function of human embryonic stem cell derived GABAergic interneuron progenitors *In vitro* and in the epileptic brain

Authors: *N. C. ANDERSON[1], M. VANZANDT[1], J. GUPTA[1], S. SHRESTHA[1], C. Y. CHEN[1], D. LAWERENCE[2], G. AARON[2], J. NAEGELE[2], L. GRABEL[1];
[1]Biol., [2]Neurosci. and Behavior, Wesleyan Univ., Middletown, CT

Abstract: The selective loss of GABAergic inhibitory interneurons is characteristic of numerous neurodegenerative diseases. Absence of these inhibitory subtypes creates an electrical imbalance in the hippocampal and cortical neural circuits. Our long-term goal is to replenish these inhibitory interneuron subtypes using an embryonic stem cell (ESC) source. During embryonic development, these inhibitory interneuron progenitors arise from a transient ventral forebrain structure known as the medial ganglionic eminence (MGE) and are characterized by the expression of Nkx2.1. We have optimized an adherent monolayer protocol for the generation of Nkx2.1+ neural progenitors from human ESCs using sonic hedgehog treatment. To test the differentiation potential of the Nkx2.1+ cells *in vitro*, we utilized co-culture and tri-culture systems with mouse cortical astrocytes and mature hippocampal cells; deriving an enriched population of interneurons in which 75% of the MAP2-positive cells are also GABA-positive after 8 weeks. Studies examining the fate of human ESC-derived ventralized neural progenitors transplanted into the mouse hippocampus of severe compromised immune deficient (SCID) epileptic mice demonstrate increased expression of the mature neuronal markers, Hu, NeuN, and the inhibitory neurotransmitter GABA between 6 and 12 weeks post transplantation. Preliminary studies suggest the transplanted cells are able to suppress recurring seizures short term in a mouse model of temporal lobe epilepsy. In addition, mice with transplanted cells exhibited significant improvement in the Morris Water Maze spatial memory task by six weeks post

transplant. Patch clamp analysis indicates that hESC derived neurons are capable of firing mature action potentials following long-term *in vitro* culture and post transplantation into mouse host.

Title: Utilizing human stem cells and cerebral organoid cultures to delineate neurodevelopmental base of schizophrenia

Authors: S. ELAHI, 14214[1], S. NARLA[1], C. A. BENSON[1], K. BRENNAND[2], S. DOYLE[1], E. K. STACHOWIAK[1], *M. K. STACHOWIAK[1];
[1]State Univ. New York Buffalo, Buffalo, NY; [2]Sch. of Med. at Mount Sinai, New York City, NY

Abstract: In this study we utilized neural progenitor cells (NPC) derived from schizophrenia and control iPSCs (Brennand et al., Nature, 2011) to elucidate the effects of schizophrenia on early neural development. RNA-sequencing revealed 1348 dysregulated genes common to schizophrenia patients with different genetic backgrounds accompanied by increased nuclear Fibroblast Growth Factor Receptor 1 (FGFR1)- genome interactions. Many of the dysregulated genes are involved in developmental pathways, i.e. WNT/β-Catenin and Notch signaling. The results point to an early (preneuronal) developmental-genomic etiology of schizophrenia and support the role of panontogenic Integrated Nuclear FGFR1 Signaling (INFS) in abnormal neuronal development. We developed 3D cerebral organoids from human embryonic stem cells (hESC) to analyze the role of nFGFR1 signaling in early human cortical development. The organoid rosettes recapitulated the inside-out pattern of the early stages of human cortical development. The innermost sub-ventricular-like zone (SVLZ) showed a highly dense population of proliferating KI67+ cells. The outermost molecular layer contained mature neurons and the intermediate-like zone (ILZ) contained neuroblasts and interneurons. The role of FGFR1

was examined by treating cerebral organoids with an FGFR1 antagonist, PD173074, from day 12 to day 22. PD173074 specifically depleted nuclear FGFR1 and reduced the size and the number of developing cortical rosettes (P-value< 0.001). Moreover, PD173074 decreased the density of immature neurons and interneurons in the intermediate subcortical zone, but had less effect on the earlier generated mature neurons. PD173074 did not affect the Number Area Density of proliferative Ki67+ cells, but the proliferating cells were no longer localized specifically in the SVLZ. In addition, PD173074 reduced the number of cells expressing nuclear FGFR1 in the molecular zone of cortical rosettes of cerebral organoids by 37%. Thus, blocking nuclear FGFR1 accumulation interferes with the neural development by preventing formation of the neurogenic SVZ and inhibiting neuronal differentiation. PD173074 had no effect on the Number Area Density of proliferative cells and formation of oligodendrocyte precursors. In contrast, schizophrenia iPSCs treated with PD173074 increased the size of cerebral organoids. Our results support the role of nFGFR1 in the early stage of human brain development and in its changes in schizophrenia. Genomic mechanisms of the observed developmental changes are currently being investigated by RNAseq and ChiPseq.

Abstract: The directed neural differentiation of patient-derived induced pluripotent stem cells (iPSC) provides us with a developmental model to better understand the role of astrocytes in BP. Dermal fibroblasts from 4 control and 4 BP individuals were reprogrammed using episomal vectors and fully characterized for pluripotency and normal chromosome number. The iPSC lines were differentiated into neural precursors via dual SMAD inhibition, followed by a 70-day incubation in medium containing N2, fibroblast growth factor-2 (FGF-2), and epidermal growth factor (EGF) in suspension (astrospheres) followed by dissociation into astrocyte monolayer cultures. CD44-positive cells ranged from 49% to 99%, and were sorted by fluorescent activated sorting. Cell doubling times at early passage number were greater in BP lines (C 99.3$\pm$11.0, BP 130.3$\pm$31.1, p=0.054). Gene expression of aquaporin 4 and the glutamate transporter EAAT2 was significantly lower in BP lines ($P<0.05$ and $P<0.01$, respectively), and gene expression of S100beta and EAAT1 were also markedly lower in BP lines. Treatment of astrocytes with bone morphogenetic protein 4 or ciliary neurotrophic factor in the absence of FGF-2 and EGF induced differential expression of the mature astrocyte-specific marker glial fibrillary acidic protein. These differences in gene expression and behavior suggest that BP astrocytes are functionally distinct from control astrocytes. Current investigations are in progress to examine gliotransmitter release and behaviors in coculture with neurons.

Title: IPSC-derived neurons as a cellular model system for neuropsychiatric disorders

Authors: L.-M. GRUNWALD[1], M. KRIEBEL[1], M. EBERLE[2], U. KRAUSHAAR[1], F. BATTKE[3], Y. SINGH[3], A. J. FALLGATTER[2], *H. VOLKMER[1];

Abstract: We develop iPSC-based test systems for neurodevelopmental disorders such as schizophrenia and autism. Such disorders are signified by a reduction in neuronal numbers, aberrations in neuronal outgrowth, a decrease in synaptic densities and dysfunctional molecular pathways. Based on these findings, we used iPSC-derived neurons from patients with schizophrenia or autism as a model to further elaborate morphological characteristics and to reveal basic mechanisms of underlying cognitive dysfunctions. Skin biopsies were obtained from unaffected donors and clinically diagnosed patients, the latter belonging to families with an increased case number to emphasize hereditary factors contributing to the pathology. By means of retroviral transduction isolated fibroblasts were reprogrammed into iPSCs which were characterized by immunocytochemistry and PCR. Subsequently, iPSCs were differentiated into neuronal progenitor cells and finally into neurons. Terminal neuronal differentiation was demonstrated through immunostaining for neuronal marker proteins like ?-III-Tubulin or brain layer specific proteins like CTip2. Further neurons were characterized by electrophysiological properties and transcriptome analysis. Differences in early neuronal development were assessed by neurite outgrowth measurements via high content analysis using the ImageXpress Setup. A reduced total outgrowth of neurons derived from patients with schizophrenia and autism compared to the healthy control group was revealed. The synaptogenic potential of iPSC derived neurons was determined via quantification of clusters of the postsynaptic marker PSD95. Consistently, cluster numbers were reduced in cultures of iPSC-derived neurons from patients with schizophrenia and autism, which may point towards shared disease characteristics with respect to synaptic differentiation. In conclusion, iPSC-derived neurons from patients with schizophrenia and autism showed reductions in total neurite outgrowth and a decreased formation of postsynaptic clusters, which has been also reported from post-mortem studies. These results suggest that the in vitro system described here may be a valid tool to investigate morphological and synaptic deficits associated with cognitive impairments observed in schizophrenia and autism. Abstract: A large number of distinct missense mutations in the *SCN1A* gene*,* encoding $Na_v1.1$ voltage-gated sodium channels result in genetic epilepsy with febrile seizures plus (GEFS+). However, the underlying cellular mechanisms contributing to this class of seizure disorders are not well understood. Previously we explored the cellular changes in a *Drosophila* knock-in fly line carrying the GEFS+ K1270T *SCN1A* mutation. Our data indicate that this mutation contributes to hyperthermia-induced seizures through a conditional gain-of-function alteration in sodium channels that reduces excitability of GABAergic neurons (Sun *et al*., 2012). To determine whether this mutation causes similar changes in human neurons, we generated induced pluripotent stem cell (iPSC) lines from two siblings, one with the K1270T mutation (GEFS+ sibling) and one without (Control sibling). The iPSC lines were differentiated into neurons. Three weeks after plating onto an astrocyte feeder layer, the majority of cells with neuronal morphology, in both the GEFS+ and Control sibling lines, fired action potentials and received glutamatergic and/or GABAergic synaptic input. We have also used the CRISPR-Cas9 system to introduce the K1270T mutation into the Control sibling iPSC line, creating an isogenic mutant line. We are now conducting comparisons at elevated temperature to determine if there are differences in excitability and synaptic transmission between neurons differentiated from the GEFS+ sibling, Control sibling and isogenic mutant lines. These studies will provide insight into cellular mechanisms contributing to febrile seizures in *SCN1A* associated epilepsy disorders.

Title: Human iPSC glial mouse chimeras reveal glial contributions to schizophrenia

Authors: *K. L. MCCOY[1], S. WANG[1], L. ZOU[1], S. SCHANZ[1], J. MUNIR[1], J. BATES[1], D. CHANDLER-MILITELLO[1], Z. LIU[1], R. FINDLING[2], R. H. MILLER[3], M. NEDERGAARD[1,4], P. TESAR[5], M. S. WINDREM[1], S. A. GOLDMAN[1,4];

Abstract: Recent genetic and neuroradiological studies have suggested a role for glial pathology in the genesis of schizophrenia. To assess this possibility, we established human glial chimeric mice using glial progenitor cells (GPCs) produced from induced pluripotential cells (hiPSCs), which were derived from patients with juvenile-onset schizophrenia and their gender- and ethnicity-matched controls. To this end, hiPSC GPCs were neonatally implanted into either immunodeficient myelin wild-type mice, in which the donor GPCs remained as progenitors or became astrocytes, or into hypomyelinated shiverer mice, in which the GPCs also gave rise to oligodendrocytes. When implanted into shiverer mice, by 4 months of age the schizophrenia-derived (SCZ) iPSC GPCs exhibited less white matter engraftment than control iPSC GPCs, instead migrating prematurely into the cortex. The density of SCZ-derived GPCs in the corpus callosum was significantly less than that in control GPC-engrafted mice (N=13; P<0.0001), which resulted in hypomyelination of the callosum (MBP expression by luminance; P< 0.0001). Moreover, the density of transferrin-defined oligodendrocytes was lower in SCZ callosum than in control-engrafted (SCZ: 15,993 ± 2,693/mm^3, N=12; control: 9,084 ± 1,249 N=16; P=0.03). Strikingly, callosal GFAP-defined astrocytic differentiation was almost 6 times higher in control-engrafted brains than in SCZ GPC chimeras (control: 6,616 ± 672/mm^3, N=12; SCZ: 1,177 ± 277/mm^3, N=19; P<0.0001). In myelin wild-type hosts, the SCZ hiPSC glial chimeras exhibited

an aberrant behavioral phenotype, characterized by: 1) diminished prepulse inhibition; 2) higher anxiety as assessed by elevated plus maze; 3) increased social avoidance in 3-chamber social testing; 4) impaired novel object recognition; and 5) anhedonia, as reflected in diminished sucrose preference, all as compared to control GPC-engrafted chimeras. Lines derived from 3 different patients and 3 age- and gender-appropriate controls were used in all experiments. These data suggest a potent contribution of cell-autonomous glial pathology to the development of schizophrenia.

Title: Synchronous oscillatory activity in human iPSC derived cortical circuits

Authors: *S. ILLES, J. ISZÁK, D. VIZLIN HODZIC, Q. ZHAI, J. STRANDBERG, T. OLSSON BONTELL, E. HANSE, K. FUNA;
The Sahlgrenska Academy, Univ. of Gothenburg, Goeteborg, Sweden

Abstract: The hallmark of the brain is the ability to generate oscillatory activity categorized in different frequency bands. This required the full neuronal maturation of neural stem cell-derived neuronal progeny into structured three-dimensional (3D) organized neuronal circuits as given e. g. in cortical brain region. We assessed *in vitro* generated human induced pluripotent stem cells (hiPSC)-derived 3D-cortical neural assemblies by super-confocal-laser microscopy imaging, patch-clamp and multi-electrode array technology and present here the structural and functional properties at the synapse towards the neuronal network level. In detail, our differentiation procedure applied on hIPSC gives rise to 3D-cortical aggregates comprising early-, middle- and late-born cortical glutamatergic as well as GABAergic neurons. These neurons are organized as polarized cell-layer embedded into a glial network generated by 3D-growing mature GFAP and S100-positive astrocytes. Neurons generating a neurite net which are interconnected by vGlut1 and PSD-95 mature synapse, allowing excitatory and inhibitory neurotransmission revealed by

whole-cell recordings. Cell-attached and extracellular recordings demonstrated that neurons within hiPSC-derived cortical aggregates show mature electrophysiological properties, i.e. generation of spontaneous action potentials and bursting. Moreover, multi-electrode array recordings reveal the autonomous generation, i. e. in the absence of electrical or chemical stimulation, of synchronized activity recorded as population bursting and oscillatory local field potentials. In this poster we provide a detailed description of the properties of oscillatory LFP recorded in *in vitro* generated human cortical circuits. Here we not only demonstrating that hiPSC-derived neurons mature into functional circuits within few weeks starting from iPSC-stage, but also show that hiPSC-derived neural circuits show principles of human brain functions.

Title: *In vitro* and *In vivo* characterization of frozen-thawed dopaminergic cell preparations for Parkinson's disease autologous cell replacement therapy

Authors: *T. M. OSBORN[1], M. BADI[1], D. DINESH[1], J. PRUSZAK[2], A. ASTRADSSON[1], J. A. KORECKA[1], R. SPEALMAN[1], J. SCHUMACHER[1], P. HALLETT[1], O. ISACSON[1]; [1]Neuroregeneration Res. Inst., McLean Hospital/Harvard Med. Sch., Belmont, MA; [2]Inst. for Cell and Gene Therapy, Univ. Med. Ctr. Freiburg, Freiburg, Germany

Abstract: Patients with Parkinson’s disease (PD) present with motor symptoms characterized by tremor, bradykinesia, rigidity and postural instability. There are approximately 1.5 million diagnosed cases of this chronic progressive disorder in the U.S. At the onset of symptoms and diagnosis ~ 70% of the midbrain DA neurons have degenerated. L-DOPA can initially restore dopaminergic (DA) levels and motor function, but with time the therapeutic window becomes increasingly narrow with L-DOPA induced dyskinesia as a common side effect. Although deep-

brain-stimulation (DBS) also can alleviate motor symptoms, such interventions ultimately lead to repeat procedures, limitations for patients in receiving other medical procedures and high medical costs. The concept of cell replacement therapy has shown benefit in clinical studies using cell preparations derived from fetal ventral midbrain. However, fetal cell transplantations are not scalable for a larger patient population and require immunosuppression. Induced pluripotent stem cells (iPSCs) can be generated from affected PD patients, differentiated into midbrain dopaminergic cells using xeno-free procedures, and frozen-thawed for use in autologous transplantations. The proof-of-concept in non-human primates has previously been shown by us (Hallett et al. Cell Stem Cell. 2015 Mar 5;16(3):269-74). In recent pre-clinical efforts, we have differentiated episomal xeno-free iPSCs, derived from human PBMCs, into midbrain DA neurons. The cell-preparations have been frozen and thawed with reliable reproducibility. Stability, cell marker characteristics and functionality of the frozen-thawed cells and such preparations are now tested in vitro and in primate and rodent models in vivo.

Title: Dynamics of human neuronal network microcircuitry on high-throughput multielectrode arrays and application in drug screening

Authors: *S. HINCKLEY, S. BIESMANS, A. BANG;
CPCCG, Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA

Abstract: Neural network activity represents the integration of multiple synaptic events and the sum output of neuronal ensembles. While human neurophysiology has been described at the single synapse level and the population field potential level of EEG, microcircuitry dynamics have not been well established. Development of technology platforms to study microcircuitry will better elucidate disease etiology and drug influence on network function in human models. Efforts toward application of higher relevance model systems in drug discovery benefit from the scalability, reproducibility and genetic background provided by patient derived induced

pluripotent stem cell (iPSC) neurons. These *in vitro* human iPSC based neural networks can be utilized for screening drugs that modulate network behavior and also for pharmacogenomic studies of human neurological disease. Using hiPSC-derived neurons, we have developed a physiological assay on multi-well multielectrode array (MEA) plates, where we simultaneously record extracellular potentials for 16 channels per well across 48-well plates. An advantage of this system, versus traditional electrophysiology, is the ability to non-invasively measure neuronal activity over days and months, utilizing each well as its own control, thereby expanding the repertoire of drug exposure paradigms to more closely resemble clinical use. hiPSC-derived neurons formed *de novo* networks on the MEA plate as evidenced by the appearance of complex synaptic activity including synchronized network bursts. Our assay displayed highly consistent well-to-well activity level and network behavior. Furthermore, manipulation of excitatory and inhibitory neurotransmission showed physiologically relevant network formation. Analysis of network function in response to a focused library of pharmacological and neurotoxin compounds revealed dynamic plasticity of network output. Development of technology platforms that can be used to perform drug screens against models of human brain microcircuitry *in vitro* with relatively high-throughput will be essential to realize their potential for disease modeling and drug discovery.

Abstract: A number of studies have suggested significant glial involvement in schizophrenia. Nonetheless, the contribution of cell-autonomous glial transcriptional dysregulation to the pathogenesis of schizophrenia has not been specifically explored. To this end, we have generated mRNA sequencing data from oligodendocyte progenitor cells (OPCs) produced from human induced pluripotent stem cells obtained from fibroblasts of patients with juvenile-onset schizophrenia, as well as from age- and gender-matched healthy controls. The OPCs were prepared using previously described methods (Wang et al., Cell Stem Cell, 2013), and then enriched to near-purity using CD140a/PDGFRa-targeted fluorescence-activated cell sorting. Differential gene expression analysis (corrected P Value < 0.05 and linear fold change > 2.00) of 4 schizophrenic- and 3 control-derived cell lines revealed marked differences in differentiation- and myelination-associated genes in schizophrenic OPCs, as compared to their controls. Both differential gene expression and differential network analyses identified disruptions in the OPC differentiation signaling pathway as indicated by significant down-regulation of a coherent set of key OPC lineage transcription factors NKX2-2, OLIG1, OLIG2, SOX10, SIRT2, MYRF, and ZNF488 as well as genes involved in myelination such as MBP, PLP1, MAG, UGT8, MOG, and FA2H suggesting a relative arrest in glial differentiation at the point of OPC specification from neural stem cells. Functional analysis of schizophrenia-dysregulated genes identified synaptic transmission, differentiation of oligodendrocytes, and myelination among the most differentially affected central nervous system functions; all were significantly down-regulated. Together, these findings reveal a major role for cell-autonomous glial pathology in the etiology of child-onset schizophrenia.

Title: Neuronal calcium signaling in stem cell models of bipolar disorder

Authors: *A. J. WILLIAMS[1], C. DELONG[2], M. BAME[2], E. MARTINEZ[2], R. DOUCETTE[2], R. PARENT[2], K. GLANOWSKA[2], M. MCINNIS[2], E. STUENKEL[2], G. MURPHY[2], K.

O'SHEA[2];
[1]Psychiatry, [2]Univ. of Michigan, Ann Arbor, MI

Abstract: A major challenge in understanding human neuropsychiatric disorders has been the lack of viable cells and tissues for analysis. Patient-derived induced pluripotent stem cells (iPSC) offer the opportunity to examine the full complement of neural tissues and the prospect of identifying underlying disease mechanisms. To study bipolar disorder (BP), we have derived and characterized iPSC from fibroblasts obtained from controls (C) and patients with BP, and have differentiated them into neurons and glia. With the fluorescent calcium indicator, Fluo-4 AM, we can measure differences in spontaneous and evoked neuronal responses in BP versus C neurons. While both BP and C neurons respond to depolarization, we find that BP neurons have greater calcium transients in response to certain types of stimulation than C neurons. We have also found that lithium pre-treatment reduces BP neuron calcium transients and wave amplitude to levels comparable to C neurons. We are currently using these cell models to investigate the role of rs1006737, a single nucleotide polymorphism in the *CACNA1C* calcium channel gene - and a genetic risk factor for BP - in neuronal differentiation and function. We used the CRISPR/Cas9 genome editing system to edit BP cells with the rs1006737 risk genotype (AA) into the nonrisk (GG) genotype, and we are now assessing calcium signaling and differentiation potential in the corrected cells. One potential BP therapeutic, ketamine, may act by altering calcium signals in target cells. To evaluate this, we are using our cell models to assess how ketamine alters patterning and differentiation in BP and C neurons. We are also studying mouse neurons lacking specific calcium channels to investigate how these channels mediate neuronal calcium transients observed by Fluo-4 AM. The overarching goal of our research is to identify novel disease phenotypes and mechanisms involved in bipolar disorder, with the ultimate aim of improving treatment.

Title: Functional synaptogenesis in human stem cell derived neurons for neurotoxicity studies

Authors: *M. J. STENSLIK, P. H. BESKE, K. M. HOFFMAN, K. L. SCHULZ, M. R. EISEN, D. L. NGUYEN, P. M. MCNUTT;
US Army Med. Res. Inst. of Chem. Def, Edgewood, MD

Abstract: Neurons derived from human pluripotent stem cells (hPSCs) have the potential to provide a physiologically relevant model to study the clinical manifestations of various toxins, such as botulinum neurotoxins. Numerous publications describe the differentiation of human pluripotent-derived neural stem cells (hNSCs) *in vitro,* and demonstrate morphological markers of neurotypic identity months after derivation. However, neuronal models often fail to exhibit active synapses with network-level responses. Therefore, we sought to accelerate conditions for the functional maturation of hPSCs into networked cultures of hNSCs. We have previously described the morphological and functional maturation of various hNSCs by immunocytochemistry and whole-cell patch-clamp electrophysiology. Results demonstrate that within 7 weeks of differentiation hNSCs displayed appropriate compartmentalization of post-mitotic morphological markers (e.g., MAP2, Tau and/or NeuN) as well as miniature post-synaptic currents (mPSCs). mPSCs were blocked with the treatment of CNQX, an AMPA agonist confirming excitatory AMPA receptor-mediated events. Addition of botulinum neurotoxin serotypes A or B to hNSCs resulted in SNARE protein cleavage and termination of spontaneous synaptic activity. Currently, we are investigating the maturation of human pluripotent stem cell-derived motor neurons (hPSC-PMNs). Preliminary studies indicate the presence of post-mitotic morphological neurotypic markers (e.g. MAP2, Tau and/or NeuN), and the emergence of immature neuronal activity in as early as 21 d after plating. In combination with previous findings, these data suggest that careful differentiation of commercially available human-induced pluripotent stem cell-derived neuronal populations can produce physiologically relevant, synaptically active neuronal cultures that are suitable for mechanistic and high-throughput therapeutic screening studies of biological and chemical neurotoxins.

Title: Long-term potentiation and depression phenomena in human induced pluripotent stem cell-derived cortical neurons

Authors: *A. ODAWARA[1,2,3], N. MATSUDA[1], G. CHENG[4], R. ARANT[4], I. SUZUKI[1]; [1]Tohoku Inst. of Technol., Sendai, Japan; [2]Tohoku university, Sendai, Japan; [3]JST, Tokyo, Japan; [4]Alpha med scientific, Osaka, Japan

Abstract: Long-term potentiation (LTP) and long-term depression (LTD) in neuronal networks has been analyzed using in vitro and in vivo techniques in simple animals to understand learning, memory, and development in brain function. Human induced pluripotent stem cell (hiPSC)-derived neurons may be effectively used for understanding the plasticity mechanism in human neuronal networks, thereby elucidating disease mechanisms and drug discoveries. In this study, we attempted the induction of LTP and LTD phenomena in a cultured hiPSC-derived cerebral cortical neuronal network using multi-electrode array (MEA) systems. High-frequency stimulation (HFS) produced a potentiated and depressed transmission in a neuronal circuit for 1 h in the evoked responses by test stimulus. The cross-correlation of responses revealed that spike patterns with specific timing were generated during LTP induction and disappeared during LTD induction and that the hiPSC-derived cortical neuronal network has the potential to repeatedly express the spike pattern with a precise timing change within 0.5 ms. We also detected the phenomenon for late-phase LTP (L-LTP) like plasticity and the effects for synchronized burst firing (SBF) in spontaneous firings by HFS. In conclusion, we detected the LTP and LTD phenomena in a hiPSC-derived neuronal network as the change of spike pattern. The studies of plasticity using hiPSC-derived neurons and a MEA system may be beneficial for clarifying the functions of human neuronal circuits and for applying to drug screening.

Title: Development of an *In vitro* patient specific neurovascular unit based on induced pluripotent stem cells

Authors: *R. PATEL, S. PAGE, A. ALAHMAD;
Pharmaceut. Sci., Texastech Univ. Hlth. Sci. Ctr., Amarillo, TX

Abstract: The blood-brain barrier (BBB) constitutes a component of the neurovascular unit formed by specialized brain endothelial cells (BMECs) surrounded by astrocytes, pericytes and neurons. It plays an important role in the maintenance of the brain homeostasis by the presence of a dual barrier providing a physical (tight junctions) and chemical (efflux pumps) barrier against pathogens and toxic compounds.
Dysfunction of the BBB function is associated with many neurological diseases, in particular with neurodegenerative diseases. However, current in vitro models of the human BBB are limited by their poor barrier properties, whereas the cellular mechanisms described in rodent-based models remain to be validated. In this study, we developed a patient-specific model of the BBB using patient-derived induced pluripotent stem cells (iPSCs) and differentiated these cells into BMECs, neurons and astrocytes using established protocols.
In our hands, iPSC-derived BMECs showed barrier properties similar or better than hCMEC/D3 monolayers (an immortalized human brain endothelial cell line), as they displayed the phenotype of a mature BBB.
Furthermore, we were capable to differentiate neurons and astrocytes from the same iPSCs. We demonstrated that such neurons were sensible to known neurotoxic compounds. In addition, such neurons and astrocytes were capable to up-regulate the barrier tightness in iPSC-derived BMECs monolayers upon co-cultures.
In this study, we demonstrated the ability to develop an all-inclusive and functional in vitro model of the neurovascular unit capable to integrate astrocytes, BMECs and neurons.
Our future direction is focused on using such model to better understand clearance of Abeta peptides across the BBB, as well as the impact of genetic factors on the BBB by differentiating iPSCs from patient suffering from a early onset of familial Alzheimer disease (eFAD).

Title: Effect of different human recombinant laminin isoforms on human pluripotent stem cell -derived neurons *In vitro*

Authors: *A. HYYSALO, M. RISTOLA, M. MÄKINEN, S. NARKILAHTI;
BioMediTech, Univ. of Tampere, Tampere, Finland

Abstract: Extracellular matrix plays a crucial role in the central nervous system (CNS). Laminins are one of the major protein groups in the extracellular matrix participating in many aspects of the CNS physiology. These large heterotrimeric glycoproteins consist of α, β and γ chains, which can be assembled into variety of different isoforms. Biological roles of laminin isoforms in developing human CNS have not previously been extensively studied, but recently human recombinant laminin isoforms have become commercially available facilitating the research. Human pluripotent stem cells (hPSCs) can be utilized for efficient production of human neuronal cells *in vitro*. Combination of human-derived cells with defined laminin isoforms enables more detailed *in vitro* research aiming to better understand the role of different laminin isoforms in the development, function and repair of the human CNS.
The aim of this study was to compare how different human recombinant laminin isoforms support the growth and development of hPSC -derived neurons *in vitro*. The functionality of developing human neuronal networks on different laminin isoforms was studied, and to our knowledge this aspect has not been considered in any previous studies.
Commercially available, human recombinant laminin isoforms 211, 332, 411, 511, 521 (Biolamina) and human recombinant laminin 511 fragment E8 (Takara Bio Inc.) were used as cell culture substrates. Cell attachment, viability, proliferation, and neuronal differentiation were studied on different laminin isoforms using immunocytochemistry and quantitative image analyses. In addition, gene expression profiles of extracellular matrix associated molecules were compared using quantitative RT-PCR and electrophysiological measurements using microelectrode array were performed to monitor the functionality of cultured neuronal networks. Laminin isoforms containing α5-chain were most supportive for hPSC -derived neurons in terms of cell attachment, viability, proliferation, and activity development. Cells formed spontaneously active neuronal networks on all tested laminin isoforms, however, distribution of the network activity was affected by laminin isoforms. Furthermore, human recombinant laminin 511 fragment E8 alone supported growth and functional development of hPSC -derived neurons equally well compared to full length laminin molecule.
In conclusion, human recombinant laminin isoforms and specific laminin fragments can be used for efficient xeno-free and defined culturing of hPSC-derived neurons. This *in vitro* system facilitate defined research concerning laminin isoforms in human CNS.

Title: iPSC lines as a model system to study the dosage effect of a human specific fusion gene CHRFAM7A

Authors: *I. IHNATOVYCH, K. E. SWIECK, A. LEW, K. SZIGETI;
Neurol., SUNY At Buffalo, Buffalo, NY

Abstract: Emerging concepts point to a role for human-specific genes in complex human diseases. *CHRFAM7A* is a human specific fusion gene, a result of multiple chromosomal rearrangements on chromosome 15 during evolution. The region has ongoing instability, and various neurological phenotypes have been reported in the context of deletions and duplications. *CHRFAM7A* has been implicated in neuropsychiatric and neurodegenerative disorders; human specific diseases affecting higher cognitive function. Recently two independent CNV GWAS studies reported an association between *CHRFAM7A* dosage and Alzheimer's disease (AD). The *CHRFAM7A* fusion gene harbors a part of the alpha 7 nicotinic acetylcholine receptor (*CHRNA7*) and 4 new exons of the FAM7 sequence corresponding to a part-functional CHRNA7 and a part-kinase (FAM/ULK4) sequence. In vitro CHRFAM7A affects cell response to the canonical CHRNA7 ion-gated channel. Furthermore, it has an important role in inflammation. We report the characterization of two iPSC lines - UB019 and UB068 - with two and zero copies of CHRFAM7A, respectively. iPSCs (three colonies/line) were generated from human skin biopsies from patients with AD by episomal transformation containing Oct4, Sox2, Klf4, c-Myc and Nanog. Three colonies per line/individual were characterized for: i) chromosomal abnormalities (aCGH), ii) genome-wide DNA methylation (RRBS), iii) gene expression profiles (Affymetrix gene expression array), and iv) lineage preference using non-directed EB differentiation followed by TagMan hPSC Scorecard Panel. The colony with the highest preference for neuroectodermal differentiation was selected for the further neuronal and microglial differentiation. The iPSC lines expressed pluripotency markers by qPCR and ICC. There were no chromosomal aberrations detected in the iPSC lines. During propagation of the cell lines the *CHRFAM7A* CNV remained stable. Genome-wide DNA methylation changes were detected as expected, but did not affect *CHRFAM7A* expression levels. Non-directed differentiation confirmed the presence of markers of all three germ layers. 60% of the colonies for each line showed neuroectodermal preference of differentiation. iPSCs differentiated into

type- specific neurons or microglia provide an in vitro assay system to study the effect of a given CNV on the pathomechanism of disease. After establishing readout and rescue, this in vitro system is also adaptable for high throughput drug screen in a genotype and mechanism-specific manner.

Title: An isogenic blood-brain barrier comprising brain endothelial cells, astrocytes and neurons derived from human induced pluripotent stem cells

Authors: *S. G. CANFIELD[1], M. J. STEBBINS[1], B. S. MORALES[1], S. W. ASAI[1,2], G. D. VATINE[2], C. N. SVENDSEN[2], S. P. PALECEK[1], E. V. SHUSTA[1];
[1]Chem. and Biol. Engin., Univ. of Wisconsin Madison, Madison, WI; [2]Board of Governors Regenerative Med. Inst., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: The Blood Brain Barrier (BBB) is critical in maintaining a physical, metabolic, transport barrier between the blood and the brain. The BBB consists of brain microvascular endothelial cells (BMECs) that form the brain micro-vasculature and are supported by astrocytes, neurons, pericytes, and neural stem cells, that altogether form the neurovascular unit. A number of in vitro BBB models have been developed to elucidate the role of BBB in brain development, function, and disease, and to develop potential therapeutic approaches. Primary isolated or transformed BMECs dedifferentiate and lose their barrier properties once they are removed from their microenvironment and often exhibit sub-par BBB phenotypes. Inter-species variations limit the translation of a number of BBB studies to a human *in vivo* setting. Additionally, previous BBB models consist of cell types from multiple species and with primary cells isolated from animals of various developmental stages. Thus, the ability to derive stem cells from healthy and diseased human patients, differentiate them into the multiple cell types of the neurovascular unit, and investigate BBB characteristics all while maintaining the original host genotype makes a

human stem cell-derived BBB model potentially powerful for dissecting human diseases. To this end, we have successfully differentiated BMECs, astrocytes, and neurons from human induced pluripotent stem cells (iPSCs). Compared to other in vitro BBB models, these iPSC-derived BMECS exhibit more physiologic BBB phenotypes, such as a high transendothelial electrical resistance, low permeability, polarized efflux transport, and expression of tight junction markers. The addition of co-culture with neurons and astrocytes further elevated trans-endothelial electrical resistance (TEER), reduced permeability, and improved tight junction continuity in the endothelial cell population. Varying the ratio of neurons and astrocytes to match that roughly similar to the human brain (1 neuron: 3 astrocytes) was found to be the most BBB enhancing. For the first time, we have developed a completely human induced pluripotent stem cell-based BBB model. The ability to derive an isogenic BBB model consisting of astrocytes, neurons, and BMECs from the same original stem cell source could have major implications in further understanding the interplay between varying cell types of the BBB in both healthy and pathological states.

Title: Exploring the role of estrogens and inflammation in neurodevelopmental disorders using human induced pluripotent stem cells

Authors: *C. SHUM[1], C. M. PARIANTE[2], P. A. ZUNSZAIN[2], D. P. SRIVASTAVA[2]; [1]King's Col. London, London, United Kingdom; [2]Inst. of Psychiatry, Psychology and Neurosci., London, United Kingdom

Abstract: Multiple studies have shown that estrogens have a powerful effect on cognitive function. At a cellular level, the actions of estrogens are mediated by multiple neuronal signalling pathways, involving classical and non-classical estrogen receptors (ERs). The "classical" pathway involves estrogens binding to ERα and ERβ, transcription factors that regulate target gene transcription via binding to estrogen response element sequences and recruitment of other regulatory proteins. The "non-classical" pathway involves estrogens binding to membrane-bound ERα and ERβ, as well as the G protein-coupled receptor GPER1. Activation of these receptors results in the activation of multiple effectors, leading to various downstream effects, including remodelling of neural circuitry, modulation of synaptic function and connectivity, as well as affecting inflammatory responses. Growing evidence from animal studies have also shown that estrogens have a positive effect on behaviours associated with neurodevelopmental disorders. Recently, clinical studies have demonstrated that adjunct treatment of 17β-estradiol, the main biological estrogen can improve negative, positive and general psychopathological symptoms in female patients with schizophrenia. Moreover, the selective estrogen receptor modulator, Raloxifene has been reported to improved attention and memory in male and female patients with schizophrenia. However, the mechanisms through which estrogens exert their beneficial effects in schizophrenia remain unclear. It has been posited that estrogens may modulate the inflammatory component and/or morphology and synaptic deficits in schizophrenia. In order to explore the potential mechanisms that underlie estrogen's positive effect in schizophrenia, and other neurodevelopmental disorders, we have used human induced pluripotent stem cells (iPSCs) as a cellular model. Using a combination of pharmacological challenges, including exposure to the cytokine Interleukin 1 beta (IL1β) in iPSCs generated from healthy and patient specific cells, we have explored the ability of estrogens to rescue deficits in neuronal morphology and synaptogenesis. To this end, we have performed immunocytochemistry and image analysis to characterise the effects of IL1β or estrogens on neuronal morphology and the expression of synaptic proteins in iPSC-derived cortical neurons. We then explored the effects of estradiol, estrogen receptor agonists and Raloxifene in modulating IL1β-induced phenotypes. Collectively, we hope these data will help us understand how estrogens may confer their positive effects in neurodevelopmental disorders.

Abstract: Ontogeny requires coordinated regulation of multi-gene programs by a plethora of epigenetic signals to execute the cell transitions between self-renewal, proliferative expansion and differentiation. Central function is played by a novel panontogenic mechanism, Integrative Nuclear Fibroblast Growth Factor Receptor 1 Signaling (INFS) *(J. Cell Physiol* 2016, 231: 1199–1218). To analyze the role of INFS in human neural development, we modeled the early formation of the human brain in 3D cerebral organoid cultures developed from hESC lines (HUES8 iCAS9N) and control and schizophrenic iPSCs. It takes approximately one month for the organoids to develop. Stem cells are cultured with various media to first induce the formation of embryoid bodies, next forms neuroectoderm, then neuroepthelial tissue, and finally differentiated cerebral organoids. Once at this step, organoids may stay in the incubator for months growing up to several mm in size.
These cerebral organoids form a ventricular zone with radial astrocytic stem cells, a subcortical zone and cortical layers containing multitudes of neurons and connecting interneurons. The functions of nuclear FGFR1 are investigated by CRISPR/CAS9 mutagenesis of different FGFR1 gene regions important in the generation of the nFGFR1. These mutations have a profound effect on the neuronal morphology and formation of intercellular connections. Our results support the major role of nuclear FGFR1 in the control of human brain development. Given the proposed role of immune activation on neural development, and its involvement in schizophrenia, we are also analyzing the effects of the immune factor, TNFα, on the formation of these neuronal networks.

To analyze the formation of functional neuronal networks, we transfected 2D cultured cells with Channel Rhodopsin (ChR) and used 488 nm laser light to activate the channel and induce calcium signaling across cellular networks, visualized by a calcium dye, Rhodamine-3, imaged at 560 nm. In addition, to improve on this technology, and for future use in the human brain interface, we designed and fabricated nano-photonic actuators (nano-lasers) and receivers (nano-photodetectors) to activate and monitor neuronal networks. Indium Gallium Arsenide Phosphide (InGaAsP) over Indium Phosphide (InP) is utilized as the active semiconductor material and substrate, respectively. In order to minimize the optical signal propagation loss, neuronal networks are being grown on top of the InGaAsP layer (following sterilization by exposure to UV light). These nanophotonic devices may facilitate our ability to monitor and interact with the cellular networks.

Title: Sex differences in synaptogenesis, behavior, and plasticity during critical periods in wild-type and serotonin 1a receptor knockout murine hippocampal development

Authors: *T. BUDYLIN[1,2], S. GUARIGLIA[1], A. MARSILLO[1], D. KERR[1], L. NEUWIRTH[1], D. MCCLOSKEY[1], K. CHADMAN[3], S. SAMMADAR[1], P. BANERJEE[1];
[1]Biol., Col. of Staten Island/ CUNY, Staten Island, NY; [2]Biol., Grad. Ctr. CUNY, New York, NY; [3]New York State Inst. for Basic Res. in Developmental Disabilities, Staten Island, NY

Abstract: Mood disorders such as anxiety and depression have strong ties to hippocampal serotonin (5-HT) signaling, and are more prevalent in women than in men. Aberrant serotonin $_{1A}$ receptor (5-HT_{1A} R) signaling, an established model of anxiety and depression, is correlated with decreased neurogenesis in the adult dentate gyrus region of the hippocampus. Little is known about neonatal sex differences in neurogenesis, synaptogenesis, behavior and plasticity in the 5-HT_{1A} R KO model. Immunohistochemical staining of immature neurons for colocalized Doublecortin and BRDU, our earlier studies have suggested that 5-HT_{1A}-R signaling through

protein kinase C epsilon (PKCε) augments neuroproliferation in the hippocampus at postnatal day 6 (P6). Our group has also found increased anxiety behavior in adult *5-HT_{1A}-R* (-/-) (KO) females, thus making sex differences in this model intriguing. Verification of this study, as well as sex differences in neurogenesis, quantification was performed with a modified stereological technique in Imaris, a powerful imaging analysis tool. Synaptogenesis and dendrite morphology are also important in brain development and sex differences remain unexplored. Our published transmission electron microscopy (TEM) studies show that hippocampal 5-HT_{1A}-R stimulation at P15 elicits a major boost in synaptogenesis. TEM in the CA1 region was performed on the CA1 region of P11 hippocampi, which is a critical period for hippocampal synaptogenesis in mice. Currently synapses are being quantified and DiI traced dendrites are being analyzed in Imaris with the Filament Tracer tool. Field recordings of the trisynaptic pathway in adolescent brain slices are being analyzed to determine if KO and wild-type mice have Schaffer collateral plasticity differences in brain development. In addition, early developmental milestones are being tested for behavioral differences that can appear postnatally. Together these studies will reveal how aberrant 5-HT_{1A}-R signaling can influence later-life mood disorders, and their sex differences, and may lead to therapeutic strategies for these debilitating disorders.

Title: The role of cadherin diversity in synapse development

Authors: ***M. TAYLOR**, R. BASU, M. E. WILLIAMS;
Neurobio. and Anat., Univ. of Utah, Salt Lake City, UT

Abstract: Variations in cadherin cell adhesion molecule genes are associated with schizophrenia, autism, obsessive compulsive disorder, and learning disabilities; disorders likely

caused by synaptic defects. Cadherins are necessary for synapse development, but their role in linking cell-adhesion to synapse formation is not well understood. Furthermore, there are 18 classic cadherins in mice and humans, and most are expressed in the brain with overlapping, yet distinct, patterns. Thus, individual neurons express multiple cadherins, but the role of cadherin diversity within individual neurons has not been systematically studied. Here we address this fundamental gap by focusing on two cadherins (N-cadherin and cadherin-9) in hippocampal synapse development. We show that both cadherins localize to the same class of synapses, but are differentially trafficked and play distinct roles in synapse development. This evidence supports a model in which diverse cadherins provide unique functions at individual synapses.

Abstract: The outgrowth of new dendritic spines is closely linked to the formation of new synapses, and is thought to be a vital mechanism underlying behavioral and synaptic plasticity. We recently identified the proteasome as a key regulator of activity-dependent spinogenesis. Here, we examined the role of the RhoGEF, Ephexin5, in connecting proteasome activation to enhanced spine outgrowth. We found that Ephexin5 acts globally as an inhibitor of spine outgrowth, and that it is degraded in an activity-dependent manner in neuronal dendrites and

mature dendritic spines. Remarkably, we also found that a degradation-resistant pool of Ephexin5-GFP accumulated on the dendrite prior to new spine outgrowth, and that removal of Ephexin5 through knockout or RNAi inhibits activity-dependent spine outgrowth induced by global or highly localized stimulation. Our data suggest that Ephexin5 serves a dual role in spinogenesis, acting both as a brake on overall spine outgrowth and as a necessary component in the site-specific formation of new dendritic spines.

Abstract: Mesencephalic dopaminergic (mDA) neurons are critically involved in various key functions of the mammalian brain, including voluntary movement, reward, attention, and learning. Dopaminergic circuitry dysfunctions are linked to the development of neuropsychiatric disorders, including obsessive-compulsive disorder (OCD) and OCD-like disorders, such as Tourette's syndrome (TS) and trichotillomania (TTM). The LIM-homeodomain transcriptional factors Lmx1a and Lmx1b are early determinants of the dopaminergic fate and are essential for each step of mDA progenitor differentiation. Using mDA primary cell cultures we found that the loss of function of Lmx1a/b alters dendritic morphology. Spontaneous miniature excitatory and inhibitory post synaptic currents (mEPSC and mIPSC respectively) were also altered in acute slices of Lmx1a/b double conditional mutant (cKO) mice. Using gene expression profiling

experiments in Lmx1a/b cKO mice, we found that Lmx1a/b controls the expression of Slitrk2 and Slitrk5, two members of the Slit and Trk-like (Slitrk) protein family. Gain and loss of function of Slitrk2/5 in mDA cell cultures induced abnormal dendritic morphology and altered synaptic inputs. More specifically, gain and loss of function of Slitrk2 caused a change in the density of excitatory synaptic puncta (PSD95 and VGLUT), but not in inhibitory ones (gephyrin and VGAT). Accordingly, we observed a difference in the frequency, but not in the amplitude, of mEPSCs, after Slitrk2 knockdown or Slitrk2 overexpression. These data suggest a role for Slitrk2 in the formation of functional excitatory synapses. Inversely, gain and loss of function of Slitrk5 induced a modification in the density of inhibitory synaptic puncta but not in excitatory ones. Accordingly, we observed a difference in the frequency, but not in the amplitude, of mIPSCs, after Slitrk5 knockdown or overexpression. These data suggest a role for Slitrk5 in the formation of functional inhibitory synapses. We also investigated the consequences of Slitrk2 and Slitrk5 inactivation on mDA neurons development in vivo and mouse behaviour. Preliminary observations in mice, in which Slitrk2 and Slitrk5 were conditionally knocked-out in mDA neurons using CRISPR-Cas9, confirm our in vitro findings. In addition, analysis of mice lacking Slitk2 in mDA neurons shows that they exhibit OCD-like behaviour. Altogether, our results suggest that Lmx1a/b and Slitrk2/5 are key players in mDA neurons development and synapses formation. This study should contribute significantly to a better understanding of mechanisms involved in OCD-like disorders.

Abstract: The functionality of the mammalian central nervous system depends on the formation of an extensively precise network of synaptic contacts assembled during development. The

Nogo-66 receptor (NgR1), a principal mediator of myelin and CSPG-dependent outgrowth inhibition, negatively regulates synapse formation and is important for the closure of the critical period. In the present study, we evaluated the role of synaptic NgR1 proteolysis in the development of excitatory synapses. We identify membrane-type MMPs (MT-MMPs), a membrane-bound MMP subfamily, to be present in the mature rodent brain and to correlate with NgR1 spatiotemporal expression. NgR1 shedding gradually increases in the postnatal cortex and correlates with periods of excitatory synapse development. We characterize MT3-MMP as the protease most likely responsible for synaptic NgR1 processing. Expression of a constitutively shed NgR1 protein increases excitatory synapse formation, while blocking NgR1 cleavage decreases the number of excitatory synapses. Furthermore, treatment with a soluble Ecto-NgR1 (1-358) fragment accelerates excitatory synaptogenesis. Our results identify synaptic Nogo-66 receptor to be subject to MT3-MMP cleavage and raise the interesting possibility that regulated NgR1 cleavage may play a role in the development of excitatory synapses in cortical neurons.

Title: Deciphering the molecular mechanisms that regulate synaptic pruning at the *Drosophila* NMJ

Authors: F. VONHOFF, ***H. S. KESHISHIAN;**
MCDB Dept., Yale Univ., New Haven, CT

Abstract: Neural circuit development generally involves the pruning of off-target synaptic contacts. In mammals low frequency calcium and cyclic nucleotide oscillations refine visual maps in an activity dependent manner. Activity-dependent synaptic refinement also occurs at the Drosophila neuromuscular junction (NMJ). Oscillatory neural activity and presynaptic calcium signaling regulate the motoneuron's response to the muscle-derived chemorepellant Sema2a, acting through the PlexinB receptor. We find that mutations in the Ca-dependent adenylyl

cyclase Rutabaga and the cAMP-dependent phosphodiesterase Dunce also disrupt normal refinement, leading to ectopic neuromuscular synapses on up to 30-40% of the examined muscle fibers. We also demonstrated a role for several molecular players acting downstream in the neuron. These include CaMKII, PKA, and Calcineurin. Loss of function of these genes lead to miswiring with ectopic frequencies of 25-35%. We also have found a role for the protein phosphatase 1 family. PP1 functions as a molecular link between several components of the pathway: PP1 is regulated by Calcineurin and PKA, and dephosphorylates CaMKII. As Ca oscillations are essential for normal refinement in this system, we tested whether cAMP must also oscillate. Optogenetic photoactivation of the bPAC adenylyl cyclase with a 15 s light:150s dark cycle suppressed the miswiring phenotype observed in rut1 adenylyl cyclase mutants. No rescue was observed using activation patterns of shorter or longer cycles (8s light: 80s dark or 30s light: 300s dark). Given that an experimentally induced cAMP oscillation is sufficient to rescue miswiring, we also tested whether cAMP oscillations are necessary. cAMP levels were adjusted to different levels by continuously activating bPAC at various light intensities. A rescue was seen only at a specific intermediate level of activation. bPAC exhibits a constitutive baseline level of activity in the dark. Thus, we examined various levels of transgene expression, using an inducible geneswitch driver. A rescue of the rut1 miswiring phenotype was once again observed with specific levels of bPAC induction. Thus we propose that presynaptic cAMP activity must exist within an optimal range for Semaphorin-dependent synaptic refinement to occur. Finally, we have performed live imaging of growth cone Ca in intact, paralyzed embryos. Ca oscillations are evident in native and ectopic contacts during synaptic development. We are currently testing the effects of Ca dynamics and various mutant backgrounds on filopodial behavior during the innervation of correct and incorrect target muscles.

Title: Alterations in the synaptic proteome of the developing mouse neocortex in the absence of MET signaling

Authors: *K. L. EAGLESON[1], P. LEVITT[2];
[1]Pediatrics, [2]Pediatrics and Inst. for the Developing Mind, CHLA, Keck Sch. of Med. of USC, Los Angeles, CA

Abstract: Alterations in the expression of the MET receptor tyrosine kinase have been associated with autism spectrum disorder and Rett syndrome. In the neocortex, MET is expressed in subpopulations of excitatory projection neurons, with peak expression corresponding to the period of process outgrowth and synaptogenesis. In mice, variations in MET signaling modulate dendritic growth, synapse formation, and circuit development and function. Recently, we showed that the MET protein interactome is enriched in proteins implicated in neurodevelopmental disorders. Here, we hypothesize that the cellular and physiological changes due to reduced MET expression will be reflected by changes in the synaptic proteome. To address this, we used quantitative proteomic methods to measure alterations in proteins expressed at the neocortical synapse at the peak of synaptogenesis in the absence of MET signaling. Four independent synaptosome preparations were generated from the neocortex of postnatal day 14 $Met^{fx/fx}/nestin^{cre}$ null mice, in which *Met* is deleted from all neural cells, and from wild type littermates. Two 4-plex iTRAQ (isobaric tag for relative and absolute quantitation) runs were performed by the Vanderbilt University Mass Spectrometry Research Center Proteomics Laboratory, each comparing 2 wild type/null pairs. After filtering to a conservative false discovery rate of <1%, and including proteins with at least two unique peptide measurements, 2728 (run 1) and 3037 (run 2) proteins were identified, with 2452 proteins common to both runs. The protein list contains 157 proteins annotated as synaptic proteins and 502 as mitochondrial proteins, the latter reflecting the high concentration of mitochondria at the synapse. Further, 2195 of the 2452 proteins were identified in an iTRAQ study using synaptosomes prepared from P21 neocortex[1]. The quantitative ratio for each protein was calculated for each null/wild type pair, with a value of 1 indicating that there was no difference between the genotypes. Proteins with an average fold-change <0.8 across the 4 replicates were considered downregulated, while those >1.2 were considered upregulated in *Met* null synaptosomes. A total of 52 proteins were differentially expressed, with 40 upregulated and 12 downregulated. These included proteins involved in proteasome assembly and ubiquitination (6), plasticity (4), cytoskeleton and process outgrowth (8) and signal transduction (5). MET receptor disruption thus results in adaptive changes to the developing synaptic proteome that are consistent with altered function. [1]Moczulska et al., J. Proteome Res. 2014, 13: 4310-4324.

Title: The γ-protocadherins interact with neuroligin-1 and inhibit its synaptogenic activity

Authors: M. J. MOLUMBY[1], R. M. ANDERSON[2], D. J. NEWBOLD[1], N. K. KOBLESKY[1], A. M. GARRETT[1], D. SCHREINER[1], J. J. RADLEY[2], *J. A. WEINER[1];
[1]Dept. of Biol., [2]Dept. of Psychology, The Univ. of Iowa, Iowa City, IA

Abstract: The α-, β-, and γ-Protocadherins (γ-Pcdhs) are cadherin superfamily adhesion molecules encoded by clustered gene families. The 22 γ-Pcdhs are combinatorially expressed in the brain, and play critical roles in synaptogenesis, dendrite arborization and patterning, and the survival of subsets of neurons. The γ-Pcdhs can interact promiscuously with each other, and with other clustered Pcdhs, in *cis*, but interact strictly homophilically in *trans*. Mice lacking the γ-Pcdhs in the cerebral cortex exhibit severely reduced dendrite arborization (Garrett, et al., *Neuron*, 2012). Recently we demonstrated that γ-Pcdhs promote dendrite arborization *in vivo* through local neuron-neuron and neuron-astrocyte homophilic interactions (Molumby et al., *Cell Reports*, 2016). Though γ-Pcdhs regulate the progression of spinal cord synaptogenesis (Garrett and Weiner, *J. Neurosci.,* 2009), a role for these molecules in cortical dendritic spines and synapses has yet not been examined.

Here, we provide evidence that the γ-Pcdhs negatively regulate synapse formation and spine morphogenesis in forebrain neurons. Mice lacking all γ-Pcdhs in the cortex exhibit significantly increased spine density *in vivo*, while spine density is significantly decreased in mice overexpressing one of the 22 γ-Pcdh isoforms. We thus asked whether the γ-Pcdhs might be inhibitory in an artificial synapse co-culture assay. Indeed, we found that multiple γ-Pcdhs can, when co-expressed in COS cells, strongly inhibit the ability of the synaptic cell adhesion molecule neuroligin-1 to promote presynaptic differentiation in contacting axons. The γ-Pcdhs physically interact in *cis* with neuroligin-1 on dendrites of cultured neurons, and can co-immunoprecipitate neuroligin-1 both *in vitro* and *in vivo*. We present *in vitro* evidence that the interaction between γ-Pcdhs and neuroligin-1 disrupts the latter's binding to its presynaptic partner neurexin1β. Additionally, we show that γ-Pcdh overexpression in cultured hippocampal neurons suppresses the increase in spine density observed upon neuroligin-1 overexpression.

This work suggests a potential new mechanism by which γ-Pcdhs regulate the "choice" between dendrite arbor growth and formation and/or stabilization of dendritic spines and synapses in the developing brain.

Title: Inhibitory synapse development: Live imaging of dynamic gephyrin clusters at the convergence of multiple interaction pathways

Authors: *S. BROMLEY-COOLIDGE, W. LU;
NINDS, NIH, Bethesda, MD

Abstract: While many aspects of excitatory synapse development have been described, inhibitory synapse development has been comparatively understudied. Excitatory synapses do not exist in a vacuum; inhibitory synapses control neuronal excitability and synchronize neural networks, and consequently must be in a dynamic balance with excitatory synapses for proper neural circuit function. Malfunctions of inhibitory synapse development have been shown to lead to many neurological and neuropsychiatric disorders. Therefore, it is imperative to study the mechanisms governing inhibitory synapse development in order to have an informed understanding of neural circuit development and function. Gephyrin is a postsynaptic scaffolding protein analogous to PSD-95 but specific to inhibitory synapses. It is a crucial element of inhibitory synapse development and plasticity; however, the underlying mechanisms converging on gephyrin during synapse development remain largely elusive. Here we used *in vitro* live imaging to examine gephyrin dynamics in developing GABAergic synapses, revealing the various pathways through which inhibitory synapse development is modulated. Dissociated hippocampal and striatal cultures were made from embryonic day 18.5 mice, and imaged at 6-8 days *in vitro*. Various pharmacological manipulations were performed, including inhibition or activation of receptors and channels, as well as the modulation of kinases, cell adhesion molecules, and glial-secreted molecules. In order to systematically evaluate the effect of each

factor on early development, we observed the changes in cell morphology as well as the production, clustering, and motility of GFP- or mCherry-tagged gephyrin clusters at GABAergic synapses. All together, the live imaging of synaptic gephyrin reveals complex dynamics and continuous remodeling important for understanding the mechanisms underlying functional and dysfunctional inhibitory synapse development.

Title: The effect of fluoxetine on c-Fos and synaptophysin expressions in the hypothalamic paraventricular organ during development

Authors: *M. J. CALIBUSO-SALAZAR[1], D. GUNDISCH[1], G. R. TEN EYCK[2]; [1]Pharmaceut. Sci., DKI Col. of Pharmacy, Univ. of Hawaii, Hilo, HI; [2]Biomed. Sci., Home Stryke M.D. Sch. of Medicine, Western Michigan Univ., Kalamazoo, MI

Abstract: Fluoxetine (FLX) is a serotonin re-uptake inhibitor commonly used to treat major depressive disorder. This antidepressant is also the most commonly prescribed drug for pregnant woman who are suffering from depression. Changes in c-*Fos* (transcription factor indicating neuronal activity) and synaptophysin (syn, glycoprotein of presynaptic vesicles; indicative of synaptic plasticity and remodeling) immunoreactivities have been demonstrated in animal, and *in vitro,* studies after chronic or acute FLX treatment. It has been shown that chronic FLX treatment increased c-*Fos* expression in the lateral septal nucleus, the nucleus of the stria terminalis, the medial amygdala, and dorsal raphe; while a decreased was detected in the locus coeruleus. Other studies have shown that chronic FLX treatment induced syn expressions in the adult rat telencephalon and hippocampal neurogenesis. We have previously demonstrated that FLX treatment during embryogenesis affected craniofacial organization. This project has two objectives: 1) determine if chronic treatment of FLX during embryonic development will alter c-*Fos* expression and 2) determine if modulation of serotonin concentration will have an effect on the expressions of syn in the hypothalamic region of the brain. This project utilized the embryo culture technique (Calibuso-Salazar and Ten Eyck, 2015) using the directly developing Puerto Rican coquí frog, *Eleutherodactylus coqui* to assess the effects of FLX on c-*Fos* and syn expressions. The *E. coqui* embryos were directly exposed chronically to FLX concentrations ranging from 0.1µM to 1mM. Immunocytochemistry (anti-cFos and anti-syn) was performed on

sectioned brains to determine changes in c-*Fos* and syn expressions. We found that chronic FLX treatment during embryonic development altered c-*Fos* and syn expressions during brain development. The number of immunopositive cells decreased as we increase the concentration of FLX. The results suggest that modulation of monoamine levels via chronic treatment of FLX during embryonic development leads to reduced dendritic branching and synaptogenesis, thus in turn, reduced chemical synapses.

Title: Impact of agonist-independent ghrelin receptor, GHSR1a, activity on calcium-mediated signals in primary hippocampal neuron cultures during synaptogenesis.

Authors: *V. MARTINEZ[1], J. LÓPEZ SOTO[2], J. RAINGO[1];
[1]Electrophysiology Lab., IMBICE, La Plata-Tolosa, Argentina; [2]Dept. of Neurosci., Brown Univ., Brown, RI

Abstract: The ghrelin receptor or *growth hormone secretagogue receptor type 1a* GHSR1a is a G-protein coupled receptor highly expressed in several regions of the central nervous system both pre- and post-synaptically. How GHSR1a controls neuronal activity is still poorly understood but multiple mechanisms seem to be implicated. GHRS1a displays two active modes, one dependent on ghrelin binding, its endogenous ligand, and another one termed constitutive active mode independent from ghrelin binding and relying only on GHSR1a expression levels. Recent data from our laboratory suggest that GHSR1a modulates pre-synaptic neurotransmitter release by controlling pre-synaptic voltage-gated calcium channels (Ca_V2) by two independent mechanisms signaling through two different cellular pathways: an acute, Gq-dependent and reversible one, mediated by ghrelin binding to the GHSR1a, and a chronic one, mediated by a Gi/o-dependent reduction of Ca_V2 membrane density due to GHSR1a constitutive activity. Ca_V2 are fundamental structures for neurotransmission, as they allow calcium influx to the pre-synaptic terminal in response to action potentials and thus trigger synaptic vesicles, SVs, fusion to the plasma membrane containing neurotransmitters. In this context, we hypothesize that this

constitutive modulation could be relevant in synapse formation when the establishment of Ca_V2 sub-localization is critical. Thus, we evaluated if GHSR1a expression modifies synapse activity at early stages in primary hippocampal cultured neurons from wild type *versus* GHSR1a knockout mouse embryos by whole-cell patch clamp experiments. We first recorded Ca_V2 total currents and found larger Ca_V2 currents in GHSR1a knockout mice cultures *versus* wild-type mice cultures. We then evaluated miniature spontaneous post synaptic currents, mSPSCs. We also studied evoked inhibitory and excitatory post synaptic currents, IPSCs, at different days *in vitro*. We found that GHSR1a constitutive activity Ca_V currents reduction correlates with smaller IPSCs. Based on our data, we propose that GHSR1a constitutive active mode differentially modulates the timing of spontaneous and action potential-evoked neurotransmitter release.

Abstract: Neuronal migration disorders comprise various cortical malformations resulting in neural network alterations, early-onset epilepsy and intellectual disability. These malformations occur when newly generated neurons fail to migrate properly and remain stuck somewhere along their migration route. Although several genes have been identified as causes for neuronal migration disorders, the pathophysiological mechanisms underlying these malformations are still poorly understood. We sought to gain a better understanding of these processes by studying synapse formation in a rat model of one such malformation called subcortical band heterotopia (SBH). This SBH model can be generated by *in utero* electroporation of a plasmid coding for an interfering RNA targeting doublecortin (Dcx), one of the genes responsible for SBH in humans. Through the same genetic method, glutamatergic and GABAergic synapses were labeled with PSD-95-GFP and GFP-gephyrin respectively, two post-synaptic proteins. In affected neurons,

Dcx knockdown lead to a major decrease of both glutamatergic and GABAergic post-synaptic sites densities. Subsequent tri-dimensional reconstruction of these neurons also revealed a drastic simplification of their basal dendritic arborization. Because both the misplacement of the neurons and the gene itself could be the origin of these defects, we are now trying to identify the relative contribution of each of these parameters to this process. To this end, we are currently analyzing two Dcx deficient animal models that do not display any migration defect: a delayed Dcx knockdown rat and the Dcx knockout mouse. Analysis of these models should help unravel the molecular processes by which synaptogenesis is impaired in our SBH rat model.

Title: VCP and ATL1 regulate endoplasmic reticulum and protein synthesis for dendritic spine formation

Authors: ***Y.-T. SHIH**, Y.-P. HSUEH;
Academia Sinica, Taipei, Taiwan

Abstract: Imbalanced protein homeostasis, such as excessive protein synthesis and protein aggregation, is a pathogenic hallmark of a range of neurological disorders. Here, using expression of mutant proteins, a knockdown approach and disease mutation knockin mice, we show that VCP (Valosin-Containing Protein), together with its cofactor P47 and the endoplasmic reticulum (ER) morphology regulator ATL1 (Atlastin-1), regulates tubular ER formation and influences the efficiency of protein synthesis to control dendritic spine formation in neurons. Strengthening the significance of protein synthesis in dendritic spinogenesis, the translation

blocker cyclohexamide and the mTOR inhibitor rapamycin reduce dendritic spine density, while a leucine supplement that increases protein synthesis ameliorates the dendritic spine defects caused by Vcp and Atl1 deficiencies. Because VCP and ATL1 are the causative genes of several neurodegenerative and neurodevelopmental disorders, we suggest that impairment of ER formation and inefficient protein synthesis are significant in the pathogenesis of multiple neurological disorders.

Title: Identification of Nek7 as a kinase mediating synapse formation in parvalbumin interneurons

Authors: A. J. HINOJOSA[1], *C. KIECKER[2], B. RICO[1];
[1]Dept. of Developmental Neurobio., King's Col. London, London, United Kingdom; [2]MRC Ctr. For Developmental Neurobio., London, United Kingdom

Abstract: Synapse formation is one of the most determining processes in brain circuit wiring. In the cerebral cortex, the two main neuronal populations, glutamatergic pyramidal cells and GABAergic interneurons, connect to each other through completely different types of chemical synapses. Whereas numerous molecular players have proved to mediate synaptogenesis in pyramidal cells, few are the ones identified in interneurons. This study aims, thereby, at revealing some of the differential molecular mechanisms that underlie GABAergic versus glutamatergic synapse formation in the cortex. To achieve that, we used microarrays to obtain the expression profiles of both neuronal types during the synaptogenetic period. To isolate the neurons we took advantage of reporter mice that expressed GFP in either pyramidal cells or interneurons and used fluorescence activated cell sorting (FACS) to get a pure RNA sample of the cell populations. Bioinformatic analysis of the microarray data produced a list of genes differentially upregulated during GABAergic and glutamatergic synaptogenesis.
Among the genes upregulated exclusively during GABAergic synapse formation, we selected

NIMA (Never in Mitosis Gene A)-Related Kinase 7, Nek7. This gene was increased 12 fold during synapse formation and was one of the most specific genes for the interneuron population. Nek7 is a serine/threonine kinase that have been proved to regulate the establishment of the microtubule-based mitotic spindle and to accelerate the dynamic instability of this cytoskeletal component. Microtubules are key regulators of axonal and dendritic arborization in neurons and its role in synapse formation and plasticity is starting to be discovered. Thus, Nek7 was a good candidate to play a role in the postnatal development of interneurons, including synapse formation. Using simultaneously *in situ* hybridization and immunohistochemistry, we demonstrated that Parvalbumin interneurons were the main population expressing Nek7 transcript. To explore whether Nek7 had a function in the process, we carried out loss-of-function experiments in vivo with viruses containing a CRE dependent vector that expressed an shRNA against Nek7. Then, to target these vectors in Nek7 expressing cells, we performed stereotaxic injections in the somatosensory cortex of an Lhx6Cre line, driving Cre recombinase expression in a population of interneurons that includes all Parvalbumin cells. Confocal analysis revealed that loss of Nek7 caused a reduction in the number of parvalbumin synapses onto pyramidal cells. Our findings, unveil a novel protein that is specifically required for inhibitory synapse formation in the cerebral cortex.

Abstract: Synapses, the specialized structures between neurons, are a vital component of neural circuitry and neurotransmission. The spatiotemporal development of synapses is strictly regulated by well-orchestrated signaling cascades. Aberrant synapse development and function are believed to be associated with neurological disorders such as autism, schizophrenia, and Alzheimer's disease. However, the molecular basis underlying synapse development is not well understood. We previously reported that EphA4 receptor, an Eph receptor tyrosine kinase, induces the retraction of dendritic spines, through a mechanism involving cyclin-dependent kinase 5 (Cdk5). Here, we investigated a novel role of EphB2, another Eph receptor, in the regulation of synapse development and function. EphB2 potentiates the phosphorylation, surface expression, and synaptic recruitment of AMPAR receptor subunit GluA1 in a Cdk5-dependent manner. Interestingly, Cdk5 and its activator p35 form a complex with EphB2 upon ligand-induced activation. Suppressing Cdk5 activity by p35 knockdown or administration of Cdk5 inhibitor perturbed dendritic spine formation and synapse maturation upon EphB2 activation, accompanied by reduced synaptic transmission. Hence, our findings strongly suggest that excitatory synaptogenesis in hippocampal neurons is regulated by EphB2 in a Cdk5-dependent manner.

Abstract: Nitric oxide (NO) is a molecule that accumulates in hydrophobic environments such as membranes and hydrophobic domains of proteins. Moreover, NO has one unpaired electron, which gives a high reactivity characteristic and which allows it to be involved in many physiological and pathological processes. In the central nervous system (CNS), NO has been involved classically involved in synaptic plasticity related processes, such as long-term potentiation. However, the role of NO in the CNS development remains unknown. The aim of this project was to evaluate gene expression (by real-time polymerase chain reaction - PCR) and protein distribution (by immunofluorescence) of the neuronal nitric oxide synthase (nNOS - an enzyme, which are related to the majority production of NO in neurons) in developing and mature retina. We measured NO production levels (by the electron paramagnetic resonance technique - EPR) during retinal development (P0, P5, P10 and P60) and under effect of pharmacological intervention (7-NI blocker). Moreover, we evaluated the effects of NO production on synaptic genes. We observed that mRNA levels of the nNOS are present at all studied ages. Moreover, nNOS seems to be distributed only in specific layers of retina. Specifically, nNOS presence was mainly observed in the inner nuclear layer, where double-labeling experiments and morphological observations revealed two distinct populations of nNOS positive amacrine cells, named as *round* and *balloon* cells. nNOS protein also was detected on inner plexiform layer, which suggest a possible involvement on synaptogenesis. Furthermore, the data obtained from the specific nNOS blocker (7-NI) showed a reduction of synapsin (2^0.41= 0.75-fold-expression; $p<0.05$), synaptophysin (2^0.79= 0.58-fold-expression; $p<0.02$) and connexin45 transcripts (2^0.75= 0.79-fold-expression; $p<0.02$). Taking together, our data suggests that NOS are present in initial stages of postnatal development and, more importantly, that nNOS plays an important role in the formation of electrical and chemical synapses during CNS development.

Title: The neurodevelopmental disorder gene Kirrel3 regulates target-specific hippocampal mossy fiber synapse development

Authors: *E. A. MARTIN[1], D. WOODRUFF[2], R. RAWSON[2], A. SCHNEGGENBURGER[2], M. WILLIAMS[2];

Abstract: Synaptic target specificity, whereby neurons make distinct types of synapses only with specific target cells, is critical for normal brain function, yet the mechanisms driving target selection remain poorly understood. We recently showed that Kirrel3 is a synaptic specificity molecule in the mammalian hippocampus. Because alterations in Kirrel3 are associated with intellectual disability and autism, understanding Kirrel3 function can provide insights to cellular and circuit changes underlying these disorders. We demonstrated Kirrel3 is required for proper development of presynaptic mossy fiber filopodia, synaptic structures connecting dentate gyrus (DG) granule neurons to GABAergic neurons in the CA3 region of the rodent hippocampus. Kirrel3 knockout mice have significantly fewer mossy fiber filopodia, suggesting a reduction in DG-GABA synapses. As GABAergic neurons regulate feed forward inhibition onto CA3 neurons, we also observed an increase in CA3 neuron activity in Kirrel3 knockout mice. This suggests that Kirrel3 is required to maintain proper excitation/inhibition balance during brain development. Here we will report on new results using serial blockface scanning electron microscopy (SBEM) to define the precise synaptic defects present in the mossy fiber layer of Kirrel3 knockout mice. We are also determining if patient-associated Kirrel3 point mutations attenuate its function. Together, our results increase our understanding of the links between Kirrel3, synapse development, and neurodevelopmental disorders.

Title: The sorting receptor SorCS1 controls axonal targeting of neurexin-1alpha via transcytosis

Authors: *J. DE WIT, K. D. WIERDA, K. M. VENNEKENS, L. F. RIBEIRO;
VIB Ctr. for the Biol. of Dis., Leuven, Belgium

Abstract: The highly polarized morphology of neurons necessitates mechanisms for sorting proteins to their appropriate cellular compartments. Precise delivery of synaptic surface receptors is essential for the proper establishment of synaptic contacts and the maintenance of neurotransmission. Neurexin-1 (Nrxn-1) is a presynaptic cell adhesion molecule that engages in trans-synaptic interactions with several postsynaptic ligands and plays a key role in the formation, maturation and function of synapses. We recently showed that SorCS1, an endosomal sorting receptor present in the somatodendritic compartment, binds Nrxn-1 and controls its synaptic abundance. However, the mechanism by which somatodendritic SorCS1 regulates the trafficking and synaptic abundance of presynaptic Nrxn-1 remains unclear.
In cultured mouse cortical neurons, Nrxn-1 is polarized to the axonal surface, but is also present in the somatodendritic compartment, consistent with previous reports. We find that blocking endocytosis increases dendritic surface expression of Nrxn-1. Importantly, this manipulation concomitantly disrupts axonal surface targeting of Nrxn-1. Interference with the formation of early and recycling endosomes, but not of late endosomes, results in the same phenotype, indicating that axonal surface expression of Nrxn-1 requires endocytosis and transport via early/recycling endosomes in dendrites. These are hallmarks of transcytosis: axonal proteins are first sorted to the somatodendritic domain and redirected to the axon after endocytosis. Indeed, following experimental release from the ER, Nrxn-1 first traffics to the dendritic surface before appearing on the axonal surface. Furthermore, overexpression of wildtype SorCS1, but not of an endocytosis-defective mutant, removes Nrxn-1 from the dendritic surface and promotes its axonal surface targeting. Together, these data support the idea that SorCS1 governs transcytosis of Nrxn-1. *SORCS1* and *NRXN1* genes have been associated with synaptic disorders, including autism, suggesting that impaired synaptic receptor trafficking contributes to defects in synaptic protein composition and function observed in synaptopathies. Current efforts are directed at determining whether SorCS1-mediated transcytosis of Nrxn-1 sustains presynaptic function.

Title: Gabapentin inhibition of alpha2delta1-mediated synaptogenesis *In vitro* and during adult neurogenesis.

Authors: *K. A. BEESON[1], G. WESTBROOK[2], E. SCHNELL[3];
[2]Vollum Inst., [3]Anesthesiol. and Perioperative Med., [1]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: The mammalian brain is remarkably plastic, in part due to the integration of adult-born granule cells into an established hippocampal neural network. Identification of the molecules that control synaptic integration of new adult-born neurons is fundamental to our understanding of neural plasticity in health and disease in the adult brain. Recently, the α2δ proteins have been identified as the receptors for thrombospondins, glia-secreted synaptogenic molecules. Excitatory synapse formation is positively regulated by expression of α2δ during development and *in vitro*, and mutations in α2δ can result in striking neurophysiological phenotypes, such as epilepsy (Barclay *et al.,* Journal of Neuroscience, 2001). Although α2δ proteins have been implicated in neural development (Eroglu *et al.,* Cell, 2009), their contribution to the integration of adult-born neurons is not well understood. Interestingly, a commonly prescribed anti-epileptic and analgesic, gabapentin, binds α2δ with high affinity antagonizing thrombospondin-mediated synaptogenic signaling. Here, using whole cell electrophysiology in organotypic slice cultures, we demonstrate reduction in miniature excitatory post-synaptic currents in gabapentin treated cultures, consistent with a role for α2δ proteins in synaptogenesis. Furthermore, gabapentin significantly reduced dendritic spine density and size in adult-born granule cells *in vivo*, indicating that α2δ contributes to synapse formation during adult neurogenesis. Using *in vitro* and *in vivo* models of neuronal development paired with single-cell morphology and electrophysiology, we hope to decipher the contribution of α2δ proteins to synaptogenesis in adult-born neurons.

Title: Retromer regulates the retrieval and recycling of neuroligins

Authors: *C. S. BINDA, J. M. HENLEY, K. A. WILKINSON;
Sch. of Biochem., Univ. of Bristol, Bristol, United Kingdom

Abstract: Surface proteins are internalised into early endosomes and either sorted for degradation by the lysosome or recycled back to the plasma membrane in a process that for many cargoes is mediated by the retromer complex. For some proteins retrieval and recycling is dependent on an interaction between the PDZ ligand in the cargo protein and the PDZ-domain containing retromer component sortin nexin 27 (SNX27). SNX27 then binds the essential retromer component VPS26 preventing the SNX27 cargo entering the lysosome and therefore rescuing it from degradation.

Retromer dysfunction plays an important role in a growing number of cognitive disorders and the core retromer subunits VPS35 and VPS26 have been reported to be downregulated in the entorhinal cortex in Alzheimer's Disease (AD) patients. SNX27 protein and mRNA is reduced in the cortex of Down's Syndrome (DS) patients. Furthermore, both $VPS26^{+/-}$ knockout mice and $SNX27^{+/-}$ knockout mice have impaired hippocampal-dependent memory and synaptic dysfunction.

Neuroligins are a family of transmembrane cell adhesion molecules that are crucial for synapse function; they bind the presynaptic cell adhesion molecule neurexin to form a trans-synaptic complex which mediates essential pre- and postsynaptic signal transduction.

Here, we show that the PDZ-ligand containing neuroligins 1-3 are cargos for retromer and that they bind SNX27 via a PDZ interaction. Knockdown of SNX27 or VPS35 in cultured cortical neurons significantly decreases total levels of neuroligins 1-3, suggesting that SNX27-retromer is involved in rescuing neuroligins from lysosomal degradation.

These results suggest that the SNX27-retromer dysfunction seen in neuropathological disorders such as AD and DS could lead to impaired synaptic function through reduced recycling of neuroligins back to the synaptic plasma membrane.

Title: Giant ankyrin-G interaction with GABARAP is critical for the formation of GABAergic synapses in mouse somatosensory cortex

Authors: *A. D. NELSON[1], K. K. WALDER[2], V. BENNETT[3], P. M. JENKINS[4];
[1]Pharmacol., Univ. of Michigan, Ann Arbor, MI; [2]Dept. of Cell Biol., Duke Univ. Med. Ctr., Durham, NC; [3]Departments of Cell Biology, Biochemistry, Neurobio., Howard Hughes Med. Institute, Duke Univ. Med. Ctr., Durham, NC; [4]Dept. of Pharmacol. and Psychiatry, Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: Several large genome-wide association studies have identified *ANK3* as having a robust association with bipolar disorder, although the mechanisms by which loss-of-function of ankyrin-G contributes to neuropsychiatric disease remains unknown. The giant, 480kDa ankyrin-G (product of the *ANK3* gene) is a critical adaptor protein that organizes membrane proteins at critical excitatory membrane domains, including the axon initial segments and nodes of Ranvier. Recently, we showed that the 480kDa isoform of ankyrin-G also plays an important role in the formation of somatodendritic GABAergic synapses. GABAergic inhibitory signaling is essential for the proper synchronization and function of neuronal networks that underlie cognition, mood, and behavior, and abnormalities in GABAergic interneuron circuitry have been linked to bipolar disorder. Although the 480kDa splice variant of ankyrin-G is a key regulator of GABAergic synapse formation, the exact mechanisms by which ankyrin-G controls inhibitory circuit development are poorly understood. Using cultured neurons, we have shown that giant ankyrin-G interacts directly with $GABA_A$ receptor-associated protein (GABARAP) to inhibit $GABA_A$ receptor endocytosis and stabilize GABAergic synapses. To test the role of this interaction *in vivo*, we generated a mouse model with a W1989R mutation in *Ank3*, which has been shown to completely abolish both ankyrin-G association with GABARAP as well as $GABA_A$ receptor clustering *in vitro.* Interestingly, preliminary data from coronal brain sections from *Ank3* W1989R mice showed the loss of inhibitory synapses on the soma, but not the axon initial segment, of cortical pyramidal neurons in layer II/III of the somatosensory cortex, suggesting a loss of inhibitory synapses from basket cells, but not chandelier cells. In addition, these mice exhibited an overall decrease in PV expression in interneurons, as well as alterations in perineuronal nets (PNNs), which are thought to stabilize GABAergic synapses. As was seen *in vitro*, axon initial segments and nodes of Ranvier are spared in the W1989R mouse, making this

a useful model to study the specific role of basket cell circuitry in normal neuronal activity and how dysfunction in these circuits might contribute to neuropsychiatric disease.

Abstract: Single neurons often receive and integrate different types of excitatory inputs at different dendritic locations. Among the critical factors that allow the postsynaptic neuron to differentiate and process these distinct inputs are the unique morphological and electrophysiological properties of these different synapses. Although functional properties of these distinct synapses are often well studied, the underlying molecular signatures that confer these unique properties remain unclear. In the hippocampus, CA1 neurons receive excitatory synaptic inputs from CA3 neurons in two synaptic layers; on their basal dendrites in stratum oriens (SO) and their apical dendrites in stratum radiatum (SR). Interestingly the synaptic plasticity rules are different in these two layers with SO exhibiting higher levels of long term potentiation (LTP) compared to SR. We discovered that loss of the classic cadherin, cadherin-9, results in reduced density of mushroom spines and a reduced level of LTP in the CA1 SO layer while the SR synapses are unaffected. Interestingly, at these synapses we show cadherin-9 is exclusively a presynaptic CA3 molecule. Given that the spine and LTP defects in cadherin-9 knockout mice likely involve postsynaptic mechanisms, we sought to identify postsynaptic binding partner(s) of cadherin-9. We screened hippocampal cadherins and confirmed cadherin-9 heterophilically binds cadherins-6 and 10, which are both expressed in CA1 but not CA3 neurons. Analysis of cadherin-10 knockout (KO) mice reveal that they have spine and LTP

defects specifically in the CA1 SO layer and similar to cadherin-9 knockout mice. Together, our data suggests that cadherins-6, 9, and 10 form a trans-synaptic signaling complex needed for enhanced LTP in CA1 SO. Though classical cadherins are known to mediate adhesion predominantly via homophilic interactions, our work suggests cadherins also use heterophilic interactions to regulate synaptic properties in vivo and cadherin function contributes to establishing complex synaptic identity codes.

Title: An NMDA receptor-dependent mechanism underlies inhibitory synapse development

Authors: X. GU, *W. LU;
NINDS/NIH, Bethesda, MD

Abstract: In the mammalian brain GABAergic synaptic transmission provides inhibitory balance to glutamatergic excitatory drive and controls neuronal output. The molecular mechanisms underlying the development of GABAergic synapses remain largely unclear. Here we report that NMDA-type ionotropic glutamate receptors (NMDARs) in individual immature neurons are the upstream signaling molecules important for GABAergic synapse development, which requires signaling via Calmodulin binding motif in the C0 domain of the NMDAR GluN1 subunit. Interestingly, in neurons lacking NMDARs, while GABAergic synaptic transmission is strongly reduced, the tonic inhibition mediated by extrasynaptic $GABA_A$ receptors is increased, suggesting a compensatory mechanism for the lack of synaptic inhibition. These results demonstrate a crucial role for NMDARs in specifying the development of inhibitory synapses, and suggest an important mechanism for controlling the establishment of the balance between synaptic excitation and inhibition in the developing brain.

Title: SRPK regulates aggregation of ELKS2 and modulates synaptogenesis in dissociated hippocampal neurons

Authors: V. I. TORRES[1], *N. C. INESTROSA[1], C. C. GARNER[2], P. L. ZAMORANO[3]; [1]Ctr. For Aging and Regeneration (CARE),P. Catholic Univ. of Chile, Santiago, Chile; [2]Neurochemistry and Mol. Biol., Leibniz Inst. for Neurobio., Magdeburg, Germany; [3]Biologia Celular Facultad de Ciencias Biologicas, Pontificia Univ. Catolica de Chile, Santiago, Chile

Abstract: The mechanisms involved in presynaptic active zone formation are not well understood. It has been reported that SRPK79D regulates the aggregation/assembly of the active zone protein Bruchpilot in *D. melanogaster*, a protein with a N-term domain highly homologous to the rat presynaptic scaffold protein ELKS. Here, we explored the role of the SRPK79D rat homologues SRPK 1, 2, 3 in modulating ELKS2 synaptic assembly and their effect in synaptogenesis in rat hippocampal neuronal cultures. In the present study, we employed hippocampal neuronal cultures and heterologous cells HEK293 as platform to asses the oligomerization of ELK2 and its regulation by SRPKs. SRPKs in the CNS show different expression pattern during development: SRPK1 decreases, SRPK2 does not change and SRPK3 increases during synaptogenesis. In neurons, expression of SRPKs is found mainly in the cell soma with a less abundant punctuated distribution in the neurites showing a scanty colocalization with ELKS2 at the growth cones. ELKS2 when expressed in heterologous cells tend to form oligomers, interestingly, SRPK2 and SRPK3 show capacity to disaggregate mRFP: ELKS2 when expressed in HEK293 cells, an effect modulated by the expression levels of SRPKs. Furthermore, expression of SRPK2 and SRPK3 in neurons decreases number of ELKS2 and synaptophysin puncta per length of neurite, but only partially affects Bassoon. These results suggest that the kinases SRPK2 and SRPK3 might be modulating the recruitment of ELKS2 at the active zone, which could also affect other presynaptic proteins

Title: The role of activity and Nova1/2 splicing factors in the development and connectivity of cortical interneurons

Authors: *B. WAMSLEY, X. JAGLIN, G. FISHELL;
Neurosci., NYU Langone Med. Ctr., New York, NY

Abstract: Cortical circuits are complex networks built of hierarchical connections between excitatory neurons and inhibitory interneurons. Cortical interneuron (cIN) function, to balance, excitation to inhibition relies on the various intrinsic electrophysiological features of different classes of INs but also on their distinct abilities to innervate specific postsynaptic partners and target unique subcellular compartments. Although it is now recognized that individual subtypes of INs play unique roles within distinct cortical circuits, the means by which they integrate into circuitry during development is not well understood.
Recent work from our lab and others has demonstrated that early network activity and subsequent modification of gene expression is critical for proper cIN development. However, little is known about the activity-dependent mechanisms underlying establishment of circuit-specific connectivity of cINs. We identified the Nova family of RNA splice factors enriched within cINs during circuit assembly. These factors are particularly attractive, as they have been shown to control the splicing and translation of distinct synaptic pre-mRNAs during development and in response to neuronal stimuli.
Utilizing mouse genetics we are investigating the role of activity and Nova1/2 in the development of cIN connectivity. We find that manipulating cINs activity *in vivo,* maintains the specificity of their contacts but acts to change the density of axonal boutons and profoundly affect Nova1/2 expression within cINs. Conditional loss of Nova1/2 in all INs results in animal lethality due to seizures. To circumvent animal death, we conditionally remove Nova1/2 cell-autonomously and are analyzing any changes in their connectivity via genetic labeling of synapses of individual cINs. Furthermore, we are identifying the genes targeted by Nova1/2 in cINs during synaptogenesis and in response to activity with RNA-seq.
This study will increase our understanding of how specific cIN populations correctly embed into cortical circuitry and how the regulation of RNA transcripts contributes to this process. Understanding these processes carries significant promise as malfunctions in interneuron development and/or synaptic transmission have been implicated in the pathophysiology of many complex neurological disorders including epilepsy, schizophrenia, and autism.

Title: Ephrin-B3 controls synapse number in an activity independent molecular competition

Authors: N. T. HENDERSON[1], *M. HRUSKA[1], S. LE MARCHAND[2], M. B. DALVA[1]; [1]Dept. of Neurosci., Thomas Jefferson Univ., Philadelphia, PA; [2]Drexel Univ., Philadelphia, PA

Abstract: In the developing brain, neurons must form specific connections in an environment with many potential synaptic partners while also controlling the number of synapses they receive. This precise number and pattern of contacts only emerges after a period of exuberant synaptogenesis, which generates an excess of synapses that are then subjected to further refinement. However, while synaptic sites are over produced during development, connectivity remains sparse, with only a small number of all possible contacts made. Since only a small fraction of the possible connections between neurons exist, how do neurons decide whether to accept or reject potential synaptic contacts?

We propose that differences in eB3 expression levels between neurons regulate the density of synaptic contacts a neuron generates relative to its neighbors though an activity independent molecular competition. A competition requires a winner and loser of a limiting resource. To ask whether eB3 determines winning and losing neurons in a competition for synapses, we used microisland cultures with one or two neurons. In two-neuron islands, cells with wild-type levels of eB3 emerged as winners, forming more synapses than cells in the same island with reduced eB3 expression. Remarkably, EphB2 ecto-domain rescued synapse density following eB3 knockdown in complex cultures and in microislands, suggesting that eB3 competes for EphB2.

To study eB3-mediated competition in genetic model system, we generated eB3 Mosaic Analysis with Double Markers (MADM) mice. These animals have sparsely labeled wild-type ($eB3^{+/+}$) tdTomato+ neurons and eB3 null ($eB3^{-/-}$) GFP+ neurons within an $eB3^{+/-}$ background. Preliminary data indicate that $eB3^{+/+}$ cortical neurons exhibit higher dendritic spine density than

eB3$^{-/-}$ neurons within the same animal. Finally, we used FACS to purify and co-culture eB3$^{+/+}$ and eB3$^{-/-}$ neurons from MADM mice. In these mixed cultures, eB3$^{+/+}$ neurons received a higher proportion of vGlut1 contacts than nearby eB3$^{-/-}$ neurons. Remarkably, blockade of neuronal activity had no effect on the ephrin-B3 dependent differences in synapse density in MADM cultures, suggesting that eB3 may control synapse number independently of activity. Together, these findings define a role for a trans-synaptic protein, ephrin-B3, in controlling synapse number through a novel molecular competition.

Abstract: Early brain development is characterized by periods of rapid synaptogenesis which requires highly coordinated trans-synaptic signaling between presynaptic boutons and postsynaptic specializations. Canonical complexes consisting of presynaptic neurexins and postsynaptic neuroligins serve as powerful mediators of synapse differentiation, maturation and activity-dependent modification. Previous studies found that neurexin interactions with neuroligin-2 were decreased in the presence of MAM domain containing glycosylphosphatidylinositol anchor proteins (MDGAs), and MDGA1 was shown to be a negative regulator of inhibitory synapse development. Using mice heterozygous for MDGA2 (*Mdga2*$^{+/-}$; full knockout was perinatal lethal), we characterized MDGA2 function *in vivo*. We discovered that MDGA2 regulates excitatory synapse formation as both the number and function of excitatory synapses was increased *Mdga2*$^{+/-}$ mouse hippocampal slices. In addition, *in vivo* analysis of cortical circuit dynamics through voltage sensitive dye imaging revealed increased cortical excitability in brain midline regions and enhanced cortical region interconnectivity. Behavioral measures yielded data consistent with an autism phenotype including impaired social interactions, increased stereotypies and reduced cognitive function. These results suggest MDGA2 haploinsufficiency enhances excitatory transmission, elevates brain circuit dynamics and compromises cognitive function.

Title: Dynamics of the mouse brain cortical synaptic proteome during postnatal brain development

Authors: *M. A. GONZALEZ-LOZANO[1], P. KLEMMER[1], T. GEBUIS[1], C. HASSAN[2], P. VAN NIEROP[1], R. VAN KESTEREN[1], A. SMIT[1], K. LI[1];

Abstract: Development of the brain involves the formation and maturation of numerous synapses. This process requires prominent changes of the synaptic proteome and potentially involves thousands of different proteins at every synapse. To date the proteome analysis of synapse development has been studied sparsely. Here, we analyzed the cortical synaptic membrane proteome of juvenile [postnatal day 9 (P9), P15, P21, P27], adolescent (P35) and different adult ages (P70, P140, P280) of C57Bl6/J mice. Using a quantitative proteomics workflow we quantified 1560 proteins of which 696 showed statistically significant differences over time. Proteins of the presynaptic active-zone and postsynaptic element showed increased levels over time; proteins involved in protein synthesis or neurite outgrowth generally decreased in abundance. In several cases, proteins from a single functional molecular entity, e.g., subunits of the NMDA receptor, showed profound differences in their temporal regulation, which may reflect specific synaptic development features of connectivity, strength and plasticity. Furthermore, we evaluated the function of Cxadr that showed high expression levels at P9 and a fast decline in expression during neuronal development, suggesting involvement in synapse formation or maintenance. Knock down of the expression of Cxadr in cultured primary mouse neurons revealed a significant decrease in synapse density.

Title: Kismet regulates presynaptic vesicle endocytosis and the localization of cell adhesion molecules at glutamatergic synapses

Authors: *F. L. WYGLE-LIEBL, T. L. DELANEY, C. GRIDLEY;
Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: Glutamatergic synaptic transmission is important for a number of behaviors including learning and memory, movement, and visual perception. This neurotransmission relies on the proper localization of cell adhesion molecules and recycling of presynaptic vesicles. We have previously shown that the chromodomain helicase DNA (CHD) binding protein, Kismet (Kis), positively regulates the synaptic localization of glutamate receptors, neurotransmission, and the apposition between glutamate receptors and presynaptic active zones at the *Drosophila* neuromuscular junction. As a transcriptional regulator, Kis likely broadly affects glutamatergic synaptic development. Indeed, we have recently found endocytosis of presynaptic vesicles is deficient at *kis* mutant synapses. Although Kis does not seem to directly regulate transcription of *glutamate receptor* subunits, there is a significant reduction in presynaptic transcript levels of *endophilin B*, *nervous wreck*, and *AP180* in *kis* mutants. Surprisingly, our knock down and rescue experiments suggest that Kis is required in postsynaptic muscles for proper presynaptic endocytosis. Kis may affect endocytosis of presynaptic vesicles and organization of the synapse by regulating the localization of synaptic cell adhesion molecules as *kis* mutants exhibit altered localization of integrins, fasciclin II, and neuroligins. We are currently investigating whether Kis signals by recruiting the chromatin remodeling protein, absent, small or homeotic discs 1 (Ash1) thereby suppressing polycomb group repression and whether Kis influences signaling via the mitogen activated protein kinase (MAPK) pathway.

Title: The kinesin 3 family member Khc-73 is a regulator of the Bone Morphogenetic Pathway and retrograde endosomal traffic

Authors: *E. LIAO, K. TSURUDOME, E. MAKSOUD, P. HAGHIGHI;
Buck Inst. For Res. On Aging, Novato, CA

Abstract: Retrograde transport from synaptic terminals to the neuron cell body is an essential process necessary for neuron survival, identity, circuit formation and plasticity. Retrograde transport requires the function of dynein-dynactin motor complexes and anterograde transport is

regulated by kinesin motors. Here we have identified an unusual role for a kinesin 3 motor protein Kinesin 73 (Khc-73) in routing endocytic vesicles to the retrograde pathway at the Drosophila larval neuromuscular junction (NMJ). At the NMJ, synaptic growth and function is regulated by the Bone Morphogenetic Pathway (BMP). During the establishment of synapses, BMP receptors traffic in the retrograde direction to coordinate growth between pre and postsynaptic partners. Our findings indicate that Khc-73 is required for efficient retrograde BMP signalling in motoneurons. Transheterozygous combination of *Khc-73* and BMP transcriptional co-factor *Medea* lead to a significant reduction in the number of presynaptic release sites. Similarly, increased accumulation of phosphorylated form of BMP transcription factor Mad as a result of activation of BMP signaling in motoneurons is fully suppressed when Khc-73 is removed. We did not find any evidence for involvement of *Khc-73* in regulating the degradation of BMP receptors as is the case for several other interactors. Therefore we set out to examine the role of Khc-73 in the regulation of retrograde routing of vesicles further. Interestingly, we found a strong reduction in the dynamics of late endosomes as marked by fluorescently tagged Rab7. Live imaging experiments showed that Rab7 vesicles were stalled along their path from synaptic boutons to the retrograde route along motor axons. In support of this observation, we found abnormally high number of late endosomal multivesicular bodies at synaptic endings using ultrastructural examination. Our result therefore provide a conceptual advance in our understanding of the interaction between dynein and kinesin motor proteins, by revealing a critical role for Khc-73 in routing endosomes onto the retrograde path.

Title: Kainate receptors regulate maturation of adult-born granule neurons

Authors: *Y. ZHU[1], A. CONTRACTOR[2];
[1]Northwestern Univ. - Chicago, Chicago, IL; [2]Northwestern Univ., Chicago, IL

Abstract: In the adult hippocampus, continuous populations of newborn granule cells (GCs) are generated and undergo successive activity-dependent neuronal maturation and incorporation into the preexisting hippocampal circuitry. Increasing evidence has demonstrated that adult-born neurons in the dentate gyrus can impact numerous cognitive and affective processes such as learning and memory, mood and stress responses. Therefore the mechanisms that control

maturation of adult-born GCs are of relevance to multiple neuropsychiatric disorders. In this study we addressed whether members of the kainate receptor subfamily of glutamate receptors, which are abundantly expressed on adult-born GCs, contribute to activity-dependent maturation of this important neuronal population. To study the maturation of adult-born GCs we used retroviral birth-date labeling of dividing neural progenitors to track their development over a four-week critical period. We compared the maturation of GCs in kainate receptor knockout (GluK2 KO) and control littermate mice using functional and morphological measures including the development of intrinsic membrane properties, dendritic morphology, and development of both inhibitory and excitatory synaptic inputs at various time points after retroviral labeling. We found that the input resistance, as a prime indicator of neuronal maturity, was significantly lower in neurons from the KO mice at 21dpi (WT: 2.46 ± 0.27 GΩ, n = 23; GluK2 KO: 1.53 ± 0.18 GΩ, n = 23, $p < 0.01$) and 28dpi (WT: 1.22 ± 0.18 GΩ, n = 15; GluK2 KO: 0.74 ± 0.07 GΩ, n = 15, $p < 0.05$), suggesting that, surprisingly, loss of GluK2 results in more rapid maturation of adult-born GCs. We also determined the dendritic length and complexity of adult-born GCs as a measure of maturation. The total dendritic length at 21dpi was increased in adult-born GCs in GluK2 KO mice (WT: 1216.4 ± 84.6 µm, n = 5; GluK2 KO: 1707.4 ± 174.9 µm, n = 6, $p < 0.05$) and number of dendritic branch points was also increased at 21dpi (WT: 9.4 ± 0.8, n = 5; GluK2 KO: 13.3 ± 0.9, n = 6, $p < 0.01$) consistent with a more advanced maturation state of adult-born GCs in the GluK2 KO mice. These measures consistently indicate that the rate of maturation of adult-born GCs is accelerated in GluK2 KO mice, which would suggest that kainate receptor signaling normally constrains their development. These results raise many questions about how loss of an excitatory receptor causes faster maturation of these neurons. We are now addressing several mechanistic questions including whether these effects are cell autonomous and whether kainate receptors potentially interact with GABA signaling which is known to play a critical role in adult-born GC maturation.

Title: Excitation-morphogenesis coupling during corticogenesis: a critical role for L-type voltage-gated calcium channel-driven spontaneous calcium elevations in neurite extension and radial migration

Authors: *S. KAMIJO[1], K. SUZUKI[1], S.-I. HORIGANE[1,2], H. FUJII[1], S. TAKEMOTO-KIMURA[1,2], H. BITO[1];
[1]Univ. of Tokyo, Bunkyo-Ku, Tokyo, Japan; [2]Dept. of Neurosci. I, Res. Inst. of Envrn. Medicine, Nagoya Univ., Chikusa-ku, Nagoya, Japan

Abstract: Calcium signaling is important for various neurodevelopmental processes such as sculpting of neurites, functional wiring and fine tuning of growing networks. Although the existence of spontaneous calcium elevations has been reported in developing neurons, their spatiotemporal pattern, the critical Ca^{2+} sources, and their physiological function have remained elusive. We previously reported that CaMKIα and CaMKIγ decoded local calcium changes and differentially contributed to the elongation of axons and dendrites (Ageta-Ishihara et al. 2009; Horigane et al. 2016). Understanding the ”calcium codes” that govern these CaMK events is thus crucial for deciphering cellular mechanisms underlying cortical development. To address this question, we here combined a membrane-tethered GCaMP with *in utero* electroporation, and imaged spontaneous calcium transients in the neurites of immature layer 2/3 excitatory cortical neurons *in vitro*. We found that spontaneous calcium activity greatly varied in location, duration and amplitude. Though largely stochastic, kymograph-based quantitative analysis revealed that a sizable fraction of local transients were regenerative, and these were termed Spontaneous Regenerative Calcium Transients (SRCaT). Intriguingly, SRCaTs were larger in axons compared to dendrites. Membrane hyperpolarization by overexpressing Kir2.1 inhibited SRCaTs, though tetrodotoxin showed no effects, indicating that SRCaTs were not driven by Na^{+} spikes. Pharmacological experiments suggested a dual calcium source requirement for SRCaT: both Ca^{2+} influx through voltage-gated Ca^{2+} channels (VGCC) and thapsigargin-sensitive IP_3-driven internal stores appeared to be involved. Up- or down-regulation of L-type VGCC resulted in significant bidirectional alteration of axonal outgrowth. Exogenous expression of gain-of-function L-type VGCC mutants harboring single nucleotide variations of Timothy syndrome, an autosomal dominant inherited form of syndromic autism, by *in utero* electroporation, resulted in impaired proper radial migration of layer 2/3 excitatory cortical neurons. Taken together, these lines of evidence suggest an essential role for spontaneous opening of L-type VGCC and SRCaTs in activity-dependent neuronal morphogenesis during corticogenesis.

Title: Distinct mechanisms control the start and end of experience-dependent plasticity at the VPm relay

Authors: *L. PAN, J. YANG, Q. YANG, H. LOU, S. DUAN, H. WANG;
Zhejiang Univ., Zhejiang, China

Abstract: Synapse plasticity, which refers the ability of synapses to be strengthened or weakened in the central nervous system, plays a critical role in normal brain function including learning and memory. Recent studies have found in addition to cortical area, thalamus is also plastic during a particular time window. However, the underlying mechanisms are still unclear. Here, by using *in vitro* whole-cell patch recording in acute brain slices we found that the precise critical period at the VPm relay synapse was from P11 to P14. Whisker deprivation later than P11 or earlier than P14 significantly altered synaptic properties within 24 hrs. Further studies found that between P10 and P11, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPAR)-EPSCs, N-methyl-D-aspartate receptors (NMDAR)-EPSCs were not significantly changed, whereas NMDAR decay constant and sensitivity to ifenprodil, a selective NR2B-containing NMDAR blocker were largely altered. These results indicate that more NR2A-containing NMDA receptors were recruited to VPm relay synapse at P11 when compared with that at P10. We next found that intraperitoneal injection of PEAQX, which selectively blocked the function of NR2A-containing NMDA receptors, delayed the maturation of VPm relay synapse. These results suggest that the recruitment of NR2A containing NMDARs may responsible for the entering of critical period at the VPm relay synapse. During the end of critical period, we did not observe any changes of synaptic properties occurred between P14 and P15. Through the method of calcium imaging, we found that the timing of the switch from depolarizing to hyperpolarizing GABA show great changes between P14 and P15 in VPm neurons. These data demonstrate that the maturation of GABAergic inhibition is concurrent with the ending of critical period.

Title: Transcriptional response to single exposures to physical exercise

Authors: *C. CHATZI, Y. ZHANG, R. H. GOODMAN, G. L. WESTBROOK;
Vollum Institute, OHSU, Portland, OR

Abstract: Neurons have the remarkable ability to process and respond to complex stimuli such as physical exercise and changes in an organism's external environment. In rodents such experiences increase hippocampal synaptic plasticity and neurogenesis, spatial memory and pattern separation. However there is still little information on the signaling pathways that underlie these experience-dependent changes. The majority of *in vivo* studies have singled out transcriptional regulators without being able to provide a model for understanding the behavior of gene networks engaged upon synaptic activity, while they also were limited by temporal and spatial resolution. We have developed a novel method for *in vivo* analysis of the transcriptional cascades of discrete populations of dentate granule cells activated by physical exercise within a specific time window.

Immediate early response gene *Fos* expression is undetectable in quiescent cells but can be rapidly and transiently induced by external stimuli such as exercise. $cFos^{cre/ERT2/Luo}$ transgenic mice use the connection between *Fos* expression and neuronal synaptic activity in order to permanently label neurons that are active over a short time period. We used a virus expressing a CAG promoter followed by a loxP-flanked ('floxed') stop cassette-controlled Histone2B Monomeric Red Fluorescent Protein (H2B-mRFP) that was injected stereotaxically into the dentate gyrus of $cFos^{cre/ERT2/Luo}$ mice. Two weeks post viral injections, mice were injected with tamoxifen while caged with a running wheel for 2 hrs or were undisturbed in their homecage, and then mice were sacrificed at several timepoints following tamoxifen administration. Voluntary exercise resulted in a significant increase of the activated mRFP +ve cells in the DG in comparison to mice left in the homecage. mRFP labeled (i.e. activated) and non-activated granule cells from exercised mice were subsequently excised from non-fixed intact tissue cryosections using laser capture microdissection and pooled in batches of 100-150 cells. RNA from microdissected cells was reverse transcribed and processed for RNASeq library construction. Additionally, we investigated how exercise-induced neuronal activity regulates synaptogenic processes including synapse development and maturation. Our experiments provide

cell and temporal specific approach to the influence of exercise-induced synaptic activity on neuronal gene expression.

Title: Neuronal inactivity dependent-undifferentiation in primary visual cortex

Authors: *H. SHIN, H. D. KAWAI;
Dept. of Bioinformatics, Soka Univ., Hachioji, Tokyo, Japan

Abstract: Recent studies reported that sensory deprivation regulated cell proliferation of NG2-expressing glia cells in somatosensory cortex (Mangin et al., 2012, Nat. Neurosci. 15, 1192-1194) and that of neural progenitor cells in the tectum (Sharma and Cline, 2010, Neuron, 68, 442-455). It is unclear whether proliferating cells existed in primary visual cortex (V1), and whether and how visual deprivation (VD) regulates proliferation or differentiation. Here we investigated these issues in V1 of binocularly enucleated juvenile mice.
We enucleated at postnatal day 15 (P15), the time of eye opening, and examined if there are proliferating cells after 7- or 10-day VD. To examine for the presence of proliferating cells, BrdU was administrated daily for 3 days from P19 to P22 (P19-22) or from P22 to P25 (P22-25). The cell density of BrdU positive (BrdU+) cells was similar at P22 and P25 in control mice. Enucleated mice however showed a general increase in the density of BrdU+ and Ki67 positive (Ki67+) cells (i.e., undifferentiated cells) throughout the cortex with about 3-fold increase in layer 6 at P25. Enucleation also increased the proportion of Ki67+ cells among BrdU+ cells throughout the cortex, especially in layers 2/3, at P25, although the total BrdU+ cell density did not change. The cell density and the proportion of undifferentiated doublet cells with their distance of 10 μm or less also increased at P25, suggesting an increase of recently divided cells due to the lack of neuronal activities during P22-25, which corresponds to the beginning of the critical period for ocular dominance plasticity. Only a very few newly proliferated cells were apoptotic as determined by the presence of Caspase-3. These data suggest that the lack of neuronal activities increases undifferentiation of proliferating cells during the important period

of synapse formation.
Next, we examined the cell type of BrdU+ cells with several markers at P25. The BrdU+ cells lacked the co-immunostaining of GAD67 (inhibitory neuronal marker), β-tubulin (immature neuron marker), NG2 (NG2 positive glia cell or oligodendrocyte progenitor cell marker), or GFAP (mature or reactive astrocyte marker). In the meantime, ~52% of BrdU+ cells co-expressed S100β in control mice, which increased to ~75% following enucleation. This increase was due to the increase in BrdU+Ki67+ cells from ~17% to ~31% without changing BrdU+Ki67- cells, suggesting that enucleation increases astrocyte progenitor cells without affecting differentiating astrocytes.
Overall, these data suggest that VD following enucleation at the time of eye opening promotes the undifferentiated state in astrocyte progenitor cells in developing V1.

Title: Examining synaptic competition between tonic and phasic motor neurons at *Drosophila* neuromuscular junctions

Authors: *N. A. APONTE-SANTIAGO[1], J. LITTLETON[2];
[1]Biol., MIT, Cambridge, MA; [2]Biol. and BCS, The Picower Inst. for Learning and Memory , MIT, Cambridge, MA

Abstract: Structural plasticity induced by neuronal competition is a common feature of developing nervous systems, and alterations in this process may contribute to neurodevelopmental disorders. Although several mammalian systems have been used to study activity-dependent synaptic competition, the molecular mechanisms underlying this process are still being elucidated. The *Drosophila* larval neuromuscular junction (NMJ), a model glutamatergic synapse with excellent genetic accessibility, may provide a useful system to study synaptic competition and compensation. Most larval muscle fibers are innervated by at least two motor neurons, a type Ib "tonic" motor neuron and a type Is "phasic" motor neuron. The Ib neuron innervates a single muscle, while Is neurons innervate a subset of muscles to coordinate contraction of distinct muscle groups. If and how the postsynaptic muscle can differentiate

between these two inputs, and how it might preferentially regulate them, is unknown. We are examining if Ib and Is motor neurons compete for synaptic drive to the postsynaptic cell by creating an input imbalance through genetic manipulation of one of the two neurons. To determine if synaptic competition at the NMJ occurs, we genetically altered the Ib neuron innervating muscle 1 (MN1-Ib). Surprisingly, complete elimination of MN1-Ib did not result in changes in innervation of the corresponding 1s neuron. In contrast, decreasing activity of the MN1-Ib neuron (rather than ablating it) using *vglut* RNAi or by expressing tetanus toxin light chain resulted in changes of the co-innervating 1s neuron. Additional studies are underway to further test the ability of the *Drosophila* NMJ to display synaptic competition. In addition, we are examining if plasticity is manifested in a synapse-specific fashion only at the target muscle where 1b motor neuron activity is altered, or across all muscles innervated by the 1s neuron.

Title: The role of cyclic adenosine monophosphate and apolipoprotein A1 on myopic eye growth

Authors: *C. H. TO[1], R. K.-M. CHUN[2], C. W. DO[2];
[1]Hong Kong Polytechnic Universi, Hong Kong, Hong Kong; [2]Sch. of Optometry, Hong Kong Polytechnic Univ., Hong Kong, Hong Kong

Abstract: OBJECTIVE. To investigate the effects of cAMP on eye growth through its interaction with apolipoprotein A1 (ApoA1) in young chicks. METHODS. Four groups of chicks were examined. Group 1: Chicks received 8-Br-cAMP (0.1 mM or 1 mM) and were fitted with -10 diopter (D) lenses on both eyes, whereas chicks in group 2 (0.1 mM 8-Br-cAMP) wore plano lenses over both eyes. 8-Bromo-cAMP (8-Br-cAMP) was injected intravitreally to the right eyes of 8-day old chicks for 4 consecutive days and control eyes received vehicle only. The levels of

retinal cAMP and ApoA1 were measured in another two groups of chicks wearing -10 D (group 3) and +10 D lenses (group 4) on their right eyes for 3 days respectively (plano lenses were worn by left eyes). RESULTS. Although, Br-cAMP had little effect on normal eye growth, it significantly inhibited the development of lens-induced myopia (group 1: 0.1 mM versus vehicle: +1.71 ± 1.22 D versus -8.00 ± 2.19 D; 1 mM versus vehicle: +1.38 ± 1.34 D versus -9.96 ± 1.14 D, mean ± SEM, $P < 0.01$ for both); 1 mM, but not 0.1 mM 8Br-cAMP increased retinal ApoA1 expression ($P < 0.01$). Both retinal cAMP and ApoA1 levels were significantly increased only in hyperopic eyes (group 4). CONCLUSIONS. 8-Br-cAMP significantly inhibited myopic growth as induced by optical lenses. Cyclic AMP activates retinal ApoA1 expression in the process and the present data suggested a possible interplay between ApoA1 and cAMP in regulating eye growth.

Title: The non-classical MHCI Qa-1 is a novel regulator of experience dependent plasticity in visual cortex

Authors: *K. S. CHEW, C. J. SHATZ;
Biol., Stanford Univ., Stanford, CA

Abstract: For the nervous system to translate experience into memory, lasting structural change at synapses must occur. This requirement is evident during critical periods of activity-dependent development during which early experience sculpts connections to establish adult circuits via strengthening of selected subsets of synapses and weakening and eliminating others. While activity-dependent mechanisms are known to be essential, molecular mechanisms underlying how activity refines connections are not well understood.

Research has identified a surprising role for several classical major histocompatibility complex class I (MHCI) proteins in activity-dependent refinement of neural networks. The presence of MHCI protein in neurons is notable because GWAS studies have linked polymorphisms in the MHC genomic cluster with several neuropsychiatric disorders including schizophrenia. There are more than 50 MHCI alleles, yet to date only two have been studied in brain. The MHCI family is subdivided into two groups: classical MHCIs are highly polymorphic, players in adaptive immunity and interact with T-cell receptors. In contrast, non-classical MHCIs are less polymorphic and interact with inhibitory and activating innate immune receptors.
Here we report that the mouse non-classical MHCI, Qa-1, is expressed in neurons and specifically enriched in layer 6 cortical neurons, as well as a subset of cerebellar Purkinje neurons. To explore the functional significance of neuronal Qa-1, we investigated its role in ocular dominance plasticity (OD) in visual cortex. During the critical period, OD plasticity in Qa-1 KO mice is enhanced following a period of monocular visual deprivation. In the mouse immune systems, Qa-1's cognate receptor is a CD94/NKG2 heterodimer, specifically CD94/NKG2A, C, or E. These putative receptors are also expressed in brain, suggesting that Qa-1 may act through a CD94/NKG2 heterodimer to regulate ocular dominance plasticity. Together, these observations point to a broadening role for both classical and non-classical neuronal MHCI proteins in plasticity and neural circuit refinement in cerebral cortex, and imply a related function for Qa-1 in cerebellar Purkinje cells.

Title: The role of serotonergic neurons in spontaneous activity of the developing mouse hindbrain

Authors: *L. E. HOOD[1], M. BOSMA[2];
[1]Univ. Of Washington, Seattle, WA; [2]Univ. of Washington, Seattle, WA

Abstract: Early in neural development, cells in the ventral midline of the mouse hindbrain spontaneously depolarize in the absence of external stimulation. These electrical events are dependent on t-type calcium channels and trigger intracellular calcium influx, which we measure with calcium imaging techniques. The spontaneous activity (SA) begins as isolated events at embryonic day (E) 10.5 and builds into synchronized waves of activity that repeatedly propagate

along the entire midline by E11.5. During this same developmental window, serotonin neurons are specified and differentiate in two columns flanking the spontaneously active midline. Pharmacology studies have implicated the involvement of serotonin in the initiation of spontaneous events; no other transmitter systems are required for the spontaneous activity. In this study, we use serotonin-receptor-specific pharmacological agents to further probe the role of serotonin in the generation of activity. We use quantitative real time PCR to examine the relative levels of expression of a range of serotonin receptors including 5HT2A and 5HT2C. In addition, we have examined the effect of blocking serotonergic signaling on the morphology of the serotonergic cells. Hindbrains cultured in antagonists specific to various serotonin receptors for 24 hours show a significant reduction in the number of 5HT+ cells. However, the same reduction in cell number does not occur when the SA is halted via blocked calcium channels. This suggests serotonin signaling is crucial for appropriate development of serotonergic neurons within the hindbrain.

Abstract: Neuronal activity regulates aspects of the structure and function of brain circuitry in part through the induction of calcium-dependent programs of gene expression. While neuronal activity-regulated genes have been profiled and shown to be important for neurological faculties, including memory and learning in model organisms, little is known about such gene expression

programs in human neurons. We have transcriptionally profiled depolarized human fetal brain cultures, and identified a new neuronal activity-dependent secreted factor Osteocrin (OSTN). *OSTN* is enriched in the neocortex of human and macaque, but is not expressed in mouse neurons. Our gene expression studies suggest that *OSTN* has been evolutionarily repurposed through the acquisition of a primate-specific activity-regulated neuronal enhancer, and our functional studies show that OSTN restricts activity-dependent dendritic growth in human neurons. These findings suggest that subtle sequence changes in cis-regulatory elements allow for neuronal activity-regulated gene programs to be tailored for lineage-specific features of brain plasticity and development.

Abstract: Experience-driven programs of neuronal gene expression have been shown to regulate the plasticity of brain circuitry in model organisms. However, it is not known if there are neuronal activity-regulated genes that control features of brain development and function that are unique to primates, including humans. We identified a new activity-dependent secreted factor Osteocrin (OSTN) by transcriptional profiling of human fetal brain cultures. While *Ostn* is exclusively expressed in bone and muscle of mouse, *OSTN* is enriched in the neocortex of human

and macaque. We find that *OSTN* gene has been evolutionarily repurposed in the primate lineage through the acquisition of a new neuronal activity-regulated enhancer. Functional studies showed that *OSTN* restricts activity-dependent dendritic growth in human neurons. These findings suggest that modification of neuronal activity-regulated gene programs, via the evolution of cis-regulatory elements, may contribute to lineage-specific features of brain plasticity.

NEUROFARBA Univ. of Florence, Florence, Italy; [4]Ctr. for Epigenetics and Metabolism, Univ. of California, Irvine, CA

Abstract: The mechanisms at the basis of cortical postnatal development are still poorly understood. It has been proposed that cortical development derives from a delicate interplay between innate and experience-dependent factors converging at the level of the regulation of gene expression. In this context, miRNAs could be molecular “chisels” used to sculpt the transcriptome during development. To understand their role in visual cortical development we performed sequencing analysis of miRNAs and mRNAs from the visual cortex of the mouse at P10 and P28, two ages corresponding to the beginning and completion of the functional development of visual cortical neurons. We found that a dramatic age-dependent regulation of the transcriptome affecting a number of KEGG pathways. Intriguingly we found that age-dependent regulation of miRNAs was paralleled by regulation of their putative targets in an

opposite manner, suggesting that miRNAs shape the cortical transcriptome during this period of development. Functional validation of the role of the regulated miRNAs will elucidate the relevance of this regulation for cortical development.

Title: N-acetyl aspartate is related to sensory processing challenges in children: A preliminary study

Authors: ***N. M. KLEINHANS**[1], N. CORRIGAN[1], M. REILLY[1], L. BARRERA[1], M. REITER[1], A. ESTES[2], T. ST. JOHN[2], T. RICHARDS[1], S. DAGER[1];
[1]Dept Radiology, [2]Speech and Hearing Sci., Univ. Washington, Seattle, WA

Abstract: Children with sensory processing challenges (SP) show atypical reactions to everyday sensory information. Current hypotheses regarding the biological basis of SP implicate cortical regions involved in primary sensory processing and multimodal sensory integration. The role of the amygdala, a subcortical structure which receives inputs from all sensory modalities, is unknown. We investigated whether N-acetylaspartate (NAA), a marker of neuronal integrity, was different in children with SP compared to typically developing (TD) children, and whether NAA levels corresponded to individual differences in parent reported sensory symptoms. Children with SP had a significantly elevated Sensory Profile score on at least 1 of 4 quadrants: Seeking/Seeker, Avoiding/Avoider, Sensitivity/Sensor, Registration/Bystander. Autism spectrum disorder was ruled out in all participants. Data collection is ongoing. The sample included 10 children with SP and 12 age- and IQ-matched TD controls between 8 and 12 years of age. 3D MPRAGE and magnetic resonance spectroscopic (MRS) data were acquired on a 3T Philips Achieva system. Single-voxel MRS data were acquired from a left amygdala-hippocampal region and a left lateral superior cerebellar region using a PRESS sequence (TE=35ms, TR 2000ms, 2048 complex time points, spectral width 2000 Hz, 32 avgs, voxel size 30x30x30mm). NAA concentrations were estimated using LCModel, referenced to water, and corrected for CSF

partial volume effects. Independent t-tests and bivariate correlations between NAA concentrations and scores on the Sensory Profile were run using SPSS. Results: The SP group had significantly higher NAA than the TD group in the amygdala-hippocampal region (p = .007), but not in the cerebellar region (p = .543). Correlations were run on the combined sample (N=22). Higher amygdala NAA was correlated with significantly more sensory symptoms in 5/6 sensory sections (not oral) and all 4 Quadrants. The most robust correlations (p < .005) were observed in the auditory (r = .545), touch (r = .690), body position (r = .593) and movement (r =.773) sections and the Seeking/Seeker (r=.749) and Registration/Bystander (r =.704) Quadrants. No significant correlations were observed in the cerebellum (p vals ranged from .225 to .959). In this preliminary study, higher levels of amygdala-hippocampal NAA were associated with more severe sensory challenges, indicating that atypical sensory processing may be related to increased dendritic arborization and synaptic connectivity. Elevated NAA does not appear to be a generalized effect throughout the brain in SP, as group differences were not observed in our cerebellar control region.

Title: Alternation of resting-state brain connectivity in the orbitofrontal & the dorsolateral prefrontal cortices of heroin addicts & its relationship with anxiety: fNIRS study

Authors: ***H. IEONG**, Z. YUAN;
Univ. of Macau, Macau, Macao

Abstract: Drug addiction is widely linked to the orbitofrontal cortex (OFC) and the dorsolateral prefrontal cortex (dlPFC) which is essential for regulating reward-related behaviors, emotional and inhibitory responses, and anxiety. Over the past 20 decades, neuroimaging has provided significant contributions revealing the functional and structural alternations in the brains of drug addicts. However, the underlying neural mechanism in the cortices and their correlates of drug addiction and anxiety still need further elucidation. In this study, we examine the local network dynamics in the OFC and dlPFC regions through resting-state functional connectivity (rsFC) by using functional near infrared spectroscopy (fNIRS) from eight chronic users in the heroin-dependent group (HD) and seven normal subjects in the control group (CG). We discovered that the HDs manifested enhanced interhemispheric correlation and functional connectivity across the OFC regions. Moreover, the small-worldness was identified in the HD brain networks. We suggest that the individuals under chronic heroin influence carry more complex local brain networks than normal individuals. Alongside the abnormal robustness, our findings also revealed that there was a dissociation in the functional connectivity between the left inferior frontal gyrus and other regions correlated with anxiety. This work may pave a new insight into the neural adaptations resulting from chronic opiate intake.

Title: The neural underpinnings of Learning Disabilities (LD) - in search of biomarkers

Authors: N. ALAHMADI[1], *L. JANCKE[2];
[1]Dept. of Special Educ., King Abdulaziz Univ., Jeddah, Saudi Arabia; [2]Univ. Zurich, Zurich, Switzerland

Abstract: Learning disability (LD) is diagnosed when an individual's achievement on individually administered, standardized tests in reading, mathematics, or written expression is substantially below that expected for the individual's age, schooling, and level of intelligence. A major problem in diagnosing LD is the strong cultural and educational influence on the diagnosis. Thus, objective and easily to apply methods would be helpful for LD diagnosis. In this paper we demonstrate first findings of our project to establish neurophysiological biomarkers helping to diagnose LD. Here we have used electroencephalographic (EEG) measurements during resting state condition in LD children and in healthy control children (HC).Using the

group independent component analysis (gICA) model to identify substantial differences between LD and HC children in terms of their spectral EEG profiles we obtained the following findings: (a) there was substantial slowing of EEG oscillations, especially for gICs located in frontal scalp positions; (b) the estimated intracortical sources of these gICs were mostly located in brain areas involved in the control of executive functions, attention, planning, and language; and (c) those LD children suffering predominantly from verbal problems (LD-Verbal) demonstrated substantial differences in EEG oscillations in language-related brain areas. The general pattern of atypical neurophysiological activation found in LD children suggests that they suffer from neurophysiological dysfunction in brain areas involved with the control of attention, executive functions, planning, and language functions. LD-Verbal children also demonstrate atypical activation, especially in language-related brain areas. Using these neurophysiological measures we were also able to correctly classify the LD children with a precision of > 90%. Thus, these EEG techniques might be useful for objective classification and diagnosis of LD children, which is particularly important for non-Western countries. In addition, these atypical neurophysiological activation patterns might provide a helpful guide for rehabilitation strategies to treat the deficiencies in LD children.

Title: Dysregulation of SRY in the male brain: a genetic basis for male susceptibility to neurological disorders?

Authors: *H. P. LOKE[1,2], P. PINARES-GARCIA[1,3], V. HARLEY[1,2,3], J. LEE[1,2,3];
[1]Hudson Inst. of Med. Res., Clayton, Australia; [2]Dept. of Mol. Translational Sci., [3]Dept. of Anat. and Developmental Biol., Monash Univ., Clayton, Australia

Abstract: Sex differences in the dopamine (DA) pathway are likely to underlie male susceptibility to neurological disorders such as Parkinson's disease (PD) and attention deficit hyperactivity disorder (ADHD). Aside from hormonal effects, recent evidence suggests that sex-chromosome genes may influence the sex differences in the healthy and diseased DA system. The Y-chromosome gene, *SRY*, is an ideal candidate to study, as it is found in various DA abundant brain regions. Our previous *in vivo* studies showed that reducing *SRY* expression in midbrain cells significantly reduced motor function and expression of DA machinery genes in male rats, suggesting that SRY regulates DA biosynthesis and motor function in males. Thus, we propose that dysregulation in SRY expression could underlie male susceptibility to DA associated disorders such as PD and ADHD. To test this hypothesis, we investigated the regulation of *SRY* in the normal and diseased male DA system using *in vitro* and *in vivo models* of PD and ADHD. In the human male dopaminergic cell line, M17, *SRY* expression was significantly increased at 1h following DA treatment with no significant changes in *GADD45γ* (a marker of DNA damage and a known regulator of *SRY*) expression and cell viability, indicating that *SRY* is regulated by a *GADD45γ*-independent (possible DA receptor-dependent) mechanism. However, increase in *SRY* expression at 6 and 12h was associated with significant increases in *GADD45γ* expression and increased cell death. Similarly, treatment with the DA toxins 6-hydroxydopamine (6-OHDA) or rotenone increased *SRY* and *GADD45γ* expression at 6 and 24h. In the 6-OHDA lesioned rat model, unilateral injection of 6-OHDA increased nigral *SRY* and *GADD45γ* expression from days 2 to 14 post-injection, which was associated with reductions in limb use and nigral *TH* expression in male rats. Injection of rotenone, also elevated *SRY* and *GADD45γ* expression at day 7 post-injection. In the spontaneously hypertensive rats (SHR), a well charaterised animal model of ADHD, male SHR showed significant hyperactivity in velocity and distance travelled as compared to the control male Wistar Kyoto rats (WKY) in the open field test. These behavioral differences were associated with significantly lower *SRY* expressions in the prefrontal cortex, hippocampus, hypothalamus and substantia nigra of male SHR compared to male WKY. In conclusion, we showed that SRY is upregulated *in vitro* and *in vivo* models of PD, and downregulated in a ADHD model, indicating that *SRY* dysregulation may underlie male susceptibility to these disorders. Thus, normalizing *SRY* expression may be a potential therapeutic strategy for treating DA-associated disorders such as PD and ADHD.

Title: Tool-induced learning and plasticity in motor control of healthy and DCD teens

Authors: *M. MARTEL[1], L. FINOS[2], A. FARNÈ[3], A. C. ROY[1];
[1]Lab. Dynamique Du Langage Univ. of Lyon, Lyon, France; [2]Dept. di Scienze Statistiche, Padova, Italy; [3]Integrative Multisensory Perception Action & Cognition team (ImpAct) CRNL Univ. of Lyon, Lyon, France

Abstract: Body Schema plasticity has recently gained increasing interest, as the update of our body-parts posture and length might be the basis for humans' exquisite mastery of tools. To efficiently control our actions, whether performed with our own body effectors or with tools, the brain needs to store and update all the metrics of the body (from the coding of initial hand position, to the evolving state of the effector, through the dimensions of the body). Previously (Baccarini et al, 2014; Cardinali et al, 2009, 2011, 2012, 2016), we reported that using a tool functionally extending the arm leads to a fast plastic update of the arm representation for action, namely the Body Schema (BS). Tool-induced modifications are reliably observable on the kinematics of subsequent free-hand movements.
Here, our aim was twofold. First, we examined whether this fast body plasticity co-exists with the slow body metrics modifications induced by growth. Second, we investigated body representations in adolescents affected by Developmental Coordination Disorder (DCD) as inaccurate body representations might lead to general clumsiness, or poor motor skills.
We assessed the kinematics of typical developing and DCD adolescents in a task requiring to reach for an object before and after having performed the same action with a tool. In addition, we examined their imitation skills using the De Renzi scale for apraxia. Their pubertal development was evaluated through a Pubertal Development Scale.
Results indicate that tool-induced plasticity develops slowly, becoming apparent only after puberty that is when an adult body dimension has been reached. Indeed, the more mature were adolescents, the more they displayed, as observed in adults, peaks of longer latencies and smaller amplitudes after tool-use. DCD adolescents did not display the typical tool-induced plasticity as they performed their movements faster after tool-use (reduced latencies, increased peaks),

kinematics values reaching a normal range.
While the body representation for action undergoes fast updates in adults, its plasticity does not seem to co-exist with the slow update required by growth. This lack of BS fast plasticity might be linked to the clumsiness described in teenagers, as further suggested by their difficulties in imitating arm and finger gestures and postures. Adolescents with DCD did not update their arm representation either, interestingly though, their free-hand movements tended to normalize after tool-use.

Title: An fMRI and fcMRI study of the motor system in children with and without dyslexia

Authors: ***T. TURESKY**[1], O. OLULADE[2], G. EDEN[2];
[1]Interdisciplinary Program in Neurosci., [2]Ctr. for the Study of Learning, Georgetown Univ., Washington, DC

Abstract: The defining feature of developmental dyslexia is difficulty in learning to read. However, motor impairments are also reported in studies of dyslexia (Wolff, 2002) and there are several theories that attempt to account for these observations. The cerebellar deficit hypothesis proposes that reading difficulties result from dysfunction in motor-articulatory systems that relate to phoneme processing and/or automatization of motor and other skills (Nicolson et al., 2001). Differences in activity in the cerebellum have been observed in adults with dyslexia during sequential finger pressing of learned and novel sequence (Nicolson et al., 1999) and serial reaction time tasks (Menghini et al., 2006). The latter also identified differences in supplementary motor area (SMA), right lateral premotor cortex, and inferior parietal cortex. It is unknown, however, if these differences also present during simple, externally paced finger movements commonly used in studies of the motor system (Witt et al., 2008). To address this question fMRI data was acquired in 17 dyslexic (10.2 ± 1.4 years; Woodcock-Johnson III (WJ III) Word ID < 92) and 16 non-impaired (9.6 ± 3.2 years; Word ID > 92) right-handed children

while performing irregularly paced, separate left and right thumb tapping tasks. Whole-brain fMRI and functional connectivity (fcMRI) analyses were performed within and between groups using SPM12 and CONN 16a with in-scanner head motion and reaction times entered as nuisance covariates. Seed-to-voxel correlations were used for fcMRI with 6 mm spheres in ipsilateral cerebellum, contralateral primary sensorimotor cortex (SM1), and SMA. Clusters of activity (height threshold $p = 0.001$, a cluster-level FDR correction at $p < 0.05$) were found in children with and without dyslexia in contralateral SM1, bilateral SMA and ipsilateral cerebellum for movements of the thumb with either hand. Between-group comparisons during right finger tapping revealed greater activation for dyslexic compared to non-impaired readers in a cluster (MNI=6, -27, 62) containing bilateral paracentral lobule (BA 5) and extending into SMA and precentral gyri (BA 6). Activity here was correlated with WJ III Reading Fluency ($r = -.48$; $p < .005$) and Rapid Automatized Naming (RAN) time ($r = -.48$; $p < .005$). FcMRI was observed for each group, but no between-group differences were found. In conclusion, there was no evidence of cerebellar dysfunction in dyslexia, but instead aberration of cortical motor function underlying right finger movement.

Title: Reduced amygdala response to fearful expressions in youth with callous-unemotional traits related to faster habituation

Authors: ***H. MEFFERT**[1], P. M. TYLER[1], M. L. BOTKIN[1], A. K. ERWAY[1], V. KOLLI[1], S. F. WHITE[1], K. POPE[1], J. R. BLAIR[2];
[1]Ctr. for Neurobehavioral Res., Boys Town Natl. Res. Hosp., Boys Town, NE; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Youth who display increased levels of externalizing behavior and whom additionally present with elevated callous-unemotional (CU) traits (lack of empathy and remorse/ guilt) show reduced sensitivity to other peoples' fear. This is accompanied by reduced amygdala responsiveness. However, the amygdala has also been shown to habituate to repeated stimulation by facial expressions, and therefore, the reduced average responsiveness to fearful facial

expressions might be related to stronger habituation to these stimuli in youth with elevated CU traits. In the current study, we included 77 youth with varying levels of externalizing behavior, who performed a gender discrimination task on photographs of actors displaying fearful expressions of increasing intensity. The task was split into two runs. Analyzes were conducted within the framework of the Research Domain Criteria project, meaning that a dimensional approach was adopted. The inverse relationship between amygdala responsiveness and level of CU traits was significantly greater in run 2 relative to run 1. In addition, connectivity between the amygdala and the anterior insula, posterior cingulate cortex and several regions in the visual cortex was significantly more inversely related to the participant's level of CU traits during run 2, compared to run 1. These data suggest that previous findings of generally reduced average responsiveness to fearful facial stimuli in youth with elevated CU traits might reflect greater habituation to these stimuli in these youth.

Abstract: With an estimated incidence rate of 1/100 live births, Fetal Alcohol Spectrum Disorders (FASD) present a unique minutiae of clinical and social implications and difficulties. As children with FASD share similar behavioral profiles with other disorders such as attention deficit hyperactivity disorder (ADHD) and oppositional defiant disorder (ODD), while simultaneously being underreported throughout society, identifying reliable neurophysiological markers is paramount to help us understand this widespread disorder, and to develop appropriate

treatment interventions. Previous studies have identified both structural and functional deficits associated with FASD, yet it is unclear how these structural deficits directly impact function. To gain further insight into the combined impact of structural and functional deficits we employed a multivariate joint independent component analysis (jICA) to identify linked components that covaried across adolescents (age 12-21) with FASD (n=11) and healthy controls (HC: n=17). We focused on measures of Fractional Anisotropy (FA) and neural responses to sensory stimuli as measured with Magnetoencephalography (MEG) using bilateral auditory (Aud), somatosensory (Som), and Visual (Vis) stimuli. We found 5 joint components representing a pattern of covariation across FA and sensory evoked responses that showed significant group differences. The first component (p=0.023) indicated that HC showed a stronger association than FASD between FA in cerebellar white matter tracts and MEG amplitude in the R temporal, R central, and L and R occipital regions (MEG) during Aud, Som, and Vis stimuli. These findings provide evidence for a correspondence between localized alterations in structural connectivity (FA) and functional responses (MEG) in FASD. Considering the majority of individuals with FASD exhibit no identifiable morphological alterations compared to HC, identifying markers specific to FASD is essential to avoid misdiagnosis and to inform early life interventions.

Title: Arithmetic processing in children with dyscalculia. An event-related potential study.

Authors: *C. S. SONIA YANIN, ESQ[1], T. FERNANDEZ[2], J. SILVA[3], B. PRIETO-CORONA[3], M. ROCA-STAPPUNG[2], G. ALATORRE-CRUZ[3];

Abstract: Dyscalculia (Dy) affects academic performance and daily life, a characteristic of this disorder is the difficulty to identify if the result of an arithmetic operation is correct or not.

Studies of Event-Related Potential (ERP) report that, unlike children with Dy, normal children show N400 and P600 components in the incorrect probe of an arithmetic operation. Objective: compare electrophyisiological activity during arithmetic processing between a group of 20 children with Dy and a group of 18 children with normal academic performance (NAP). We recorded ERP during an arithmetic verification task. Each trial corresponds to one-digit sum followed by a correct or incorrect probe (experimental conditions). Children decided if their own result match or mismatch regarding the probe. ERP were obtained time-locked to onset of the probe. A non-parametric permutation multivariate analysis was applied to evaluate differences between conditions. In both groups there was a higher percentage of right answers for the incorrect-probe compared to correct-probe. In both conditions, the percentage of right answers was higher in NAP than Dy group. NAP group showed an N400 effect (higher amplitudes to incorrect-probes than correct-probes) and a late positive component with widespread distribution (higher amplitudes to correct-probes than incorrect-probes). In contrast, Dy group displayed no significant N400 effect but a focal (P4, O1, O2, T6) late positive component. This suggests that Dy group has significant problems from arithmetic and matching-probe processes, reflected by N400, to a deficient verification process manifested by the late positivity. Abstract: Bilirubin-induced neurological dysfunction (BIND) is implicated in a wide range of neurodevelopmental disorders. In jaundiced Gunn rats (jjs) hyperbilirubinemia (HB) peaks between 16-21days of age, and jjs exhibit hyperactivity and gait abnormalities implicating cerebellar dysfunction. Determining cerebellar effects of HB at the time of high exposure and subsequently may provide biomarkers to diagnose BIND and new targets for intervention. In order to do this, we used ^{1}H-MRS in a 9.4T MRI to quantify neurochemicals related to oxidative stress, astroglial activation, inflammation, excitatory neurotransmission, bioenergetics, and neuronal integrity in the cerebellum of jjs and their non-jaundiced (Nj) littermates at 21days and 4 mos of age. We also measured body weight, total plasma bilirubin, locomotor activity, and MRI cerebellar volume. At 21 days bilirubin levels in jjs were 13.5±1.1 mg/dL and 13.3±0.4 mg/dL in jjs that were in the 21 days and 4 mos imaging groups, respectively. At 21 days jjs exhibited significant increases in neurochemicals related to glutamate turnover (glutamine and glutamine/glutamate ratio), excitotoxicity (serine), astroglial activation/inflammation (myo-inositol), oxidative stress (ascorbate, glutathione), cell membrane turnover and breakdown (glycerophosphocholine, phosphocholine), and significant decreases in bioenergetic function (aspartate), and neuronal integrity (N-acetylaspartate, taurine). At 4 months markers of decreased neuronal integrity were still present, and glutamate and macromolecules were decreased in jj rats, but the other markers were no longer different between jjs and Njs. Cerebellar volume was significantly decreased in jjs at both ages, and in 21 day jj rats, cerebellar glucose was significantly correlated positively with myo-inositol (r=0.86) and negatively with body weight (r=-.76) and cerebellar volume (r=-.77). In summary, we found abnormal neurochemical events in the cerebellum of jj rats. The transitory effects at the time of peak HB, including the potential relationships between glucose and measures of astroglial activation/inflammation, oxidative stress, cerebellar volume, and body weight, provide therapeutic targets for intervention in BIND, and long-term abnormalities suggest possible ^{1}H-MRS biomarkers in older children and/or adults to implicate BIND.

Title: Early detection of reading impairment with virtual maze environment: a longitudinal study

Authors: I. MAITA[1], A. BATTISON[1], D. TRUONG[4], N. ESCALONA[1,4], J. BOSSON-HEENAN[4], J. PFAFFMANN[2], J. R. GRUEN[4], E. JOHNSON[5], *L. A. GABEL[3];

Abstract: Reading disorder (RD, a.k.a. Dyslexia) is a specific learning disability that affects reading. If learning disabilities remain untreated, a child may experience long term social and emotional problems which influence future success in all aspects of their lives. Early detection and intervention will help to close the gap between typically developing and reading impaired children in acquiring reading skills. Although our understanding and treatment for dyslexia has greatly increased in the last 20 years, a significant percentage of children with dyslexia are either identified too late, or have a specific manifestation of the disorder that is not understood well enough to design and deliver a successful remediation. Research examining the connection among genetic, cognitive and behavioral aspects of reading disorder offers promise for early identification and intervention to successfully address specific phenotypes of RD. Recent research from our laboratory demonstrates that 8-13 year olds with RD exhibit impaired performance on a virtual Hebb-Williams (vHW) maze task. In this study we examined performance on the vHW maze in 5-6 year old children who identified as either typical or struggling readers. This virtual maze test does not rely on text or require rapid access to phonological processing; therefore was not influenced by a potential difference in reading experience between groups. The goal of this study was to determine if pre-readers at risk for RD, exhibit altered visuo-spatial processing on the vHW maze task and risk variants of candidate dyslexia susceptibility genes (CDSGs). Our data demonstrate that struggling readers are impaired at the vHW maze task and performance on this task correlates with specific CDSG risk variants. Since the predictive validity of the early reading measures with later reading ability vary from as low as .38 to as high as .74, children who present as at risk at a young age may develop strong reading skills over time, and vice versa. In addition, sensory impairments can change over the course of development (i.e. experience) leading to a change in behavior. Therefore the 5-6 year old children were reexamined at ages 8-9 for reading and vHW maze performance. These studies are essential in order to understand the link between CDSG risk variants and cognitive processing deficits reported in individuals with dyslexia so that more comprehensive interventions can be developed to reach students with RD currently labeled as ‘non-responders’ to conventional methods. This is an important first step to early detection of RD, which may lead to a significant decrease in the delayed acquisition of reading skills.

Title: Studies of the molecular pathways behind dyslexia

Authors: ***A. BIEDER**[1], H. MATSSON[1], A. FALK[2], J. KERE[1], I. TAPIA-PÁEZ[1];
[1]Dept. of Biosci. and Nutr., Karolinska Institutet, Huddinge, Sweden; [2]Dept. of Neurosciences, Karolinska Instituet, Solna, Sweden

Abstract: Dyslexia is a complex learning disability characterized by deficits in reading despite adequate intelligence, normal senses and proper socio-cultural opportunities. It is the most common reading disorder, affecting 5-10% of the population. Dyslexia has a strong genetic component and many susceptibility genes have been identified among which *DYX1C1*, *DCDC2* and *KIAA0319* are the most replicated. The molecular functions of these genes are little investigated, yet all the above have been implicated in neuronal migration and development. More recently, our group and others have shown a link between dyslexia candidate genes and cilia. We are investigating the role of dyslexia candidate genes in relation to cilia and centrosome.We are thus performing assays in a human ciliated cell line (RPE1, retinal pigment epithelial cells) and in tissues for sub-cellular localization by immunofluorescence (IF). In addition, we are looking for common molecular pathways of the candidate genes *DYX1C1*, *DCDC2* and *KIAA0319* by functional assays. We are using neuroepithelial-like stem cells (NES cells) derived from induced pluripotent stem cells (iPSCs) as a model to further dissect the molecular mechanisms involved in dyslexia. NES cells are self-renewing and can be differentiated along the neural and glial lineages. We have shown by qRT-PCR and IF that *DYX1C1*, *DCDC2* and *KIAA0319* gene expression is upregulated in NES cells during their

differentiation to neurons and glia. In addition, they are growing cilia during differentiation, as shown by IF and qRT-PCR of ciliary markers. NES cells are thus a valid model system to study the function of the dyslexia candidate genes and their role in cilia. We observe a localization of DCDC2 in the axoneme of some neuronal cilia upon differentiation and a localization of DYX1C1 around the basal body. Interestingly, CPAP/CENPJ - a centrosomal protein with a role in the regulation of microtubule assembly and disrupted in microcephaly - interacts and co-localizes with DYX1C1 at the centrosome. In a parallel approach, we are using lentiviral expression constructs to overexpress *DYX1C1*, *DCDC2* and *KIAA0319* in NES cells in order to study the downstream pathways of these genes.

Title: Acute and chronic treatment of methylphenidate improve and impair the sinaptic plasticity by change in the insertion of AMPA-GluA1 receptor subunits in pyramidal neurons of the hippocampal CA1 area

Authors: *C. A. CARVALLO[1], D. CONTRERAS[2], R. FARIAS[2], D. MORALES[2], G. UGARTE[2], R. DELGADO[2], C. ROZAS[2], M. ZEISE[3], B. MORALES[2];
[1]Univ. De Santiago De Chile, Santiago, Chile; [2]Biología, Univ. de Santiago de Chile, Estacion Central, Chile; [3]Psicology, Univ. de Santiago de Chile, Santiago, Chile

Abstract: Methylphenidate (MPH) is widely used in the treatment for Attention Deficit Hyperactivity Disorder and recently as a drug of abuse. It is known that acute exposure of MPH improve and chronic administration impairs the long term memory. However, the cellular and molecular and mechanisms involved in these synaptic processes are poorly understood. We address this question studying the visuo-spatial memory (VSM), hippocampal long term potentiation (LTP) and insertion of AMPA receptors in the plasma membrane in both conditions. Six sessions in the Morris Water Maze (MWM) were used to evaluate the acute and chronic effects on the VSM; rats p21 were administered i.p with a single dose of 1 mg/kg MPH or repeated dose during 6 days, respectively. Hippocampal slices of 400 μm of thickness were obtained of the same Sprague-Dawley rats used in the behavior test. LTPs were induced by theta burst stimulation (TBS) applied in Schaeffer collateral and recording field excitatory postsynaptic potentials in the Striatum radiatum of CA1. Finally, the slices were processed to evaluate the changes of surface-associated AMPA receptor employing western blot and crosslinking assays. Control and rats treated with single dose of MPH reduced the time to reach the platform in consecutive trials of MWM. A significant decrease was found in the 2th session (Control: 83.3±5.7 s; MPH: 58.8±7.3 s; $p<0.05$; n=21). In contrast, a significant increase was observed during the 2th (54.1±8.9 to 88.9±7.3 s; $p<0.05$; n=21) and 4^{th} (33.4±5.9 to 62.9±9.8 s) sessions between the controls and chronically treated rats (n=21, $p<0.05$). To study the electrophysiological correlate of behavioral studies, we induce LTP in slices from the same animals used in behavioral studies. A significant increase from 150.1±0.2% to 179.9±0.3% (n=4,7; $p<0.001$) was observed in the TBS-dependent LTP in acute conditions, in contrast, a significant decrease from 156.14±0,3% to 131.19± 0.5% (n=4,6; $p<0.001$) was observed in chronical conditions. To investigate the molecular mechanisms we evaluate the insertion of new AMPA receptors in the surface. Consistent with our electrophysiological results, we found a significant increase in the protein levels of GluA1 subunit from 0.46±0.02 to 0.73±0.02 (n=4, $p<0.05$) in acute conditions and a significant decrease from 0.45±0.01 to 0.29±0.02 (n=4, $p<0.05$). These results suggest that acute and chronic applications of MPH induce a differential effect on the plasticity. MPH improved the behavior performance enhancing LTP by insertions of AMPA-GluA1 receptor subunits and impaired the behavior performance decreasing the LTP due to removing of AMPA-GluA1 receptor subunits in plasma membrane.

Title: Altered brain bases of rapid naming in adults with dyslexia

Authors: *T. M. CENTANNI[1], S. N. DEL TUFO[2,1,3], J. D. E. GABRIELI[1], J. A. CHRISTODOULOU[1,4];
[1]MIT, Cambridge, MA; [2]Univ. of Connecticut, Storrs, CT; [3]Haskins Lab., New Haven, CT; [4]MGH Inst. of Hlth. Professions, Boston, MA

Abstract: Performance on rapid automatized naming (RAN; the ability to automatically and efficiently retrieve labels for abstract visual stimuli) predicts reading ability and relates to reading fluency. RAN performance is often impaired in readers with dyslexia but no study has yet compared the difference in brain activation during RAN performance between typical reading and struggling reading groups. Using letter, number, and alternating alphanumeric stimuli, we compared brain activations for adults with dyslexia to an age-matched sample of typically reading individuals. To evaluate developmental differences of brain activations during this task, we also included a sample of typically reading adolescents. As expected, adults with dyslexia and typically reading adolescents were significantly slower at performing all conditions of the in-scanner RAN task (letters, numbers, and alternating alphanumeric stimuli) compared to typical adults. Typically reading adults recruited posterior networks significantly more than adults with dyslexia during tasks containing letter stimuli (letter and 2set naming). Compared to typical adult and adolescent readers, adults with dyslexia exhibited more activation in right frontal and parietal areas during RAN letter tasks, while RAN number tasks evoked more activation in bilateral frontal and several right hemisphere areas in both adult groups compared to the typical adolescent group. Activation during RAN letter naming in the posterior occipital brain regions not only correlated with performance across groups on several word-reading measures, but was also correlated with rapid naming speed for all stimulus conditions. These results support previous hypotheses that the system for rapid naming overlaps with the reading brain system, and this differs between reader groups. Specifically, rapid naming activates the reading network of the brain, and activation patterns are comparable in reading and RAN in individuals with dyslexia. Implications for understanding the neural system associated with reading and component skills are discussed.

Title: Predictors of treatment outcome for neurofeedback trainings in adult attention deficit hyperactivity disorder (ADHD)

Authors: *A.-C. EHLIS[1], B. BARTH[1], K. WITTKE-LAUBE[2], K. MAYER[3], U. STREHL[3], A. J. FALLGATTER[1];
[1]Dept. of Psychiatry and Psychotherapy, Univ. Hosp. Tuebingen, Tuebingen, Germany; [2]FernUniversitaet in Hagen, Hagen, Germany; [3]Inst. for Med. Psychology and Behavioral Neurobio., Univ. of Tuebingen, Tuebingen, Germany

Abstract: Over the last decades, neurofeedback trainings have been established as a complementary neurobiological intervention in attention deficit hyperactivity disorder (ADHD). Even though meta analyses in childhood populations indicate clinical improvements over the course of neurofeedback interventions with typically medium effect sizes, the specificity of the training effects is discussed controversially. In the present study, 60 adult patients with ADHD were randomly assigned to 30 sessions of either a conventional EEG-based neurofeedback protocol (slow cortical potential / SCP training), a newly developed neurofeedback training based on near-infrared spectroscopy (NIRS) and focusing on frontal lobe function, or an electromyography-based biofeedback training (control group). Linear regression analyses were applied to identify predictors of treatment outcome in terms of changes in hyperactivity, impulsivity and inattention scores (self-report measure). For the overall sample, comorbid depressive and borderline symptoms at baseline as well as patient expectations regarding the success of the treatment were tested as potential (unspecific) predictors of the training outcome. In subgroup analyses, we furthermore tested the hypothesis that a particularly impaired frontal lobe function at the beginning of the training (as indicated by frontal lobe activation during NoGo trials of a Go/NoGo task) would predict a particularly good treatment outcome specifically within the NIRS frontal lobe training group. Preliminary data analyses show 1) significant symptom improvements in all three trainings groups, with some indications of a superiority of the NIRS training regarding impulsivity scores; 2) no significant prediction of treatment outcome by comorbid symptoms or patient expectations; and 3) a significant

differential prediction of treatment outcome by initial frontal lobe function in both the NIRS and EEG training group. In more detail, a particularly weak initial frontal lobe function was associated with particularly pronounced improvements in impulsivity scores in the NIRS training group, whereas in the SCP group, a particularly strong frontal lobe function at baseline predicted the best training outcome (inattention and hyperactivity scores). The results indicate that an assessment of frontal lobe function before the beginning of a neurofeedback training might be a useful tool to assign adult ADHD patients to either an SCP (EEG) or frontal lobe training (NIRS), which might contribute to a more individualized treatment and optimize the effects of neurofeedback interventions.

Neurosci., [5]Berlin Ctr. for Advanced Neuroimaging, Charité Universitätsmedizin, Berlin, Germany; [6]Berlin Sch. of Mind and Brain, Humboldt-University, Berlin, Germany; [7]Dept. of Neurol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Alterations in reinforcement sensitivity are a well-established finding in patients suffering from attention deficit hyperactivity disorder (ADHD) and are thought to depend on dopaminergic dysfunctions in the striatum (Luman, 2010). However, in addition to dopaminergic activity, reinforcement learning also depends on reward representations in the orbitofrontal cortex (OFC; Kahnt, 2010). It is unclear whether OFC reward representations differ in ADHD

patients as well.
In the current study, 16 ADHD patients and 18 typically developing (TD) children and adolescents (11-16 years) performed a delayed perceptual decision-making task in which the orientation or color of triangles had to be reported. The combination of both visual features indicated whether a high or a low reward was provided for a correct response. To obtain high-resolution measures from the OFC despite reduced BOLD sensitivity in this region, we developed an optimized BOLD sequence (partial volume, 24 slices, voxel size = 1.25x1.25x 1.8 mm^3, TE=30ms) allowing complete coverage of the OFC with improved sensitivity.
We found that both groups showed similar activation patterns during receipt of reward in several brain areas, including the bilateral OFC, insula and parahippocampus. However, during anticipation of high rewards, compared to TD, children and adolescents with ADHD displayed significantly stronger activity in the bilateral OFC as well as parahippocampus, left amygdala and left anterior cingulate.
Our results suggest that while OFC representations for received reward value are generally intact in children and adolescents with ADHD, patients show enhanced OFC activity for large expected rewards, suggesting a higher sensitivity to anticipated reward value in the disorder.

Title: Developmental deltamethrin exposure alters adult learning and behavior

Authors: *E. M. PITZER[1], M. T. WILLIAMS[1,2], C. V. VORHEES[1,2];
[1]Univ. of Cincinnati, Cincinnati, OH; [2]Cincinnati Childrens Med. Ctr., Cincinnati, OH

Abstract: Attention-deficit hyperactivity disorder (ADHD) is estimated to affect 8-12% of school age children. It has been suggested that environmental factors may contribute to the

etiology of ADHD. In this regard, pesticides have been suspected. We exposed Sprague-Dawley rat pups to the Type II pyrethroid deltamethrin (DLM) at doses of 0, 0.25, 0.5, and 1.0 mg/kg from postnatal day 3-20. DLM increased mortality at the 1 mg/kg dose and reduced body weight at 0.5 and 1 mg/kg. In the Morris water maze (MWM) on acquisition for path efficiency there was a significant treatment main effect ($P<0.04$) whereas on reversal the effect fell short of significance ($P=0.066$). This pattern was similar for latency and path length on both acquisition and reversal. There was also a trend for a treatment effect on conditioned fear ($P=0.0725$). In the open-field there was a treatment x interval interaction ($P<0.02$) that by slice-effect ANOVA was in intervals 1 and 7 in which DLM groups were less active than Controls (recorded in 5-min intervals for 1 h). For prepulse-inhibition (PPI) of acoustic startle, there were significant treatment x sex ($P< 0.01$) and Treatment x Sex x PPI ($P<0.03$) interactions. Further analyses showed the effects to be in females ($P<0.01$). Among females, the effects were on the no-prepulse ($P<0.003$) and low-intensity prepulse trials ($P<0.002$). In both cases the differences were between the 0.5 and 1 mg/kg DLM groups vs. Controls ($Ps<0.01$). On these trials, DLM dose-dependently reduced startle amplitude (V_{max}). PPI assesses sensorimotor gating, an attention-related process that may relate to attentional aspects of ADHD. More litters are being tested. The data indicate that neonatal DLM exposure has adverse long-term effects on learning and attention, effects consistent with an ADHD-like phenotype.

Sch., Seoul, Korea, Republic of

Abstract: Attention-deficit/hyperactivity disorder (ADHD) is the most common neurodevelopmental disorder affecting ~ 5% to 10% of children worldwide. It characterized by

the three core symptoms of hyperactivity, impulsivity, and inattention. To date, the exact cause of ADHD is still unknown, but substantial evidence has shown that this disorder has a significant genetic component. Genetic animal models have been highly valuable in understanding this disorder. Though it cannot exactly reflect the human condition, animal models can give understanding into the disorder that cannot be achieved from human subjects because of various limitations. Due to its complexity (heterogeneous disorder), a sole model is unlikely to be able to simulate all of its symptoms. Nonetheless, a model that recapitulates key endophenotypes can be beneficial in understanding its etiology and providing specific therapeutic implications. Thus, the present study sought to develop an animal model of ADHD which would recapitulate the hyperactive phenotype of the disorder. Towards this, we studied common differentially expressed genes (DEGs) in the prefrontal cortex of SHR/Ncrl, the most validated animal model of ADHD. SHR shows hyperactivity in the open-field test, as compared to Wistar and WKY rats, a strain representing the "normal" heterogeneous population. Furthermore, hyperactivity in SHR was attenuated by treatment of psychostimulants. The common DEGs in the PFC of SHR vs. WKY/NCrl and Wistar rats are those involved in transcription, circadian rhythm, and corticotropin secretion. We then made transgenic animal models overexpressing one of these genes. Here we report our initial finding that mice overexpressing one of the candidate genes indeed showed hyperactive behavior. Additional studies are underway to further characterize the behavior of this new transgenic animal model and to exemplify any underlying neurobiological mechanisms.

Title: Age effect on brain functional network graph metrics in patients with attention deficit hyperactivity disorder and normal children and adolescents.

Authors: *B. MOHAJER, N. ABBASI, A. ABDOLALIZADEH, N. HOSSEINI;
Student Scientific Res. Ctr. of Tehran Unive, Tehran, Iran, Islamic Republic of

Abstract: Introduction: attention deficit hyperactivity disorder (ADHD), as one of the most common childhood and adolescent's neuropsychiatric disorders, has shown to demonstrate impairments of structural and functional neural connectivity networks, a finding that occurs in

the maturation and pruning period of the brain synapses. Comparing effect of ageing on brain network development between healthy children and adolescents and ADHD patients would help to clarify this process. **Methods:** We used resting-state functional correlation matrices of 190 ADHD patients and 330 age and sex matched healthy children and adolescents from ADHD200 study (umcd.humanconnectomeproject.org). Minimum, maximum and average ages were 7.17, 21.74 and 11.83 years respectively. Each matrix consisted of undirected weighted correlations between 200 regions in fMRI of subjects (Craddock atlas). Graph theoretical analyses were performed using the Brain Connectivity toolbox. In order to enable comparison of global network properties across groups we applied 20% sparsity threshold based on previous studies. Global efficiency, Transitivity, Assortativity and Modularity were calculated as global network measures. Using R for statistical analyses, measures were fed into general Linear Model (GLM), to investigate the age effect controlled for gender effect. **Results**: We found significant decrease in Assortativity with increase of age in healthy subjects after FDR correction (P value=0.018, t-value=-2.3) compared to non-significant result with slower slop of asoortativity decrease in ADHD (P value=0.19, t value=-1.3) patients. The remaining measures did not reveal any significant changes with increase of age. **Discussion:** Number of neighboring nodes that sharing an edge with a node, defines as the degree. Assortativity indicates how preferentially nodes of similar degree connect to each other. As previously shown, adult and child functional brain networks both demonstrate small-world features, although consisting of different communities of nodes. The difference here is nodes arrangement: children's communities arranged by anatomical proximity on the other hands adults' predominantly reflect functional relationships. Above results may indicate architectural changes in functional network of normal population, from anatomical proximity connectivity through functional relationships. This connectivity pattern shift may be the main reason behind neural network malfunctions in ADHD, what reflects in amount of assortativity. Future functional connectivity studies focusing on the regional measures may clarify network dynamics in ADHD population.

Title: Optimized stimulation protocol of the rIFG for the application of tDCS in children and adolescents with ADHD

Authors: *C. BREITLING[1], K. KRAUEL[1,4], T. ZAEHLE[2], J. TEGELBECKERS[1], H.-H. FLECHTNER[1], V. LESSMANN[3,4], C. SEIDENBECHER[5,4], S. GULER[6,7], M. Biol. and Dept. of Behavioral Neurol., Leibniz Inst. for Neurobio., Magdeburg, Germany; [6]Scientific Computing and Imaging Institute, Ctr. for Integrated Biomed. Computing, Univ. of Utah, Salt Lake City, UT; [7]Dept. of Electrical and Computer Enginieering, Northeastern Univ., Boston, MA

Abstract: Transcranial direct current stimulation (tDCS) is a non-invasive method that can induce changes in intracortical excitability, plasticity and neuronal activity and its use in patients with ADHD has been suggested as a promising alternative to psychopharmacological treatment approaches. Results of a prior investigation (Breitling et al., 2016, Front. Cell. Neurosci.) suggest that anodal tDCS of the right inferior frontal gyrus (rIFG) could improve interference control in adolescents with ADHD but results were inconsistent between patients. However, a simulation of the induced current flow revealed a diffuse current densitiy distribution in widespread brain areas due to the stimulation. For future applications we wanted to increase precision and effectiveness of the setting. A method with enhanced spatial focality that induces maximum current flow directly under the stimulation electrode uses a 4x1 ring electrode configuration that, in contrast to conventional tDCS, restricts the current flow to the area under the electrodes. The software "SCIRun5/BrainStimulator" and a multimodal child head model were used to compute an optimized electrode configuration for the stimulation of the rIFG in children and adolescents. We found that the optimized montage induces more current flow in the rIFG than conventional tDCS while diffuse current flow in the rest of the brain was reduced. To provide improved controllability of stimulation is of special importance in children and adolescents in order to avoid side effects. Currently, data are collected in children and adolescents with ADHD to investigate whether optimized stimulation of the rIFG yields indeed superior results.

Title: Perinatal nicotine exposure mouse of attention deficit hyperactivity disorder

Authors: *L. ZHANG;
Ctr. for Brain Repair, Biomed. Sci., Florida State Univ., Tallahassee, FL

Abstract: Attention deficit hyperactivity disorder (ADHD) is a neurobehavioral disorder affecting children and adults. Cigarette smoking by pregnant women is associated with significant increase in ADHD risk for their offspring, suggesting a link between exposure of the developing brain to nicotine and ADHD risk. To model developmental nicotine exposure, we developed a mouse model of pre- and early postnatal (i.e. perinatal) nicotine exposure. Female C57/Bl6 mice received drinking water containing nicotine (100μg/ml)+saccharin (2%) or saccharin (2%) alone starting 3 weeks prior to breeding, throughout pregnancy and until 3 weeks postpartum (i.e. during the nursing period). Another group of female mice received plain drinking water without any additives. The offspring from each group were weaned 3 weeks after birth, and behavioral analyses were performed between 3 and 5 months of age. We examined spontaneous locomotor activity, working memory (using a Y-maze) and attention (using an Object Based Attention test; OBA). Perinatal nicotine exposure produced hyperactivity in female but not male mice, working memory and attention deficits in male but not female mice at 3 and 5 months of age. Exposure to saccharin alone did not produce significant changes in any of the measurements at either age. These data suggest that the perinatal nicotine exposure produces hyperactivity, working memory and attention deficit in a sex-specific manner. Our earlier work showed that nicotine exposure occurring during the 3 weeks prior to conception and lasting until birth (but not during the nursing period) produced hyperactivity, working memory deficit and attention deficit in both male and female mice. In this prenatal nicotine exposure model the offspring were cross fostered to drug-naïve nursing dams. In the present perinatal nicotine exposure mouse model the offspring remained with the nicotine+saccharin exposed or saccharin exposed biological mothers until weaning. Despite these differences in the design of the animal models, our data show that prenatal and perinatal nicotine exposures produce significant deficits in motor and cognitive phenotypes known to be associated with ADHD.

Title: New insights into compensatory strategy of cortical processing in Attention Deficit Hyperactive Disorder

Authors: *F. J. ZAMORANO-MENDIETA[1,2], P. BILLEKE[1], L. KAUSEL[4], J. LARRAIN[1], X. STECHER[2], X. CARRASCO[3], V. LOPEZ[4], J. HURTADO[1], F. ABOITIZ[4];

Abstract: Attention Deficit Hyperactive Disorder (ADHD) is the most common neuropsychiatric disorder in infancy, affecting 5% to 10% of school-aged population. In order to investigate cerebral activation patterns involved in interference control in ADHD, a functional MRI study was conducted on 40 right-handed 10-12 year old boys, 20 ADHD combined type and 20 age and IQ-matched typical developing controls, while they were solving the multi source interference task (MSIT). The task presents a set of 3 digits to participants and they have to identify the number that is different from the other two. In the “congruent” condition (CC), the target number is placed congruently with its position on the response-pad, whereas in the “incongruent” condition (IC), the target number is never placed congruently with its position on the response-pad. Significant differences where observed in response accuracy between groups (Mixed ANOVA, Group factor: F=4.2, p=0.04) and interestingly, the MSIT effect measured as the reaction time (RT) between IC-CC contrast, was greater in CONTROL than in ADHD group (Control: 193.6ms, ADHD: 152.7ms, t31=2.3, p=0.02). The neuroimaging results for the MSIT effect showed a significant enhancement in the activation of cerebral areas involved in executive control for ADHD as compared to controls. Specifically, ADHD showed more activity in a cluster that includes both right Medial Frontal Gyrus and right Pars Opercularis of Inferior Frontal Gyrus (Mixed effect model, p-value=0.04, corr.). A psycho-physiological interaction (PPI) analysis was performed using this cluster as seed. By mean of this, we found that ADHD group presents a significant greater functional connectivity with bilateral orbitofrontal cortex (OFC) as compared to CONTROL group (Mixed effect model, p=0.02 corr.). A correlation analysis between performance in IC and connectivity between right Medial and Inferior Frontal Gyrus and bilateral OFC showed that a worse performance correlated positively with the

connectivity between these brain regions in both groups. Taken together our results could be interpreted in terms that the frontal activation elicited in MSIT by the ADHD represents a compensatory strategy resulting from the effort to maintain an adequate performance during the task. At the same time, our results can be interpreted in terms of underlying abnormalities in the switching between task positive and task negative networks.

Abstract: Due to a hyperfunctioning mesocorticolimbic system, the Naples-High-Excitability (NHE) rats have been proposed as a model for the mesocortical variant of ADHD. Compared to Naples Random-Bred (NRB) controls, NHE rats show hyperactivity, impaired non-selective attention(large number of rearing episodes with very low scanning duration), and impaired selective spatial attention (low performance in an eight-arm radial maze). Alteration in limbic functions has been proposed; however, resulting unbalance among forebrain areas has not been assessed yet. In the present work, by resting-state functional Magnetic Resonance Imaging (fMRI) in vivo, we investigated the connectivity of neuronal networks belonging to limbic vs.

cortical loops in NHE and NRB rats (n=10 each). Notably, resting-state fMRI was applied (3x10 min timeseries) using a multi-slice sagittal, gradient echo sequence. Voxel-wise connectivity maps at rest, based on temporal correlation among fMRI timeseries, were computed by seeding the hippocampus (Hip), nucleus accumbens (NAcc), dorsal striatum (dStr), amygdala (Amy) and prefrontal cortex (PFC) in both hemispheres. To summarize patterns of altered connections, clear directional connectivity was evident within the cortical loop, from PFC through the dStr and hence towards Hip: such communication was reduced.

Title: Impaired hippocampal plasticity and AMPA receptors phosphorylation in a mouse model of ADHD induced by prenatal nicotine exposure

Authors: D. CONTRERAS[1], C. CARVALLO[1], G. UGARTE[2], R. FARIAS[1], R. DELGADO[1], M. ZEISE[3], M. ALBORNOZ[4], J. KLAGGES[4], B. MORALES[1], *C. A. ROZAS[2];
[1]Biol., [3]Psychology, [4]Med., [2]Univ. of Santiago de Chile, Santiago, Chile

Abstract: Attention deficit hyperactivity disorder (ADHD) is the most common neurodevelopmental disorder characterized mainly by hyperactivity, impulsivity and inattention. Drugs used for the treatment of ADHD, such as Methylphenidate (MPH), improve cognitive behavior. We have shown that acutely applied MPH increases the TBS-dependent long tem potentiation (LTP) in CA3-CA1 synapses of hippocampus, promoting the insertion of AMPA receptors in the postsynaptic membrane of wild type rats. Little is known about the molecular

basis or modifications on LTP in mice models of ADHD. Using electrophysiological approaches and Western blot analysis we investigated LTP and AMPA receptor phosphorylation in an ADHD model induced by prenatal nicotine exposure (PNE). Female mice received nicotine 3 weeks before mating and during pregnancy (0.1 mg/ml nicotine + Saccharin 2%, in drinking water). Locomotor activity was assessed in PNE mice using an Open Field Test (OFT), working memory with Y-Maze and attention with Object-Based Attention test (OBA). LTP in CA3-CA1 was induced by applying theta burst stimulation (TBS, 5 trains, 100 Hz) in hippocampal slices obtained from Control and PNE mice (3-4 weeks old). Locomotor assessment show hyperactivity in PNE mice, total traveled distance in OFT was 81.8± 1.7m, n=8 compared with 55.4± 1.9m, n=8 in controls mice ($p<0.05$, Mann-Whitney U-test). Attention deficits are also evident in PNE mice; in OBA test these mice shown an impaired attention, since they spent more time with the known object (41.2 ± 1.3s, n=4) than the controls (4.3±0.3, n=4; $p<0.05$). As expected from hyperactive mice, Y-maze reveals higher number of entries in PNE mice (55.6±21, n=7) than controls(36.5±3.3, n=6; $p<0.05$), working memory assessments in this test shown reduced spontaneous arm entries (PNE: 32±3.1, n=7 ; Controls:47.2±3.7,n=6 ;$p<0.05$), increased alternate arm return (PNE: 33.3±2.3, n=7; Controls: 20.8±2.2,n=6 ;$p<0.05$) and decreased same arm returns(PNE: 14.6±1.2, n=7; Controls: 24.5±0.7,n=6 ;$p<0.05$). A reduced LTP was found in PNE mice (126±0.4%, n=8) compared with controls (151.2±0.5%, n=4,8;$p<0.05$). A significant decrease in phosphorylation ratio for GLUA1-Ser831 was found in PNE mice (0.67±0.05,n=5) versus controls mice (0.93±0.01,n=4;$p<0.01$). No significant change in the phosphorylation ratio of GLUA1-Ser845 was observed (PNE:0.55 ±0.9,n=5, control:0.6 ±0.12 n=4; $p > 0.05$).
Altogether our data indicate this model display all the behavioral hallmarks for ADHD: hyperactivity, impaired attention and memory deficits, which also are correlated with impaired LTP and lower phosphorylation of GLUA1-Ser831 subunit.

Title: Nicotine-induced epigenetic modification of the paternal germline DNA and ADHD symptoms in offspring

Authors: *D. M. MC CARTHY[1], S. E. LOWE[1], T. J. MORGAN, Jr[1], T. J. SPENCER[2], J. BIEDERMAN[2], P. G. BHIDE[1];
[1]Ctr. for Brain Repair, Biomed. Sci., Florida State Univ. Col. of Med., Tallahassee, FL; [2]Clin. and Res. Program in Pediatric Psychopharmacology and Adult ADHD, Massachusetts Gen. Hosp., Boston, MA

Abstract: Cigarette smoking and other forms of tobacco use remain a leading cause of disease, disability and death in the United States. When a pregnant woman smokes cigarettes, her fetus is at risk for both physical and cognitive deficits. In fact, cigarette smoking during pregnancy nearly doubles the risk for ADHD in the offspring. While more men than women smoke cigarettes, little is known about the impact of father's nicotine use upon his offspring. With this in mind, we developed a paternal nicotine exposure mouse model in which adult male mice were exposed to nicotine (200μg/ml) in drinking water for 12 weeks. While the nicotine exposure was ongoing, the mice were bred with drug naïve females. To our surprise, the offspring of the nicotine-exposed fathers displayed hyperactivity and inattention, phenotypes commonly associated with ADHD. Interestingly, the nicotine-exposed mice (fathers) did not display either of these phenotypes. The offspring also displayed region- and sex-specific alterations in dopamine receptor mRNA expression in the brain. This led us to investigate the mechanisms underlying the expression of ADHD-related behavioral and molecular phenotypes in the offspring. One plausible mechanism is epigenetic modification of the father's germ cell DNA. We found a significant increase in DNA methylation in the nicotine-exposed fathers' spermatozoa. Specifically, DNA methylation was significantly altered in the dopamine D2 receptor promoter region. These data suggest that epigenetic modification of father's germline is associated with ADHD related behavioral and molecular phenotypes in the offspring.

Title: A prospective EEG study of adolescent development demonstrates baseline disturbances in spatial working memory and associated cortical oscillations are predictive of substance use

Authors: *C. P. WALKER[1], N. POLIZZOTTO[2], N. RAMAKRISHNAN[2], Y. JHON[3], N. DAY[3], D. LEWIS[3], R. CHO[2];
[1]Psychiatry, [2]Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX; [3]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Adolescence is a developmental period marked by substantial refinement of reward and impulse control circuitry in the brain. It has been hypothesized that increases in risk-seeking behavior seen in adolescents are a product of behavioral exploration and social and environmental learning that informs one's approach to social interaction. However, with increased risk-seeking comes the potential for negative impacts from behaviors such as illicit substance use. Currently, the manner in which early adolescent substance use affects brain maturation is unclear as much of our existing knowledge of the impact of adolescent substance use is based on retrospective studies. Therefore, we recruited a prospective cohort of 96 participants at 12 years of age who were determined to be high-risk for adolescent substance use, but had not reported any substance use at that time. Of this sample, 75 participants returned at 15 years, and 36 individuals were identified as having used either marijuana, alcohol, or tobacco. At the baseline and follow-up assessments, general demographic data and various cognitive batteries were collected. Participants also completed a spatial working memory task with a high vs. low load manipulation (3 vs 1 items) during an electroencephalographic (EEG) recording. Behavioral analyses identified a significant age by load by substance use interaction for error rates (ER), $p=.017$, which reflected a larger load effect at baseline for non-users compared to users. This effect remained after controlling for baseline differences in IQ, and the behavioral regulation index (BR), metacognition index (MI), and global executive composite (GEC) scores measured by the Behavior Rating Inventory of Executive Function (BRIEF). Additional main effects of age (ER) and load (ER & reaction time (RT)) were observed ($ps<.05$). A closer look at the BRIEF composite scores revealed significant age by substance use interactions for MI, $p=.007$, and GEC, $p=.024$ and a substance use main effect for BRI scores, $p=.003$, with substance users having higher scores overall or developing higher scores at later time points. Time-frequency analyses of the EEG data found group differences over central and parietal electrodes at 12 years with non-users showing a higher load-induced modulation of beta/gamma-band activity (20-40 Hz) during working memory maintenance, $p<.001$. This effect was absent in the substance use group, and these differences remained at the 15 year follow-up. Taken collectively, our data suggests that maturational differences in cortical high frequency oscillations may underlie a predisposition toward early adolescent substance use.

Title: Local efficiency of brain's functional connectivity reflects longitudinal changes in temporal cortex lateralization in school-age children and adolescents

Authors: *Z. GRACIA TABUENCA, E. NAVARRETE, B. MORENO, F. A. BARRIOS, S. ALCAUTER;
Dept. of Behavioral and Cognitive Neurobio., Univ. Nacional Autónoma De México, Queretaro, Mexico

Abstract: Lateralization is a dynamic process along age and unbalanced functional asymmetries are related with developmental disorders such as dyslexia. In order to improve the better understanding of normal and atypical development, this study focuses on characterize functional asymmetries in healthy school-age children and adolescents, and identify gender and age effects. The sample consists in two subsamples acquired during 2010 and 2015, respectively, all of them were healthy participants with resting state functional MRI scans (TR=2s; 150-300 volumes). First sample includes 66 subjects (6-10 years old, 36 girls), and second sample includes 44 subjects (11-19 years old, 34 girls), 32 of which participated in the first sample.
After standard preprocessing (no global signal regression), five noise-based components and movement-affected volumes (relative RMS > 0.25) were regressed out, and subjects with less than 120 non-affected volumes (4 minutes) were exclude from further analysis (6 subjects were excluded with this criteria).
For each subject, the average signal from 54 brain regions from each hemisphere was extracted and the Pearson correlation between all possible pairs of ipsilateral regions was obtained. A threshold of 0.35 was applied based on the best scale-free adjustment in a set of 0.05-step thresholds, and graph theory's Local Efficiency was obtained for each region in each hemisphere, then an asymmetry index was computed for each of the 54 unique bilateral regions. In order to consider the longitudinal aspects of the sample a linear mixed effects model was applied with age, gender, and their interaction as fixed effects and mean relative RMS as confounding variable. Significance effects were computed with a Likelihood Ratio Test and significance was defined as $p<0.05$ (corrected for multiple comparisons using false discovery rate at $q<0.05$). Significant effect was only found in the interaction of age and gender in the superior temporal gyrus (chisq=15.52; p=8.17e-05), where the rightward asymmetry increases with age only in males. No gender or age effects alone were found.

This study showed functional connectivity asymmetries in a region surrounding the Sylvian fissure, which is related with auditory and speech processing. In our results this effect was only evident along the interaction with the age, so this asymmetry could be established during the adolescent period when language differences between genders are more patent. The hemispheric asymmetries in functional connectivity described in this study contribute to the better understanding of normal development.
This research was supported by CONACyT 619683/330142.

Abstract: Adolescence is a time of significant change in social behavior and emotional regulation. During this time, individual and sex-specific differences are seen in developmental trajectories of brain maturation. One hypothesis is that the process of puberty, including increases of gonadal and adrenal hormones, may be linked to both structural and functional brain maturation. Of particular interest is the sex difference in the developmental trajectory of emotion processing. Previous research has shown both structural and functional sex differences in brain regions linked to socioemotional processing. Here, we examined sex and pubertal stage effects on neural processing while viewing emotional faces in well-characterized, healthy children. Fifty four typically developing children participated in the study (26 girls), all having a body

mass index between the 15th and 85th percentiles, and skeletal age within two standard deviations of age-specific population norms as determined by wrist x-rays. Pubertal development was assessed by physical examination of breast (girls) and testicular development (boys) and participants were categorized into two groups: pre-pubertal (N=26, 8.2 ± 0.1 years, 13 girls) and pubertal (N=28, 12.6 ± 0.1 years, 13 girls). Functional MRI data were collected on a 3T GE scanner while participants viewed blocks of aversive and non-aversive faces. Data were pre-processed in SPM5, normalized to a study-specific MNI template using ANTS, spatially smoothed (8 mm), and motion corrected using ART. Whole-brain voxel-wise analyses in AFNI used a multivariate model to determine the main and interaction effects of sex and pubertal status on BOLD signal during viewing of aversive versus non-aversive faces.
Across both groups, there was a main effect of sex during aversive face viewing such that girls showed greater activation than boys in the right intraparietal sulcus, left orbitofrontal cortex (OFC), left dorsolateral prefrontal cortex (DLPFC), right superior temporal sulcus, left anterior cingulate cortex (ACC), and right posterior cingulate cortex ($p<0.001$ FDR). There were no regions in which boys showed greater activation than girls, no main effects of pubertal status, and no interactions between sex and pubertal status. These data are consistent with previous findings in adults showing greater activation in women than men in the ACC, OFC, and DLPFC. These results also suggest that some sex differences in neural processing related to social and emotional behaviors may be established prior to puberty and may develop independently of gonadal sex-steroid secretion.

Abstract: The capacity to inhibit a pre-potent response is a crucial executive function that matures over the course of development. Poor impulse control during adolescence has been explained by a dual-systems model in which rapid development of limbic regions precedes that of cognitive control areas. The Stop-Signal task, which requires the participant to withhold an already-initiated response, is a reliable metric of inhibition. The current fMRI study investigated the effects of pubertal development and sex on neural recruitment during response-inhibition in healthy children and adolescents.

Fifty-two typically-developing children and adolescents performed the Stop-Signal task in a 3T GE MRI scanner. Participants were divided into two pubertal groups based on clinician-determined Tanner Stage: 27 Tanner Stage 1 pre-pubertal children (8.7$\pm$0.3 yrs, range=8.1-9.3; 12 girls) and 25 Tanner Stage 2-5 adolescents (13.1$\pm$0.7 yrs, range=12.2-14.6; 9 girls). Data were pre-processed and registered to a study-specific template in MNI space using SPM, and motion-corrected using ART. Using AFNI, we compared whole brain voxel-wise BOLD signal during inhibition (i.e. Successful-Stop events) to that of non-inhibition trials (i.e. Go events) to test for main and interaction effects of sex and pubertal group.

Pre-pubertal children had slower average reaction times to Go signals than pubertal children (633$\pm$76 ms vs 583$\pm$82 ms, p=0.014), as well as fewer completed Go trials (83.8$\pm$.12% vs 90.9$\pm$0.05%, p=0.012). Girls had slower go reaction times than boys (636$\pm$76 ms vs 590$\pm$69 ms, p=0.028) and higher stop accuracy (52$\pm$0.13% vs 42$\pm$0.15%, p=0.015). In fMRI, there was more robust BOLD signal in Successful-Stop than in Go trials in bilateral inferior frontal gyrus, supplementary motor area, and subthalamic nucleus, as well in visual processing areas ($p<1x10^{-7}$, FDR). Main effects of pubertal group and sex were not significant, but a pubertal group by sex interaction was found in in the right medial prefrontal cortex ($p<0.06$, FDR). Post-hoc analyses showed that in prepubertal girls this area is deactivated, but becomes activated following the onset of puberty ($p<0.001$). This pattern was opposite in boys (p=0.03).

Neither pubertal stage nor sex significantly affected activation within regions typically involved in response inhibition. However, a sex-by-pubertal stage interaction was observed in a region important in social/emotional function. The fact that sex differences in mPFC activity were observed before puberty and were altered with puberty suggests an early dimorphism that is independent of gonadal steroids, but responsive to age or to the endocrine events of puberty.

Title: Motivation, goals, and intelligence mindset in the adolescent striatum during feedback-based learning

Authors: *S. DEPASQUE, A. GALVAN;
UCLA, Los Angeles, CA

Abstract: Performance-related feedback is an important tool used by educators to help adolescents learn. However, the learning efficacy of such feedback depends upon motivational factors that can vary within individuals and across situations. Corticostriatal brain systems play a critical role in both motivation and learning, so it is important to understand how well-established ontogenetic changes in these systems during adolescence might scaffold learning and influence susceptibility to motivational factors. The present study used fMRI in conjunction with a motivational manipulation to compare adolescents' (n=15, M_{age}=13.5) and adults' (n=13, M_{age}=25.3) neural and behavioral responses to performance-related feedback. Participants completed a learning task in three phases: 1) a study phase outside of the scanner, 2) a scanned feedback phase, 3) and a post-test immediately after the scan. The feedback phase was divided into blocks of trials, half of which were framed as a test (threat) and half as opportunities to practice learning strategies (nonthreat). In both conditions, adults outperformed the adolescents, across both the feedback and post-test phases. However, on the post-test, adolescents performed as well as adults on items that were previously answered incorrectly, suggesting that they were just as capable of correcting their errors based on feedback. For items learned under the threat condition, adolescents exhibited even higher numbers of corrected errors than adults. On average, the motivational condition did not influence task performance for either age group; however, in youth, normative goals (i.e., goals to outperform others) were associated with greater effects of the threat manipulation on the correction of errors. In other words, teens who aimed to outperform their peers showed a greater threat-related improvement in the correction of incorrect responses. This relationship was not observed in adults. Feedback engaged similar brain networks in both age groups, including the striatum, medial prefrontal cortex, and posterior cingulate. ROI analyses identified age by threat interactions in the nucleus accumbens, caudate nucleus, amygdala, and hippocampus. In both adults and adolescents, neural responses to the threat manipulation related to participants' beliefs about intelligence: individuals who believe

intelligence is fixed exhibited stronger effects of threat in the striatum. These results highlight the importance of considering the interaction between contextual factors and individual differences when studying developmental influences on learning.

Title: Effects of Val158Met catechol-O-methyltransferase polymorphism on structural striatocortical connectomes in children and adolescents: a neuroimaging PheWAS

Authors: ***L. ZHAO**, K. CLARK, C. GONZALEZ-ZACARIAS, F. SEPEHRBAND, A. TOGA;
USC, Los Angeles, CA

Abstract: Introduction: The Val158Met (or known as rs4680) polymorphism within the catechol-O-methyltransferase (COMT) gene results in valine (Val) to methionine (Met) substitution, with different dopamine release in subcortical regions, e.g. the striatum, and the cortex in Val158 and Met158 carriers. The variations in dopamine levels influenced by Val158Met has been linked to changes in cognitive functioning. Few studies have examined possible neuroanatomic effects. This work investigated effects of Val158Met on structural brain connectomes using a phenome-wide association study (PheWAS) approach, i.e. to identifiy which brain phenotypes are influenced by a genotype of interest.
Methods: We obtained volumetric measures of subcortical regions and surface-based morphometric (SBM) measures of the cortex (including the cortical thickness, surface area, volume, gyrification index and gray to white matter ratio) from structural magnetic resonance imaging (MRI) scans of two neurodevelopmental cohorts: 1. the Pediatric Imaging, Neurocognition, and Genetics (PING) dataset (464 subjects, age=11.69±4.84, 223 females); 2. the Philadelphia Neurodevelopmental Cohort (PNC) (662 subjects, age=14.79±3.35, 331 females). Structural striatocortical networks were constructed by respectively correlating the caudate and putamen volumes with the SBM measures across the cortex. Effects of Val158Met

on the structural connectomes were assessed with analysis of variance (ANOVA).
Results: As expected, Val158Met explained a significant amount of variance in the striatal connectivities with the lateral prefrontal cortex (PFC), which was found in the putamen-to-cortical thickness network in the PNG cohort and in the caudate-to-cortical volume network in the PNC cohort. This may account for the changes in cognitive performance related to dopamine level variations in different Val158Met carriers. Additionally, in PFC cohort, significant genetic effects on the caudate-to-cortical volume correlations were also found in the insula, the cingulated, temporal and visual cortices. This is in line with previous findings that Val158Met is associated with processing of sensory emotion and pain and with the brain development in these areas.
Conclusion: This work yields new insight into the mechanisms of how the COMT gene influences the brain in children and adolescents, and especially illustrates that Val158Met plays an important role in determining the biological factors that underlie structural striatocortical connectomes.

Title: Reduced frontal and parietal cortical thickness in adolescents with a family history of alcohol use disorder

Authors: *K. E. RASMUSSEN[1], J. G. VAIDYA[2], J. KRAMER[2], S. KUPERMAN[2], D. LANGBEHN[2], D. S. O'LEARY[2];
[1]Interdisciplinary Grad. Program in Neurosci., [2]Psychiatry, The Univ. of Iowa, Iowa City, IA

Abstract: Individuals with a family history (FH+) of alcohol use disorder (AUD) are 2 to 5 times more likely to abuse alcohol in their lifetimes than individuals with no family history of AUD (FH-) (Spadoni et al., 2008). Even in the absence of heavy alcohol use, FH+ adolescents tend to perform worse than their FH- peers on cognitive, emotional, and decision-making tasks, perhaps due in part to underlying neurobiological differences (Acheson et al., 2009). The purpose of this study is to determine whether FH+ individuals show neuroanatomical differences

compared to FH- controls. Here, individuals with at least one biological parent diagnosed with AUD are defined as FH+, and those with no biological parent with AUD are defined as FH-. By design, our sample had limited or no past substance use thereby minimizing confounds due to alcohol consumption. Structural brain scans of 94 FH- and 95 FH+ adolescents aged 13-18 were obtained using magnetic resonance imaging (MRI). Measurements of cortical thickness were obtained using the FreeSurfer software package. Subjects were binned into one of three age categories for analysis (13-14, 15-16, or 17-18 years). Analysis of covariance (ANCOVA) was conducted for each region of interest using SPSS software with age bin and FH group as independent variables and gender and total intracranial volume (ICV) as covariates. First, individual cortical lobes (frontal, parietal, occipital, and temporal) were analyzed. Then, any lobes showing group effects were broken down into individual regions for further analysis. Lobe level analysis showed group effects ($p<0.10$) for the frontal and parietal lobes. Follow-up analyses within these lobes demonstrated that FH+ had, on average, reduced cortical thickness in the in the right lateral and medial orbitofrontal cortices of the frontal lobe ($p<0.05$) as well as in the right postcentral region of the parietal lobe ($p<0.10$). These main effects were qualified by a significant interaction with age ($p<0.05$). FH+ subjects had thinner cortices across the age range, however the declines in thickness were more dramatic in FH- subjects. These findings demonstrate that the frontal and parietal lobes of adolescents are affected by family history of AUD. Decreased cortical thickness in FH+ at early adolescence may indicate deficient development prior to adolescence, and reduced cortical thinning during adolescence may reflect lack of pruning in these regions. As the frontal and parietal lobes are associated with executive functions and behavioral regulation, improper development of these regions may lead to a greater susceptibility to substance use disorders.

Title: Morphometric similarity networks: a novel integrative method for studying inter-individual differences in brain structure

Authors: *J. SEIDLITZ[1,3], F. VÁŠA[1], M. SHINN[1], R. ROMERO-GARCIA[1], K. WHITAKER[1], P. VÉRTES[1], F. LALONDE[3], A. RAZNAHAN[3], E. BULLMORE[1,2,4,5]; [1]Brain Mapping Unit, [2]Behavioural and Clin. Neurosci. Inst., Univ. of Cambridge, Cambridge, United Kingdom; [3]Developmental Neurogenomics Unit, Natl. Institue of Mental Hlth., Bethesda, MD; [4]Cambridgeshire and Peterborough NHS Fndn. Trust, Huntingdon, United Kingdom; [5]Academic Discovery Performance Unit, GlaxoSmithKline, Stevenage, United Kingdom

Abstract: There is a large body of work demonstrating profound inter-individual differences in cortical brain structure, as measured by magnetic resonance imaging. Recent research suggests that these inter-individual differences in the structure of a given brain region co-vary with inter-individual differences in the structure of other brain regions, referred to as structural covariance (SC). However, compared to studies of functional brain networks, where a brain network is derived for each subject in a cohort, SC has been limited to analyses at the group-level due to the use of a single morphometric feature (e.g. cortical thickness) in the generation of a brain network. Although some methods have been proposed to generate individual SC networks, these have still been restricted to the use of a single morphometric feature, and have not made use of other aspects of brain morphometry, such as regional brain curvature and cortical white matter content. Thus, using a multiparametric MRI sequence in a cohort of 296 typically developing adolescents (148 females), we extracted 10 morphometric features for each brain region in a 308-region parcellation, capturing diverse aspects of cortical morphometry. We constructed connectivity matrices using the pairwise Pearson correlation of the scaled regional morphometric features, resulting in individual 308x308 morphometric similarity networks (MSN). Network analyses of the individual MSNs produced graph metrics similar to those of traditional structural and functional brain networks (i.e. small-world and highly modular), and yielded a consensus modular decomposition which recapitulated the lobar organization of the brain. Edgewise analysis at the group level revealed differences in the spatial patterning of the most extreme left-tail (negative) and right-tail (positive) edges, with the former mediating primarily inter-modular and long distance connections, and the latter mediating intra-modular and inter-hemispheric connections (bilaterally homologous regions). A significant decrease in individual global brain similarity - the absolute edgewise mean of each MSN - was observed with increasing age, suggesting that brain regions are becoming morphometrically differentiated during adolescence. Overall, by providing a new approach to measure regional morphometric relationships across the whole brain in a single subject, we believe this method will help us better understand the normative changes that occur during neurodevelopment, and will be sensitive to the individual differences in brain structural network organization that are a result of disease-specific processes or psychopathological abnormalities.

Title: The short timescale neural contributions to resting state correlations

Authors: *D. F. MONTEZ[1], S. MAREK[1], B. LUNA[2];
[1]Neurosci., [2]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Study: fMRI studies have revealed the underlying network structure of the resting brain and have informed our understanding of how networks continue to develop during adolescence. Very little is known about the time scales of neuronal activity that underlay the BOLD signal correlations typically analyzed in fMRI resting state analyses. Here, we leverage combined measurements of fast time scale MEG correlations and fMRI correlations within the same set of subjects to understand the temporal structure of neural activity observed indirectly in BOLD signal correlations. Methods: *MEG:* We collected 5 minutes of eyes open fixation resting state MEG (1000Hz sampling frequency) and fMRI (1Hz sampling frequency) data from 33 subjects, ranging in age from 14-31 years. We extracted BOLD and MEG time series from a set of 333 cortical ROIs from each of the subjects. To characterize the temporal structure of MEG correlations, we computed cross-correlograms for each ROI pair across a 10 second interval. Next we computed the relationship between each lag of the MEG cross-correlograms to their corresponding BOLD signal correlations. This analysis reveals the temporal structure of MEG correlations that contribute to BOLD signal correlations. Results**:** We find that BOLD signal correlations across the cortex reflect structured temporal correlations occurring on time scales that are much faster that the typical BOLD signal sampling rates. In particular, higher BOLD signal correlations are associated with rhythmic 1Hz and 10Hz oscillations, as well as relatively short time scale synchronous correlations.

Title: Sleep loss amplifies the relationship between stress and neural correlates of risky decision-making in adolescents and adults

Authors: *J. PHUONG, A. GALVAN;
Psychology, UCLA, Los Angeles, CA

Abstract: Insufficient sleep has been associated with increased risk-taking and poor decision-making. Sleep deprivation has been shown to amplify physiological responses to stress, but it is yet unknown how sleep deprivation interacts with acute stress to affect the neural correlates of risky decision-making in adolescents. In the current study, daily self-reports of stress were documented in adolescents (n = 22; ages 15-17 years) and adults (n = 22 adults; ages 25-30 years). Participants also self-reported their recent sleep duration and completed two fMRI visits during which they performed an adaptive risky decision-making task: once each when they endorsed a high and low level of stress. Results revealed that under high stress, decreasing hours of sleep per night was associated with more disadvantageous risks and more gain-focused risks in both adolescents and adults. In addition, as sleep duration decreases, ventromedial prefrontal cortex activation increases when deciding not to take disadvantageous risks; this effect was stronger in adolescents than in adults. Sleep duration was not associated with risky decision-making or neural activation under low stress, suggesting that insufficient sleep may amplify the effects of stress and affect decision-making behavior through modifications of the prefrontal cortex, a region undergoing significant development during adolescence.

Title: Receptive verbal ability in autism spectrum disorder: a preliminary fmri investigation

Authors: *S. HUEMER[1], F. KRUGGEL[2], V. MANN[3], J.-G. GEHRICKE[4];
[1]Psychology, Loyola Marymount Univ., Los Angeles, CA; [2]Med. Bioengineering, [3]Cognitive Sci., [4]Pediatrics, Univ. of California Irvine, Irvine, CA

Abstract: Introduction: The present fMRI experiment compares brain activity of adolescents with Autism Spectrum Disorders (ASD) to those of typically developing adolescents as they listen to their own first names, familiar people's names, numbers, and names objects of high interest. Carmodey et al. (2007) investigated hearing one's name in ASD in an fMRI study with a 4-year-old sedated girl with ASD and found that the greatest volume of overall activation was recorded in response to numbers as compared to her first name and the word 'hello'. **Methods:** 9 participants with ASD and 9 controls (12 - 20 yrs) were enrolled, the diagnosis confirmed, and the Peabody Picture Vocabulary Test (PPVT-III), a test for verbal ability, administered. Subjects passively listen the stimuli. T1-weighted MR images were acquired on a Philips Achieva 3T scanner. T2-weighted images were acquired using a single-shot EPI protocol. During each of the three functional imaging sequences, 110 volumes were taken. Spm software was used for data anlysis, $p < 0.05$ and $p < 0.1$. **Results:** When hearing their own name, the ASD group showed overall less areas of activation and they relied more heavily on prefrontal structures (especially the frontal pole, BA 10) as compared to controls in support of the findings from Carmody et al., 2007. Interestingly, we also found activity in the left thalamus in the group that scored lower on the verbal ability measure, the PPVT.
When hearing their own name, controls and the individuals who scored higher on the verbal ability measure, the PPVT, (HS group) showed activation in areas of self-referential processing and areas associated with hearing one's name (including BA 7, BA 9, BA 13, BA 17, BA 22, BA 31, BA 19). Also notable was a reliance on more anterior regions in the ASD and the lower-scoring (LS group) vs. the more posterior activation in the control and HS groups. Interestingly, we found an involvement of the right hippocampus (BA 53) in the HS group. **Conclusions:** Overall, our results showed that, when listening to our highly self-referential stimuli, the neurotypical adolescents relied more on brain regions associated with self-recognition that were expected to be activated when hearing their own name and stimuli of high self-referential value. Adolescents with an ASD, on the other hand, relied on frontal-occipital areas linked to visual memory recognition and episodic memory.
We infer that adolescents with ASD, especially those with lower verbal abilities, may

"remember" their own name like they remember another familiar person's name, a desirable familiar object, or a number but they may not implicitly "know" self-referent words as distinct from other words.

Title: Functional connectivity changes throughout childhood to adolescence

Authors: *E. NAVARRETE, Z. GRACIA, F. BARRIOS, S. ALCAUTER;
Lab. C-12, Inst. De Neurobiología., Querétaro, Mexico

Abstract: Introduction: Adolescence is an important transition in the life of human beings, characterized by rapid growth and pace changes, involving biological, cognitive and psychosocial aspects. The study of brain functional development during this period contributes to the better understanding of the brain-behavior relation. Here, we explore the developmental properties of the brain network based on measures of functional connectivity (resting state fMRI) and methods from graph theory.
Methods: The sample consisted in two subsamples acquired during 2010 and 2015, respectively, all of them were healthy participants with resting state functional MRI scans (TR=2s; 150-300 volumes). First sample included 66 subjects (6-10 years old, 36 girls), and second sample included 44 subjects (11-19 years old, 34 girls), 32 of which participated in the first stage. After standard preprocessing (no global signal regression), five noise-based components and movement- affected volumes (relative RMS > 0.25) were regressed out, and subjects with less than 120 non-affected volumes (4 minutes) were exclude from further analysis (6 subjects excluded). For each subject, the average signal from 116 brain regions (AAL atlas)was extracted and the Pearson correlation between all possible pairs of regions was obtained. A threshold of 0.35 was applied based on the best scale-free adjustment in a set of 0.05-step thresholds, and graph theory's weighted degree was obtained for each region. A linear mixed effects model was fitted, with age, gender, and their interaction as fixed effects and mean relative RMS as confounding variable. Significance effects were defined as $p<0.05$ (corrected for multiple comparisons using false discovery rate at $q<0.05$).

Results: We observed a significant negative effect of WD with age (i.e., more age less WD) in 56 regions, mainly including the frontal and parietal lobes and cerebellum. Of these regions, 14 were frontal and 5 parietal.
Conclusions: The decrements of WD with age, suggest functional specialization, which may be related to the synaptic pruning during adolescence. It is possible that the decrease of the WD on parietal and frontal regions, obey the process of massive elimination of short-range connections that occurs concomitantly with selective strengthening of long-range connections, which would result in a more efficient network and give raise to the complex reasoning seen in this period.

Abstract: Characterizing the interactions between reward and inhibitory control brain systems are critical to gain a fuller understanding of decision-making across the lifespan. Individual differences in resting state functional connectivity (rs-fcMRI) patterns can predict performance on a range of cognitive tasks, as well as individual differences in BOLD activity during tasks. However, relationships between rs-fcMRI and incentivized IC task performance have yet to be fully characterized. The current study applies extended unified structural equation modeling (euSEM) to rs-fcMRI data in children, adolescents, and adults in order to investigate developmental and individual differences in these patterns. In addition, we examined whether these differences are predictive of performance on an incentivized oculomotor anti-saccade task. Typically developing individuals (N=43, ages 10-18) completed a resting state scan and an incentivized oculomotor anti-saccade task. Exploratory euSEM provides confirmatory tests of a priori factor structures, relationships between latent factors and multigroup tests of mean structure measurement invariance. This approach allows for the recovery of effective connectivity maps for both groups and individuals and estimates lagged and contemporaneous directed paths between brain regions of interest (ROIs) simultaneously. ROIs were selected

based on previous literature delineating regions involved in incentive processing (e.g. NAcc, amygdala), saccade generation (FEF, PPC), and inhibitory control (infPCS, vlPFC). Our preliminary results indicate higher contemporaneous resting state connectivity (RSC) between right and left (right -> left) vlPFC, and that this is associated with slower reaction times (RTs) on reward, loss and neutral trials. Children, relative to adolescents, have significantly slower RTs in all three conditions (no significant difference between adolescents and adults). Greater lagged connectivity in fefl and ppcr was associated with slower RTs on reward and loss trials in children relative to adolescents. Adults demonstrated greater contemporaneous connectivity between PPC left -> PPC right, and this was associated with faster reaction times on loss trials. Finally, compared to adults, children had greater resting activity from ppcr -> ppcl. Our results highlight specific differences in connectivity and their relationship to behavior across development.

Title: Functional diversity of group II (mGlu2 and mGlu3) metabotropic glutamate receptors in the thalamus.

Authors: *C. S. COPELAND[1], T. M. WALL[2], S. A. NEALE[3], E. NISENBAUM[2], T. E. SALT[1];
[1]Univ. Col. London, London, United Kingdom; [2]Lilly & Co, Indianapolis, IN; [3]Neurexpert Ltd., London, United Kingdom

Abstract: The ventrobasal thalamus (VB) and thalamic reticular nucleus (TRN) transmit somatosensory inputs to S1 cortex. This circuitry can mediate sensory discrimination, enabling relevant information to be discerned from background activity. Group II metabotropic glutamate (mGlu) receptors (subtypes mGlu2/mGlu3) located within this circuitry can modulate somatosensory transmission. However, due to a lack of subtype selective compounds, the relative contributions of the two subtypes to this overall Group II receptor effect remains unclear. We address this using electrophysiology techniques and novel pharmacological tools. Whole-cell recordings were made *in vitro* from VB relay neurons in brain slices from Sprague-

Dawley rats, wild-type and mGlu3 knock-out mice. The Group II agonist LY354740 presynaptically suppressed GABAergic IPSCs arising from TRN in both rat and wild-type mice slices, but had no effect upon IPSCs recorded from mGlu3 knock-out mice. This suggests that the presynaptic modulation of inhibition is predominantly mGlu3 receptor mediated. We then made extracellular single-neuron recordings *in vivo* with multi-barreled iontophoretic electrodes in the VB of anaesthetized Wistar rats. Single vibrissae deflections to activate single VB neurons were performed and compounds locally applied. The action of the dual mGlu2 agonist/mGlu3 antagonist LY395756 provided further evidence that the Group II effect on somatosensory transmission is largely mediated via mGlu3: when applied alone the predominant LY395756 effect mimics the Group II antagonist LY341495 under the same conditions. However, when LY395756 was co-applied with the mGlu2 selective positive allosteric modulator (PAM) LY487379, an increase in responses to vibrissa deflection was observed, an effect similar to the Group II agonist LY354740 under the same conditions. This can be attributed to the PAM revealing the underlying LY395756 mGlu2 agonism component.
These results show that mGlu2 and mGlu3 receptors have different actions in the VB thalamic circuit, with mGlu3 directly modulating GABA release from TRN terminals. This heterogeneity in Group II receptor physiology bears consequence, as compounds active exclusively at mGlu2 are unlikely to perturb maladapted VB firing patterns associated with somatosensory aberrations, such as those described in psychiatric disease. Targeting activity at mGlu3 receptors is likely more appropriate. Indeed, polymorphisms in mGlu3, but not mGlu2, gene alleles have been detected in patients with schizophrenia.

Abstract: The kynurenine pathway (KP) of tryptophan metabolism generates a plethora of compounds acting on different targets. Xanthurenic acid (XA), a kynurenine metabolite that has long been considered as part of the detoxification process of 3-hydroxykynurenine (3-HK), has recently emerged as a putative neurotransmitter in the central nervous system. While the mechanism of action of XA is not entirely clarified, some of the effects mediated by XA involve type-2 metabotropic glutamate receptors (mGlu2 receptors). Recently, several kynurenine derivatives have been tested as hypotensive agents, and L-kynurenine itself has been identified as an endothelium-derived factor that strongly influences the regulation of vascular tone during inflammation (Wang et al., Nat. Med. 16:279-285, 2010). Here, we examined the vasoactive properties of XA for the potential role of this compound in mechanisms of neuroinflemmation and associated vascular changes. We found that: i) XA (2.5 to 1000 μmol/l) almost completely abolished phenylephrine-induced constriction of mesenteric arteries both in the presence or in the absence of the endothelial layer; ii) under the same conditions, L-kynurenine behaved similarly to XA but with lower efficacy and potency; iii) XA was unable not able to relax aorta preconstricted with phenylephrine; iv) in conscious C57BL/6N mice (n = 5) XA (10 and 100 mg/kg) reduced blood pressure; v) in mice pulsed with lipopolysaccharide (LPS) (10 mg/kg, i.p.), levels of kynurenines and XA (detected by HPLC/mass-mass spectrometry) raised by about tenfold at 36 hours; vi) mice pretreated with RO 61-8048 (an inhibitor of kynurenine monooxygenase that transforms L-kynurenine in the XA precursor, 3-HK) did not respond to LPS with a reduction of blood pressure. These data suggest that XA is involved in the regulation of the vascular tone in mice.

Abstract: Presynaptic, release-regulating metabotropic glutamate 2 and 3 (mGlu2/3) autoreceptors exist in central nervous system (CNS). They represent suitable targets for therapeutic approaches to central diseases that are typified by hyperglutamatergicity. The availability of specific ligands able to differentiate between mGlu2 and mGlu3 subunits allows to further characterize these autoreceptors. This study aims at investigating the pharmacological profile of mGlu2/3 receptors in selected CNS regions and at evaluating their functions in mice suffering from experimental autoimmune encephalomyelitis (EAE).
The comparative analysis of presynaptic mGlu2/3 autoreceptors was performed by analyzing the effect of selective mGlu2/3 receptor agonist(s) and antagonist(s) on the release of [^{3}H]-D-aspartate from cortical and spinal cord synaptosomes in superfusion. Experiments were also carried out to analyze mGlu2/3 autoreceptor-mediated releasing functions in EAE animals and whether *in vivo* LY379268 administration can restore impaired glutamate release in these mice. Western blot analysis and confocal microscopy confirmed the presence of presynaptic mGlu2/3 receptor proteins. Cortical synaptosomes possess LY541850-sensitive, NAAG-insensitive autoreceptors having low affinity for LY379268, while LY541850-insensitive, NAAG-sensitive autoreceptors with high affinity for LY379268 exist in spinal cord terminals. In EAE mice, mGlu2/3 autoreceptors lost completely their inhibitory activity in cortical, but not in spinal cord synaptosomes. *In vivo* LY379268 (1-0.01 mg kg^{-1}) administration restored glutamate exocytosis capability in spinal cord but not in cortical terminals. We propose the existence of mGlu2-preferring and mGlu3-preferring autoreceptors in mouse cortex and spinal cord, respectively. The mGlu3-preferring autoreceptors could represent a target for new pharmacological approach for demyelinating diseases.

Sapienza, Rome, Italy

Abstract: The mGlu5 receptor is expressed at different levels of the pain neuraxis and its activation contributes to the development of nociceptive sensitization underlying chronic pain (reviewed by Montana and Gereau, Curr. Pharm. Biotechnol., 2011). Selective negative allosteric modulators (NAMs) of mGlu5 receptors have consistently shown analgesic activity in experimental animal models of inflammatory and neuropathic pain. However, the precise anatomical site of action of these drugs within the pain neuraxis remains to be determined. One way to address this question is to locally inject mGlu5 receptor NAMs in different stations of the pain neuraxis. However, the validity of this approach is limited by the diffusion of the drugs to neighbour regions, and the difficulty to perform accurate dose-response studies. An alternative approach is to systemically inject photoactivable drugs, which are activated by light irradiation specifically delivered into discrete brain region. This allows to control drug activity in specific localizations and time intervals. Here, we used a caged derivative of the mGlu5 receptor NAM, raseglurant (compound, JF-NP-026), which is activated by light at a wavelenght of 405 nm, in two mouse models of pain: (i) the formalin model of inflammatory pain; and (ii) the chronic constriction injury (CCI) model of neuropathic pain. In both models, JF-NP-026 and raseglurant were injectd i.p. at the dose of 10 mg/kg. Light was delivered by means of optic fibers bilaterally implanted in the ventrobasal thalamus. Systemic injection of raseglurant was higly effective in reducing nocifensive behavior in the first and second phase of the formalin test, regardless of light irradiation. In contrast, systemic injection of JF-NP-026 caused analgesia exclusively following light irradiation in the thalamus. The analgesic activity of the photoactivable compound was more ramarkable in the second phase of the formalin test, which reflects the development of central sensitization. Similar data were obtained in mice developing neuropathic pain, in which systemic injection of JF-NP-026 caused analgesia only after light irradiation in the thalamus at 7 and 14 days after CCI of the sciatic nerve. These findings show for the first time that thalamic mGlu5 receptors are targeted by mGlu5 receptor NAMs in the induction of analgesia.

Abstract: Mechanisms of neuroadaptation of glutamatergic and dopaminergic transmission lie at the core of drug addiction. These mechanisms are modulated by mGlu2 and mGlu3 receptors, *via* the regulation of neurotransmitter release and other mechanisms, and pharmacological activation of mGlu2/3 receptors is reported to reduce the rewarding effect of commonly abused drugs and inhibit the reinstatement of drug seeking behavior. Therefore, mGlu2 and mGlu3 receptor ligands are considered as candidate drugs in the treatment of drug addiction. A main role for mGlu2 receptors in drug abuse was hypothesized on the basis of data obtained with mGlu2 receptor knockout mice undergoing cocaine sensitization (Morishima et al., Proc. Natl. Acad. Sci. USA, 102:4170-5, 2005). Here, we studied sensitization to motor effects of the psychostimulant, methamphetamine (METH), in mice lacking either mGlu2 or mGlu3 receptors and their wild-type counterparts. Mice were treated with METH (1 mg/kg) daily for 5 days. Motor behavior was assessed for 1 hour after METH or saline injection at day 1 and 5 of treatment, as well as after 6 days of withdrawal in response to an additional METH challenge (day 11). In wild-type mice, stimulation of locomotor activity by methamphetamine increased with time and was significantly higher at day 11. mGlu3 receptor knockout mice showed a greater motor response to METH, with sensitization being already significant at day 5. Interestingly, mGlu2 receptor knockout mice showed a blunted locomotor response to METH at day 1, but then locomotor sensitization was robust at both day 5 and day 11. All mice were killed at the end of the behavioral session (day 11) for measurements of METH-induced activation of the MAP kinase pathway in the nucleus accumbens (NAc) and other brain regions. Unexpectedly, METH was able to enhanced ERK1/2 phosphorylation in the NAc of wild-type mice, but not in the NAc of mGlu2 or mGlu3 receptor knockout mice. These findings suggest that mGlu2 receptors are required for the acute motor response to METH, and that both receptor subtypes contribute to mechanisms of behavioral sensitization.

Abstract: Activation of polyphosphoinositide (PI) hydrolysis by the group-I metabotropic glutamate (mGlu) receptor agonist 3,5-dihydroxyphenylglycine (DHPG), in rat and mouse cortical and hippocampal slices was amplified by the mGlu2/3 receptor agonist (1R,4R,5S,6R)-4-amino-2-oxabicyclo[3.1.0]hexane-4,6-dicarboxylic acid (LY379268). This potentiation was seen at all developmental ages with the exeption of the first 7-8 days of postnatal life in which the stimulation of PI hydrolysis by DHPG was too high to be further enhanced by LY379268. At this age, however, LY379268 could stimulate PI hydrolysis on its own, albeit to a small extent. All effects of LY379268 disappeared in cortical slices prepared from mGlu3 or mGlu5 receptor knockout mice, but persisted in slices prepared from mGlu2 receptor knocout mice or from *crv4* mice lacking mGlu1 receptors. Interestingly, DHPG-stimulated PI hydrolysis was halved in cortical slices from mGlu3 receptor knockout mice suggesting that endogenous activation of mGlu3 receptors is permissive for mGlu5 receptor-stimulated PI hydrolysis. The existence of a functional interaction between mGlu3 and mGlu5 receptors was supported by data obtained with the selective mGlu3 receptor negative allosteric modulator (NAM), VU0650786. Treatment of mouse cortical slices with VU0650786 dose-dependently reduced DHPG-stimulated PI hydrolysis in cortical slices from mice at postnatal day (PND) 7/8. In slices prepared from PND14/15 mice, compound VU0650786 abrogated the enhancing effect of LY379268 on DHPG-stimulated PI hydrolysis. The interaction between LY379268 and DHPG was also abolished by the mGlu5 receptor NAM, MPEP, but not by the mGlu1 receptor NAM,

JNJ16259685. An interaction between mGlu3 and mGlu5 receptors was also demonstrated in HEK-293 cells where it appeared to be mediated by the βγ subunits of Gi/o proteins. Experiments are ongoing to determine in which cell type (neurons, astrocytes, oligodendrocytes, microglia) the interaction between native mGlu3 and mGlu5 receptors takes place, and what is the functional relevance of this interaction during development and in the adult life.

Title: Targeting mGlu1 receptors in the treatment of retinal degeneration

Authors: M. ROMANO[1], D. BUCCI[1], F. LIBERATORE[1], L. DI MENNA[1], M. MADONNA[1], R. GRADINI[2,1], V. BRUNO[2,1], G. BATTAGLIA[1], *F. NICOLETTI[2,1];
[1]IRCCS Neuromed, Pozzilli (IS), Italy; [2]Univ. Sapienza, Rome, Italy

Abstract: Glaucoma is chronic neurodegenerative disorders characterized by progressive degeneration of retinal ganglion neurons, in which age and increased intraocular pressure (IOP) are major risk factors. Drugs that lower IOP are standard in the glaucoma treatment and there are no neuroprotective drugs that shows clinical efficacy. Thus, the identification of a new therapeutic target in the treatment of glaucoma is an important medical need. We found recently that stimulation of polyphosphoinositide (PI) hydrolysis by excitatory aminoacid in the retina is exclusively mediated by metabotropic glutamate mGlu1 receptors (Romano et al., Neurochem. Res., 2016). These receptors are involved in neurodegeneration/neuroprotection mechanisms because their activation stimulates Ca^{2+} release from intracellular stores. Depending of the extend and the dynamic of Ca^{2+} release as well as on the cellular contest receptor activation by either enhance or attenuate neurodegeneration. We are examining the role of mGlu1 receptors in retinal neurodegeneration by using selective mGlu1 receptor ligands and mutant mice lacking mGlu1 receptors (*crv*4 mice). We are using two models to investigate retinal degeneration: (i) systemic injection of monosodium glutamate in neonatal mice; and, (ii) DBA/2J mice which develop an increase of IOP after five months of age. Mice are systemically treated with either the selective mGlu1 receptors NAM, JNJ16259685 or the selective mGlu1 receptors PAM, Ro 07-11401. In DBA/2J mice and their controls, treatment was performed by subcutaneously

implanted osmotic minipump during either the pre-symptomatic phase (from five to seven months of age) and symptomatic phase (from seven to nine months of age). Current data obtained with DBA/2J mice treated with JNJ16259685 for two months started in pre-symptomatic phase suggest that mGlu1 receptors might represent a potential therapeutic target in the drug treatment of glaucoma and other disorders characterized by retinal degeneration.

Title: Role of ubiquitination in glutamate receptors trafficking

Authors: ***R. GULIA**, R. SHARMA, S. BHATTACHARYYA;
Biol. Sci., Indian Inst. of Sci. Educ. and Res., Mohali, India

Abstract: Glutamate is a major excitatory neurotransmitter in the central nervous system (CNS). Glutamate receptors which bind to glutamate are categorized into two groups: ionotropic glutamate receptors (ion channels) and metabotropic glutamate receptors (GPCRs). Group I metabotropic glutamate receptors (mGluRs) consists of two members viz., mGluR1 and mGluR5. They are predominantly localized at the post-synaptic side are key players in the process of neuronal development as well as in synaptic plasticity in the CNS. These receptors are positively coupled to Gq pathway. Accurate temporal and spatial localization of these receptors at postsynaptic surface is crucial for normal signaling, and their spatiotemporal localization is maintained by trafficking of the receptor. Trafficking also play crucial role(s) in the regulation of these receptors. Thus, studies of the trafficking of these receptors are of utmost importance. Furthermore, these receptors upon activation result in the endocytosis of AMPA receptors, leading to mGluR-dependent Long-term depression (mGluR-LTD). We are interested in investigating the cellular and molecular mechanisms that govern the group I mGluR trafficking and it effect on mGluR-mediated AMPAR endocytosis. Our data suggest that ubiquitination plays critical role in the trafficking of these receptors. We have found that these receptors get ubiquitinated upon binding with the ligand and subsequently get endocytosed. We further

demonstrated that lysine residue present at the C-terminus of mGluR1 plays critical role in the endocytosis of mGluR1. In addition, E3 ligase, Siah-1A was found to be involved the ubiquitination of mGluR1. Acute knockdown of Siah-1A also enhanced group1 mGluR mediated AMPAR endocytosis in primary neurons.

Title: Acute stress exposure mediates circuit-specific, neuroadaptations in glutamate inhibition in VTA-dopaminergic neuron

Authors: *J. PARRILLA-CARRERO, P. GOSWAMEE, C. BAILES, B. PAVLINCHAK, A. RIEGEL;
Med. Univ. of South Carolina, Charleston, SC

Abstract: Environmental stressors contribute to the reinforcing effects of drugs of abuse. Stress triggers the release of corticotropin-releasing factor (CRF) in the brain, which potentiates glutamatergic signaling at dopamine (DA) neurons in ventral tegmental area (VTA) via ionotropic receptors. However, glutamate also recruits inhibition in VTA neurons via activation of postsynaptic metabotropic glutamate receptors (mGluRs). Activation of mGluRs mobilizes intracellular calcium stores to activate inhibitory small-conductance calcium-activated potassium (sK) channels. This mGluR/sK inhibition impacts DA neuron firing patterns and presumably affects the processing of salient information in VTA-projection areas, such as the nucleus accumbens (NAc). Here we investigate how stress-associated CRF impacts mGluR/sK inhibition in dopamine neurons. Because the NAc core and shell subregions likely regulate value coding and prediction monitoring differently, we distinguished between core projecting (VTA◊Core) and shell projecting (VTA◊Shell) VTA neurons with the use of fluorescent microspheres. Three weeks after fluorescent microsphere injection, rats (male, P70) were exposed to filter paper wetted with either alcohol vehicle (control) or TMT (1%). Brain slices were made either 2hrs or

24 hrs later. Inhibitory sK channel currents were measured using whole-cell patch clamp electrophysiology, in response to synaptic stimulation or flash photolysis to uncage intracellular calcium (NP-EGTA). CRF (200 nM) or forskolin (1 uM), an activator of adenylyl cyclase, was applied by superfusion to stimulate stress hormone related signaling. In control animals, sK currents were stronger (larger amplitude and slower decay kinetics) in ***VTA Core*** than ***VTA shell*** projecting DA neurons. A single TMT(24hr) exposure reduced the maximal (basal) sK current in ***VTA Core*** cells and appeared to inactive/desensitize the CRF or forskolin facilitation of sK currents as observed under control or TMT(2hr) conditions. In contrast, in the ***VTA shell*** cells possessing comparatively weak (basal) glutamate inhibition, TMT (24hr) treatment potentiated (basal) IPSCs and simultaneously occluded the CRF or forskolin facilitation. Both populations of cells displayed sK-dependent inhibitory spontaneous miniature outward currents (SMOCs) following TMT(24hrs) treatment, further corroborating an action of stress on glutamate inhibition. Thus, TMT stress alters glutamate inhibition in the VTA, inducing a loss of function in ***VTA Core*** circuitry and a gain of function in ***VTA shell*** circuitry. Such changes are predicted to modulate DA release during reward-predictive cues.

Title: Dynamic regulation of $GABA_B$Rs by neural activity and phosphatase signaling

Authors: *S. L. WISEMAN[1], M. TERUNUMA[1,2], A. C. NAIRN[3], P. A. SLESINGER[4], S. J. MOSS[1];
[1]Neurosci., Tufts Univ. Sch. of Med., Boston, MA; [2]Neuroscience, Psychology and Behaviour, Univ. of Leicester, Leicester, United Kingdom; [3]Psychiatry, Yale Univ. Sch. of Med., New Haven, CT; [4]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Activation of metabotropic GABA type-B receptors ($GABA_BRs$) mediates slow, sustained neural inhibition and critically limits the damage caused by excess excitation, such as occurs during seizure or stroke. $GABA_BRs$ comprise heterodimers of R1 (GABA-binding) and R2 ($G_{i/o}$-binding) subunits. They act presynaptically to block neurotransmitter release via inhibition of voltage-gated Ca^{2+} channels and postsynaptically to hyperpolarize neuronal membrane potential via activation of inwardly rectifying K^+ (GIRK) channels. Our lab has previously identified a bi-phasic regulation of $GABA_BRs$ by activation of NMDA-type glutamate receptors (NMDARs) and increases in intracellular Ca^{2+}. Initially, 5'AMP-dependent protein kinase (AMPK)-mediated phosphorylation of Ser-783 of the R2 subunit increases, in turn stabilizing $GABA_BRs$ at the plasma membrane, but during prolonged or excitotoxic stimulation, protein phosphatase 2A (PP2A)-dependent dephosphorylation of Ser-783 becomes predominant and $GABA_BRs$ are endocytosed and degraded. This NMDAR-mediated impairment of $GABA_BR$ signaling may exacerbate excitotoxic neuronal death, and has also been observed in response to chronic stress and psychostimulant administration. Therefore, preventing R2 Ser-783 dephosphorylation may represent a promising therapeutic intervention for multiple neurological and psychiatric disorders. Our preliminary data indicate that this regulation of R2 is engaged in hippocampal slices in response to NMDA stimulation, oxygen-glucose deprivation (OGD) – an ischemic stroke model – and exposure to Mg^{2+}-free conditions – a seizure model, as well as *in vivo* in the hippocampi of mice subjected to kainate-induced seizures. Ongoing experiments investigate whether these effects are altered in knock-in mice bearing either constitutively de-phosphorylated (Ser to Ala; S783A) or putatively phospho-mimetic (Ser to Asp; S783D) mutations of R2 Ser-783. Additional experiments combining affinity purification and mass spectrometry approaches seek to identify the motif in the R1 $GABA_BR$ subunit to which PP2A binds and the PP2A isoforms that participate in this interaction. Disruption of R1 binding to PP2A is predicted to ameliorate the dephosphorylation of R2 Ser-783 observed in various models of neuropathology, which may guide the development of novel therapeutics.

Title: Autoregulation of $GABA_B$ receptor signaling through with extracellular signal-regulated kinase activation in rat locus coeruleus

Authors: *R.-N. WU[1], M.-Y. MIN[1], H.-W. YANG[2];
[1]Dept. Life Science, Natl. Taiwan Univ., Taipei, Taiwan; [2]Dept. Biomed. Sci., Chung-Shan Med. Univ., Taichung, Taiwan

Abstract: The metabotropic $GABA_B$ receptor ($GABA_BR$) plays important roles in regulating neuronal excitability in the brain. $GABA_BR$ is well known to exert both pre- and postsynaptic inhibition through inhibiting voltage-gated Ca^{2+} channel and activating K^+ (GIRK) channel, respectively. Beside these effects, here we found that $GABA_BR$ activation caused an increase in phosphorylated extracellular signal- regulated kinase (pERK) level in locus coeruleus (LC), which consists of noradrenergic neurons and plays divers roles in behavior. Using western-blot analysis, LC tissue punched out form brain slices bathed in 50 μM baclofen showed an increase in pERK1 and pERK2 by, respectively, 23±7% and 35±13% ($P<0.05$ for both cases, N=6), compared to tissue from slices bathed in normal medium. This effect was specific to $GABA_BR$ activation as it was not observed in LC tissue from slices bathed with baclofen and 10 μM CGP54626, a $GABA_BR$ blocker. The activated ERK seems paly a role in stabilizing $GABA_BR$ signaling. Bath application of baclofen for 15 min induced a CGP54626 sensitive outward current (I_{Bac}) in LC neuron (Vm -70 mV) that underwent slow and partial desensitization. In slices pretreated with or bathed in ERK blockers, U0126 or FR180204, I_{Bac} showed a faster and more prominent desensitization; the half-decay time of I_{Bac} reduced to 51 ± 8% of control for U0126 treatment ($p<0.01$, N=7) and to 57 ± 7% for FR180204 ($p<0.05$, N=7). Since $GABA_BR$ has been shown to mediate a tonic inhibition, defined as rebound increase in firing rate (FR) upon $GABA_BR$ blocker application, of LC neurons, we tested the effect of ERK-dependent desensitization of I_{Bac} on it. In slice pretreated with baclofen for 30 min, FR of LC neurons increased to 239 ± 54% of baseline upon CG54626 application (N=8); it while reduced to 134 ± 10% as for pretreatment with baclofen plus U0126 and to 120 ± 5% as for pretreatment with baclofen plus FR18024 (N=8). Together, the above results show that $GABA_BR$ activation recruits ERK-signaling pathway for an autoregulation that prevents $GABA_BR$ from quick desensitization, therefore maintains tonic inhibition, an important mechanism for tuning FR of LC neurons.

Title: The nogo-$A^{-/-}$ mouse, a model for schizophrenia, exhibits altered hippocampal CA3 function and mglu3 receptor expression

Authors: ***S. BERRY**[1], O. WEINMANN[1], A.-K. FRITZ[2], D. WOLFER[2], M. E. SCHWAB[3], U. GERBER[1], J. STER[4];
[1]Brain Res. Inst., [2]Inst. of Anat., Univ. of Zurich, Zuerich, Switzerland; [3]Dept. of Hlth. Sci. and Technol., ETH, Zuerich, Switzerland; [4]Inst. de Génomique Fonctionnelle, Universités de Montpellier, Montpellier, France

Abstract: Nogo-A is a membrane protein well established as an inhibitor of neurite outgrowth in the CNS that regulates the formation of neuronal circuits during development, but curtails axonal regeneration after CNS injury. Recent evidence from human genetic analyses and experiments in animals implicates Nogo-A dysfunction in certain forms of schizophrenia. Using electrophysiology, microscopy and behavioral tasks in transgenic mice, we characterized the roles of Nogo-A in the hippocampus. Patch clamp recordings from CA3 hippocampal pyramidal cells revealed that the absence of Nogo-A caused a significant increase in spontaneous excitatory activity. In addition, mGlu3 metabotropic glutamate receptors, which can exhibit mutations in schizophrenia, were down-regulated specifically in the CA3 region of Nogo-$A^{-/-}$ mice. This reduction in mGlu3 receptors was accompanied by abnormal CA3 theta oscillations manifesting as a decrease in incidence and frequency, as well as a shift in polarity from inhibitory to predominantly excitatory. These disruptions to CA3 function altered processing of reference frames during spatial navigation in that Nogo-$A^{-/-}$ mice exhibited a greater dependence on global as opposed to local reference frames. These results show that the absence of Nogo-A disrupts hippocampal activity by increasing CA3 excitation and reducing the expression of mGlu3 receptors. Previous data suggested that alterations in either protein can contribute to psychosis. While there is a long list of candidate genes for psychiatric diseases, which typically display multifactorial etiologies, in most cases potential interactions have not been determined. The characterization of a functional link between Nogo-A and mGlu3 receptors, may thus provide novel insights into the underlying pathophysiology of schizophrenia.

Abstract: Metabotropic glutamate receptor 2 ($mGlu_2$) offers a promising neurotherapeutic target for the treatment of various brain disorders. Previous work demonstrates that $mGlu_2$ positive allosteric modulators (PAMs) exhibit efficacy in preclinical models of schizophrenia, pain, addiction, epilepsy, and anxiety disorders. Likewise, dual $mGlu_{2/3}$ negative allosteric modulators (NAMs) display cognitive enhancing properties and efficacy in preclinical models of depression. Recently, medicinal chemistry efforts directed at specifically targeting $mGlu_2$ have successfully developed several chemically distinct $mGlu_2$ PAMs and NAMs. In order to better understand the pharmacology and binding modes of these novel $mGlu_2$ allosteric modulators, we characterized their *in vitro* binding to recombinant rat $mGlu_2$ ($RmGlu_2$) using competition binding experiments with an $mGlu_2$ PAM radioligand. Additionally, we characterized their functional properties using *in vitro* assays in wildtype and mutant $RmGlu_2$ that, along with the competition binding experiments, aimed to understand if these novel allosteric modulators act through a common binding site or distinct sites on $mGlu_2$. Finally, we performed further experiments to better understand how $mGlu_2$ agonists modulate the affinity of various $mGlu_2$ allosteric modulators. Taken together, these studies will improve our understanding of both the pharmacology and binding modes of $mGlu_2$ allosteric modulators.

Title: Post-translational modifications regulate mGluR7 trafficking and signaling

Authors: S. LEE, S. HAN, H. LEE, S. KIM, S. PARK, *Y. SUH;
Dept. of Biomed. Sci., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: The metabotropic glutamate receptors (mGluRs) are seven membrane-spanning proteins that are linked via G-proteins to intracellular signaling cascades. Among eight family members of mGluRs, mGluR7 is a predominant group III mGluR that is highly expressed at the presynaptic active zone and acts as an auto-regulatory receptor to limit neurotransmitter release. Like many GPCRs, mGluR7 undergoes constitutive and agonist-dependent endocytosis. Besides phosphorylation, GPCR endocytosis can be tightly regulated by post-translational modifications of lysine residues such as SUMOylation and ubiquitination. Previously we showed that SUMO modification at Lys889 residue of mGluR7 modulates constitutive and agonist-dependent mGluR7 trafficking. As mGluR7 harbors eight lysine residues in the cytoplasmic domain and

additional four lysine residues in the intracellular loops, we now have mapped the sites of ubiquitination that may affect mGluR7 trafficking and turnover. Given the importance of the ubiquitin-proteasome system in neurodegenerative and neuropsychiatric disorders, mechanisms underlying mGluR7 ubiquitination will provide insights into the functional role of mGluR7 in neurological diseases as well as in learning and memory.

Title: Neurotensin depresses gaba type-b receptor-mediated neurotransmission in the substantia nigra through pre- and postsynaptic mechanisms.

Authors: ***C. TSCHUMI**[1], M. J. BECKSTEAD[2];
[2]Physiol., [1]Univ. of Texas Hlth. Sci. Ctr. San Anto, San Antonio, TX

Abstract: Midbrain dopamine neurons play physiological roles in many processes including reward learning and motivated behavior. Conversely, dysfunction of these neurons is implicated in disorders such as schizophrenia and drug abuse. Midbrain dopamine neurons are tonically inhibited by γ-Aminobutyric acid (GABA)ergic inputs from multiple brain regions. Neurotensin (NT) is a neuropeptide which modulates midbrain dopamine neuron excitability through multiple mechanisms, including a decrease of GABA mediated inhibition of dopamine neurons. However, it is not known if NT acts post-synaptically on GABA type-B receptor signaling, pre-synaptically at GABA terminals to alter GABA release, or through a combination of synaptic mechanisms. Here we utilize whole cell patch-clamp electrophysiology of dopamine neurons in brain slices to show that neurotensin acts both pre- and postsynaptically to decreases GABA type-B receptor-mediated currents in the substantia nigra in mice. Bath perfusion of neurotensin produced a sustained depression of GABA type-B receptor-mediated currents that was more pronounced when GABA was released endogenously (due to electrical stimulation) compared to when GABA was directly applied to the cell (via iontophoresis). GABA type-B receptor mediated currents exhibited paired pulse depression when currents were elicited with electrical stimulation, but not GABA iontophoresis. Bath application of neurotensin increased the paired

pulse ratio with electrical stimulation but had no effect on paired pulse currents elicited by GABA iontophoresis, providing further evidence neurotensin modulates GABA release. As NT is an endogenous peptide present at high levels in the midbrain, determining the mechanism of action by which NT alters midbrain dopamine neuron excitability is a crucial step in understanding the importance of NT in dopamine mediated behavior and related disorders.

Abstract: The rationale for M_1-selective muscarinic acetylcholine receptor (mAChR) activators for the treatment of cognitive impairment associated with psychiatric and neurodegenerative disease is well established in the literature. M_1 activation by a positive allosteric modulator (PAM) is a new approach for achieving subtype selectivity. Here, we present a correlation between mouse amphetamine stimulated locomotor activity of 5 CNS penetrant M_1-subtype selective PAM-agonists with in-vivo increases in mouse striatal inositol phosphate (IP_1) levels. IP_1 accumulation in the striatum was measured from microwaved brain tissue 2 hours after dosing mice with an M_1 mAChR PAM and LiCl and quantified as a multiple over baseline effects. The IP_1 accumulation assay is shown to be a robust biochemical measure of M_1 activation that correlates well with in-vivo pharmacodynamic activity from the amphetamine stimulated locomotor activity assay. Pharmacokinetic-pharmacodynamic modeling of the IP_1 response was used to examine the relationship between exposure and in-vivo IP_1 accumulation, permitting rank ordering of compounds by their ability to potentiate M1 in-vivo under an endogenous level of acetylcholine.

Title: Evaluation of metabotropic glutamate receptor 5 allosteric ligands in recombinant and native tissues: evidence for biased agonism and modulation.

Authors: *K. SENGMANY;
Univ. of Nottingham, Nottingham, United Kingdom

Abstract: Emerging evidence implicates altered glutamatergic neurotransmission in various CNS disorders, with the metabotropic glutamate receptor subtype 5 ($mGlu_5$) representing a particularly promising new therapeutic target. Design of small molecule $mGlu_5$ allosteric ligands offers the advantage of spatial and temporal fine-tuning of endogenous agonist activity, allowing for increased selectivity, reduced adverse effects and improved clinical outcomes. Positive allosteric modulators (PAMs) enhance, whereas negative allosteric modulators (NAMs) inhibit, $mGlu_5$ activity. Recently, we have shown that $mGlu_5$ allosteric ligands classified as 'PAMs' or 'PAM-agonists' for intracellular Ca^{2+} (iCa^{2+}) mobilization display biased agonism, relative to the orthosteric agonist, DHPG, when comparing iCa^{2+} mobilization with $mGlu_5$-mediated ERK1/2 phosphorylation and IP_1 accumulation in both recombinant cells and mouse cortical neurons. Further, VU0360172 exhibited different degrees of cooperativity with DHPG in a signalling pathway-dependent manner. To gain a better understanding of the full scope of $mGlu_5$ allosteric ligand actions, therefore, it is apparent that such rigorous pharmacological profiling also needs to be extended to $mGlu_5$ ligands currently classified as 'NAMs'. Here, we describe the signalling profile of diverse $mGlu_5$ allosteric NAMs, at iCa^{2+}, IP_1 and pERK1/2 receptor signalling endpoints. All NAMs were inverse agonists for IP_1 accumulation in HEK293A expressing $mGlu_5$, however inverse agonism was not apparent in cortical neurons, indicating context-dependent activity. The rigorous profiling of $mGlu_5$ allosteric ligands was further extended to native peripheral cell types. Previous studies suggest that $mGlu_5$ can modulate pain responses, as evidenced by glutamate enhancement of capsaicin activity and sensitised pain responses both *in vivo* and *in vitro* (1,2). Thus, we assessed the modulatory activity of select $mGlu_5$ allosteric

ligands on the transient receptor potential cation channel, TRPV1, in rat dorsal root ganglia. In summary, our work aims to provide a greater appreciation of the pharmacology of $mGlu_5$ allosteric ligands in both recombinant and native cell systems – laying the groundwork for rational design and discovery of drugs with greater clinical efficacy and reduced adverse effects.

Title: A new positive allosteric modulator specific of subtype 2 metabotropic glutamate receptors ($mglur_2$) modulates native receptor activity in the rat hippocampus

Authors: *S. BOSSI[1], P. SCHOLLER[2], D. NEVOLTRIS[2], X. ROVIRA[2], E. DUPUIS[3], D. BATY[4], J.-P. PIN[2], P. RONDARD[2], H. DANIEL[1], H. MCLEAN[1];

Abstract: Metabotropic glutamate receptors (mGluRs) are G protein coupled receptors abundantly found in the central nervous system. Expressed at both pre- and postsynaptically, these receptors can strongly influence synaptic transmission. As such, mGluRs are a potential

target for therapeutic treatment of diverse neurological disorders. mGluRs are dimeric receptors with a large extracellular glutamate binding domain (the venus flytrap domain) whose structure is highly conserved among the 8 subtypes of mGluRs. As such, developing molecules that are specific to one particular subtype of mGluR is challenging issue. An innovative pharmacological tool with which to study these receptors resides in single-chain antibodies (nanobodies) raised in *camelidae* that are directed to specific conformations of a specific subtype of mGluR. We studied the effect of a high affinity nanobody, developed as a **P**ositive **A**llosteric **M**odulator (PAM) of $mGluR_2$, on the activity of this receptor in an *ex vivo* model system, the hippocampal slice preparation.

In the hippocampus $mGluR_2$ are found on Mossy Fiber (MF) terminals where their activation reduces glutamate release at the MF-CA3 pyramidal cell synapse by negatively regulating calcium entry and exocytosis. Using photometric calcium imaging techniques and pharmacological tools, we first verified the presence of $mGluR_2$ on MF terminals. MF were stimulated every 30 seconds, with a single 100-Hz train of 5 electrical stimuli, through a saline-filled glass electrode positioned in the mossy fiber tract. Stimulation evoked presynaptic calcium transients were reversibly depressed by bath application of the group II mGluR orthosteric ligand DCG IV (100 nM). Subsequent application of high affinity nanobodies specifically directed against $mGluR_2$ induced a positive modulation of the orthosteric ligand affinity. Both the overall amplitude and the time course of DCG IV effects were significantly accentuated in the presence of micromolar concentrations of the nanobody. Furthermore, this enhancement was stronger than that observed with a well-known $mGluR_2$ positive allosteric modulator (PAM), LY487379 (50microM).

Our results suggest that site directed nanobodies function as efficient PAMs for mGluRs. This new pharmacological tool is extremely attractive for studying the molecular basis of metabotropic glutamate receptor activity, and should allow us to further dissect the physiological role of different subtypes of mGluRs in the brain.

Title: Metabotropic glutamate receptor 2 modulates thalamostriatal neurotransmission.

Authors: *K. A. JOHNSON[1], D. M. LOVINGER[2];
[1]Lab. for Integrative Neurosci., NIH, Rockville, MD; [2]NIAAA/NIH, Rockville, MD

Abstract: The striatum plays important roles in motor control and action learning. The activity of striatal projection neurons is controlled by inputs from several brain regions, and the strength of these inputs can be modulated by presynaptic G protein-coupled receptors (GPCRs). Most previous efforts to evaluate GPCR-mediated modulation of glutamatergic transmission in the striatum have attributed changes in electrically-evoked transmission to modulation of corticostriatal circuits. However, the contributions of excitatory inputs originating in the thalamus, which represent almost half of excitatory inputs to medium spiny neurons (MSNs), are frequently overlooked. Activation of group II metabotropic glutamate receptors ($mGlu_2$ and $mGlu_3$) is known to produce a strong inhibition of electrically-evoked glutamatergic transmission onto striatal medium spiny neurons (MSNs). To evaluate the input specificity of the $mGlu_{2/3}$-mediated modulation of striatal glutamatergic transmission, we used a viral strategy to express Channelrhodopsin-2 (ChR2) in thalamostriatal projection neurons of C57Bl/6J mice. 3-6 weeks after virus injection, coronal slices containing the striatum were prepared, and optically-evoked thalamostriatal excitatory postsynaptic currents (oEPSCs) were recorded from MSNs in the dorsolateral striatum. Bath application of the group II mGlu receptor agonist LY379268 (100 nM, 5 min) produced a robust reduction of oEPSC amplitude (peak depression 27.4±6.0% of baseline). Inhibition of oEPSCs by LY379268 was long lasting, persisting for at least 45 minutes after the onset of drug application (oEPSC amplitude 44.5±5.0% of baseline 40-45 minutes after LY379268 application). Interestingly, inhibition of optically-evoked corticostriatal oEPSCs by LY379268 was less robust. To identify which receptor subtype(s) contribute to the inhibition of thalamostriatal transmission, we evaluated the effect of the $mGlu_2$ agonist/$mGlu_3$ antagonist LY395756 (10 μM, 5 min). LY395756 produced a strong, reversible inhibition of oEPSC amplitude (peak depression 22.3±2.5% of baseline), suggesting a major role for $mGlu_2$ in the modulation of thalamostriatal transmission. Conversely, a negative allosteric modulator of $mGlu_3$ failed to block the effect of LY372968. These findings add to our limited knowledge of the mechanisms regulating the thalamostriatal system and demonstrate the utility of optogenetics for the study of input-specific modulation of neurotransmission.

Abstract: Mutation or duplication of the Methyl CpG Binding Protein 2 (*MECP2*) gene results in the disorders Rett syndrome (RS) and *MECP2* Duplication syndrome (MDS), respectively. Based on their reciprocal molecular origins, RS and MDS might be viewed as opposing diseases with distinct phenotypes; however, the striking overlap of some symptoms (e.g., respiratory phenotypes, autism, cognitive impairments, seizures) suggests that certain disease-relevant pathways may be similarly disrupted between the two disorders, pointing to a potentially paradoxical, yet shared, therapeutic strategy. We have found that the gene encoding one of the metabotropic glutamate receptors (mGlus), *GRM7*, is a transcriptional target of MeCP2. *GRM7* codes for the presynaptically-expressed $mGlu_7$ receptor, a regulator of both GABA and glutamate release. We have observed dramatic reductions in $mGlu_7$ expression in *Mecp2*-deficient mice, a model of RS, as well as an approximately 50-70% reduction in $mGlu_7$ protein levels in cortical and cerebellar samples from RS patients. Reduced $mGlu_7$ expression correlates with attenuated hippocampal long term potentiation (LTP) at the Schaffer Collateral-CA1 (SC-CA1) synapse in *Mecp2*-deficient mice, and potentiation of $mGlu_7$ using positive allosteric modulators (PAMs) can normalize LTP and rescue learning and memory deficits. These findings led us to the hypothesis that increased MeCP2 expression in the MeCP2-Tg1 model of MDS might result in increased $mGlu_7$ levels and function, suggesting that an $mGlu_7$ *negative* allosteric modulator (NAM) could be effective in reversing abnormalities. However, contrary to our hypothesis, we have now generated data indicating that disease progression does not occur on a

linear path in MDS model mice, but rather evolves as the disease progresses. While hippocampal $mGlu_7$ protein levels are similar to controls in 6-week-old mice, by 20 weeks of age, levels in MeCP2-Tg1 animals are reduced by approximately 50%. Consistent with this finding, an $mGlu_7$ *PAM* normalizes learning and memory responses in 20-week-old MeCP2-Tg1 mice. Remarkably, this is the same treatment strategy we utilized in *Mecp2*-deficient mice. These findings suggest that the biology underlying RS and MDS may merge over time, pointing to a potential common etiology. It will now be critical to understand the regulation of $mGlu_7$ levels and function longitudinally across these disease states to understand temporal and spatial changes that might occur during disease course to explore the therapeutic potential of $mGlu_7$ modulation in these two disorders.

Title: Differential contribution of Kv1 channels to action potentials and firing patterns of defined primary sensory neuron subtypes

Authors: P. LIU, Y. ZHENG, D. D. GINTY, *B. P. BEAN;
Harvard Med. Sch., Boston, MA

Abstract: Mammalian neurons display a wide variety of action potential shapes and firing patterns, reflecting differences in the expression levels of different types of ion channels. We explored how differences in expression of voltage-dependent potassium channels in different types of primary sensory neurons are correlated with differences in firing patterns, focusing on Kv1 family channels. Using mouse genetic models in which defined types of mouse dorsal root ganglion neurons are identified by fluorescent labels, we made electrophysiological recordings from acutely-isolated cell bodies of defined neuronal types. The mRNA expression levels of

channels were also determined in each cell type using FACs purified neurons with next generation deep sequencing. In three different cell types corresponding to mechanoreceptive Abeta fibers, there was high expression of mRNA for Kv1.1 and Kv1.2 channel subunits, with little expression of other Kv1 family subunits. In these neurons, action potential clamp experiments showed that a major component of current during the action potential was carried by dendrotoxin-sensitive Kv1 potassium channels. The dendrotoxin-sensitive Kv1 current activated before the threshold of the action potential and peaked during the action potential falling phase. With maintained current injections of increasing size, most Abeta cell bodies fired only one or two action potentials under control conditions but could fire repetitively after Kv1 channels were blocked by dendrotoxin. In contrast to the Abeta fiber cell bodies, small-diameter neurons corresponding to non-peptidergic nociceptors expressed much lower levels of mRNA for Kv1.1 and Kv1.2 channels, and in these neurons there was only a small contribution of dendrotoxin-sensitive current to the repolarization of the action potential and dendrotoxin had little effect on the firing pattern, which was characterized by repetitive spiking at low and moderate frequencies. Thus, Kv1 channel expression determined by mRNA levels is much higher in DRG neurons corresponding to Abeta fibers than those corresponding to non-peptidergic nociceptors and mRNA levels are well-correlated with different functional contributions of Kv1 current to the firing properties of the neurons.

Title: Cell-type specific activity-dependent regulation of potassium currents in CPG neurons

Authors: *D. SALLOUM[1], J. GOLOWASCH[2];
[1]NJIT, Newark, NJ; [2]Biol. Sci., New Jersey Inst. of Technol., Newark, NJ

Abstract: Regulation of K^+ currents is one of the most prominent mechanisms neurons utilize to alter their excitability in an activity-dependent manner. Many studies have shown activity-dependent changes in ionic currents in STG neurons (Golowasch et al 1999; Turrigiano et al

1995; Haedo & Golowasch 2006). In inferior cardiac (IC) neurons, for example, depolarizing current injections elicited a decrease in the high threshold K^+ current, I_{HTK}, and an increase in the transient K^+ current, I_A. We tested the hypothesis that different cell types within a single motor network regulate ionic current levels in response to patterned activity differently given their distinct intrinsic properties. We measured both I_{HTK} and I_A in pyloric dilator (PD), lateral pyloric (LP), and IC neurons before and after imposing up to two hours of patterned activity using two electrode voltage clamp. We drove the membrane potential of the neurons with three different activity profiles: (1) depolarizing stimuli with square pulses from -60mv to -10mv at a frequency of 1Hz, a patterned voltage fluctuation comparable to their endogenous activity (2) hyperpolarizing stimuli to range from -60mV to -110mV also at 1Hz (3) clamping to -60mV with no change over time. We measured currents every 30 minutes to test for changes in current amplitude assuming post-translational mechanisms are occurring. PD neurons exist as pairs within each ganglion and comprise the pacemaker kernel, giving this neuron a role in setting network frequency. Only when neurons were depolarized, I_{HTK} showed a decrease in current amplitude compared to neurons that were held at -60mV while currents in hyperpolarized neurons did not change amplitude compared to those clamped at -60mV. In contrast to what was previously reported in IC neurons, I_A does not change in response to any of the stimulations we imposed. When LP neurons were depolarized we found that I_{HTK} also decreased while I_A maintained stable levels whether the neurons were depolarized or maintained at -60mV. This suggests, contrary to our predictions, that K^+ current levels change in response to the same activity pattern. Furthermore, only depolarizing stimulations elicited changes in I_{HTK} while hyperpolarizing and holding at -60mV elicited no change, while IA was not sensitive to stimulation. Although each of these neuron types receives different synaptic input and project to distinct target muscles, the K+ currents of all these cells respond similarly to activity patterns, indicating that there is uniformity in the regulation of intrinsic properties across this motor network. Finally, our data confirm that ionic currents in these neurons may be tuned to specific activity patterns.

Title: Novel point mutation in the KCNJ10 gene of a severely-disabled patient leads to impaired function of the inwardly-rectifying K^+ channel Kir4.1 and Kir4.1/Kir5.1

Authors: *S. M. HASAN[1,2], A. BALOBAID[3], O. DABBAGH[3], R. RAWASHDA[3], M. PESSIA[1], M. AL-OWAIN[4], M. C. D'ADAMO[1];

Abstract: A 2 year old boy from non-consanguineous parents presents with tonic-clonic seizures, ataxia, hypotonia, hypothyroidism, profound developmental delay, gut hypomotility, and failure to thrive. EEG recordings were typical of hypsarrhythmia. All family members were clinically unaffected. Genetic screening revealed a novel heterozygous missense variant in the gene KCNJ10 that encodes for the Kir4.1 channel known to be essential for glial function, control of neuronal excitability, and systemic K + homeostasis. The mutation c.652C>T resulted in a leucine to phenylalanine substitution at site 218, a highly conserved residue site located at the c-terminal domain of the channel. To examine the functional consequence of the mutation on Kir4.1, mutant and wild-type KCNJ10 constructs were cloned and heterologously expressed in Xenopus laevis oocytes. Whole-cell K + currents were measured using the two-electrode voltage-clamp technique. Wild-type KCNJ10 expression resulted in robust and typical inward rectifier currents. In contrast, currents from oocytes expressing the mutation were significantly reduced. Kir5.1 subunits display highly selective heteromultimerization with Kir4.1 subunits constituting channels with unique current kinetics. The effect of the mutation on the current from the heteromeric Kir4.1/5.1 channel was examined and was also found to be significantly reduced. In this study, we present a heterozygous KCNJ10 mutation that results in the reduction of inwardly rectifying currents from homomeric Kir4.1 and heteromeric kir4.1/5.1 channels. This loss-of-function mutation was found in a patient with a novel severely-disabling phenotype involving dysfunction of multiple organs.

Title: Computational studies on Parkinson disease- Role of K-ATP channel in modulating subthalamic nucleus electrical activity

Authors: *C. MAHAPATRA[1], R. MANCHANDA[2];
[1]IIT Bombay, IIT Bombay, Powai,Mumbai, India; [2]Bio sciences & Bio Engin., IIT Bombay, Mumbai, India

Abstract: Increased burst firing in the subthalamic nucleus (STN) has been shown to correlate with symptoms of Parkinson's disease (PD). In STN neurons, intrinsic membrane properties enable burst firing whereas synaptic inputs control the timing of burst discharges. From recent experimental studies, it is documented that ATP-sensitive K+ (K-ATP) current plays as a modulating factor in triggering burst firing. The major key for physiological modeling is a better understanding of the main physiological processes involved. The aim is to establish a mathematical platform of sufficient biophysical detail to quantitatively simulate K-ATP channel in STN neuron model and to investigate contribution of this active conductance in pathophysiological condition of these neuron with respective to PD. The magnitudes and kinetics of this ionic current are described by differential equations, in terms of maximal conductances, electro chemical gradients and ATP dependent activation gating variables. In our model, K-ATP current has reduced the duration of plateau potentials (from 700 ms to 185ms), resting membrane potential (by 10mV) and suppressed NMDA-induced burst firing. Because burst firing in STN neurons is associated with symptoms of Parkinson's disease suppression of bursting may be a potential strategy for improving symptoms of this disease. In summary, this mathematical model provides an elemental tool to investigate the physiological K-ATP channel ionic mechanisms underlying the bursting in STN neuron, which in turn can suggest application of K-ATP channel blocker as a possible treatment for Parkinson disease.

Autifony Therapeutics

Title: Modulators of Kv3 channels regulate firing rate and temporal accuracy of auditory brainstem neurons in a mouse model of Fragile X syndrome

Authors: *L. EL-HASSAR[1], L. SONG[2], G. ALVARO[3], C. H. LARGE[3], L. K. KACZMAREK[1];
[1]Pharmacol. department SHMB 309, Yale Univ. Sch. of Med., New Haven, CT; [2]Dept. of Surgery, Yale Sch. of Med., New Haven, CT; [3]Autifony Therapeut. Limited, Imperial Col. Incubator, London, United Kingdom

Abstract: Fragile X syndrome (FXS) is the most common form of inherited intellectual disability. In common with autism, FXS is characterized by hypersensitivity to many types of sensory stimuli, including environmental sounds. Our previous work has shown that mice lacking the gene for FMRP (*Fmr1*$^{-/y}$ or Fragile X mice) have abnormally elevated levels of Kv3.1 potassium currents ("high threshold" K^+ currents) and significantly decreased levels of Na^+-activated K^+ currents in auditory brainstem neurons in the medial nucleus of the trapezoid body (MNTB). Both of these changes in K^+ currents are predicted to increase the firing rate of the postsynaptic neurons and to substantially degrade the accuracy of timing of action potentials. Consistent with this, we have found that the firing pattern of MNTB neurons in response to stimulation is severely abnormal in Fragile X mice. The threshold for action potential generation is significantly reduced in Fragile X mice over that in wild type mice. Moreover, in contrast to MNTB neurons from wild type animals, sustained depolarization triggers repetitive firing rather a single action potential at on onset of a stimulus pulse. We have also found that wave IV of the Auditory Brainstem Response (ABR) recorded *in vivo* is significantly enhanced in Fragile X mice, suggesting that loss of FMRP alters central processing of auditory signals. Based on these results we are now testing, in Fragile X mice, the physiological effects of potential therapeutic compounds, AUT2, which modulate the activity of Kv3 family channels in cell lines. We found that, in Fragile X mice, AUT2 improved the accuracy of timing of action potentials in response to repetitive stimulation, presumably by shifting the activation curve of high threshold potassium currents to hyperpolarizing potentials, thereby increasing the low threshold potassium currents and restoring the accuracy and the timing of action potentials. We are now testing the effects of the AUT2 compound on ABR *in vivo*.

Title: The ERK signaling pathway as a component of the Cav3-Kv4 interaction

Authors: *X. ZHAN, A. P. RIZWAN, H. ASMARA, R. W. TURNER;
Cell biology and Anat., Univ. of Calgary, Calgary, AB, Canada

Abstract: Our previous work revealed an interaction between Cav3 T-type calcium channels and Kv4 A-type potassium channels that can regulate A-type (IA) current availability in cerebellar stellate and granule cells. Cav3-mediated calcium influx increases I_A by rightward shifting the half-inactivation potential (Vh) of Kv4 channels through a nanodomain interaction supported by an association between Cav3 and Kv4 C-termini. We know that the Cav3-Kv4 interaction depends on the calcium-sensitive potassium channel interacting protein isoform 3 (KChIP3), but the molecular basis by which calcium signals a KChIP3-mediated change in Kv4 Vh has yet to be determined. In order to define the process for calcium-dependent activation of KChIP3 and the Cav3-Kv4 interaction, we conducted coimmunoprecipitations (co-IPs) from tsA-201 cells and found a calcium-independent coIP between Kv4 and KChIP3. A co-IP was also found between Cav3.1 and KChiP3 that was reduced in nominally free calcium (BAPTA-AM) but consistent for physiological levels of calcium. Whole-cell voltage-clamp recordings were conducted in tsA-201 cells transfected with Cav3.1, Kv4.3, and KChIP3 cDNA, or a KChIP3 mutant construct lacking two calcium binding EF hand motifs (E186Q, E234Q). Applying mibefradil or Ni^{2+} to block Cav3 channels produced a leftward shift of I_A Vh in cells expressing wildtype KChIP3, but not in cells expressing the KChIP3 double mutant. The mibefradil-induced shift in IA Vh was also blocked by applying a tat peptide (TAT-PP1) against amino acids 7-23 of the Kv4 N-terminus involved in binding KChIP3 to Kv4.3. Moreover, intracellular application of PD98059 to block phosphorylation of MEK but not AIP to block CaMKII inhibited the mibefradil-induced shift in IA Vh. The results indicate that calcium regulation of Kv4 availabilty depends on the the integrity of the KChIP3 - Kv4 interaction site and involves both the ERK signaling pathway and EF hand calcium-binding motifs of KChIP3.

Title: A glial K^+ channel augments *Drosophila* visual contrast sensitivity by facilitating inhibitory synaptic transmission

Authors: Z. LUAN, 01605, P. GUO, *H.-S. LI;
Neurobio., Univ. Mass. Med. Sch., Worcester, MA

Abstract: The mechanism regulating visual neuronal circuits by glial cells to attain contrast sensitivity in human and animal eyes is unknown. Here we report an essential role for a glial inwardly rectifying K^+ channel (Kir) Irk2 in *Drosophila* visual contrast sensitivity. Both systemic and glia-specific Irk2 deficiencies caused electrical oscillation in electroretinogram during light stimulation, and reduced fly behavioral responses to moving gratings at low contrast. Further analyses indicated that Irk2 in glia controls light-triggered extracellular K^+ increase in the visual ganglion lamina and prevents abnormal excitation of laminar neurons postsynaptic to histaminergic photoreceptors, suggesting the importance of glia-mediated K^+ buffering to inhibitory synaptic transmission. Since decreased glial Kir channel activities are observed in human diabetic retinopathies with reduced contrast sensitivity, this work may have revealed a conserved glial function that optimizes visual contrast sensitivity.

Title: Radial glial activation by Kv3 deletion in suppressing inflammatory demyelinaton and axon degeneration

Authors: *C. GU;
Biol. Chem. and Pharmacol., Ohio State Univ., Columbus, OH

Abstract: The development of neuroprotective and repair strategies for treating progressive multiple sclerosis (MS) requires new insights in axonal injury and recovery. 4-aminopyridine (4-AP), a blocker of voltage-gated K^+ (Kv) channels, is used in symptomatic treatment of progressive MS, but the underlying mechanism remains unclear. Here we report that deleting Kv3—a channel with the highest 4-AP sensitivity—reduces clinical signs in experimental autoimmune encephalomyelitis (EAE), a mouse model for MS. In Kv3 knockout (KO) mice, EAE lesions in both sensory and motor tracts of spinal cord markedly reduced, and radial astroglia were activated with increased expression of brain derived neurotrophic factor (BDNF). Kv3 and activated BDNF receptors were upregulated in demyelinating axons in EAE and MS lesions. In spinal cord myelin coculture, BDNF enhanced myelination and altered neuronal firing partially through upregulating Kv3. Therefore, suppressing Kv3 increases neural activity and enhances BNDF signaling, which may protect axons from inflammatory injury.

Title: Calcium activated potassium currents in different cell types of the neonatal hippocampus

Authors: A. MONICAL, *M. MYNLIEFF;
Biol. Sci., Marquette Univ., Milwaukee, WI

Abstract: Calcium (Ca^{2+}) regulates many different processes in neurons, including excitability. One way in which Ca^{2+} influx regulates excitability is by activation of Ca^{2+} activated potassium (K^+) channels such as BK, SK and KCNQ channels, which may be involved in mediating action potential repolarization and afterhyperpolarization. The expression of K^+ channels is not uniform across cell types so in the wide variety of neurons in the hippocampus (up to 40 types), a different complement of K^+ channels may contribute to excitability. The various interneuron subtypes play different roles in controlling excitability and overall output of the pyramidal cells. Understanding how Ca^{2+} activated K^+ channels control the excitability of the different cell types will contribute to our appreciation of how modulation of Ca^+ influx can regulate excitability in single cell types as well as excitability of the overall circuitry. In this study whole cell patch clamp recording was used to measure K^+ currents in primary cultures of the superior region of neonatal rat hippocampus. The total K^+ current demonstrated a fast activing, transient current (I_A) and long lasting, sustained current (I_K). Currents were elicited by stepping from -50 to +50

mV in 10 mV increments from -90 mV for total current or -50 mV for I_K. I_A was determined by subtracting I_K from the total current. The cells were divided into three groups based on the rise time of the total current: cells with a slow rise time and no I_A, cells with an intermediate rise time and I_A, and cells with a fast rise time and large I_A. This classification also corresponded to cell size, with smaller cells having less I_A. Nimodipine (40μM), an L-type Ca^{2+} channel antagonist, blocked 35.5% of I_K in cells with little I_A (N=2), blocked 81.3±4.65% of I_K in cells with intermediate I_A (N=3), and 65.3±5.74% of I_K in cells with large I_A (N=11). These data suggest that Ca^{2+} influx through L-type channels activates K^+ channels involved in I_K. In cells with a large I_A (N=11), nimodipine blocked 29.9±4.55% of the I_A current suggesting that influx of Ca^{2+} through L-type channels contributes more to I_K than to I_A . Two large conductance (BK) Ca^{2+} activated K^+ channels antagonists, iberiotoxin (10 μM; N=7) and verruculogen (10 nm; N=4) had very little effect on the total I_A and I_K in all of the three cell types. The effect of nimodipine and selective K^+ channel antagonists on action potential and afterhyperpolariztion duration will be tested in heterogeneous neonatal cells. Co-localization of specific Ca^{2+} activated K^+ channels and various interneuron markers will be used to correlate the electrophysiological findings with interneuron identities.

Title: Structural insights into the mechanism of KCa3.1 channel-small molecule interactions

Authors: *H. M. NGUYEN[1], V. SINGH[1], H. WULFF[1], V. YAROV-YAROVOY[2];
[1]Pharmacol., [2]Physiol. and Membrane Biophysics, UC Davis, Davis, CA

Abstract: Ion channels play a key regulatory role in many biological processes and thus are a major pharmacological target for drug development. The calcium-activated intermediate-conductance KCa3.1 channel is an effective regulator of intracellular calcium and an attractive pharmacological target for immunosuppression, fibroproliferative disorders, hypertension and various neurological diseases. However, the development of drugs for this medically relevant

channel is hindered by the unavailability of a crystal structure useful for structure-guided drug design. To gain insights into the possible active sites underlying channel-small molecule interactions, we utilized the Rosetta molecular modeling suite to generate a homology model of the KCa3.1 channel transmembrane region using the Kv1.2-Kv2.1 channel structure (pdb id: 2R9R) as a template. Upon docking of known KCa3.1 small molecule blockers into this homology KCa3.1 model, we identified, surprisingly, two independent sites for the dihydropyridine nifedipine and for its isoster methyl-5-acetyl-4-(4-chloro-3-(trifluoromethyl)phenyl)-2,6-dimethyl-4*H*-pyran-3-carboxylate. While nifedipine is predicted to bind in the fenestration between the pore-lining S5 and S6 segments, the pyran isoster has its lowest energy binding configurations in the inner pore region. We then tested and confirmed these predictions via a combination of site-directed mutagenesis and electrophysiological patch-clamp recording. Blocking of KCa3.1 by nifedipine was significantly reduced by replacing the side chains at the fenestration positions L209, T212 and V272 with either alanine or valine. Replacement with bulkier phenylalanines confirmed T212 and V272 as the main interacting sites for nifedipine without compromising the affinity of inner pore blockers like TRAM-34 or the 4-phenyl pyran. In contrast, the inner pore T250S and V275A mutants, which are known to nullify TRAM-34 binding disrupted binding of the 4-phenyl pyran but did not interfere with nifedipine binding. We conclude that the Rosetta modeling approach can be useful to distinguish the molecular mechanisms of action of KCa channel modulators and has promising potential in guiding the development of clinically relevant drugs.

Title: Signaling of neuronal Ca^{2+} sensor proteins in hippocampal neurons

Authors: N. I. KONONENKO[1], J. VIVIANO[2], A. V. DOVGAN[1], V. P. CHERKAS[1], J. ZHANG[2], V. VENKATARAMAN[2], *P. V. BELAN[1,3];
[1]Bogomoletz Inst. of Physiol., Kiev, Ukraine; [2]Dept. of Cell Biology, Grad. Sch. of Biomed. Sci., Rowan Univ. Sch. of Osteo. Med., Stratford, NJ; [3]Intl. Ctr. for Mol. Physiol., Kiev, Ukraine

Abstract: Structurally similar neuronal Ca^{2+} sensor (NCS) proteins, Neurocalcin δ (NCALD) and Hippocalcin (HPCA), control many neuronal processes including slow afterhyperpolarization (sAHP) and long-term depression (LTD). Both sAHP, which tunes neuronal activity, and LTD, which regulates the synaptic strength, are likely controlled by HPCA and NCALD translocation from the cytosol to the plasma membrane. Difference in AA sequence between HPCA and NCALD suggests different Ca^{2+}-dependent signaling of these proteins. To test this hypothesis we studied $[Ca^{2+}]_i$ regulation and Ca^{2+}-dependent translocation of HPCA, NCALD, and their chimeras and mutants tagged by different fluorescent proteins. Minor increases in $[Ca^{2+}]_i$ were observed when the resting membrane potential was increased stepwise in a range of from -80 through -40 mV. These increases resulted in gradual translocation of NCALD rather than HPCA to the plasma membrane thus activating membranous NCALD targets and depriving a cytosolic pool of NCALD for the following fast translocation. The fast depolarization-induced $[Ca^{2+}]_i$ transients led to different time courses, amplitudes, and locations of fast translocation of HPCA, NCALD and their chimeras and mutants. We found that N-terminal AA sequence including EF1 domain was important determinant for differences in kinetics, localization and Ca^{2+}-dependency of NCS protein signaling. NCALD mutants, in which dimerization was prevented, did not reveal substantial translocation indicating that Ca^{2+}-dependent dimerization may be necessary for NCALD translocation. We conclude that structural distinctions in AA sequence of HPCA and NCALD may result in differential Ca^{2+}-dependent regulation of their targets and plasma membrane conductance, thus far differentially regulating dendritic integration and synaptic plasticity.

Title: A single pre-exposure to methamphetamine potentiates methamphetamine self-administration and attenuates changes in DNA methylation and expression of potassium channels in the rat nucleus accumbens.

Authors: *S. JAYANTHI, M. GERRA, N. TERRY, M. MASNATA, B. LADENHEIM, I. N. KRASNOVA, M. T. MCCOY, J. L. CADET;
Mol. Neuropsychiatry Br., NIDA-IRP, Baltimore, MD

Abstract: Drug addiction is a chronic relapsing neuropsychiatric disorder associated with transcriptional and epigenetic changes in brain reward circuitries. Methamphetamine (METH) addiction is a major problem in the world with its prevalence outpacing that of cocaine. Transition from occasional use to dependence state can be accelerated by un-prescribed use of psychostimulants. An earlier study from our lab has shown that a single non-contingent METH injection increased cocaine self-administration (SA). Although the molecular mechanisms underlying this behavioral response to cocaine is not known, a single METH injection has also been shown to impact gene expression and DNA methylation in the brain. In the present study, we tested the possibility that a single METH injection could impact METH SA. Towards that end, we administered a single dose of METH (10 mg/kg) or saline to rats prior to training them to self-administer METH (0.1mg/kg, 3h-6h/day, 18days). This approach resulted in three experimental groups: (1) control- saline-saline group (SS), (2) single saline injection followed by METH SA (SM) and (3) single METH injection followed by METH SA (MM). We found that the MM group showed significantly higher METH intake than the SM group. Cue-induced METH seeking was examined using extinction tests on day 2 (WD2) and 29 (WD29) of forced withdrawal from METH SA. Both SM and MM groups showed higher cue-induced reward seeking on WD29 compared to WD2. There were no differences between the SM and MM groups. Because our recent genome-wide DNA hydroxymethylation experiment had identified potassium channels in the nucleus accumbens as discriminators of compulsive METH takers and abstinent rats, we wondered if changes in the expression of potassium channels might help us to distinguish SM from MM groups. Interestingly, the SM rats showed increased mRNA expression of *shaker-related* voltage-gated potassium channels (Kv1-*Kv1.1, Kv1.3, and Kv1.6*) in comparison to MM rats. SM rats also showed decreased DNA methylation at the CpG-rich sites near the promoter region of *Kv1.1* and *Kv1.3* genes in comparison to MM rats. Together, our results provide further evidence for the potential involvement of potassium channels in METH addiction.

Title: Epigenetic reversal of maternal deprivation-induced dopamine cell hyperexcitability and synaptic dysfunction within the VTA

Authors: *H. KASSIS, L. D. LANGLOIS, S. GOUTY, M. E. AUTHEMENT, R. D. SHEPARD, B. M. COX, F. S. NUGENT;
Pharmacol., Uniformed Services Univ., Bethesda, MD

Abstract: Child abuse and neglect as early life stressors are shown to increase the risk of developing stress-related disorders and substance abuse. The increased vulnerability seems to be related to brain monoaminergic dysfunction including an altered dopamine (DA) signaling from the ventral tegmental area (VTA). Recently, we demonstrated that a 24h early maternal deprivation (MD, an animal model of child abuse), on postnatal day 9, induces synaptic abnormalities at GABAergic synapses onto VTA DA neurons through disruption of A kinase anchoring protein (AKAP150) signaling in juvenile rats (p14-p21). These synaptic defects were normalized by *in vitro* histone deacetylase (HDAC) inhibition suggesting the potential clinical benefits of targeting the VTA by HDAC inhibitors soon after the insult. Here we further investigated the synaptic and epigenetic modifications associated with MD in VTA DA neurons and tested the effects of a single in vivo injection of a selective class I HDAC inhibitor (CI-994) on these MD-induced changes within the VTA. We found that MD indeed increased HDAC2 (a class I HDAC) expression specifically in VTA DA neurons resulting in reduction of histone H3 acetylation at lysine 9 (Ac-H3K9). The levels of Ac-H3K9 in VTA of MD rats were restored 3 hours after a single *in vivo* injection of MD animals with CI-994. We also detected that MD induced DA cell hyperexcitability which was also normalized by the *in vivo* HDAC inhibition. Our preliminary data suggest that GABAergic and glutamatergic synaptic dysfunction could also be reversed through restoration of synaptic localization of AKAP shortly after a single *in vivo* injection of CI-994. Taken together, our results suggest that a single *in vivo* HDAC inhibition may be sufficient to epigenetically reverse MD-induced changes in AKAP localization, DA cell excitability and synaptic dysfunction within the VTA.

Abstract: Normal brain function is strongly dependent on the correct development and assembly of the neuronal cytoskeleton. Failure to achieve the correct neuronal layout or to form the right interconnections between nerve cells underlies disorders involving cognitive deficits and mental disability. During development and other processes that include changes in cell architecture, as seen for example in plasticity, neurons have to undergo in some cases extensive reorganization of their actin scaffolding. Synaptic plasticity is associated with mechanisms such as the dynamic changes in spine size and number and the ability of excitatory glutamate-activated synapses to alter their strength in response to changes in activity patterns. Members of the Rho small GTPase subfamily have been shown to orchestrate many cellular processes involving intraneuronal actin dynamics. Essentially working like binary switches, they cycle between inactive GDP-bound states and active GTP-bound states, to which they are driven by GTPase activating proteins (GAPs) and guanine nucleotide exchange factors (GEFs), respectively. A variety of these regulators have by now been shown to play critical roles within neurons. We identified ARHGAP8 as a novel Rho GAP which is localized to spines in a GluN2B-NMDA receptor dependent manner. Using quantitative mass spectrometry, we have found ARHGAP8 to be absent from postsynaptic densities (PSDs) of mouse neurons that lack the developmentally regulated NMDA-type glutamate receptor subunit GluN2B, while it is identified in PSDs isolated from wild-type neurons. We are currently characterizing its function within neurons and our data from biochemical and immunocytochemical experiments suggest a brainwide expression pattern and a partial localization to active synapses. Furthermore, ARHGAP8

overexpression in rat neuronal cultures affects spine maturation. Overall our data suggest that ARHGAP is a novel regulator of excitatory synapses.

Title: Distinct molecular conformations of AKAP79/150 in hippocampal spine synapses

Authors: ***X. CHEN**[1], A. FENG[2], K. CROSBY[3], A. PURKEY[3], C. WINTERS[2], V. CROCKER[2], M. ARONOVA[4], R. LEAPMAN[4], T. REESE[2], M. DELL'ACQUA[3]; [1]Lab. Neurobiol, [2]NINDS-NIH, Bethesda, MD; [3]Dept. of Pharmacol., Univ. of Colorado Sch. of Med., Aurora, CO; [4]NIBIB-NIH, Bethesda, MD

Abstract: Protein kinase A (PKA), protein kinase C (PKC) and calcineurin (CaN) are signaling molecules working in conjunction with AMPA-type and NMDA-type glutamate receptors in long-term potentiation (LTP) and depression (LTD). While glutamate receptors are localized to the synaptic membrane through the PSD-95 family of MAGUK scaffold proteins, these kinases and phosphatases are targeted to the synapses through binding to the scaffold protein A-Kinase anchoring protein (AKAP) 79/150. AKAP79/150 contains a membrane-targeting domain characterized by three subdomains with a PKC anchoring site at the N-terminus, a MAGUK binding region downstream, and CaN and PKA anchoring sites at the C-terminus. Despite extensive studies of the function of this AKAP, very little is known about its nanometer scale localization and molecular conformation at the spine membrane and at the postsynaptic density (PSD). We expressed N or C terminally GFP tagged AKAP79 constructs in rat hippocampal cultures and used immunogold EM to map their localization and determine their conformations at the spine membrane and in the PSD. We also used scanning transmission electron microscopy (STEM) tomography to reconstruct entire PSDs at 6 nm resolution in spine membranes positively labeled for AKAP79. Our results show extensive AKAP localization at the spine membrane both outside the PSD and in regions within the PSD. STORM/PALM super-resolution fluorescence microscopy with mEOS-tagged AKAP79 confirmed distinct clustered localizations

in spines both outside the PSD and overlapping with PSD-95 in the PSD. At the spine membrane outside the PSD, EM also revealed that the N and C termini of AKAP79 are located at similar distances from the plasma membrane, suggesting they assume a closed or horizontally extended orientation. At the PSD, the N terminus is located near the membrane but the C terminus is located ~ 10 nm away, suggesting that AKAP79/150 molecule is vertically oriented relative to the membrane and in an extended conformation. These results demonstrate that AKAP79 adopts distinct molecular conformations at the PSD different from those at the spine membrane outside the PSD. Our results provide an initial look at the molecular organization of the AKAP79/150 postsynaptic signaling complex in dendritic spines and might lead to further understanding of the molecular inner-workings of the PSD in synaptic transmission and plasticity.

Title: Lithium increases synaptic GluA2 by elevating the autism-related δ-catenin protein in hippocampal neurons

Authors: ***S. KIM**[1], M. FAROOQ[2], S. PATEL[2], L. KHATRI[2], E. ZIFF[2];
[1]Biochem., NYU Sch. Med., New York, NY; [2]New York Univ. Langone Med. Ctr., New York, NY

Abstract: Lithium (Li+) is a drug widely employed for treating bipolar disorder, however the mechanism of action is not known. Here we study the effects of Li+ in cultured hippocampal neurons on a synaptic complex consisting of δ-catenin, a protein associated with cadherins whose mutation is linked to autism, and GRIP, an AMPA receptor (AMPAR) scaffolding protein, and the AMPAR subunit, GluA2. We show that Li+ elevates the level of δ-catenin in cultured neurons. This elevation is consistent with Li+ inhibition of GSK3β, a kinase that phosphorylates and destabilizes δ-catenin. δ-catenin binds to the ABP and GRIP proteins, which are synaptic scaffolds for GluA2. We show that Li+ increases the levels of GRIP and GluA2, consistent with Li+-induced elevation of δ-catenin. Using GluA2 mutants, we show that the

increase in surface level of GluA2 requires GluA2 interaction with GRIP. Furthermore, Li+ fed animals show elevated synaptic levels of δ-catenin, GRIP, and GluA2 in the hippocampus, consistent with the finding in cultured neurons. This work supports a model in which Li+ stabilizes δ-catenin by inhibition of GSK3β, elevating δ-catenin, GRIP and GluA2 in synapses of hippocampal neurons. Thus, it suggests a mechanism by which Li+ can alter brain synaptic function that may be relevant to its pharmacologic action in treatment of neurological disease.

Title: Phosphorylation of EphB2 receptor tyrosine kinase ectodomain

Authors: H. WASHBURN[1], K. HANAMURA[3], S. SHEFFLER-COLLINS[2], N. XIA[1], *Y.-T. MAO[4], S. HASSLER[5], G. ZHANG[6], T. NEUBERT[6], T. PRICE[5], M. DALVA[4];

Abstract: Extracellular phosphorylation of proteins was suggested in the late 1800's when casein was shown to contain phosphate. More recently extracellular kinases that phosphorylate

extracellular serine, threonine, and tyrosine residues of numerous of proteins have begun to be identified. However, the significance of extracellular phosphorylation of specific residues for protein function in the nervous system is poorly understood. Crucial for proper synaptic development is the EphB family of receptor tyrosine kinases and their membrane bound ligands, the ephrin-Bs. The binding of ephrin-B2 to the ligand binding domain (LBD) of EphB2 drives a direct extracellular interaction between the EphB2 receptor and the N-methyl-D-aspartate receptor (NMDAR), an ionotropic glutamate receptor required for synaptic plasticity. Normal brain function requires that NMDARs are properly localized to synaptic sites, whereas absence of the NMDAR is lethal in mice. EphB2 is necessary for the correct localization and function of NMDAR at synapses. However, because the interacting domains between EphB2 and the NMDAR are yet to be determined, the mechanisms enabling extracellular interactions have not been well studied. We demonstrate that EphB2 undergoes post-translational modification of its extracellular domain that enables it to interact with the NMDAR. Unbiased mass spectrometry data suggest that a specific tyrosine reside, Y504, in the fibronectin type III (FN3) repeat domain of the extracellular region of EphB2 undergoes ephrin-B2 ligand-dependent phosphorylation. Furthermore, mutation of the predicted extracellular phosphorylation site shows it is required for the EphB-NMDAR interaction. Y504 is phosphorylated in both the brain and spinal cord and data show that constitutive phosphorylation of this site results in mechanical hypersensitivity in mice expressing a phospho-mimetic mutant of EphB2. Given that several recent publications have demonstrated the existence of ectokinases and ectophosphatases, we are investigating the possibility that a secreted kinase is a candidate for extracellular phosphorylation of EphB2. Because of the importance of the Eph-NMDAR interaction, identifying the extracellular kinase allows for a potential therapeutic target as well as insight into the phenomenon of extracellular phosphorylation. Taken together, our results suggest that extracellular phosphorylation by a secreted kinase might be an underappreciated mechanism in regulation of protein interaction and protein trafficking.

Title: NMDA receptor mediated activation of pannexin1 channels at hippocampal mossy fiber synapses support burst-firing output in CA3 pyramidal neurons

Authors: *D. L. HUNT[1], W.-P. LI, 20147[2], E. SCEMES[3], P. E. CASTILLO[3];
[1]Janelia Res. Campus, Ashburn, VA; [2]Janelia research campus, Ashburn, VA; [3]Albert Einstein Col. of Med., Bronx, NY

Abstract: Pannexin1 channels are a distinct category of large pore ion channels expressed throughout the mammalian brain. While pannexins have been shown to participate in various neuropathologies, the extent of their physiological role remains largely unexplored. Here we combine pharmacological and genetic tools with acute slice electrophysiology to demonstrate NMDA receptor (NMDAR)-mediated activation of pannexin1 channels in CA3 pyramidal neurons at hippocampal mossy fiber synapses. Pannexin1-mediated secondary currents are revealed at physiological temperature (35 °C) but not at room temperature (25 °C), and probabilistically occur following the peak of NMDAR-mediated synaptic responses. These currents are abolished by the pannexin1 inhibitory peptide Panx10 (50 μM), carbenoxolone (30 μM), and intracellular loading of BAPTA (10 mM). Additionally, we provide immunohistological evidence that pannexin1 is highly expressed in *stratum lucidum,* and immunoelectron microsocopy revealed pannexin1 near the postsynaptic density of thorny excrescences. Moreover, we show that pannexin1 channels are preferentially recruited when NMDAR activation enters a supralinear regime, resulting in burst-firing output. In line with the hypothesized role for mossy fiber synapses as potent drivers or "detonators" of CA3 pyramids during episodic memory, we found that by mimicking the structure of *in-vivo* activity, pannexin1 mediated secondary currents can be bidirectionally modulated by burst-timing dependent plasticity of NMDAR-mediated transmission. Our data suggest that pannexin1-mediated secondary currents provide a mechanism for signal amplification, eliciting temporally delayed burst-firing of hippocampal CA3 pyramidal neurons. This delay likely enables particularly salient stimuli that drive NMDARs into a supralinear regime, to extend associativity windows of co-activated CA3 pyramids during auto-associative functions of the CA3 region of the hippocampus.

Title: Investigating the role of csmd2 in reelin-dab1 function at synapses

Authors: B. E. DWYER, M. A. GUTIERREZ, *S. J. FRANCO;
Pediatrics, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Reelin is a secreted glycoprotein that regulates the development and function of the cerebral cortex by initiating a signaling cascade via its downstream adaptor protein Dab1. The developmental roles of Reelin/Dab1 signaling have been extensively studied, and many of the molecular and cellular mechanisms of Reelin's critical functions during neuronal migration and differentiation have been elucidated. On the other hand, the role and mechanisms of Reelin signaling in the mature brain are considerably less understood. Reelin continues to be secreted by inhibitory interneurons in the adult forebrain and emerging evidence suggests Reelin signaling is important for synapse function and learning and memory. However, the mechanisms that control synapse function and brain physiology downstream of Reelin and Dab1 are not known. We have identified a novel interaction between Dab1 and Csmd2, which belongs to a family of single-pass transmembrane proteins of unknown function. We found that the cytoplasmic tail of Csmd2 binds to Dab1 via an NPxY motif, and to several synaptic scaffolding proteins via a PDZ-binding domain. Csmd2 localizes to synapses in vitro in rat primary hippocampal cultures, as well as in vivo in mouse cerebral cortex. Introduction of a truncated form of Csmd2 into mouse cortical neurons by in utero electroporation caused a dramatic reduction of dendritic spine number and density in vivo. This phenotype was relieved in a mutated form of the truncated protein that no longer localizes to synapses. Together these data indicate a role for Csmd2 in synapse formation, maintenance and/or function. Based on the similarities between the extracellular domain architecture of Csmd2 and several synaptic auxiliary proteins, we are now testing the hypothesis that Csmd2 serves as an auxiliary subunit of ionotropic glutamate receptors. We have also begun testing the hypothesis that the interaction between Dab1 and Csmd2 is required for proper synapse function, and that Reelin signaling modulates this interaction.

Abstract: Schizophrenia is a devastating disorder that affects about 1% of the worldwide population. This multifactorial disease, with a strong genetic component, is characterized by delusions, hallucinations and confusion thoughts. Furthermore schizophrenia onset and stress are inextricably related. It has been suggested that schizophrenia patients present a disruption of normal homeostatic adaptation of neuronal circuits to changes in the environment, as a consequence of impaired synaptic function, since several *de novo* mutations in synaptic networks components have been found in these patients. Stargazin is an auxiliary subunit for AMPAR and it is required for AMPAR trafficking to the surface and for the homeostatic scaling up of AMPAR upon blockade of activity. Using whole-genome sequence analysis, we identified a new CACNG2 variant, Stg^{SCZ}, which, along with Stg^{ID}, previously identified in intellectual disability, altered the surface trafficking properties of stargazin and failed to deliver AMPAR to synapses. Furthermore, Stg^{ID} was not able to mediate homeostatic plasticity whereas Stg^{SCZ} increased the number and decreased the length of primary dendrites, as well as the number of inhibitory synapses. Tianeptine, a commercial memory enhancer and powerful antidepressant, described to increase AMPAR trapping at synapses by increasing stargazin phosphorylation, rescued AMPAR levels in neurons expressing STG^{SCZ}. The correlation between stargazin disease-related

variants and specific alterations in the function of the protein will allow elucidating the mechanisms underlying the development of these neuropsychiatric disorders.

Title: Analysis of specific synaptic proteomes in the mouse brain

Authors: *J. N. SAVAS, Y.-Z. WANG, C. STROJNY;
Northwestern University, Feinberg Sch. of Medici, Chicago, IL

Abstract: Synapses are protein rich cell junctions and synaptic malfunction plays a key role in many neurodevelopment disorders and neurodegenerative diseases. While a near comprehensive description of the proteins which can be present at synapses has been obtained, an understanding of which specific proteins are present at distinct synapses represents a critical gap in our understanding of synapse diversity. Up till now, there have been only a few reports which have described neuron-specific proteomes and none have investigated neuron-specific perturbations. In traditional neuroproteomic mass spectrometry (MS) studies, samples are prepared from brain which represent complex mixtures of proteins from multiple cell types and suffer from "averaging". If one synapse is affected while another is not, and tissue is simply homogenized, the resulting analysis can be misleading since the measured signal will be an average. To overcome this limitation, we developed a new approach which couples synaptic membrane targeting, proximity biotin ligation, conditional expression, and isotope based quantitative MS analysis.
We fused BirA* biotin ligase with the transmembrane regions of NRXN1 or NLGN1 (from GRASP), which will target pre- or post-synaptic locations. As expected, both BirA*-pre and -

post are expressed on the cell surface. Our constructs exhibited strong biotinylation activity and when expressed in rat hippocampal neurons, both BirA*-pre and -post showed punctate distribution patterns. Based on co-localization with synaptic markers our fusion proteins predominantly localized to excitatory and to a lesser degree inhibitory synapses. Next, we moved our fusion proteins into AAV-FLEx vectors which express only in presence of Cre and injected AAVs into the striatum of dopamine receptor -1 (D1) – and (D2) - Cre mice. Biotin was injected, and the biotinylated proteins were isolated with streptavidin, and MS analysis identified a contrasting set of proteins. By crossing different Cre lines with various mouse models of neurological disease we will monitor specific synaptic proteomes over the time course of disease onset and progression. We believe that determining specific synaptic perturbations on the proteome level will provide new insight into neurological disease.

Title: Role of phosphorylation of Neuroligin-2 at inhibitory synapses

Authors: ***N. F. SHANKS**[1,2], M. A. BEMBEN[1], Y. LI[1], K. W. ROCHE[1];
[1]NINDS, [2]Nigms, NIH, Bethesda, MD

Abstract: Integration between excitatory and inhibitory neurotransmission is critical for proper brain function, and disruptions of this balance have been implicated in many neurological disorders including epilepsy, schizophrenia, and autism spectrum disorders. Neuroligins (NLs) are postsynaptic cell adhesion molecules that are ubiquitously expressed in the brain, and are thought to play pivotal roles in synapse assembly, organization and function. The NL isoform, NL-2, is located and specifically functions at inhibitory synapses, whereas other NL isoforms function only at excitatory synapses or can act at both synapse types. Phosphorylation of other NL isoforms has been shown to modulate their function at synapses, and we believe that phosphorylation may be a mechanism involved in their differential roles at inhibitory vs. excitatory synapses. We demonstrate that NL-2 is a substrate for c-AMP dependent kinase

(PKA), and using mass spectrometry determined the exact residue in the intracellular C-tail that is phosphorylated. We have generated a phospho-specific antibody against this site, and demonstrate it's specificity. With this great tool, we are now characterizing NL-2 phosphorylation and regulation. We observe that NL-2 is basally phosphorylated in cultured cortical rat neurons and in rodent brain, and we are characterizing NL-2 phosphorylation over developmental time points, in different brain regions, and in different brain fractions. We have demonstrated that NL-2 phosphorylation is regulated by synaptic activity, and are investigating the precise mechanisms by which this occurs. Finally, by comparing the function of NL-2 phospho mutants, we have observed that this NL-2 phosphorylation site is important for inhibitory synapse function.

Title: Differences in phosphorylation of neuroligins: 4x vs. 4y

Authors: ***T. A. NGUYEN**[1,2], M. A. BEMBEN[1], Y. LI[1], K. W. ROCHE[1];
[1]NINDS, Bethesda, MD; [2]Pharmacol. and Physiol., Georgetown Univ., Washington, DC

Abstract: Autism Spectrum Disorders (ASDs) are a diverse set of cognitive developmental disorders that result in a wide range of behavioral deficits. Interestingly, ASDs have long been reported to affect many more males than females. This sex bias in ASDs has been a puzzle in the field. Neuroligins (NLs) are postsynaptic cell adhesion molecules involved in synapse formation and modulation. There are five NLs (NL-1, NL-2, NL-3, NL-4X, NL-4Y) encoded in the human genome, whereas in rodent there are four (NL-1, NL-2, NL-3, NL-4-like). NL-4X and NL-4Y are of particular interest because they are sex-linked genes located on the X and Y chromosome, respectively. In addition, multiple mutations in both the extracellular domain (ECD) and the intracellular domain (ICD) of NL-4X have been shown to associate with ASDs. Interestingly, NL-4X and NL-4Y are highly conserved with only eight amino acid differences in the ECD and five in the ICD. Although NL-4X has been shown to be phosphorylated by protein kinase C (*Bemben et al., 2015*), there are no studies on phosphorylation of NL-4Y. Here, using an *in vitro* kinase assay, we report that phosphorylation of NL-4Y by PKC is significantly weaker than NL-

4X. Furthermore, using different kinases in conjunction with mass spectrometry, we show that NL-4X and NL-4Y are phosphorylated at different residues. Taken together, our results suggest that NL-4X and NL-4Y are regulated in a fundamentally different manner, and through a better investigation of the sex-linked isoforms of NLs, we hope to further understand the sex bias associated with ASDs.

Title: Functional differences between NLGN4X and NLGN4Y

Authors: R. HODGE[1], *M. B. DALVA[2,1];
[1]Dept. of Neurosci., Thomas Jefferson Univ., Philadelphia, PA; [2]Dept Neurosci, Univ. of Pennsylvania Dept. of Neurosci., Philadelphia, PA

Abstract: Correct assembly and function of neural circuits relies on the proper formation and maturation of a diverse array of synapses. Synapse formation requires contact between pre- and postsynaptic neurons and is thought to be induced by interactions between synaptic cell adhesion molecules. One of the most widely studied pairs of synaptic cell adhesion molecules are the presynaptic neurexins (NRXN) and postsynaptic neuroligins (NLGN). Binding of NRXN to NLGN is crucial for recruitment and clustering of pre- and postsynaptic complexes and synaptic transmission. Nearly all vertebrates encode four NLGNs and, while NLGN1-3 are well characterized, little is known about the localization and function of NLGN4. In most mammals NLGN4 resides on the X chromosome. Interestingly, humans and higher order primates carry a fifth male-specific NLGN located on the Y chromosome. Having approximately 98% sequence homology to NLGN4X, this additional NLGN is often referred to as NLGN4Y. With both X and Y NLGN4 isoforms in humans, males and females naturally express a different composition of NLGN4, the functional implications of which are as yet unexplored. Mutations in NLGN4X and NLGN4Y have been identified in individuals as a cause of several disorders characterized by

synaptic dysfunction such as autism spectrum disorder (ASD). Furthermore, in XYY males there is a correlation between NLGN4Y expression levels and an increased risk for ASD. Despite these observations, a role for NLGN4 at synapses has not yet been established. This largely overlooked area has prompted us to investigate the function of NLGN4 and potential differences in function between NLGN4X and NLGN4Y. Using an established fluorescent-based in vitro affinity assay, we have examined the affinity of NLGN4X and NLGN4Y for NRXN1-β and determined whether binding to NRXN1-β is altered upon coexpression of NLGN4X and NLGN4Y. To monitor the functional impacts of coexpression, we have used a heterologous co-culture assay to determine whether or not potential differences in affinity lead to differences in synaptogenesis between NLGN4X and NLGN4Y when expressed individually or together. Additionally, it is unclear whether NLGN4 is located at excitatory synapses, inhibitory synapses, or both. Towards this end, have examined the impact of exogenous expression of human NLGN4X and NLGN4Y in primary rat cortical neurons on excitatory versus inhibitory synaptic organization. Taken together, our studies may shed light on a potential role for NLGN4 at synapses and could uncover functional differences between NLGN4X and NLGN4Y.

Title: Regulation of synaptic glutamate receptor distribution in mutant huntingtin expressing neurons

Authors: W. AMBROZIAK, *J. M. MONTGOMERY;
Univ. of Auckland, Auckland, New Zealand

Abstract: Huntington's disease (HD) is a neurodegenerative genetic disorder caused by expansion of a CAG repeat tract in the *HTT* gene. Although striatal degeneration that causes late-onset movement impairment is the most pronounced, psychiatric and cognitive symptoms appear earlier in HD progression and have been proposed to originate from the prefrontal cortex and hippocampus. N-methyl-D-aspartate receptors (NMDARs) are glutamate receptors underlying excitatory synaptic transmission and plasticity. Electrophysiological studies on transgenic HD mouse models suggest that extrasynaptic NMDARs drive neurodegeneration by triggering cell

death-associated signalling pathways via pCREB shutoff. Activity of synaptic NMDARs increases pCREB levels and promotes neuronal survival. To study the role of extrasynaptic NMDARs in HD hippocampal pathogenesis, we transfected hippocampal cultured neurons with normal (25 CAG repeats) or mutant Huntingtin protein (mHTT; 97 CAG repeats). To visualise synaptic vs extrasynaptic NMDARs, we applied dSTORM imaging and demonstrated that in hippocampal neurons expressing mHTT the NMDAR localisation is significantly shifted towards the extrasynaptic sites. To determine whether the receptor shift to extrasynaptic sites can be rescued, we focussed on Synapse-Associated Protein-97 (SAP97), a major synaptic protein responsible for distribution of glutamate receptors. Alternative splicing of SAP97 gives rise to two N-terminal isoforms, alphaSAP97 and betaSAP97, the former acting as a scaffolding protein in the synapse and the latter participating in receptor segregation and trafficking. Our data show that overexpression of either SAP97 isoform alters NMDAR distribution in mHTT neurons. However, while alphaSAP97 reinstates the normal synaptic receptor distribution, betaSAP97 upregulates the synaptic NMDARs beyond the level of the controls. This effect is only seen in mHTT-expressing cells and not in controls. Moreover, alphaSAP97 is down-regulated in the hippocampus and striatum of YAC128 mouse HD model. Our data suggest that a change in balance between SAP97 isoform expression levels is a part of the HD pathogenesis, and that restoring the isoform balance has the potential to return the balance of synaptic and extrasynaptic receptors

Title: Altered neuromuscular structure and function in sedentary adult mice

Authors: ***S. BARBAT**, R. ROBITAILLE;
Univ. De Montréal, Montreal, QC, Canada

Abstract: Sedentarity has been associated with muscle weakness and atrophy. Here, we investigated the alterations at the neuromuscular junction (NMJ), the synapse conveying the motor command from the brain to the muscle. We compared soleus muscles of sedentary adult mice (12 months) to age-matched active mice. NMJ structure was assessed by immunolabeling of pre-, post and glial elements while synaptic properties were studied using electrophysiological recordings. As expected, the body weight was larger in sedentary mice (51.6±1.0 vs. 44.8±1.0 g,

p=0.001) while soleus muscle mass was lower (19.0±0.4 vs. 21.2±0.4 mg, p=0.001). NMJs of sedentary mice were more fragmented than those of active mice (3.7±0.3 vs. 1.9±0.2 fragments, p=0.023) and their quantal content tended to be higher (3.8±0.3 vs 3.1±0.2, p=0.065). Furthermore, short-term synaptic potentiation following high frequency stimulation (60 Hz, 30 s) was smaller (9±5% vs. 36±4%, p=0.002). We hypothesise that the observed changes in NMJ properties are influenced by glial cells owing to their regulation of NMJ structure and function. Hence, sedentarity is associated with NMJ alterations that can lead to muscle weakness and atrophy.

Title: PDZ domain-containing protein FRMPD2 promotes synaptogenesis and synaptic activity

Authors: ***Y. HUO**;
Biol., Boston Univ., Boston, MA

Abstract: FRMPD2 is a FERM- and PDZ-domain containing protein highly expressed in the brain. In epithelia cells, FRMPD2 has been shown to have a unique polarized basolateral localization pattern, and is involved in the formation of tight junctions. FRMPD2 contains three PDZ domains, a structural feature shared among many synaptic proteins such as PSD-95. However, its role in neurons remains unknown. Our work shows that FRMPD2 is highly expressed during brain development. In cultured neurons, we find that FRMPD2 is enriched at the synaptic domain. Over-expression of FRMPD2 increases synapse density and alters spine morphology, while a down regulation in synapse formation is observed after siRNA-mediated knockdown of FRMPD2. Its role in synaptogenesis is dependent on neuroligin 1. The interaction of FRMPD2 with F-actin recruits actin to the spine as a scaffold facilitating spine growth. In line with its role in synapse formation, expression of FRMPD2 results in an increase in mEPSC amplitude and frequency. This data reveals FRMPD2 as a novel synaptic PDZ molecule that plays a critical role in neural circuit establishment and synaptic transmission.

Title: Neuronal pentraxin receptor induces postsynaptic specialization

Authors: ***S. LEE**[1], M. WEI[2], C. ZHANG[2], T. C. SÜDHOF[1,3];
[1]Mol. and Cellualr physiology, Stanford Univ., Stanford, CA; [2]Peking Univ., Beijing, China;
[3]Howard Hughes Med. Inst., Stanford, CA

Abstract: Neuronal pentraxins (NPs) act as synaptogenic molecules via their interaction with AMPA-type glutamate receptors (GluRs). The neuronal pentraxin receptor (NPR) is a unique NP in that it possesses a transmembrane domain and can be tethered to the synaptic membrane, but how it regulates synaptogenesis is unclear. We observed that membrane-tethered NPR is solely sufficient for the recruitment of both excitatory and inhibitory postsynaptic specialization. It works as a typical synaptic adhesion molecule through binding with its postsynaptic adhesion partners, GluRs in excitatory synapse. NPR binding to GluR1 enhances its channel activity and the blocking AMPAR activity in neurons inhibits NPR-dependent postsynaptic specialization. On the other hand, NPR also induces in inhibitory postsynaptic specialization. Blocking GABA channel activity reduces the NPR-dependent postsynaptic specialization. These results suggest that NPR promotes synaptogenesis through both AMPA and GABA channels in excitatory and inhibitory synapses, respectively.

Title: Synaptic adhesion molecule IgSF11 interacts with PSD-95 and regulates AMPA receptor-mediated synaptic transmission and plasticity

Authors: *S. JANG;
Inst. For Basic Sci. (IBS), Daejeon, Korea, Republic of

Abstract: Synaptic adhesion molecules regulate synapse development and plasticity through mechanisms including trans-synaptic adhesion and recruitment of diverse synaptic proteins. We report here that the immunoglobulin superfamily member 11 (IgSF11), a homophilic adhesion molecule preferentially expressed in the brain, is a novel and dual-binding partner of the postsynaptic scaffolding protein PSD-95 and AMPAR glutamate receptors (AMPARs). IgSF11 requires PSD-95 binding for its excitatory synaptic localization. In addition, IgSF11 stabilizes synaptic AMPARs, as shown by IgSF11 knockdown-induced suppression of AMPAR-mediated synaptic transmission and increased surface mobility of AMPARs, measured by high-throughput, single-molecule tracking. IgSF11 deletion in mice leads to suppression of AMPAR-mediated synaptic transmission in the dentate gyrus and long-term potentiation in the CA1 region of the hippocampus. IgSF11 does not regulate the functional characteristics of AMPARs, including desensitization, deactivation, or recovery. These results suggest that IgSF11 regulates excitatory synaptic transmission and plasticity through its tripartite interactions with PSD-95 and AMPARs.

Abstract: Studies indicate that enriched environmental conditions (EC) can exert protective effects against depression and addiction. Using unbiased transcriptomic analysis in the nucleus accumbens (NAc) of EC rats mRNAs coding for glycogen synthase kinase 3 (GSK3) and the voltage-gated Na^+ channel Nav1.6 were identified as part of a protective genetic program against depression and addiction. With a combination of *in vivo* Adeno-Associated Virus (AAV) vector gene silencing and acute brain slice patch-clamp electrophysiology in the nucleus accumbens we found that silencing of either GSK3 or Nav1.6 with selective AAV short hairpins leads to a reduction in maximum firing frequency and persistent Na^+ currents in medium spiny neurons (MSN). On the other hand, MSN in GSK3 knock-in mice expressing GSK3 isoforms resistant to inhibitory PI3K/AKT phosphorylation exhibited an opposite phenotype with increased firing and augmented persistent Na^+ currents. To provide an *in vitro* mechanistic model, we characterized the effect of GSK3 inhibition on Nav1.6-encoded currents demonstrating that suppression of the kinase activity decreases Nav1.6 currents. Using *in vitro* phosphorylation and mass-spectrometry we identified a GSK3 phosphorylation site on Nav1.6 and designed a 15-mer peptide flanking this site along with alanine mutants to selectively reverse hyper-excitability of MSN in GSK3 knock-in mice. Altogether, these results provide a novel molecular model of how changes in GSK3 signaling might result into functional neurocorrelates associated with depression and addiction leading to potential new therapeutics targeting posttranslational modifications within the GSK3 intracellular cascade.

Title: Excitation-alternative splice coupling (E-AS coupling) supports homeostatic regulation of neuronal excitability

Authors: *B. LI, B. SUUTARI, R. W. TSIEN;
Neurosci. Institute, Tsien Lab., New York Univ. Med. Ctr., New York, NY

Abstract: In contrast to the positive feedback in Hebbian plasticity, homeostatic plasticity maintains the information transfer capacity of brain circuit by negative feedback regulation. We have clarified the signaling mechanisms by which reduced neuronal activity leads to the changes in alternative splicing and thereby contributes to homeostatic regulation of neuronal excitability. Chronic inactivity (48 hr TTX) prolongs action potential (AP) duration, in large part via alternative splicing of BK channels. Inclusion of exon 29 (E29) in BK channel dropped to ~50%, while total BK mRNA remained unchanged; in turn, BK channels lacking E29 exhibited lower channel activity and led to wider APs than BK channels including E29. Moreover, overexpression of E29-included BK channel completely blocked TTX-induced AP prolongation, confirming that TTX-induced E29 skipping contributes to homeostatic regulation of excitability. Alternative splicing of E29 was regulated by Nova-2, which directly binds to the intron downstream of E29. Overexpression of Nova-2 drove E29 inclusion in E29 minigene-transfected N2A cells; knockdown of Nova-2 strongly reduced E29 inclusion in cortical neurons, which could be reversed by shRNA-resistant Nova-2. These data suggest that Nova-2 is both sufficient and necessary for E29 inclusion. Chronic inactivity triggered nuclear export of Nova-2 in a Ca_V1-CaMKK-CaMKIV-dependent manner: TTX-induced Nova-2 translocation and regulation of E29 splicing was prevented upon blocking Ca_V1 channels by nimodipine, CaMKs by KN-93, CaMKK by STO-609 or upon buffering of nuclear CaM by CaMBP4(nu). Indeed, 48 hr TTX induced activation of cytosolic CaMKII and nuclear CaMKIV, which directly binds to and phosphorylates Nova-2; phosphomimetic mutations led to Nova-2 translocation. These events appear to be linked by TTX-induced translocation of CaMKK2, and apparently CaM shuttling to the nucleus. Knockdown of CaMKK2 expression blocked TTX-induced E29 splicing. We confirmed the involvement of Nova-2 and BK channel splicing in an *in vivo* model of homeostasis, mice undergoing monocular deprivation. 5 d monocular deprivation led to Nova-2 displacement from the nucleus and decreased E29 splicing in the visual cortex contralateral to the deprived eye, consistent with findings in cultured neurons. Thus, E-AS coupling contributes to homeostatic regulation of neuronal excitability *in vivo* as well as *in vitro*.

Title: Neurons in rat retrosplenial cortex are intrinsically heterogeneous in firing type and morphology

Authors: *A. N. NYE[1], J. A. TUMA[2], J. R. MOYER, Jr.[2];
[2]Psychology, [1]Univ. of Wisconsin Milwaukee, Milwaukee, WI

Abstract: Retrosplenial cortex plays a vital role in the learning and memory of temporal, spatial, and contextual information. Additionally, recent data suggest that retrosplenial cortex is also involved in multiple aspects of trace fear conditioning, including memory for the CS, the context, and extinction learning. Unfortunately, few studies have investigated the intrinsic electrophysiological properties of retrosplenial cortical neurons. In the current study, coronal brain slices were prepared from experimentally naïve adult F344 rats. An upright microscope equipped with infrared DIC optics was used for visualizing the neuron and patch electrode, and whole-cell recordings were made from neurons located throughout different layers of granular retrosplenial cortex, also known as Brodman's area 29. Electrodes included biocytin in order to confirm laminar location of neurons, and obtain detailed morphological analyses. Data from 76 neurons revealed several distinct firing patterns, which included afterdepolarizing (ADP) regular spiking, double spiking, late spiking, and fast spiking. ADP-regular spiking neurons fired single action potentials with a pronounced afterdepolarization in response to a just-suprathreshold current injection. In contrast, double spiking neurons fired a doublet. In response to a just-suprathreshold current injection, late spiking neurons uniquely delayed their firing until near the end of the 1-sec current injection (mean spike latency ~807 ms), as compared to neurons from all other firing types (mean spike latency ~403 ms). Further experiments utilizing CNQX (AMPA receptor antagonist) and D-AP5 (NMDA receptor antagonist) revealed that the distinct firing patterns are intrinsic to the neurons and not due to glutamatergic synaptic input. Initial analyses has revealed morphological differences between late spiking neurons and both ADP-regular spiking and double spiking neurons. Ongoing experiments are investigating the specific ion channels contributing to neuronal firing patterns. These studies will contribute important physiological and morphological data and lay the foundation for understanding how retrosplenial cortex contributes to learning and memory as well as aging-related learning deficits. **Funding: NIA grant**

Title: Essential oil of Ocimum basilicum L and (-)linalool blocks the excitability of rat sciatic nerve

Authors: *F. W. FERREIRA[1], A. M. VENANCIO[2], K. S. SILVA-ALVES[1], H. C. PIMENTEL[2], M. M. LIMA[2], M. F. D. SANTANA[2], P. B. ALVES[2], G. B. D. SILVA[2], J. H. LEAL-CARDOSO[1], M. MARCHIORO[2];
[1]State Univ. of Ceará, Fortaleza, Brazil; [2]Federal Univ. of Sergipe, Aracaju, Brazil

Abstract: The racemate linalool and its levogyrus enantiomer, [(-)LIN] are present in many essential oils and possess several pharmacological activities, such as antinociceptive and anti-inflammatory. In this work it was studied the effects of essential oil obtained from the cultivation of the *Ocimum basilicum* (EOOb) derived from Germplasm Bank rich in (-)LIN content in the excitability of peripheral nervous system. We used rat sciatic nerve to investigate the EOOb and (-)LIN effects on neuron excitability and it was used the extracellular recording technique to register the compound action potential (CAP). EOOb and (-)LIN blocked the CAP in a concentration-dependent way and these effects were reversible after washout. EOOb blocked positive amplitude of 1st and 2nd CAP components with IC_{50} of 0.38 ± 0.2 and 0.17 ± 0.02 mg/mL, respectively. For (-)LIN, these values were 0.23 ± 0.07 and 0.13 ± 0.02 mg/mL. Both components reduced the conduction velocity of CAP and the 2nd component seems to be more affected than 1st component. In conclusion EOOb and (-)LIN inhibited the excitability of peripheral nervous system in a similar way and potency, revealing that the effects of EOOb on excitability is due to the presence of (-)LIN on the essential oil.

Title: Reduced labeling of Perineuronal Nets and decreased Parvalbumin Neurons in the Peritumoral Cortex of a Glioma mouse model

Authors: *B. P. TEWARI[1], S. L. CAMPBELL[2], H. SONTHEIMER[3];
[1]Glial Biol. in Health, Dis. and Cancer Ctr., [2]Ctr. for Glial Biol. in Health, Disease, and Cancer, Virginia Tech. Carilion Res. Inst., Roanoke, VA; [3]Ctr. for Glial Biol. in Health, Disease, and Cancer, Virginia Tech. Carilion Res. Inst., Ronaoke, VA

Abstract: Glioma associated epileptic seizures have been attributed to the imbalance of excitatory and inhibitory neurotransmission. Peritumoral niche in the cerebral cortex exhibits unique physiological properties including decreased parvalbumin expressing interneurons and lower expression of KCC2 leading to abnormally high intracellular chloride thereby rendering GABA responses excitatory. Perineuronal nets (PNNs) are specialized extracellular matrix structures surrounding parvalbumin expressing interneurons and shown to protect neurons from oxidative stress and also possess ion sorting properties. Gliomas secrete matrix metalloproteinase which degrade extracellular matrix of brain parenchyma thereby facilitating glioma spread and invasion. Using a clinically relevant mouse model of glioma, we studied the changes in PNNs and the physiology of parvalbumin expressing interneurons that are associated with PNNs in peritumoral cortex. Immunohistochemical staining of PNNs by Wisteria floribunda agglutinin (WFA), revealed a progressive degradation of PNNs in the peritumoral region. Moreover, parvalbumin expressing interneurons also exhibited progressive decrease in numbers. Electrophysiological recordings of the remaining parvalbumin interneurons that are associated with PNNs exhibited significantly lower action potential firing rates compared to that of contralateral hemisphere. Neurons which were not associated with PNNs in the same peritumoral area, showed higher firing rates compared to that of contralateral hemisphere. Overall our results suggest that the alteration of peritumoral PNNs and the firing properties of their associated parvalbumin expressing interneurons is a potential mechanism that could contribute to decreasing inhibitory neurotransmission in peritumoral hyperexcitability.

Title: Cholinergic-dependent intrinsic homeostatic plasticity in a subset of CA3 neurons

Authors: *C. J. PUHL, W. WEFELMEYER, J. BURRONE;
Ctr. for Developmental Neurobio., King's Col. London, London, United Kingdom

Abstract: Neurons respond to long-lasting perturbations of activity by adjusting their properties to stabilise their firing. In the hippocampus modulatory signals induce oscillations that drastically alter the ongoing activity in the network.
Here, we studied how increases in network activity induced by activation of cholinergic pathways modulate the intrinsic firing properties of hippocampal neurons.
Acute treatment of rat organotypic hippocampal slices with carbachol (CCh), an acetylcholine receptor agonist, led to long-lasting gamma oscillatory behaviour observed in population spike recordings of CA3 pyramidal neurons. After long-term (48hrs) treatment with CCh, whole-cell patch-clamp recordings revealed two different populations with strikingly different response properties. Whereas most (70%) of CA3 cells showed no changes in intrinsic excitability, a subset of cells (30%) showed a dramatic reduction in excitability, characterised by only firing single action potentials in response to 500ms current injections and a large decrease in their input-output curve. We also observed a decrease in input resistance (175.51±16.91 MΩ in control to 122.65±9.83 MΩ in single spiking; p=0.0164)., as well as an increase in current density threshold (from 1.63±0.27 pA/pF to 3.88±0.45 pA/pF in single-spiking neurons; p=0.0003) . Pharmacological blockade of the Kv7/M-current normalised their input resistance and allowed these neurons to fire repetitively, in a manner similar to control cells. We are currently characterising the dendritic morphology of this subset of cells and testing the idea that long-term plasticity of Kv7 channels may be responsible for this form of hyperadaptation in CA3 neurons.

Title: Transcriptomic correlates of brain-wide electrophysiological diversity

Authors: *S. TRIPATHY, D. TEBAYKIN, B. LI, O. MANCARCI, L. TOKER, P. PAVLIDIS; Ctr. for High-throughput Biol., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Despite thousands of studies characterizing electrophysiological diversity of cell types throughout the brain, the relationship between neuronal biophysics and gene expression remains poorly understood. Here, by combining databases on neuron type specific transcriptomics and electrophysiology (neuroexpresso.org and neuroelectro.org), we present a proof-of-concept approach for relating brain-wide electrophysiological diversity to gene expression. Specifically, we identified 865 genes whose expression levels were significantly correlated with neuronal phenotypic diversity (FDR < 0.1); for example, Hcn3, Gabrd, and Mef2a correlated with resting potential, and Nkain1, Calb2, and Kcnab1 correlated with input resistance. Moreover, the majority of these gene-electrophysiology correlations (76%) replicated using an independent Allen Institute dataset on single cell RNAseq and electrophysiology (celltypes.brain-map.org). In ongoing work, we are validating whether these gene-electrophysiology correlations reflect true causal relationships, in part, by assessing the consistency of these correlations using previous literature on gene knockout models and ion channel specific pharmacology.

Title: Long-term modulation of excitability by NMDA receptor signaling in cerebellar stellate cells

Authors: *R. ALEXANDER, D. BOWIE;
McGill Univ., Montreal, QC, Canada

Abstract: The action potential (AP) is a fundamental signaling unit used by neurons to communicate across distance. The AP is generated by a complex interplay of several voltage-gated ion channel families, including Na+ and K+ channels, which determine the threshold and frequency of firing rates. We have observed a long-term increase in cerebellar stellate cell excitability by signaling of NMDA receptors that modulates both Na+ and K+ channel activity. Local application of NMDA induced a persistent increase in spontaneous action current frequency during cell-attached electrophysiological recordings. During whole-cell current clamp recordings stellate cells exhibited a time-dependent increase in evoked AP frequency and hyperpolarization of spike threshold, both of which were eliminated by pharmacological block of CaMKII. Voltage clamp experiments revealed that CaMKII inhibition eliminates the development of a putative TTX-resistant Na+ current as well as an outward K+ current. Our work provides insight into the role of NMDAR-dependent signaling in regulating inhibitory neuronal circuits of the cerebellum.

Title: Cannabinoid receptor 2 induced modulation of spatio-temporal firing dynamics in dopamine neurons of the ventral tegmental area

Authors: *H. J. STRATTON[1], J. WU[2];
[2]Neurol. Res., [1]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: The Ventral Tegmental Area is an important midbrain nucleus containing dopamine (DA) neurons that project to and receive projections from a variety of cortical and sub-cortical targets implicated in mediating a range of complex behavioral responses. Recently, cannabinoid receptor 2 has been isolated in neural tissue and functionally identified within the VTA, where it influences DA neuron firing activity. The CB2 receptor is a G-Protein coupled receptor bound to

internal Gi/o elements that can alter cellular excitability through modifications in potassium conductance and changes to intracellular calcium permeability and release. The endogenous ligands for CB2 act in a retrograde fashion upon presynaptic terminals that synapse on either GABAergic or DA neurons of the VTA. This retrograde signaling behaves primarily as a localized inhibitory mediator of cellular excitability through presynaptic attenuation in an input dependent fashion. The distribution of CB2 proteins within the VTA is currently not well known, but it is thought that these receptors are not homogeneous across synapses and instead are lightly spread across very specific subregions corresponding to particular neuronal microcircuits. In this study, we examined extracellular potentials recorded from the VTA using planar microelectrode arrays in acute slices prepared from C57BL/6J mice and corresponding CB2 knockout mice. The potentials recorded at a total of 64 sites spread across the entirety of the VTA were analyzed for local field potential content as well as single-unit spiking activity. Signal processing was performed offline and a differential threshold method was applied to identify spike events followed by a clustering algorithm, which analyzed waveform structure using principal components. This method allows for the identification of spike source neurons with high levels of certainty in order to characterize particular neuronal phenotypes across channels and across slices. Changes in the local field potential oscillation and spiking activity were observed between C57 and KO animals with perfusion of 1 micro molar carbachol to elicit higher baseline firing rates. In addition, JWH-133 and AM-630, CB2 receptor specific agonist and antagonist respectively, were applied to the bath in order to characterize effects of CB2 receptor activation on the spatial activity pattern recorded across the 8x8 grid of electrodes in the planar array. As expected, variations in power spectra and bursting characteristics were observed across medial as compared to lateral regions of the VTA indicating distinct populations of neurons that respond in a unique manner to CB2 modulation.

Title: Kv7/M-current function in axons: high-pass filtering of plateau potentials promotes full action potentials, also during cholinergic activation

Authors: *J. F. STORM, R. MURPHY, P. MATEOS-APARICIO;
Univ. of Oslo, Oslo, Norway

Abstract: Axons are equipped with Kv7/KCNQ/M potassium channels whose main function remains unknown. Here we propose that they perform high-pass filtering of depolarizing plateau potentials originating in dendrites and soma, to prevent inactivation of axonal Na^+ channels, thus promoting efficient axonal generation and propagation of full amplitude spikes throughout plateau depolarizations.Using patch clamp recordings from distal mossy fiber boutons (MFBs) in rat hippocampal slices, and the Kv7/M channel blocker XE991, we have confirmed (Alle..Storm, SfN Abst 42.2, 2009) that these axon terminals have a large Kv7/M-current (I_M) that causes local resonant filtering of subthreshold signals in the theta frequency range, affects summation of subthreshold synaptic potentials ("EPreSPS"; Alle & Geiger, Science 2006) and generates a "medium after-hyperpolarization" (mAHP), but contributes almost nothing to spike repolarization. Computational modelling reproduced these results and showed that the axonal I_M can also perform resonant filtering of subthreshold signals during propagation from soma to terminals; but this is weak except when the axon is depolarized. Long-lasting somatic plateau depolarizations activated the axonal I_M, which then strongly attenuated the depolarizations, preventing it from spreading along the axon, promoting axonal spikes during the plateau, by preventing Na^+ channel inactivation. (Apostolides et al., Neuron 2016, found that axonal K^+ channels can do this.) Our model showed that the voltage-dependence and slow kinetics of I_M makes it ideally suited for such high-pass filtering.
Acetyl choline (ACh) can suppress I_M and is essential for cortex and forebrain activation during conscious wakefulness and REM sleep. ACh promotes somato-dendritic depolarizing plateaus by suppressing K^+ currents, including I_M, and enhancing inward currents. But if I_M is suppressed also in the axon, it cannot perform its high-pass filtering function during cholinergic plateaus. Hence, we hypothesize that the distal axonal IM is resistant to cholinergic modulation. Indeed, our patch clamp recordings from distal MFBs showed that the axonal I_M was resistant to both muscarine (n=4) and oxotremorine (n=4) that block the somatic I_M.
We conclude that the axonal Kv7/M-current (I_M) perform filtering of depolarizing plateau potentials originating in dendrites and soma, thus promoting efficient axonal spike generation and propagation throughout the depolarizations, and that this function is maintained during cholinergic activation, thus presumably during conscious wakefulness. We propose that this is the main function of the axonal Kv7/M-current.

Title: The role of $Ca_v3.2$ Ca^{2+} channels in influencing Layer II Medial Entorhinal Cortex stellate cell activity along the dorsal-ventral gradient.

Authors: *A. P. TOPCZEWSKA[1], A. C. DOLPHIN[2], M. M. SHAH[1];
[1]Sch. of Pharm., [2]Neurosci. Physiol. and Pharmacol., UCL, London, United Kingdom

Abstract: Layer II (LII) Medial Entorhinal Cortex (MEC) stellate cell (SC) intrinsic membrane properties vary along the MEC dorso-ventral axis. This has been attributed partly to altered HCN and K^+ conductances[1,2]. The subthreshold active T-type $Ca_V3.2$ Ca^{2+} channels, though, are also expressed in the MEC[3]. $Ca_V3.2$ channels are known to influence neuronal excitability but their effects on the dorsal and ventral LII MEC SC properties remain unknown. To investigate this, we obtained acute entorhinal-hippocampal parasagital slices from $Ca_V3.2$ wildtype ($Ca_V3.2^{+/+}$) and null ($Ca_V3.2^{-/-}$) 5-8 week old mice and made electrophysiological recordings from dorsal and ventral LII MEC SC. $Ca_V3.2^{-/-}$ ventral neurons displayed significantly reduced input resistance but had little difference in resting membrane potential compared with $Ca_V3.2^{+/+}$ ventral neurons. Consequently, depolarizing steps generated fewer action potentials in $Ca_V3.2^{-/-}$ ventral SC than in their wildtype littermates. In contrast, dorsal $Ca_V3.2^{-/-}$ and $Ca_V3.2^{+/+}$ SC properties were similar. The Ca_v3 inhibitors, $NiCl_2$ (50 μM) and TTA-P2 (100 nM), also significantly reduced input resistance and excitability in $Ca_V3.2^{+/+}$ ventral neurons, whilst having little effect on $Ca_V3.2^{+/+}$ dorsal or $Ca_V3.2^{-/-}$ neurons. Our results suggest that $Ca_v3.2$ channels selectively affect the LII MEC ventral SC characteristics, thereby contributing to the intrinsic membrane gradient across the MEC dorsal-ventral axis.

Abstract: Spontaneous spiking activity plays critical roles in the function of many neurons and neuronal networks. The activities of several ion channels provide sub-threshold currents and drive repetitive spiking. *Helisoma trivolvis* buccal ganglia B5 neurons are tonically spiking neurons in situ and in single cell culture. Here we demonstrated that the tonic spiking activity of these neurons requires two major ionic currents, namely a persistent Na current (I_{Nap}) and a hyperpolarization-activated current (I_h).Both, I_{Nap} and I_h, and thus the spontaneously spiking activity of B5 neurons, were found to be under the control of calcium release from ryanodine receptors (RyR-CR), because the inhibition of RyR-CR significantly reduced I_{Nap} and I_h and silenced these neurons. Evoked spiking activity was affected by the reduction of I_{Nap} and I_h in response to inhibition of RyR-CR as well. Our experimental data showed that the inhibition of I_h, I_{Nap}, and RyR-CR narrowed action potential (AP) width. The mechanism of how the inhibition of I_{Nap} and I_h resulted in a decrease in AP's width was provided by mathematical modeling of spontaneous spiking activity. This model implicates an increase in interspike interval that inactivates Ca currents contributing to the width of APs. Taken together, our findings highlight the importance of RyR-CR in setting neuronal spiking activity via upregulation of the inward currents, I_{Nap} and I_h and, in turn, the regulation of the intracellular calcium concentration via modulation of AP width.

Title: Role of slow temporal dynamics in reliability of stochastically driven neurons

Authors: *S. S. MOKASHE, S. NADKARNI;
Dept. of Biol., Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: Mutually inhibiting neurons is a common motif across many systems like Hippocampus, CPGs(Central Pattern Generators) and Olfaction. Their synaptic interaction ensures that they show alternating activity. The frequency of switching from an active to a quiescent period is a function of the biophysical properties of ion channels present in the neurons, synaptic interaction timescales, network properties, the stimulus and possibly channel fluctuations from small number of channels. Switching allows neurons to associate with different networks and coordinate patterns of activity that may be relevant for function. The frequency of switching dictates the sequential order of activity of neurons required for locomotion, for example in Lamprey. In this context, reliable switching might be a critical functional requirement. How do networks of mutually inhibiting neurons, a simple most functional module of switching, achieve this reliability despite a noisy framework and environment? We have developed a conductance based model of two mutually inhibiting neurons wherein inherent switching takes place via a potassium current, sAHP that is triggered by calcium ions. We investigate the role of slow buildup time scales associated with sAHP current in integrating calcium signal generated by stochastic opening of mediated by Voltage Dependent Calcium Channels(VGCCs). Furthermore we systematically study the effect of various sources of noise including channel conductance noise, synaptic noise and input noise on switching and robust generation of sequences.Our results show that switching frequency can be tuned with noise amplitude. Separately, there exists an optimal regime of noise where coefficient of variance of the inter-burst interval (IBI) is lowest, indicating precise switching. Our understanding on the effects of various sources of noise in this illustrative network motif is likely to be applicable to a wide variety of systems.

Ctr., Oklahoma City, OK; [8]Nuclear Magnetic Resonance Core Facility, [9]Aging & Metabolism Res. Program, Oklahoma Med. Res. Fndn., Oklahoma City, OK

Abstract: Purpose: ELOngation of Very Long chain fatty acids-4 (ELOVL4) is an elongase responsible for biosynthesis of very long chain (VLC; ≥C28) fatty acids; it makes VLC polyunsaturated fatty acids (VLC-PUFA) in retina and testes, and VLC saturated fatty acids (VLC-SFA) in skin and brain. A 2011 case study linked homozygous inheritance of the Stargardt's (STGD3) mutation in ELOVL4 with a central nervous system (CNS) phenotype in humans, including seizures, intellectual disability, spastic quadriplegia and death. We hypothesize that ELOVL4-synthesized VLC-SFA play an essential role in neural cell structure and function. **Methods:** We generated a successful animal model for STGD3/STGD3 inheritance (-/-). ELOVL4 localization within the CNS was determined in wild type mice (+/+) using immunofluorescence (IF) microscopy. Hippocampal lipids were analyzed by triple quadrupole mass spectrometry. Synaptic membrane fractionation was performed on baboon hippocampus for lipid analysis. Positron emission tomography (PET) was used to assess CNS uptake of fluorodeoxyglucose (FDG) in (-/-) mice. HPLC was used to assess intermediary metabolism in (-/-) mice. Hippocampal slices from (+/+) and (-/-) mice were subjected to spontaneous multi-

electrode array (MEA) recordings. Primary neuronal cultures from hippocampus of (+/+) and (-/-) mice were subjected to FM1-43 assessment of synaptic vesicle exocytosis rates. **Results:** Our STGD3/STGD3 mice recapitulate the human phenotype, developing seizures at P19 followed by death at P21. IF showed highest immunoreactivity in hippocampus. Hippocampal lipidomic analysis of (+/+) mice confirmed the presence of 28:0/30:0 in sphingolipids. Membrane fractionation of baboon hippocampus revealed enrichment of 28:0/30:0, but not VLC-PUFA, in synaptic vesicle membranes. PET imaging revealed a 3-fold increase in the amount of FDG uptake into the CNS of (-/-) mice. Metabolomic analysis revealed a significant increase in brain ATP levels in (-/-) mice. MEA recordings showed a significant increase in the amplitude and decrease in the inter-spike interval of action potentials in (-/-) vs (+/+) hippocampal slices. FM1-43 studies showed a significant increase in synaptic vesicle exocytosis rates in (-/-) vs (+/+) primary hippocampal neurons. **Conclusions:** This is the first study to demonstrate mutations in *Elovl4* causing a CNS phenotype in an animal model. The described studies suggest a neuron-specific role for VLC-SFA in the regulation of pre-synaptic synaptic function by impacting the rate of synaptic vesicle release.

Abstract: Dopamine (DA) neurons play a central role in guiding motivated behaviors. However, complete understanding of computations these neurons perform to encode rewarding and salient stimuli is still forthcoming. Intrinsic properties of the neurons determine the neuron's response to stimuli, its synchronization properties and the computations it performs in the brain. We investigated the dynamical mechanisms underlying the excitability type of DA neurons and its regulation by synaptic currents using a biophysical model. We concentrated primarily on the influence of GABA input, considering that a substantial proportion of the synaptic drive to DA neurons comes from GABA neurons. Particularly, we considered the DA neuron excitability type, its dependence on the tonic coactivation of GABA with NMDA or AMPA receptors, and the effect of temporal organization of GABA inputs on the dynamics of DA neuron firing. DA neurons can switch from type I excitability to type II depending on the conductance composition. During balanced activation of GABAR and NMDAR, DA neurons exhibit low frequency tonic firing and type I excitability, whereas activation of AMPAR or elevation of GABAR reversal potential switches it to type II. Type I excitability might be important for achieving low basal DA concentration necessary for normal brain functioning and is perfect for calculation of reward prediction error, as type I neurons are best suited for coding stimulus intensity. Switching to type II excitability, however, enables robust transient DA release, partially due to evoked DA population synchrony in response to correlated inputs. Our investigations have revealed that the firing pattern of the DA neuron depends on the level of synchronization among GABA neurons. Synchronous GABA input enables an increase in DA neuron firing and bursting. Distinct from previous mechanisms, the increases were not based on lowered GABA firing rate or weaker hyperpolarization by the GABAR current. A mechanism of GABA-mediated increases in firing is based on a dynamical reduction the Ca^{2+} -dependent K^{+} currents. The biological relevance of predictions made by our model was validated by calculating cross-correlograms between pairs of simultaneously recorded putative VTA GABA neurons. We observed a large number of pairs (76 out of 197) that exhibit millisecond timescale synchrony, which is, according to our modeling results, more than necessary to achieve an increase in DA burstiness. Our results provide mechanistic understanding of the diverse mechanisms whereby GABA inputs regulate DA neuron burst firing.

Title: Bi-stable states allow neurons to generate highly irregular spike trains with weakly fluctuated inputs.

Authors: *R. HOSAKA;
Fukuoka Univ., Fukuoka, Japan

Abstract: The irregular firing of a cortical neuron is thought to result from a highly fluctuating drive that is generated by the balance of excitatory and inhibitory synaptic inputs. A previous study reported strange responses of the Hodgkin-Huxley neuron to the fluctuated inputs where an irregularity of spike trains is inversely proportional to an input irregularity. In the current study, we investigated the origin of these strange responses with the Hindmarsh-Rose neuron model, map-based models, and a simple mixture of interspike interval distributions. First, we specified the parameter regions for the bifurcations in the Hindmarsh-Rose model and confirmed that the model reproduced the strange responses in the dynamics of the saddle-node and subcritical Hopf bifurcations. For both bifurcations, the Hindmarsh-Rose model shows bistability in the resting state and repetitive firing state, which indicated that the bistability was the origin of the strange input-output relationship. Similarly, the map-based model that contained bistability reproduced the strange responses, while the model without bistability did not. These results were supported by additional findings that the strange responses were reproduced by mimicking the bistable firing with a mixture of two different interspike interval distributions. Decorrelation of spike trains is important for neural information processing. For such spike train decorrelation, irregular firing is key. Our results indicated that irregular firing can emerge from fluctuating drives, even weak ones, under conditions involving bistability. The strange responses therefore contribute to efficient processing in the brain.

Title: STIM1 and neuronal excitability important for cerebellum-dependent learning

Authors: C. RYU, D. JANG, D. JUNG, *S. KIM;
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: The dynamics of Ca^{2+} between the cytosol and intracellular stores has been considered as an important process for cellular mechanisms of learning and memory. Stromal interaction molecule 1 (STIM1) plays a pivotal role in maintaining Ca^{2+} store. However, its function in these mechanisms, including synaptic plasticity and neuronal excitability, remains obscure. Here, by using cerebellar Purkinje neuron-specific STIM1 knockout ($STIM1^{PKO}$) mice, we identify that STIM1-mediated Ca^{2+} dynamics contributes to the excitability of Purkinje neurons and cerebellum-dependent memory. Firing activity of STIM1-deleted Purkinje neurons is reduced with strengthened spike frequency adaptation, while their long-term synaptic plasticity is not affected. In cerebellum-dependent motor learning, $STIM1^{PKO}$ mice show impaired memory consolidation without defects in memory acquisition. Our findings suggest that the neuronal excitability regulated by STIM1 enables Purkinje neurons to transfer neuronal information properly for persistent memory.

Title: Serotonergic modulation of fast-spiking interneurons in medial prefrontal cortex

Authors: *J. ATHILINGAM, K. BENDER, V. SOHAL;
Neurosci., Univ. of California San Francisco, San Francisco, CA

Abstract: The prefrontal cortex is a highly evolved brain region that is responsible for directing higher order cognitive functions ranging from decision making to social cognition. Patients with schizophrenia exhibit marked deficits in prefrontal-dependent tasks such as working memory and rule shifting and also have alterations in a specific subtype of inhibitory interneuron in this region. Indeed, restoring the function of these fast-spiking interneurons (FSIs) can rescue behavioral deficits in mice that model aspects of this disease (Cho et al., 2015).
Most second-generation antipsychotic drugs target the neuromodulator serotonin (5HT) with high affinity. However, the effect of 5HT on fast-spiking interneurons in prefrontal cortex and how this might influence cortical information processing at the cellular and network levels and/or affect cognition is unknown.
Here, we use patch-clamp electrophysiology and optogenetics to demonstrate that 5HT acts on 5HT2A receptors to increase the intrinsic excitability and responses to input in FSIs by closing leak potassium channels. Further, we explore how serotonergic modulation of FSIs can influence synaptic integration and network oscillations. These findings can broadly inform our understanding of the role of neuromodulation in prefrontal function, and may provide insight into the etiology of schizophrenia as well as potential new avenues for rescuing prefrontal dysfunction in this disorder.

Title: Mechanisms regulating persistent spiking in rodent neocortical neurons *In vitro*

Authors: E. D. CUI, *B. W. STROWBRIDGE;
Case Western Reserve Univ., Cleveland, OH

Abstract: While all brain regions respond transiently to synaptic input, some brain circuits also generate long-lasting firing epochs following stimulation. The cellular mechanisms governing the dynamics of these persistent responses are not well understood. We examined this question using whole-cell patch clamp recording in rat temporal association neocortical slices exposed to low (2 μM) carbachol (CCh), a cholinergic receptor agonist previously demonstrated to promote persistent firing in a variety of cortical brain regions. We find evidence for multiple calcium-sensitive mechanisms regulating persistent activity. Chelating intracellular calcium ion with 10 mM 1,2-bis(o-aminophenoxy)ethane-N,N,N',N'-tetraacetic acid (BAPTA) abolished persistent firing evoked by depolarizing step stimuli in regular spiking layer 5 pyramidal cells (PCs; N=6), likely reflecting a role for a prolonged calcium-sensitive depolarization underlying persistent spiking. However, the frequency of persistent firing was not maximal immediately following depolarizing step stimuli, when intracellular calcium concentration was likely maximal. Instead, the firing rate slowly increased over 22.6 sec (N=7). Increasing extracellular calcium levels from 2.5 to 4 mM decreased persistent firing frequency by 36%, measured 10 sec following offset of triggering depolarizing step (N=5). Both the slow ramp-up in persistent firing frequency and the inhibitory effect of enhanced calcium influx likely reflect critical roles for calcium-activated inhibitory conductances in modulating persistent firing. Consistent with this hypothesis, we found that bath application of the SK channel activator (NS309) decreased the duration of persistent firing following depolarizing step stimuli. With only CCh, 71% of regular spiking layer 5 PCs generated persistent responses that lasted at least 30 sec; the remaining 29% of recordings failed to generate any persistent activity. With SK currents enhanced with NS309, persistent firing spontaneously terminated before 30 sec in most (11/18) recordings. The duration of self-terminating persistent firing was graded with the degree of SK activation (2250 ms with 1 μM, N=5; 10700 ms with 0.5 μM NS309, N=6). These results suggest that the duration of persistent spiking responses can be modulating by calcium-activated potassium currents. Using this mechanism, individual neurons could regulate their calcium-sensitive responses to reliably encode different types of information over diverse timescales.

Title: Direct leptin action on hippocampal neuron excitability and behavioral responses

Authors: J. G. WANG[1], M. GUO[2], *X.-Y. LU[1];
[1]Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX; [2]Binzhou Med. Univ. Hosp. / IMND, Shandong, China

Abstract: We have previously shown that leptin target neurons within the hippocampus are largely restricted to the granule cell layer of the dentate gyrus (DG) and constitute a small percentage of DG granule cells that represent a subpopulation devoid of stress-induced activation (*Wang et al., 2015, Mol. Psychiatry 20:509-19*). Despite prior reports demonstrating leptin effects on excitability of hippocampal neurons, evidence is lacking for the direct effect of leptin on its target neurons. To determine whether leptin directly influences excitability of its target neurons expressing the leptin receptor (LepRb), we utilized the $Lepr^{Cre}$:tdTomato reporter mice that allowed us to precisely identify LepRb-expressing neurons. Whole-cell patch-clamp recordings were made from acute hippocampal slices of $Lepr^{Cre}$:tdTomato reporter mice. We found that leptin decreased intrinsic excitability of DG LepRb-expressing granule cells. The rheobase was increased, and the firing rate of action potentials was decreased by leptin. Furthermore, we examined whether selective inhibition of LepRb neurons in the DG affects depressive-like behaviors. AAV-DIO-hM4D(Gi)-mCherry (DREADD) was injected into the DG of Lepr-Cre transgenic mice, in which LepRb neurons specifically expressed hM4Di. We found that inhibition of DG LepRb neurons with DREADD induced antidepressant-like effects without affecting locomotor activity, consistent with the behavioral effects of intra-DG infusion of leptin. These results suggest that leptin induces direct inhibition of DG granule neurons and inhibition of DG leptin target neurons leads to antidepressant-like responses.

Title: Melatonin decreases neuronal excitability in a sub-population of DRG neurons in Wistar rats

Authors: K. OLIVEIRA-ABREU[1], K. S. SILVA-ALVES[1], F. W. FERREIRA-DA-SILVA[1], N. M. SILVA-DOS-SANTOS[1], F. G. D. AMARAL[2], A. C. CARDOSO-TEIXEIRA[1], *A. N. COELHO-DE-SOUZA[3], J. CIPOLLA-NETO[2], J. H. LEAL-CARDOSO[1];
[1]Superior Inst. of Biomed. Sci., State Univ. of Ceará, Fortaleza, Brazil; [2]Biomed. Sci. Inst., Univ. of São Paulo, São Paulo, Brazil; [3]Univ. Estadual Do Ceara, Fortaleza, Brazil

Abstract: Melatonin is a neurohormone mainly produced and secreted at night by the pineal gland. In the central nervous system, it has many effects related to physiological and pathological processes, such as circadian regulation, neuroprotection, antinociception and antioxidant activities. However, physiological effects of melatonin on the peripheral nervous system (PNS) remain poorly understood. Thus, this study investigated the effects of melatonin on excitability of a neuronal subpopulation (N_0 neurons) of intact dorsal root ganglion (DRG) from rats using intracellular recording technique in current clamp mode. Male Wistar rats were kept on a 12:12 h light/dark cycle with food and water available *ad libitum.* All animals used for electrophysiological experiments were sacrificed at Zeitgeber Time (ZT) 3 (lights-on at 06:00 h). Melatonin blocked the generation of action potentials (AP) in a concentration-dependent manner: 1 nM melatonin blocked AP generation in only one of 15 DRG neurons (6.6%). At concentrations of 10, 100 and 1000 nM, this blockade was 21.4% (6/28), 24% (6/25) and 30% (9/30), respectively. In neurons in which melatonin did not block the AP, there was an increase in rheobase. A hyperpolarizing effect of resting potential (E_m) was observed in these neurons. The magnitude of E_m hyperpolarization for melatonin at 10, 100 and 1000 nM was -1.70, -1.73 and -2.61 mV, respectively. Both 10 and 100 nM melatonin increased input resistance (R_{in}) values from 16.98 ± 2.33 to 27.54 ± 3.79 MΩ (10 nM; n = 22) and 14.13 ± 1.50 to 28.18 ± 3.73 MΩ (100 nM; n = 19). Additionally, melatonin significantly increased the peak AP amplitude and the maximal rate of both depolarization and repolarization. To determine the signal transduction pathway for melatonin in DRG neurons, qPCR analyses were performed for the

melatonin receptors MT_1 and MT_2. It was observed that DRG neurons express only MT_1 and that receptor expression peaks at ZT3. In conclusion, melatonin reduces excitability of N_0 DRG neurons in a concentration-dependent manner probably through the MT1 receptor. These type of neurons conveys information about mechanoception but also nociception information. Thus, excitability inhibition promoted by melatonin could act as a relevant mechanism of control of PNS.

Title: Attempts to measure calcium currents in substantia nigra dopaminergic neurons

Authors: *U. COLLIENNE[1,2], A. C. KLEIN[1,2], S. HEß[1,2], S. BREMSER[1,2], P. KLOPPENBURG[1,2];
[1]Biocenter, Inst. For Zoology, Cologne, Germany; [2]Cologne Excellence Cluster on Cell. Stress Responses in Aging-Associated Dis. (CECAD), Univ. of Cologne, Cologne, Germany

Abstract: Midbrain dopaminergic (DA) neurons are categorized in three groups: the retrorubral area, the ventral tegmental area (VTA) and the substantia nigra pars compacta (SNpc). Morphologically, these groups are associated with two systems: the nigrostriatal pathway, which is mainly build by projections of the SNpc neurons and the mesocorticolimbic system, which arises primarily from the VTA neurons. Historically, the nigrostriatal pathway has been associated with the modulation of motor functions, while the mesocorticolimbic system was thought to be involved in motivation, reinforcement and reward-seeking behaviors. However, it becomes increasingly clear that SNpc and VTA neurons have overlapping projections and that

all three DA neuron subpopulation contribute to reward-related behaviors.
DA neurons are autonomous pacemakers. Synaptically isolated, they generate action potentials with a constant, very regular frequency. *In vivo*, this regular firing can be modulated by synaptic input leading to a burst firing pattern and a hyperpolarized, non-firing state. The resulting firing patterns determine the DA release in the projection areas and are correlated with the prediction and detection of rewards.
In SNpc neurons the autonomous pacemaking depends critically on the precise control of intracellular calcium dynamics. The calcium influx that is necessary to mediate pacemaking is thought to be generated by orchestrated activation of several voltage-activated calcium channels with specific functional properties. Especially L-type calcium channels are thought to mediate a substantial part of the calcium influx present during the pacemaker activity, because these channels are known to activate at sub-threshold membrane potentials. However, direct, quantitative and stable measurements of the voltage-activated calcium currents have been challenging due to 1) imperfect voltage control due to the complex morphology of SNpc neurons, 2) the presence of large outward current and 3) a rapid wash-out of the calcium currents. While the mean peak amplitudes typically reached -2.0 +/- 0.2 nA at the beginning of whole-cell patch clamp recordings in acute adult brain slice preparations, these calcium currents ran down within several minutes. Therefore, we aim to improve the recordings by optimizing the extra- and intracellular solution used for whole-cell measurements, and/or by combining several approaches including perforated patch clamp recordings and discontinuous single electrode voltage clamp.

Title: Histone deacetylase inhibitor improved the dysfunction of hippocampal gamma oscillation and fast spiking interneurons in Alzheimer's disease model mice

Authors: *K. TAKASU, K. NIIDOME, M. HASEGAWA, K. OGAWA;
Pain & Neuroscience, Shionogi Co., Ltd., Toyonaka, Osaka, Japan

Abstract: Hippocampal gamma oscillation is reported to be associated with cognitive functions, and accumulating evidence suggest that deficit of gamma oscillation is related to cognitive

impairment in Alzheimer's disease (AD). Recent studies suggest that post-translational modification of histone protein via acetylation is a fundamental molecular mechanism for regulation of synaptic plasticity and memory formation. However, little is known about roles for histone acetylation in the hippocampal gamma oscillation. In this study, we investigated whether histone acetylation regulate kainate-induced gamma oscillation and its important regulator, fast-spiking interneurons, by using acute hippocampal slices of AD model mice (PSAPP transgenic mice). We found that deficits of kainate-induced gamma oscillation in PSAPP mice, and application of Donepezil, a clinically used drug for AD treatment, recovered the gamma oscillation. We demonstrated for the first time that histone deacetylase (HDAC) inhibitor suberoylanilide hydroxamic acid (SAHA) elevated the gamma oscillation level, and the effect of SAHA was accompanied with the elevation of histone H3 and H4 acetylation. The effects of SAHA on the gamma oscillation and histone acetylation were abolished by co-application of histone acetyltransferase (HAT) inhibitor C646, showing that histone acetylation is a key mechanism for regulation of gamma oscillation by SAHA. To further investigate the mechanisms underlying the reduction of gamma oscillation in PSAPP mice and its rescue following treatment of SAHA, we evaluated function of fast spiking interneurons, which were reported to mainly regulate gamma oscillation. We found impairments of both synapse-dependent and independent activity of fast spiking interneurons in PSAPP mice; the former being depolarized resting membrane potentials and increased spontaneous firing frequency and the latter being impaired intrinsic and kainate-induced excitability. Interestingly, SAHA and donepezil, both which improved reduction of gamma oscillation in PSAPP mice, differently rescued impairments in fast spiking interneurons. SAHA rescued both synapse-dependent and independent dysfunction by restoring spontaneous firing activity and intrinsic and kainate-induced excitability of fast spiking interneurons. By contrast, donepezil rescued only synapse-dependent dysfunction by restoring spontaneous firing activity. These results have indicated a novel mechanism that HDAC inhibition improved impairment of gamma oscillation in PSAPP mice by restoring synapse-dependent and independent dysfunction of fast spiking interneuron as pathological mechanism of AD.

Title: Maintaining neuronal properties during growth with local and global homeostatic regulation

Authors: *H. GURNANI[1], T. O'LEARY[2], E. MARDER[3];
[1]Indian Inst. of Science, Bangalore, Bangalore, India; [2]Dept. of Engin., Univ. of Cambridge, Cambridge, United Kingdom; [3]Volen Ctr., Brandeis Univ., Waltham, MA

Abstract: Neurons in the pacemaker circuit of the crustacean pyloric rhythm can maintain similar bursting rhythms despite morphological growth (Bucher et al 2005). However, intrinsic and synaptic properties, membrane resistance and capacitance, as well as calcium dynamics change dramatically as neurons grow and dendritic trees elaborate. How can neurons maintain ongoing activity in spite of these perturbations? Using computational modelling, we show that biologically plausible activity-dependent feedback can maintain bursting rhythms in growing neurons. We first explored a global regulation model in which calcium homeostasis is maintained through activity-dependent plasticity of ionic conductances. Although the model maintained calcium homeostasis and generated steady state bursting rhythms, different-sized single compartment geometries resulted in variable burst period and duty cycle. We then modified the regulation scheme by introducing local activity-dependent protein translation and degradation in dendritic compartment, along with global transcriptional regulation at the soma. This allowed geometries of varying surface area develop steady state bursting rhythms with similar burst period and duty cycle. Interestingly, geometries beyond a critical neuronal size were able to maintain steady state bursting, suggesting an asymmetry in the emergence of activity homeostasis with varying neuronal size. To further test of the regulation model, we implemented it in large-scale, morphologically realistic, reconstructed Stomatogastric Ganglion neuron models and modeled neuron growth. We first constructed morphologies at intermediate stages of branching by removing higher order dendrites. We observed that morphologies beyond a certain stage of branching developed similar steady state bursting under local regulation of different conductances, despite significant increase in dendritic area. Finally, in a model of continuous isometric growth, the rhythm stabilized when the morphologies reached 30-40% of their full size and the burst period was maintained through constant evolution of the conductances while the morphology continued to grow. These results show how the development and maintenance of activity patterns during neuronal growth can be achieved by a combination of global and local activity-dependent processes and indicate the existence of critical phases of growth where stable activity emerges.

Title: Ectopic spike firings of the hippocampal mossy fibers by application of kainate to the distal axons

Authors: *H. KAMIYA[1], C. MULLE[2];
[1]Hokkaido Univ. Grad. Sch. of Med., Sapporo, Hokkaido, Japan; [2]Interdisciplinary Inst. for Neuroscience, CNRS UMR 5297, Univ. of Bordeaux, Bordeaux, France

Abstract: Spike initiation at the proximal part of the axon, usually at the axon initial segment (AIS), is supported by the high excitability due to dense expression of voltage-gated sodium channels in the proximal axons. Robust directional propagation of axonal spikes from AIS to the distal axons and the terminals are well preserved for orthodromic conduction in the physiological conditions. However, in particular pathological conditions such as epilepsy, it has been suggested that ectopic spikes are generated at the distal axons and propagate antidromically to the soma. In this study, loose patch clamp recordings of axonal spikes from single mossy fiber boutons, in combination with local perfusion around the recording sites, were performed in mouse hippocampal slice preparations. Ca^{2+} free perfusing solution in the bath was used for minimizing indirect actions due to neurotransmitters released from surrounding cells. Hippocampal mossy fiber boutons were identified under observation with IR-DIC optics with large size of 4-8 μm in diameter and localization in the stratum lucidum, and were confirmed by the similar appearance of fluorescent labelled structures in Thy1-GFP transgenic mice. Mossy fiber boutons elicited spikes in all-or-none fashion following stimulation to the granule cell layer in the dentate gyrus. Under resting conditions, few spontaneous firings of axonal spikes were observed in most recordings from single mossy fiber boutons. Upon switching of the local perfusing solution to that containing low concentration of kainate at 0.2 μM, sporadic axonal spikes appeared immediately in most cases, possibly reflecting ectopic spontaneous discharges at distal axons by depolarization due to application of kainate. In some recordings, bursts of axonal spikes appeared and outlasted the period of kainate application for a prolonged time up to 5-10 min, similar to barrage firings observed in some neurons after strong neuronal activities. These results suggest the existence of cellular mechanisms leading to plastic changes in excitability of the distal axons of hippocampal mossy fibers by activation of kainate receptors.

Title: Effect of axotomy injury on the membrane elasticity of neurons

Authors: *S. BAY, B. POLAT, G. OZTURK;
Regenerative and Restorative Med. Res. Ctr. (REMER), Istanbul Medipol Univ., Istanbul - TURKEY, Turkey

Abstract: Plasma membrane stiffness/elasticity/tension is defined as the total force needed to deform the plasma membrane and has two components; the in plane tension which is the actual stiffness of the lipid bilayer. And the cortical tension which is due to membrane to cortex attachments and is derived from the cytoskeletal meshwork attached to the plasma membrane at the cell cortex. Evidence shows that numerous biological processes like vesicle trafficking and cell motility, is due to the active interplay of these forces and the cell stiffness actually play role in control of cell polarization and shape maintenance.
Among a lot of techniques for measuring the membrane tension, optical tweezers provide the most direct measurement by pulling an optically trapped bead and extracting a force value from the displacement of the bead. There are numerous studies about the effect of the extracellular substrate to neuron structure, morphology and axonal features, yet there are no studies. In this study, we aim to explore the changes in neural membrane tension after axonal damage.
In accordance with this purpose, dorsal root ganglia neurons were enzymaticly and mechanically dissociated. Neurons were sorted via density gradient centrifugation and cultured on laminin coated glass bottom petri dishes. The surface of 3 μm diameter polystrene beads were positively charged via an overnight poly-l-lysine coating protocol and beads were then tethered to neurons with an optical tweezer at 100X magnification. Laser axotomy was performed, the bead was pulled perpendicular to the cortical forces. Displacement was measured and forces were calculated.
In high percentage of axotomised neurons (60%) cortical forces increased upon axotomy. With help of newly avaliable technology and a well constructed experimental paradigm we were able to gather data about neural cell membrane machanics. Possible implications and applications of this increase will be discussed.

Title: Electrophysiological characterization of paraventricular nucleus neurons

Authors: *A. C. KLEIN[1,2], P. KLOPPENBURG[1,2];
[1]Biocenter, Inst. For Zoology, Cologne, Germany; [2]Cologne Excellence Cluster on Cell. Stress Responses in Aging-Associated Dis. (CECAD), Univ. of Cologne, Cologne, Germany

Abstract: The Paraventricular Nucleus of the Hypothalamus (PVN) is an important autonomic control center in the brain that contains a heterogeneous neuron population. It plays an important role in regulating autonomic renal and cardiovascular functions, stress responses, and is also crucial for controlling the energy balance. For instance, lesioning the PVN causes hyperphagic obesity in rats (Physiol & Behav 1981; 27(6): 1031-1040) and injection of the melanocortin-4 receptor agonist melanotan-2 into the PVN reduces food intake, while the antagonist agouti-related-protein (and neuropeptide Y) increases food intake (Neuron 1999; 24: 155-163). These results demonstrate, that the PVN is an important integration sites in the hypothalamus for both neuroendocrine and autonomous pathways.
Within the PVN three different types of neurons have previously been identified in rats: Magnocellular neuroendocrine neurons (MC), parvocellular neurosecretory (NS) and preautonomic (PA) neurons (J Physiol 1991; 434, 271-93). These neuron types can be identified by a number of anatomical features, molecular markers, and intrinsic electrophysiological properties. While the cell bodies of MC neurons are relatively big and mainly located in the medial part of the PVN, cell bodies of parvocellular NS and PA neurons are smaller and predominantly located in the anterior and posterior PVN respectively. Furthermore, MC and parvocellular NS neurons extend their projections primarily to the median eminence where they regulate pituitary function, whereas PA neurons mainly project to hindbrain nuclei and the spinal cord. In addition, these neurons differentially express a variety of peptides such as oxytocin, vasopressin, corticotropin-releasing factor, or thyrotropin-releasing hormone (J Comp Neurol 2009; 10(5), 423-41). In rats, PVN neurons can also be identified by their distinct electrophysiological properties (J Physiol 1991; 434, 271-93).
Here we provide a comprehensive electrophysiological characterization of the three PVN neuron

types in mice to establish a solid base for future experiments that aim to investigate the modulation of the PVN network under physiological and pathophysiological contexts. By performing perforated patch-clamp recordings in hypothalamic mouse brain slices we found that the distinct neuron types can be identified by specific electrophysiological characteristics such as delayed action potential onset after hyperpolarization in the case of MC neurons, generation of low threshold spikes in parvocellular PA neurons, and typical spike frequency adaptation behavior in parvocellular NS neurons.

Title: Characterization of ion channel conductance and mRNA expression levels in identified neurons of a parthenogenetic crayfish

Authors: *C. STAEDELE, A. G. VIDAL-GADEA, W. STEIN;
Sch. of Biol. Sci., Illinois State Univ., Normal, IL

Abstract: The activity of individual neurons is achieved through the combined action of ion channels in the cell membrane. However, the ion channel conductance levels vary between animals of the same species, and between neurons of the same type (Schulz et al. 2006; Golowasch et al. 1999, 2002; Liss 2001), indicating that this variability may be an important factor in maintaining robust neural function over time. While all neurons have mechanisms that homeostatically regulate intrinsic excitability and responses to synaptic input, it is unclear whether differences between animals are due to genetic variability between individuals or to experience-dependent homeostatic plasticity. Addressing this question has been challenging in existing animal models due to lack of identified neurons and circuits, weak access to cellular and circuit dynamics, or the availability of genetic tools. We are studying conductance level variability using single-cell electrophysiology and molecular tools in identified neurons of the marbled crayfish, *Procambarus fallax forma virginalis*. Marbled crayfish are an all-female species with genetically homogenous animals that reproduce parthenogenetically. To determine conductance diversity, we are measuring ion conductance levels in the same identified neurons of the stomatogastric ganglion and compare them across animals. In addition, we are measuring ion channel expression levels using single-cell qRT-PCR to confirm the results of our electrophysiological measurements. Previous studies in this system were carried out in wild-

caught crustaceans, and revealed a large variability of ion channel conductances levels and correlated mRNA levels (Schulz et al. 2006, 2007). We hypothesize that the variability between identified neurons is reduced in marbled crayfish as a result of their genetic homogeneity. To test this, we are raising animals under identical environmental conditions, minimizing differences in life-history, before conductance and expression levels are compared. A second test group consists of animals raised at different environmental conditions, for which we predict distinct conductance and expression levels in comparison to control as a result of homeostatic feedback mechanisms. We are also considering the possibility to manipulate gene expression using transgenic animals by introducing genetic constructs into the germline of marbled crayfish.

Title: Effects of periodic stimulation on cortical circuits as a function of stimulated population properties

Authors: *A. DABACAN, V. V. MOCA, R. C. MURESAN;
Exptl. and Theoretical Neurosci., Romanian Inst. of Sci. and Technol., Cluj Napoca, Romania

Abstract: Novel experimental techniques, such as optogenetics, aim to dissect network function, acting on subsets of cells with various physiological and functional properties. The study of oscillatory mechanisms involved in information processing greatly benefits from these tools. In particular, it is important to understand the differential involvement of neuron subtypes in the entrainment and sustainment of robust cortical oscillations.
We used models of cortical microcircuits to test network frequency-response as a function of stimulated population (excitatory: E or inhibitory: I). Excitatory neurons were modeled as pure integrate-and-fire (IF) neurons, while interneurons were either IF or Izhikevich neurons exhibiting membrane resonance (RES). By switching interneuron model, we obtained two network types: IF-IF and IF-RES.
When either E or both E and I neurons were periodically stimulated, we found circuit resonance for all networks. At low stimulation frequencies (< 15 Hz), both IF-IF and IF-RES networks sustained oscillations, with a frequency in the range of 18-30 Hz, irrespective of the input. For

stimulation frequencies in the range of 18–40 Hz, networks were locked to input frequencies, while at higher stimulation frequencies, oscillation stabilized within the 18-30 Hz range, frequency was higher for the IF-RES network and power was higher for IF-IF networks. The latter exhibited circuit resonance peaks at multiples of main peak frequency when only E neurons were stimulated, indicating an m-to-n locking phenomenon. This was not the case for IF-RES networks, where interneuron resonance constrained the circuit resonance to a limited domain. When input was delivered to I cells only, IF-IF networks were not able to sustain oscillations, while IF-RES nets exhibited a circuit resonance peak matching interneuron resonance frequency. Our results indicate complex network responses to periodic stimulation, dependent on input populations and their properties, with important implications for optogenetic studies of cortical oscillations.

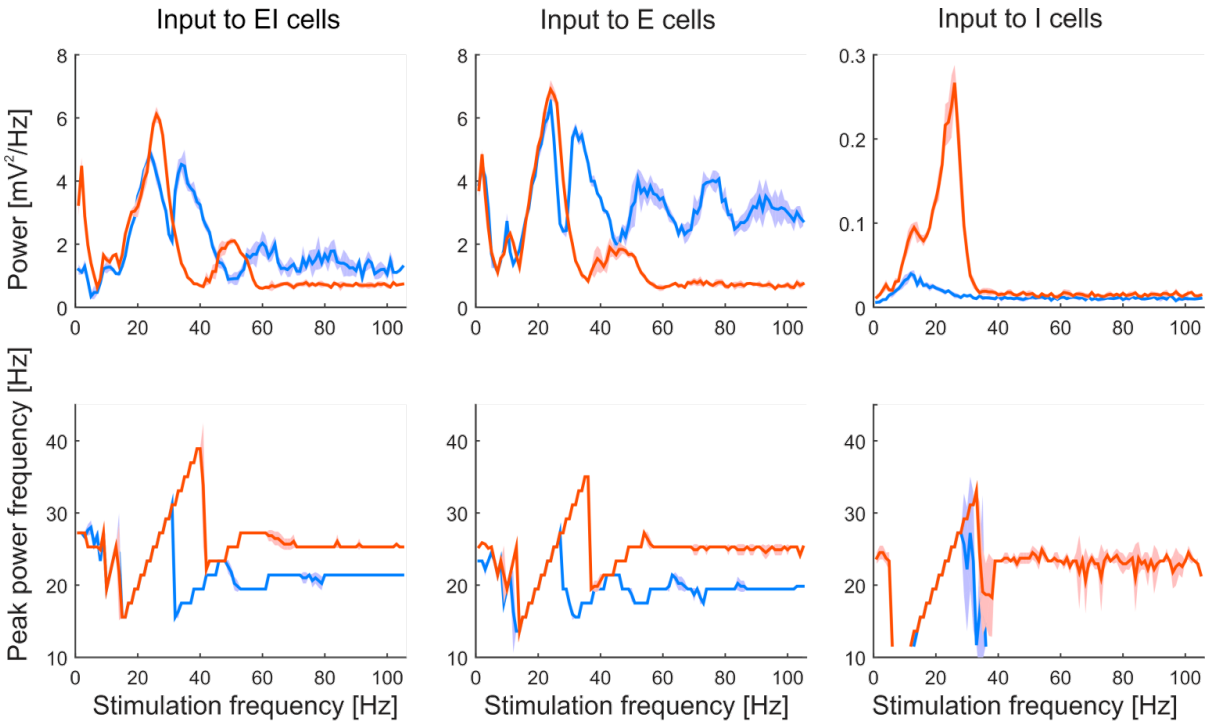

***Figure 1*. Network response to periodic stimulation**: **Blue**: IF-IF networks; **Orange**: IF-RES networks; **Top**: maximum power vs. stimulation frequency; **Bottom**: frequency of maximum power vs. stimulation frequency; **Left**: Stimulation delivered to E and I cells; **Middle**: Stimulation delivered to E cells only; **Right**: Stimulation delivered to I cells only; Mean and standard deviation are computed across 5 randomly generated networks.

Title: Using genetically encoded voltage sensors to measure voltage propagation along neuronal cables

Authors: *M. RIGBY[1], J. BURRONE[2];
[1]Ctr. for Developmental Neurobio., [2]King's Col. London, London, United Kingdom

Abstract: The propagation of voltage along neuronal cables depends on the resting and active properties of the membrane, as well as the intracellular resistivity. Although many studies have characterized the distribution of voltage-gated ion channels that contribute to the steady-state and active conductances of a neurite, much less is known about how localized changes in axial resistance influence voltage attenuation. Here we used the genetically-encoded voltage indicators ASAP-1 and ACE-2N-4AA to simultaneously record the membrane voltage at many locations along the dendritic and axonal arbors of dissociated neurons. Negative current steps were injected at the soma using a patch pipette, and the passive propagation of the hyperpolarizing pulse imaged along the neurites. By correlating the length constant of the voltage decay to structural features of the sub-compartments we highlight how variability in passive neuronal properties can modulate slow changes in membrane potential. These findings have important implications for how neurons integrate synaptic inputs and regulate the action potential. By imaging at much higher frequencies we next aim to examine how such fast changes in membrane potential are affected by local differences in steady-state conductances and intracellular resistivity

Abstract: Transcranial alternating current stimulation (tACS) is a non-invasive technique capable of interacting with endogenous brain oscillations in a frequency-specific manner, which offers a unique opportunity to study the causal role of brain rhythms in behaviour and how they relate to dysfunction, thus paving the way to new therapeutic applications in disorders associated with abnormal neuronal oscillations, such as Parkinson's disease. However, current understanding of the mechanisms that underlie the effects of tACS is limited, which in turn hampers the rational optimization of human experiments.
Recent work on tACS for the first time has provided evidence that oscillations at beta (15–30 Hz) and gamma (30–90 Hz) frequency range are causal, rather than epiphenomenal, to motor behaviour. The aim of the present study was to investigate the neurophysiological effects of beta- and gamma-frequency tACS in healthy subjects (n=20). To this end, we employed TMS to evaluate the effects of tACS on the following: (1) the global corticospinal excitability, as indexed by motor evoked potentials (MEPs), elicited by single-pulse TMS; (2) short interval intracortical inhibition (SICI) and (3) intracortical facilitation (ICF) in the left primary motor cortex (M1) following paired-pulse TMS, considered to reflect $GABA_A$-mediated synaptic inhibition and glutamatergic facilitation, respectively. tACS was applied over the left M1 and the contralateral orbit for 20 min at intensity adjusted below individual phosphene- and discomfort threshold. All TMS protocols were performed at rest before, during (at 5 and 15 min) and after tACS. A single MEP and SICI were also recorded during movement preparation before and after tACS.
We found that high gamma tACS affected a single MEP and SICI in a differential manner during the stimulation. Specifically, SICI was decreased at an early stimulation period (5 min) but increased during a later period (15 min) as compared to the sham group. The opposite effect was observed for a single pulse TMS protocol. Moreover, we found that the observed responses at an early stimulation period proved to be a good predictor for individual responses measured during a later period. Finally, we found no after-effects of tACS. These experimental data provide evidence in support of differential duration-dependent online effects of tACS, which resemble

homeostatic-like plasticity, although no effect lasting beyond the stimulation period was observed. In addition, the data demonstrate the predictive power of initial responses to tACS, which could be helpful in screening responsive subjects or probing stimulation efficacy before therapeutic application.

Title: Oscillations contribute to memory consolidation by changing criticality and stability in the brain

Authors: ***J. WU**[1], Q. M. SKILLING[2], N. OGNJANOVSKI[3], S. J. ATON[3], M. ZOCHOWSKI[2]; [1]Applied Physics Program, [2]Biophysics Program, [3]Dept. of Molecular, Cellular, and Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: Oscillations are a near universal feature of every level of brain dynamics and have been shown to contribute to many functions, such as neural binding, information encoding and processing, and subsystem integration. Despite almost a century of active research and many proposed hypotheses, the role of oscillations in shaping network dynamics is still not fully understood. To investigate the fundamental mechanism underpinning oscillatory activity, the properties of heterogeneous networks are compared in situations with and without oscillations, both computationally and experimentally. Our results show that both network criticality and stability are changed in the presence of oscillations. Criticality describes the network state of neuronal avalanche, a cascade of bursts of action potential firing in neural network. The

branching parameter σ is defined as the average number of subsequent active neurons at the next time point triggered by one neuron. σ<1, σ=1, σ>1 correspond to subcrtitical, critical and supercritical state respectively. Preliminary results indicate that an increase of σ is associated with better learning performance. Stability measures how stable the spike timing relationship between neuron pairs is over time. Using a detailed spiking model, we found that the branching parameter σ changes relative to oscillation and structural network properties, corresponding to transmission among differnt critical states. Also, analysis of functional network structures shows that the oscillation helps to stabilize neuronal representation of memory. Further, quantitatively similar results are observed in biological data recorded in vivo. By inhibiting parvalbumin-expressing (PV+) interneurons, delta (0.5-4Hz), theta (4-12Hz) oscillations are blocked, leading to poor learning behavior. Previously, supracritical state is thought to be associtated with a high Excitatory/Inhibitory ratio. However, the change in branching parameter reflects that the system does not have to transit to supracriticality, even though the network becomes more excitatory caused by inhibition of PV+. In summary, we have observed that, by regulating the neuronal firing pattern, oscillations affect both criticality and stability properties of the network, and thus contribute to memory formation.

Title: Abnormal theta and gamma oscillations in mice lacking the GluA1 AMPAR subunit

Authors: ***A. BYGRAVE**[1], D. KULLMANN[2], D. BANNERMAN[1], D. KÄTZEL[1,3,2];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Univ. Col. London, London, United Kingdom; [3]Univ. of Ulm, Ulm, Germany

Abstract: α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs) mediate the majority of excitatory neurotransmission in the mammalian brain. AMPARs are tetramers, formed from GluA1-4 subunits. The GluA1 subunit is of particular interest, as AMPARs containing this subunit are involved in certain forms of synaptic plasticity. The lack of pharmacological agents to manipulate AMPARs with subunit specificity has led to the

generation of genetically modified mice which lack different AMPAR subunits. Mice lacking the GluA1 subunit (GluA1 KOs) lack specific forms of synaptic plasticity, but maintain intact spatial reference memory. In contrast, spatial working memory (SWM), and other forms of short term memory, is abolished in GluA1 KO mice. In addition, GluA1 KO mice show profound novelty induced hyperactivity. The in vivo electrophysiological phenotype of GluA1 KO mice has been studied less. Local field potential (LFP) oscillations in the theta (4-12 Hz) and gamma (30-80 Hz) frequency range are thought to be important for memory processes including SWM. We have recorded LFPs from the hippocampus and prefrontal cortex of awake, behaving, GluA1 KO and wildtype control mice. During exploration of a novel environment the relative theta power in GluA1 KO mice is increased, and the peak frequency of the oscillation is reduced in the dorsal hippocampus compared to control. Under the same conditions the relative gamma power in the dorsal hippocampus is reduced in GluA1 KO mice compared to controls. Furthermore, we engineered a virus to express GluA1, to test if it was possible to rescue these oscillatory deficits by reintroducing GluA1 into the hippocampus of adult GluA1 KO mice. Injection of this rescue virus into the hippocampus led to expression of GluA1, particularly in the CA3 region. The rescue virus was able to normalise the relative theta power, but not the relative gamma power in the dorsal hippocampus. Reintroduction of GluA1 also partially rescued novelty induced hyperactivity in GluA1 KO mice. Our results suggest that GluA1 is required for normal theta and gamma oscillations, and indicate that a loss of GluA1 from the hippocampus could, at least in part, underlie the novelty induced hyperactivity seen in GluA1 KO mice.

Title: Modeling spike synchrony generated by modulatory common input through nmda-type synapses

Authors: *N. WAGATSUMA[1], R. VON DER HEYDT[2], E. NIEBUR[2];
[1]Tokyo Denki Univ., Saitama, Japan; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Common excitatory input to neurons increases their firing rates and the strength of the spike correlation (synchrony) between them. Little is known, however, about the synchronizing effects of modulatory common input. Here we show that modulatory common input with the slow synaptic kinetics of NMDA receptors enhances firing rates and also produces synchrony. Tight synchrony (correlations on the order of milliseconds; Amarasingham et al, J. Neurophysiol. 107:517, 2012) always increases with modulatory strength. Unexpectedly, the relationship between strength of modulation and strength of loose synchrony (tens of milliseconds; Dong et al, J. Vis. 8: 1, 2008) is not monotonic: The strongest loose synchrony is obtained for intermediate modulatory amplitudes. This finding explains recent neurophysiological results showing that in cortical areas V1 and V2, presumed modulatory top-down input due to contour grouping increases (loose and tight) synchrony, but that additional modulatory input due to top-down attention does *not* change tight synchrony, and actually *decreases* loose synchrony (Martin and von der Heydt, J. Neurosci 35:6860, 2015). These neurophysiological findings are understood from our model of integrate-and-fire neurons under the assumption that contour grouping as well as attention lead to additive modulatory common input through NMDA-type synapses. In contrast, circuits with common projections through model AMPA receptors did not exhibit the paradoxical decrease of synchrony with increased input. Our results suggest that NMDA receptors play a critical role in top-down response modulation in visual cortex.

Title: Influence of whole-body vibration exercise on cortical activity in chronic stroke patients: functional near-infrared spectroscopy study

Authors: *J. JUNG[1], D.-S. CHOI[1], A. LEE[2], E. PARK[1], H.-G. KIM[2], H.-J. LEE[1], S. LEE[1], W. CHANG[1], Y.-H. KIM[1];

Abstract: Introduction: Whole-body vibration (WBV) exercise can provide a proper somatosensory stimulation in stroke patients to promote functional improvement. However, there was a lack of study to investigate the neuroplasticity according to WBV exercise in stroke patients. The purpose of this study was to investigate the effects of whole-body vibration (WBV) exercise on cortical activity in patients with chronic stroke. **Methods:** Eighteen chronic stroke patients were randomly assigned to either the WBV group (n = 12) or control group (n = 6). The WBV group received vertical whole-body vibration (Galileo Advanced plus, Novotec Medical, Germany**)** with intensity of the 20 Hz and the amplitude of 4 mm for 5 minutes with half-squat position on the platform. Cortical activation was measured before and after stimulation period by relative changes of oxygenated hemoglobin (oxyHb) in primary motor cortex (M1), premotor cortex (PM), supplementary motor area (SMA), somatosensory cortex (S1), and prefrontal cortex (PFC) using a functional near infrared spectroscopy (NIRScout, NIRx, Germany). Two-way repeated measures ANOVA was used for statistical analysis. **Results:** OxyHb concentration for M1 and S1 of the unaffected side was significantly increased after vibratory stimulation in the WBV group, but not in the control group. There were also significant interaction effects in group and time for M1. OxyHb concentration for PFC of the affected hemisphere and SMA of the unaffected side was significantly higher in the WBV group than the control group. There were significant main effects between groups in the affected PFC and the unaffected SMA. **Conclusion:** This study provided the evidence that WBV exercise have positive influences on cortical activity of motor network and prefrontal area in the chronic stroke patients (Supported by the NRF grant funded by the Korea government (NRF-2014R1A2A1A0128)).

Title: Metastable dynamics underlying the multiscale organization of slow oscillations

Authors: *M. MATTIA[1], M. PEREZ-ZABALZA[2], N. TORT-COLET[2], M. V. SANCHEZ-VIVES[2,3];
[1]Inst. Superiore di Sanità, Roma, Italy; [2]IDIBAPS (Institut D'Investigacions Biomediques August Pi I Sunyer), Barcelona, Spain; [3]ICREA (Institut Catala de Recerca i Estudis Avançats), Barcelona, Spain

Abstract: Slow oscillations (SO) are a stereotyped activity pattern pervasively expressed during slow-wave sleep and deep anesthesia by the cerebral cortex of many species. SO in sensorial cortices are known to mirror early neuronal processing of environmental stimuli, and occur

simultaneously in cell assemblies at different cortical depths and positions as a concerted multiscale activity. In visual cortex (V1) for instance, such nonlinear network dynamics may contribute to sustain input-related activity once visual stimuli are removed or when the stimulation sequence is incomplete, a computational primitive allowing integration of information across time. The dynamic roots of such concerted activity is still an open issue which here we address by carrying out a detailed exploration of the multiscale dynamics of SO to understand the rules of columnar function. To this end, we recorded the synaptic and neuronal activity underlying SO from V1 of anesthetized rats (ketamine-medetomidine, n =18 adult male Wistar rats), by extracting from a 16-channel silicon probe both current source densities (CSDs) and MUAs across all cortical layers.Our first finding is that layer 5 (L5) assemblies give rise to hysteresis loops like in flip-flop computational units. This confirms the leading role of L5 in generating and sustaining the Up states of SO with the highest firing rate. Yet, it supports the long standing hypothesis that local cortical networks are capable to express attractor dynamics, also suggested to underlie cognitive functions like working memory and decision making. We demonstrate that this attractor dynamics are history-dependent and most likely mediated by synaptic reverberation and activity-dependent adaptation mechanisms. Columnar activation during SO display a stereotyped ascending pattern, reproducibly initiated in layer 6 (L6) spreading upward towards the cortical surface. From CSD analysis, this is due to an early synaptic input that L6 assemblies receive, inducing a time lag of 14 ± 11 ms between L6 and L5 Up onsets. By inactivating LGN by TTX injections, we demonstrate that the input to L6 is of cortical origin, likely due to travelling Up wavefronts. Although the thalamus had no apparent role in columnar activation, we found that it contributes to modulate the stability of Down states in infragranular layers. This evidence recasts the cortico-thalamo-cortical loop as also a modulator of SO in sensorial areas, strengthening the role of L6 as a fundamental hub of neuronal activity produced at macroscopic scale. A role expressed not only in response to sensory stimulation but also under self-sustained or spontaneous state like slow-wave activity.

Title: Slow wave propagation in the cortical network and laminar excitability

Authors: *M. V. SANCHEZ-VIVES[1,2], C. CAPONE[3,4], B. REBOLLO[1], P. DEL GIUDICE[4], M. MATTIA[4];
[1]IDIBAPS (Institut D'Investigacions Biomediques August Pi I Sunyer), Barcelona, Spain; [2]ICREA (Institut Catala de Recerca i Estudis Avançats), Barcelona, Spain; [3]PhD Program in Physics, Sapienza Univ., Rome, Italy; [4]Inst. Superiore di Sanità, Rome, Italy

Abstract: Slow oscillations of neural activity spontaneously emerge and propagate across the cerebral cortex during deep sleep and anesthesia, an activity also expressed in brain slices and cortical slabs. The mechanistic origin of slow oscillations integrates the local excitability of cell assemblies and their mutual interaction. Here, we address this issue focusing on ongoing slow waves spontaneously generated in neocortical slices and recorded by means of a 2D array of 16 electrodes designed to probe the neuronal activity at different spatial scales. On top of the largely variable propagation modes observed, we reproducibly found a smooth strip of loci leading the slow wave fronts that overlapped with cortical layer 4 and 5. Along this strip, Up states were the longest and displayed the highest firing rate. Under control conditions of excitability and at a frequency of oscillations of 0.31 ± 0.12 Hz, the propagation mode was uncorrelated in time, highlighting a memoryless generation of slow waves. To model all these features, a multi-modular large-scale network of spiking neurons must incorporate a specific balance between local and intermodular connectivity. Modules must also work as relaxation oscillators with a weakly stable Down state and a peak of local excitability to model layer 4 and 5. These peculiar settings combined together provide an optimal sensitivity to the network structure and generate a richness of available propagation modes, a potential neuronal substrate for experience-driven flexibility.Figure legend. A. Two example slow-waves propagating in opposite directions across a cortical slice probed with a 16 electrode MEA (grey circles). Dotted lines with arrows indicate the early propagation strip (EPS) of the wavefronts. Consecutive (color coded) wavefronts are separated by 50 ms. B. EPS density and area covered by the MEA superimposed to the image of the corresponding cortical slice stained after electrophysiological recordings. Dashed lines, boundaries between layers. EPS density below 0.05 is not shown.

Title: Non-synaptic wave propagation: modulation of slow oscillations by endogenous electric fields

Authors: ***B. REBOLLO**[1], S. GONZALEZ-ANDINO[2], R. GRAVE DE PERALTA MENENDEZ[2], M. SANCHEZ-VIVES[1,3];
[1]IDIBAPS, Barcelona, Spain; [2]Ecole Polytechnique Federal de Lausanne (EPFL), Lausanne, Switzerland; [3]ICREA (Institut Catala de Recerca i Estudis Avançats), Barcelona, Spain

Abstract: The cerebral cortex is organized in circuits of neurons that interact via synaptic mechanisms. The synaptic activity co-exists with endogenous electric fields (EF) generated by neuronal activity. These changes in the electric environment of neurons due to the network activity have a feedback effect onto neurons (Fröhlich and McCormick Neuron, 67: 129. 2010; Anastassiou et al. Nature Neuroscience, 14: 217, 2011). To study the endogenous EF effect onto

the local network, we used an *in vitro* preparation of ferret visual cortex that generates slow oscillations (Sanchez-Vives and McCormick, Nature Neuroscience, 3: 1027, 2000), a pattern of activity typical of slow wave sleep and anesthesia. A complete vertical cut of the slice, perpendicular to the cortical surface, was performed, while the two sides of the cut remained in contact without discontinuity between them. This resulted into two independent networks on each side, each of which had its own oscillatory pattern of spontaneous UP states. The vertical cut allowed to isolate synaptic transmission from the EF propagation. We then characterized how the EF induced by slow wave oscillations propagated in the cortical tissue across the cut, therefore independent from synaptic transmission. Up states originated and propagated within one side of the slice, could be recorded across the cut albeit with strongly reduced amplitude, losing more than 50% of their original amplitude. Dampening was accompanied by an average delay of the propagated signal by 104 ms, resulting in a EF propagation speed of 14 mm/s, a value similar to the speed of wave propagation of slow oscillations under intact synaptic connections. The propagated EF had an impact on the activity generated across the cut. We explored this phenomena under different conditions, including spontaneous slow waves, electrical and chemically-induced responses and epileptiform discharges. Our results suggest that cortical patterns do not exclusively emerge from synaptically interconnected neurons but they are also shaped by the fields generated by the active network.

Abstract: The complexity of EEG-measured human cortical response evoked by transcranial magnetic stimulation can be estimated by the perturbational complexity index (PCI) (Casali et al. Science Translational Medicine, 5(198): 198ra105, 2013). PCI shows a significant correlation with the level of consciousness in human subjects across different conditions (sleep, anesthesia, coma), being thus valuable for diagnoses. Upon loss of consciousness, the complex pattern of causal interactions observed during wakefulness collapses into a stereotypical slow wave, suggesting that cortical bistability may play a role. Bistability is mainly expressed in the form of slow oscillations, a default pattern of activity that emerges from cortical networks in conditions of functional or anatomical disconnection. Here we aimed to investigate the cortical mechanisms underlying the regulation of complexity and causality in different brain states taking advantage of an in vitro preparation of the cerebral cortex that displays emergent slow oscillations (<1Hz). Recordings were obtained with a 16 channel multi-electrode array and network perturbation was induced by electric stimulation. The PCI algorithm used in humans was adapted to the local scale of the cortical slice. Different brain states were simulated by pharmacological manipulation. In particular, we investigated 3 network states: 1) spontaneous slow oscillations, 2) a state of increased network excitability through bath-applied kainate, and 3) an “awake-like” state, induced by means of mimicking the ascending activating systems by means of norepinephrine and carbachol. During slow oscillations we observed a response similar to that observed in non-REM sleep: an initial activation, followed by a silent state and break-off of deterministic activations. Under the effect of norepinephrine and carbachol instead, we observed a significant increase in PCI, correlated with prolonged deterministic effects similar to those corresponding to the awake state. These observations were not reproduced though by kainate. This in vitro results give us hints into the cortical mechanisms regulating complexity and causality, highlighting the central role of the intrinsic bistability typical of states of unconsciousness and demonstrating that complexity can be modulated pharmacologically.

Title: Cortical population dynamics during spindles and at the transition from NREM sleep

Authors: *D. LEVENSTEIN[1,2], B. O. WATSON[2,3], J. RINZEL[1], G. BUZSÁKI[2];
[1]Ctr. for Neural Sci., New York Univ. - Ctr. for Neural Sci., New York, NY; [2]NYU Neurosci. Inst., New York, NY, NY; [3]Dept. of Psychiatry, Weill Cornell Med. Col., New York, NY

Abstract: Neural activity during sleep is highly choreographed over multiple time scales, from global brain states at the scale of minutes to oscillatory events at the scale of seconds and neuronal assemblies at the scale of 10-100ms. Previously, we found that the sleep process shows distinct effects on the activity of high and low firing rate cortical neurons. These effects are sleep-state-specific and can be distinguished by their correlation with the incidence of different sleep oscillations. To this end, we sought to further characterize how the state-dependent choreography of sleep oscillations organizes the activity of specific neuronal populations. From in vivo multi-site recordings in frontal cortices of naturally sleeping rats, we find that the transition out of NREM sleep is characterized by increased power in a broad range of intermediate frequencies (8-30Hz, “sigma” and “beta" bands of the LFP) and an increased incidence of thalamocortical spindles. While this transitional state has been previously described in the rodent as intermediate sleep for the transition from NREM to REM, we find that it is also seen before brief NREM “microarousals”, as well as rare transitions directly from NREM to wakefulness. However, the transition from NREM to REM uniquely shows coherent activity in these frequency ranges between the cortex and hippocampus and is associated with increased activity of cortical low firing rate neurons. We find that the population activity of putative inhibitory neurons shows strong spindle-band fluctuations during this transitional state and that a subpopulation of inhibitory neurons are tightly rate- and phase-coupled to the thalmocortical spindle oscillation. These spindle-locked interneurons are activated early in the spindle and burst with reliable spindle-cycle inter-burst intervals. Paralleling this population, we find another subpopulation of spindle phase-coupled putative inhibitory units which are inactivated at the beginning of the spindle and gradually increase in firing rate over the course of the spindle. While we see counterparts to these inhibitory populations in the high firing rate excitatory populations, the more striking finding is that spindles act to segregate high and low firing rate putative pyramidal units, which show highly correlated firing within their own rate groups but anti-correlated activity with each other. These results suggest that one function of thalamocortical sleep spindles is to temporally segregate specific cortical populations and that the transition out of NREM is a unique time in sleep during which this can happen.

Title: Functional properties of distinct excitatory cell types in the hippocampal dentate gyrus

Authors: *Y. SENZAI[1], L. ROUX[2], E. STARK[3], G. BUZSAKI[2];
[2]Neurosci. Inst., [1]New York Univ., New York, NY; [3]Sagol Sch. of Neurosci., Tel Aviv Univ., Tel Aviv, Israel

Abstract: The dentate gyrus (DG) in the hippocampus has two types of excitatory cells: granule cells, which are the main output cells from DG to CA3, and mossy cells, which reside in the hilus proper and provide recurrent connections to granule cells. To understand computation in the DG circuitry, it is important to unequivocally identify granule cells and mossy cells in terms of physiological characteristics. However, there is only a limited amount of knowledge regarding these issues to date. To address these questions, we performed large-scale recordings of local field potential (LFP) and unit firing from DG of freely moving mice combined with physiological and optogenetic identification of each cell type. For physiological identification, we used several parameters, including the spike width of the averaged waveform, the burst index based on the auto-correlogram, the ratio of the firing rates during awake to during slow wave sleep (SWS), and the amplitude of the dentate spikes types 2 (DS2) observed during SWS. By taking the DS2 amplitude at the exact recording site each unit was recorded, we estimated the anatomical location of each unit. Based on these parameters, we found two clusters of putative excitatory cells: one closer to the molecular layer and another closer to the hilus of DG. We detected putative monosynaptic connections between these units based on unit-unit cross-correlogram and found the significant spike transmission with 2-3 ms delay from units in the cluster closer to the molecular layer to units in the cluster closer to the hilus but not the other way. Considering the known strong synaptic connections from granule to mossy cells, we conclude that the two clusters correspond to granule cells and mossy cells, respectively. Optogenetic tagging using Drd2-Cre mice, which specifically label mossy cells in DG, confirmed that the hilus cluster corresponds to mossy cells. Based on this classification, we then

characterized the physiological properties of granule cells and mossy cells. We found that granule cells had lower firing rates compared to mossy cells, especially during awake periods . We also found that granule cells' firing rate is more strongly modulated by gamma oscillation and DS2 during SWS. Next, we characterized the spatial information coding by each cell type on a linear or a figure eight maze. Mossy cells had multiple place fields and higher peak firing rates, whereas granule cells typically had a single place field and lower firing rates. In summary, our results revealed the important differences between granule cells and mossy cells in terms of physiological characteristics and spatial information coding in behaving and sleeping mice.

Title: Neurogrid: high-frequency hippocampal-neocortical coordination

Authors: *D. KHODAGHOLY, J. N. GELINAS, G. BUZSAKI;
New York Univ. Langone Med. Ctr., New York, NY

Abstract: Large-scale recording from neural networks and their interactions are critical for understanding how information is processed and transmitted in the brain. Coupling between specific limbic and neocortical brain regions is implicated in aspects of memory acquisition, consolidation, and retrieval, but how these interactions are coordinated over topographically diverse functional networks during online task performance and in offline states is unclear. We designed and developed a large-scale array to cover most of the dorsal surface of rat cortex, allowing simultaneous recording from multiple cortical areas and improved localization of activity in higher order association cortices. The array consists of 120-384 electrodes arranged in clusters of 4 microelectrodes (20μm) for the purpose of spike recording and clustering. These clusters are spaced 200μm apart to cover an area shaped to match the dorsal cortical surface.Here

we examine large-scale hippocampal-neocortical interactions by simultaneous recording of local field potential (LFP) and spiking activity from a large part of the dorsal neocortical surface, from bregma to lambda, and hippocampus in freely moving rats. We identified a spatially confined, prominent high frequency oscillation (100-150 Hz) in posterior parietal cortex (PPC) that occurs mainly during NREM and waking immobility, and has similar waveform characteristics to hippocampal ripples. Furthermore, these oscillations appear to be coordinated with hippocampal ripples across behavioral states and during performance of a hippocampal-dependent memory task. This finding was facilitated by the scalability of our array, and establishes how this feature could be an important advantage in the design of neurophysiological experiments to understand functional topographic interactions among brain regions.

Title: Sustained effects of a lifelong closed loop control of absence epilepsy in rats

Authors: *G. KOZAK[1], A. BERENYI[2,3];
[2]Dept. of Physiol., [1]Univ. of Szeged, Szeged, Hungary; [3]Neurosci. Inst., New York Univ., New York City, NY

Abstract: Epilepsy affects 1% of the population worldwide. Despite the development of drug therapies, still one-third of the patients remain unresponsive to any currently available anti-epileptic drug. The aberrant brain activity, which occurs in epilepsy, in principle, can be restored through electrical stimulation. In epilepsy, abnormal patterns emerge intermittently, and therefore, a closed-loop feedback brain control that leaves other aspects of brain functions unaffected is desirable. Formerly, it has been shown by our group that seizure-triggered, closed-loop transcranial electrical stimulation (TES) can dramatically reduce the duration of spike-and-wave (SW) episodes in a rodent model of generalized epilepsy. The long-term effects of such approach however have not been investigated yet due to the technical challenges of the reliable continuous seizure monitoring, automated detection and stimulation. In this study we developed

a custom designed non-supervised FPGA-based closed loop system, which automatically detected the onset and the internal pattern of each seizure from ECoG signal, and delivered temporally targeted transcranial electrical pulses to disintegrate the seizure related oscillations. To evaluate the long term effects of this on-demand transcranial seizure interruption, we divided chronically implanted freely moving Long Evans rats into three subgroups: on-demand stimulation, random stimulation and no stimulation group. All stimulated rats received the treatment up to 3 months continuously. We found that our closed loop approach is effective in terms of seizure duration reduction, which effect was immediate and did not deteriorate over long time. The animals did not show any overt behavioural change due to treatment. These findings promote the closed loop control as a safe and reliable alternative for seizure suppression in drug resistant patients.

Title: Coordinated gamma inputs to CA1 place cells determine the strength of phase-precession

Authors: *A. FERNÁNDEZ RUIZ[1,2], A. OLIVA[1], G. A. NAGY[1], G. BUZSÁKI[2], A. BERÉNYI[1,2];
[1]Sch. of Medicine, Univ. of Szeged, Szeged, Hungary; [2]Neurosci. Inst. and Ctr. for Neural Science., New York Univ., New York, NY

Abstract: During the exploration of an environment most CA1 pyramidal cells fire in specific locations. These “place cells” have a plastic nature, varying their firing rate during successive

crossings through the same location. Another remarkable characteristic of hippocampal place cells is that in addition to this rate code they also express a temporal code. This temporal code exhibits a relationship between the position of the rat within the place-field and the timing of the place cell's spikes relative to the ongoing theta rhythm. This relationship arises from the gradual shift of cell firing to earlier phases of local theta oscillation as the animal travels through the place-field. It has been suggested that both intrahippocampal (CA3) and cortical (entorhinal -EC-) inputs contribute to place cell expression. However, the mechanisms by which those inputs interact or their relation with phase precession remains unknown.In previous work we developed a method to isolate CA3 and EC layer 3 (EC3) gamma inputs to the CA1 region in the behaving rat (Schomburg et al., 2014). We showed that EC3 fast gamma input (70 - 110 Hz) dominated at the theta peak and was followed by slower (30 - 60 Hz) CA3 input at the descending theta phase and a even faster (110 - 180 Hz) local gamma oscillation at the theta through. CA3 and EC3 inputs can compete or cooperate to modulate the firing of CA1 pyramidal cells and interneurons according to behavioral demands. In the present work we employed large-scale silicon probes (up to 512 channels) to record local field potentials (LFPs) and single-unit activity simultaneously in all hippocampal subfields during various navigational tasks and sleep. Most place cells displayed strong phase precession in the linear track. However a lap-by-lap analysis revealed that the magnitude of phase precession varied from trial-to-trial within a given session. The distribution of the relative strength of CA3 and EC3 gamma inputs to CA1 place cells followed a specific pattern along the place-field transversal. In the first half of the place-field, EC3 input dominated while CA3 input took over in the second half. This pattern was absent in laps without phase-precession. We propose that the coordination of CA3 and EC3 theta-modulated gamma inputs to CA1 place cells control the expression of phase-precession.

Title: Cortical read out of hippocampal neural sequences

Authors: *S. A. MCKENZIE, D. F. ENGLISH, G. BUZSÁKI;
NYUMC, New York, NY

Abstract: In the hippocampus, the order in which neurons fire maximally during movement is preserved on a faster time scales during active behavior and also during offline periods, such as sleep. However, the function of these sequences is unknown, in part due to a lack of information as to how downstream structures integrate such sequential activity. To address this issue, simultaneous recordings were performed in CA1 and its cortical output areas while spike timing of CA1 pyramidal cells was modulated on fine-time scales via focal ChR2 activation in behaving rats. First, in the absence of light stimulation, we observed tight coordination of sequences in CA1 and the subiculum during during linear track behavior. In both regions, sequences were organized by theta that began with representations of the track's beginning on the falling phase,represented current position at the trough and ended with the goal location at the rising phases. The degree of temporal compression varied as a function of distance away from these goals. Preliminary experiments show that low intensity, intra-hippocampal optical stimulation of pyramidal cell evoked local high frequency oscillations and cortical up states with spiking responses at a lag of about 70ms after CA1 stimulation. The efficacy of the cortical response correlated with the power and phase of cortical rhythms at the time of stimulation in the delta band and at 15-20 Hz. Surprisingly, stimulation of a second CA1 site before *or after* stimulation of the first blocked the cortical spiking response and upstate suggesting a competitive temporal or spatial summation downstream of the hippocampus. These results show that relative spike timing can strongly influence downstream spiking properties, a prerequisite for readout of endogenous sequences.

Abstract: Transcutaneous electric stimulation (TES) using weak currents has been used extensively in attempts to influence brain activity. In vitro and in vivo experiments in rodents and computational modeling suggest that the magnitude of voltage gradient of the induced electric field should exceed 1 mV/mm to directly influence brain networks. Evidence for direct neuronal effects of TES in the human brain is still lacking, mainly due to the saturation of the recording amplifiers by the large induced electromagnetic fields. For many therapeutic applications, it is desirable to affect neurons in a regionally constrained manner to reach maximum on-target effects and reduce side effects on unintended brain networks.
Here, we describe a spatially focused TES protocol, test it in rodents, determine the needed TES currents in human cadavers to achieve 1 mV/mm fields and demonstrate direct TES effects on alpha waves in human subjects. Using multiple site, rotating fast pulse (2.5 μs) stimulation, we demonstrate how transcranial electric fields can be focused to differentially activate single neurons in anesthetized rats. DC, AC and fast pulse stimulation was applied via Ag/AgCl electrodes directly to the skull or the scalp in human cadavers, while recording the three-dimensional distribution of electric fields in the brain, using >200 recording sites.
Scalp stimulation greatly reduced the generated intracerebral electric fields (>50% in cadavers)

and these measurements predicted that ~5 mA is needed to achieve 1mV/mm electric field gradient via scalp stimulation. Fast pulse stimulation allowed for simultaneous recording of scalp EEG in human subjects up to 9 mA. As predicted from the cadaver measurements, up to 4 mA stimulation failed to show detectable alterations but 7 mA and 9 mA integral-amplitude pulses significantly increased the amplitude of alpha waves. Currents above 4 mA stimulation induced multiple adverse effects, including dizziness, burning feeling and auditory effects.

Title: Coordinated reactivations in the hippocampus-amygdala networks during slow-wave sleep

Authors: *G. GIRARDEAU, I. INEMA, G. BUZSAKI;
New York Univ. Langone Med. Ctr., New York, NY

Abstract: The hippocampus and the amygdala are brain areas thought to be critical for emotional memory consolidation. The hippocampus processes episodic and spatial memories while the amygdala signals emotional valence related to fear and reward. However, it is unknown how the two structures interact to associate an emotional event to a specific context. Since hippocampal memories are reactivated and consolidated during slow-wave sleep (SWS),

we hypothesized that sleep-related coordinated reactivations in the hippocampus-amygdala networks might sustain the formation of contextual emotional memories.
To test this, we designed a novel task in which rats learn the daily location of an aversive airpuff on a linear track where they're running for water rewards. We recorded large hippocampal and amygdala neuronal ensembles during training and extensive periods of sleep preceding and following training.
Our results show coordinated reactivations of hippocampus and basolateral amygdala (BLA) ensembles during slow-wave sleep (but not REM-sleep) following training. Interestingly, the BLA cells that contribute most to the reactivations are the ones that are positively modulated during hippocampal ripples. These findings suggest that the consolidation of contextual emotional memories might involve coordinated reactivations in hippocampal-amygdala networks during SWS hippocampal ripples.

Title: Sharp wave ripples stabilize hippocampal spatial map during learning

Authors: *L. ROUX[1], B. HU[2], R. EICHLER[3], E. STARK[4], G. BUZSÁKI[1];
[1]NYU Med. Center, Neurosci. Inst., New York, NY; [2]Dept. of Physiol., Third Military Med. University, Col. of Basic Med. Sci., Chongqing, China; [3]Departments of Neuroinformatics and Neurophysiol., Radboud Univ. Nijmegen, Donders Ctr. for Neurosci., Nijmegen, Netherlands;

[4]Dept. of Physiol. and Pharmacol., Tel Aviv University, Sackler Fac. of Medicine, Sagol Sch. of Neurosci., Tel Aviv, Israel

Abstract: Replay of behaviorally-relevant spike sequences in the hippocampus during sharp wave ripples (SPW-Rs) is thought to provide a crucial mechanism for memory consolidation. Indeed, the compressed temporal scale of place cell reactivations, combined with the strong synchronous activity associated with SPW-Rs, provides an ideal setting for synaptic modifications. Yet the role of SPW-Rs in stabilizing the hippocampal network during learning has never been tested directly. To address this question, we used the spatial information coded by place cells: we reasoned that if SPW-Rs are necessary for the network stabilization, disrupting neuronal activity specifically during those events would result in an altered mental representation of space ("cognitive map"). Mice performed a spatial memory task requiring daily learning of three goal locations (hidden rewards) on a familiar multi-well maze (Dupret et al., 2010). Similar to previous studies, SPW-Rs occurred regularly during reward consumption at the goal locations. We used online position tracking, high-density extracellular recordings, closed-loop feedback, and optogenetic stimulation to selectively suppress pyramidal cell activity in the CA1 region contingent upon detection of awake SPW-Rs, specifically at the goal locations. Silicon probe recordings, combined with focal light delivery, allowed us to simultaneously record "SPW-R-silenced" and “control” place cells (non-illuminated/non-silenced and/or place cells silenced with a delay relative to SPW-R occurrence). Following learning, control place cells typically maintained the location of their place fields and showed a significant increase in their spatial information content. In contrast, the place fields of SPW-R-silenced place cells were modified after learning (“destabilized”), and the quantity of spatial information carried by these neurons was unaltered. SPW-R silencing did not impact the firing rates or the proportions of place cells. These observations indicate that SPW-R-associated neuronal activity is necessary to "refine" and maintain hippocampal place fields upon learning. SPW-Rs could thus play a dual role, promoting both change and stability in the cognitive map.

Title: Mapping rodent behavioral states onto the firing of dCA1 pyramidal cells

Authors: *J. D. LONG II[1], G. BUZSAKI[2];
[1]Neurosci. Inst., New York Univ., New York, NY; [2]Neurosci., New York Univ. Langone Med. Ctr., New York, NY

Abstract: The hippocampus is necessary for both episodic memory formation and spatial navigation. The central hypothesis of this work is that the unifying function of the hippocampus is to infer associations between sequences of behavior and their consequences. We predict neural correlates of specific behaviors exist within rodent dorsal CA1 hippocampus above and beyond spatial location and head direction. In this study, we utilized a cheeseboard maze, allowing the rats (n = 5) to form stereotyped, idiosyncratic behavioral plans while foraging for water reward. Next, the time-series of the subjects' behavioral output was quantified using a custom-made markerless motion capture system that generated accurate 3D kinematic tracking data of our subjects at 50 frames per second. Lastly, the behavioral states of the subjects were automatically identified using a unsupervised learning framework we have developed. This system enables us to calculate correlations between these behaviors and the time-series of neural data (all subjects were implanted with 6-8 shank silicon probes bilaterally in dCA1). We define behaviors as sequences of stereotyped dynamics in the kinematic data. We leverage recently developed techniques in machine learning to identify stereotyped dynamic features derived from the kinematic data (van der Maaten and Hinton 2008; Berman et al. 2014). To compose these features into models of behavior, we adapted the Bayesian Generative Model (BGM) framework of Lake et al. 2015 to our context. By first parsing the kinematic data into movement bouts, and then weakly labeling these with the learned features, BGMs were then used to leverage the statistics across all movement bouts to both improve the feature labeling and to produce parsimonious, quantitative compositions of the sequence of features making up a putative behavior. With this framework in place, we applied analysis methods in systems neuroscience to search for neural correlates of rodent behavior in dCA1 hippocampus. Reverse correlation is used to determine whether the firing of individual neurons map onto specific behaviors. Ensemble decoding techniques are used to determine whether information about the moment to moment variations in the subjects' behaviors reflected by the population activity. This ongoing research may offer new insights into the function of the hippocampus.

Title: Role of network functional connectivity in the formation of theta sequences

Authors: *C. DRIEU, R. TODOROVA, M. ZUGARO;
CIRB, Collège De France, Paris, France

Abstract: The hippocampus codes for spatial and episodic memories. Hippocampal 'place' cells are selectively activated in restricted locations of the environment ('firing fields'). Because firing fields overlap in space, as the animal traverses successive fields the spikes emitted by place cells appear intermingled in time. However, during single cycles (~100ms) of the theta oscillation (7-10Hz), these cells fire in a stereotyped order, paralleling the order of the fields within the trajectory. Such 'theta sequences' are thought to be related to episodic-like memory.
Two frameworks have been proposed to account for the formation of theta sequences. The first theory posits that sequences result from delays in propagation of spiking activity between asymmetrically connected cell assemblies. In the second model, external inputs trigger activity in independent cell assemblies. Due to phase precession, each assembly advances its firing in successive theta cycles, which results in theta sequences. Here, asymmetric connections between assemblies results from, rather than cause, theta sequences.
To test and contrast these hypotheses, we have passively transported rats on a model train ('passive' condition). As previously documented, this perturbed phase precession. In the control experiments, rats were trained to run on a miniature treadmill while transported on the train ('active' condition), a condition in which we have previously reported that cells phase precess and form theta sequences. We thus asked whether theta sequences would be disrupted in the passive condition. Place cells and LFP were recorded during three successive sessions: PASSIVE-1, ACTIVE, PASSIVE-2. We compared place cell spatial properties and dynamics between the three conditions.
Spatial specificity and theta modulation of place cell activity decreased during both passive sessions compared to the active session. Fields often shifted between PASSIVE-1 and ACTIVE, but subsequently remained stable between ACTIVE and PASSIVE-2. The proportion of significant theta sequences increased two-fold during ACTIVE compared to PASSIVE-1. This

appears inconsistent with the notion that pre-established connectivity between cell assemblies underlies theta sequences. Intriguingly, we found a similar difference between ACTIVE and PASSIVE-2. The sequences formed during ACTIVE were not stabilized and preserved during the subsequent passive session, an observation at odds with the idea that theta sequences would induce changes in synaptic connectivity between cell assemblies. Thus, our results so far appear at least partly inconsistent with both theoretical models of theta sequences.

Title: Optogenetically assisted identification of spike transmission between pyramidal neurons and interneurons *In vivo*

Authors: *D. F. ENGLISH[1], S. MCKENZIE[1], K. KIM[2], E. YOON[2], G. BUZSAKI[1]; [1]Neurosci., NYU Neurosci. Inst., New York, NY; [2]Electrical Engin. and Computer Sci., Univ. of Michigan, Ann Arbor, MI

Abstract: Hippocampal microcircuits have been the subject of intense investigation for decades. A major goal is to understand the cellular-synaptic mechanisms of precise spike timing of hippocampal neurons, which is required for temporal coding. One such mechanism is the spike transmission between pairs of neurons. Studies of synaptic and spike transmission between identified presynaptic and postsynaptic neurons are typically performed in reduced preparations such as acute brain slices. In vivo studies typically sacrifice control of neuronal activity with single cell resolution in order to study an intact system. In such *in vivo* experiments synaptic coupling can be observed as short (1-2ms) latency peaks in spike train cross-correlations between PYR and INT. However, these findings are limited by the fact that common inputs to both the PYR and INT could underlie part of the fast time-scale peak. This technical shortcoming

can now be overcome due to recent advances in high-channel count silicon probes equipped with blue light emitting micro-LEDs (Si-uLED probe; Wu et al. 2015) which can be combined with optogenetics to maintain the benefits of an *in vivo* preparation while gaining single cell control and identification. We took advantage of this technology to investigate monosynaptic interactions between pyramidal neurons (PYR) and GABAergic interneurons (INT) in the CA1 region of the hippocampus in freely sleeping and behaving mice. To disengage the PYR spiking from network activity and thus common input we optically elicited spiking in PYR using CaMKII:ChR2 mice and quantified the strength of spike transmission in pairs of PYR and INT. Preliminary data demonstrate that both spontaneous and experimentally induced PYR spikes drive spiking in postsynaptic INT at monosynaptic latencies. Future experiments will determine the dynamic range and temporal dynamics of these connections and their regulation by brain state and behavioral conditions. Abstract: Sharp-wave ripples (SPW-Rs) are network oscillations in the mammalian hippocampus that are implied in memory consolidation as shown by observational and interventional experiments. However, the mechanism of their generation remains unclear. SPW-R complex consists of two components: the sharp wave (SPW) and the ripple. The sharp wave is a negative deflection in the extracellular potential that reflects the depolarization of the apical dendrites of CA1 pyramidal cells as a result of the synchronous discharge of the CA3 axonal input to those dendrites, and a ~140 Hz ripple at the pyramidal cell body layer representing a network response of CA1 pyramidal cells and interneurons to the strong synchronous drive. While the CA3 region has been implicated in the generation of the SPWs, the role the adjacent CA2 region has been neglected so far. However, the CA2 region mirrors some aspects of CA3: the recurrent collaterals of CA2 pyramidal neurons are as dense as those of CA3a neurons, and CA2 also innervates CA1, leaving open the possibility that CA2 could be involved in ripple generation as well. In this study we examined whether the activity of CA2 region plays a role in SPW-R burst initiation, which has not been investigated until now. We employed high-density silicon-probes (256 channels) to record both LFP and unit firing from all layers of the CA1-CA2-CA3 regions in the dorsal hippocampus in rats during behavior and sleep. The location of the CA2 region was assessed by immuno labeling using the CA2-specific marker PCP4. We found that synchronous activation of neuronal ensembles in the CA2 region preceded SPW-R-related population activity in CA3 and CA1 regions. Deep CA2 neurons showed a gradual increase in activity prior to ripples and become strongly suppressed whenthe population activity built up in CA3-CA1 neurons (*ripple ramp cells*). Superficial CA2 cells organized into a population burst prior to the activity surge in CA3-CA1 (*phasic cells*). The population activation spreads through CA3b and c and finally to CA1 stratum radiatum where it elicits an excitatory SPW. Although CA2 neurons contribute to SPW-Rs during both sleeping and waking, their contribution to wake events is stronger. These results implicate the CA2 region as an initiation zone of SPW-Rs. Title: Interictal epileptiform discharges induce hippocampal-cortical coupling in temporal lobe epilepsy

Authors: *J. GELINAS, D. KHODAGHOLY, O. DEVINSKY, G. BUZSAKI;
New York Univ., New York, NY

Abstract: Interactions between the hippocampus and the cortex are critical for memory. Interictal epileptiform discharges (IEDs) identify epileptic brain regions and can impair memory, but the mechanisms by which they interact with physiological patterns of network activity are mostly undefined. We show in a rat model of temporal lobe epilepsy that spontaneous hippocampal IEDs correlate with impaired memory consolidation, and that they are precisely coordinated with spindle oscillations in the prefrontal cortex during nonrapid-eye-movement (NREM) sleep. This coordination surpasses the normal physiological ripple-spindle coupling and is accompanied by decreased ripple occurrence. IEDs also induce spindles during rapid-eye movement (REM) sleep and wakefulness—behavioral states that do not naturally express these oscillations—by generating a cortical 'down' state. In a pilot clinical examination of four subjects with focal epilepsy, we confirm a similar correlation of temporofrontal IEDs with spindles over anatomically restricted cortical regions. These findings imply that IEDs may impair memory via the misappropriation of physiological mechanisms for hippocampal-cortical coupling, which suggests a target for the treatment of memory impairment in epilepsy.

Title: Transformation of head-direction signal into spatial code

Authors: *A. PEYRACHE[1,2], G. BUZSAKI[2];
[1]Montreal Neurolog. Inst. and Hosp., McGill Univ., Montreal, QC, Canada; [2]Neurosci. Inst., New York Univ. Med. Ctr., New York, NY

Abstract: The head-direction (HD) system forms the building block of the navigation system. Spatial coding, represented for example by place and grid cells, must result from the integration of multiple sources of information, distributed over large class of sensory features, in particular vestibular signals. The mechanisms enabling such computation remain largely unknown. It is often assumed that the HD signal is primarily used, along with speed information, to update the estimate of the current location by path integration. Here we show that the HD signal may be transformed directly into a spatial code under behavioral constraints. In the antero-dorsal nucleus of the thalamus, relaying the signal to the cortex, HD neurons convey high level of spatial information that results from behavioral bias during exploration. In the post-subiculum, the main cortical stage of HD signal processing, the amount of spatial information conveyed by HD neurons is increased by the combination of the HD signal with other sensory modalities. In addition, the hippocampus may receive direct sensory inputs from the HD system, thus participating directly in the generation of a spatial code. These findings demonstrate a simple integration principle in the navigation system that transforms vestibular inputs into spatial information.

Title: Exploration of Hippocampal-Lateral Septal interactions across behavioral states

Authors: *D. TINGLEY[1,2], G. BUZSÁKI[2];
[1]New York Univ., New York, NY; [2]NYU Neurosci. Inst., New York, NY

Abstract: Relative to other major output structures of the hippocampal formation (HPC) the lateral septal complex (LSC)- its function, behavioral correlates, and physiological relationship with HPC - remains to a great extent unexplored. Lesion, anatomy, and a handful of *in vivo* physiology experiments have demonstrated that the LSC plays a role in contextual, social, and affective aspects of cognitive function. Here we investigate the role of the lateral septum in navigation and contextual encoding with simultaneous HPC/LSC in vivo recordings. LSC neurons were phase-locked to the theta rhythm and modulated by hippocampal sharp wave ripples. High frequency oscillations (80-160 Hz) were also present in the LSC local field potential, were accompanied by an increase in LSC firing rates, and traveled in a directional manner within LSC. Surprisingly, a large number of HPC/LSC neuron pair cross-correlograms showed suppressed spiking with a ~20-40 millisecond delay, suggesting that HPC output has an indirect inhibitory effect on LSC activity, possibly through feedforward inhibition. During goal directed spatial navigation a subset of LSC neurons showed a novel form of phase precession relative to HPC theta oscillations. They precessed over long segments of maze runs (up to 3 meters), were independent of the heading and velocity of the animal, and were not accompanied by large firing rate changes. An additional subset of LSC neurons were found to be strongly modulated by a specific local context, independent of allocentric location and distal cues. These neurons fired almost exclusively when the animal occupied its home cage, and were greatly suppressed during exposure to novel environments (with or without task demands), familiar environments (up to one month of daily exposure), and home cages with clean bedding or the bedding from other rats. These data suggest that certain contexts may hold privileged neural representations in the LSC. Experiments in progress will continue to investigate the mechanisms underlying these phenomena and whether they reflect local computations, or interactions with other structures such as the hippocampal formation.

Title: Selective hippocampal-accumbal plasticity is a key substrate of cocaine conditioned place preference

Authors: *L. L. SJULSON, A. CUMPELIK, D. CASSATARO, G. BUZSÁKI;
NYU Sch. of Med., New York, NY

Abstract: Cocaine conditioned place preference (CPP) is one of the simplest models of a cocaine-addiction related behavior, but its underlying neural mechanisms are not understood. To test the hypothesized role of plasticity of the projection from hippocampus to nucleus accumbens, we performed simultaneous dual site silicon probe recording in mice undergoing a cocaine CPP protocol. Our results suggest that CPP is associated with selective strengthening of hippocampal-accumbal synapses arising from place cells encoding the cocaine-paired location. Further preliminary results suggest differential effects of synapses onto D1- vs D2-positive cells in accumbens, as well as behavioral evidence indicating a causal role for this plasticity in CPP.

Title: Unit and field potential changes in rats after antidepressant dose ketamine

Authors: *B. O. WATSON[1], J. P. GREENE[2], M. DING[3], G. BUZSAKI[4];
[1]Weill Cornell Med. Col., New York, NY; [2]Univ. of Chicago, Chicago, NY; [4]Neurosci. Inst., [3]New York Univ., New York, NY

Abstract: Low dose ketamine has gathered interest as a rapid-acting antidepressant with efficacy on many patient groups including those with unipolar, bipolar and treatment resistant-depression. Here we explore the neurophysiologic correlates of anti-depressant dose ketamine in rats using silicon probe recordings in the dorsal hippocampus and frontal cortical regions. Clinical findings indicate that ketamine may work with a truly unique mechanism of action relative to other antidepressant treatments. Firstly it is known to have unique pharmacologic properties since it acts as an NMDA antagonist, an opioid receptor agonist and has cholinergic and dopaminergic effects among others. Perhaps more importantly, it is able to alleviate depressive symptoms within hours and that effect lasts for days. Understanding the mechanism of action of this uniquely effective medication has the potential to teach us a great deal about depression treatment approaches fundamentally. We have given 10mg/kg ketamine intraperitoneally to 7 adult male Long Evans rats while recording from frontal cortex and dorsal hippocampus. We find that during the period immediately following ketamine animals are hyperlocomotive for 25-45 minutes each before reliably going to sleep. During the period of hyperactivity we see increased average spike rates among both putative excitatory and putative inhibitory neurons. This is in contrast to published findings from similar experiments using other NMDA antagonists (1). In many cases we see specific subsets of neurons that are particularly responsive to ketamine. We also see increased gamma oscillatory power. We observe a temporary increase in the coefficient of variation of population firing rates, decreased bursting activity and an increase in excitatory-to-inhibitory ratio. However, none of these changes deviate from what would be predicted simply by the increase in locomotion by the animal, given the relationship between each of these metrics and times of movement. It is possible that persistent elevated activity in the frontal cortex lasting ten of minutes is a mechanism itself for network change due to ketamine, consistent with optogenetic stimulation results (2).

Title: Near-critical dynamics in stimulus-evoked activity of the human brain and its relation to spontaneous resting-state activity

Authors: *O. SHRIKI[1], A. GOLDSTEIN[2], O. ARVIV[2];
[1]Ben-Gurion Univ., Beer-Sheva, Israel; [2]Bar-Ilan Univ., Ramat-Gan, Israel

Abstract: In recent years, numerous studies have found that the brain at resting-state displays many features characteristic of a critical state. Here we examine whether stimulus-evoked activity can also be regarded as critical. Additionally, we investigate the relation between resting-state activity and stimulus-evoked activity from the perspective of criticality. We found that cortical activity measured by MEG is near critical and organizes as neuronal avalanches at both resting-state and stimulus-evoked activities. Moreover, a significantly high intra-subject similarity between avalanche size and duration distributions at both cognitive states was found, suggesting that the distributions capture specific features of the individual brain dynamics. When comparing different subjects, a higher inter-subject consistency was found for stimulus-evoked activity than for resting-state. This was expressed by the distance between avalanche size and duration distributions of different participants, and was supported by the spatial spreading of the avalanches involved. During the course of stimulus-evoked activity, time-locked to the stimulus onset, we demonstrate fluctuations in the gain of the neuronal system, and thus short time-scale deviations from the critical state. Nonetheless, the overall near-critical state in stimulus-evoked activity is retained over longer time-scale, in close-proximity and with a high correlation to spontaneous (not time-locked) resting-state activity. Spatially, the observed fluctuations in gain manifest through anti-correlative activations of brain sites involved, suggesting a switch between task-negative (default mode) and task-positive networks and assigning the changes in excitation-inhibition balance to nodes within these networks. Overall, this study offers a novel outlook on evoked activity through the framework of criticality.

Title: Oscillations and neuronal avalanche shape in spontaneous cortical activity

Authors: ***S. R. MILLER**[1,2,3], S. YU[3], D. PLENZ[3];
[1]UMCP, Washington, DC; [2]Inst. for Physical Sci. and Technology, Biophysics, Univ. of Maryland Col. Park, College Park, MD; [3]Lab. for Systems Neurosci., Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Spatiotemporal synchronization in the form of phase-locked gamma oscillations (i.e. at a time scale of ~30 ms) has been robustly found during cortical processing. Such synchronization based on oscillations seems in apparent contradiction to an alternative form of spatiotemporal synchronization consistently identified as neuronal avalanches. Avalanches are intermittent spatiotemporal bursts of activity governed by power laws and thus lack spatial or temporal scale. Previous work demonstrated that the power law in avalanche sizes embeds the waxing and waning of nested cortical oscillations (Gireesh and Plenz, 2008). However, the temporal domain of avalanches and its relation to oscillations has not been addressed. Here, we utilize a shape collapse function, which tests for scale-invariance in avalanche shapes of different durations, and relate the quality of this collapse to gamma oscillations.
Ongoing local field potential (LFP) fluctuations were recorded in three awake Macaque monkeys, each with two chronically implanted high-density arrays in superficial cortex (10x10 electrodes; 400 μm interelectrode distance; 2 premotor, 4 prefrontal). During recordings the monkeys were sitting alert without performing any particular task (26 hours total; ~4 hrs/array; 4 - 23 recording sessions distributed over 5-74 days). LFPs (1 - 100 Hz) were thresholded (-2 SD) for each electrode and assembled into peak LFP time rasters (>70 channels/raster). Avalanches were extracted at successively increasing time bins Δt (0.5 ms - 30 ms). For each temporal resolution, avalanche size and duration distributions were calculated, shapes were averaged by duration, and the collapse function was optimized with respect to the scaling exponent.
Our two main findings suggest gamma oscillations provide a specific temporal scale to neuronal

avalanches. First, critical exponents calculated from avalanche probability distributions underestimated theoretical values, yet were a better predictor than theory for the collapse-optimized scaling exponent. Second, prominent oscillatory activity was associated with heterogeneous avalanche shapes and a failure of shape collapse. This result was found only for the range of temporal resolutions (2 ms < Δt < 15 ms) that resolved multiple gamma-cycles without overly coarse-graining fine LFP waveform features. We thus conclude that the cortex is able to balance oscillations with avalanche activity. In particular, gamma oscillations leave an 'imprint' on the lifetime distribution of avalanches when studied at gamma-resolvable scale, but not otherwise.

Title: Avalanche dynamics during processing of visual stimuli in the awake mouse

Authors: *T. L. RIBEIRO[1], S. SESHADRI[1], J. MISHLER[1], D. WINKOWSKI[2], P. KANOLD[2], D. PLENZ[1];
[1]Section on Critical Brain Dynamics LSN/NIMH, NIH, Bethesda, MD; [2]Dept. of Biol., Univ. of Maryland, College Park, MD

Abstract: Neuronal avalanches are spatiotemporal clusters of activity that propagate in superficial cortical layers. They have been considered evidence of critical dynamics as their sizes, defined as the number of neurons composing the cluster, are power-law distributed and therefore scale-free. In theory, criticality optimizes stimulus sensitivity, information transmission, computational capability, and mnemonic repertoires size. Yet, the stability of this dynamical regime during external stimulus remains unanswered. Here we study the role of functionally different sub populations, in particular cells with different orientation preference in the primary visual cortex (V1), in avalanche dynamics.We employed two-photon imaging to measure spiking activity in pyramidal cells from V1 of head-fixed mice positioned on a running wheel. Viral-injection into cortical layer 2/3 of wild-type mice resulted in robust expression of the genetically encoded calcium indicators (GECIs) YC2.6 or GCaMP6s after about 2 weeks. A chronic cranial window was centered over V1 and mice were subjected to passive viewing of drifting bars at 16 angles (4 s each, randomly chosen) at maximum contrast interspaced by 4 s of a gray screen. During stimulation, mice could self-initiate locomotion. Pupil diameter was

assessed continuously to measure the animal's state of arousal. About 70 neurons were recorded consistently in a ~560 x 560 μm area at a frame rate of ~30 Hz. Spiking increased moderately during locomotion and sub populations of neurons were identified to have preferred orientations. We analyzed neuronal avalanche statistics in those populations with and without visual stimulus present, separating periods according to state of arousal. Power law statistics was found to be robustly maintained during stimulation independent of orientation. When directionally selective neurons were analyzed separately we also observed power law statistics, similarly to what was seen for non-selective cells. Strikingly, these results remain even when only periods of stimulation are considered for the analysis, regardless of the specific orientation presented. In conclusion, neurons responsible for processing different characteristics of a visual stimulus follow the same dynamical rules as those which do not respond to that same feature.

Title: Leveraging iPSC-derived cortical neurons harboring known epilepsy mutations to advance personalized medicine

Authors: *C. B. CARLSON, M. MCLACHLAN, B. MELINE, C. MCMAHON, T. BURKE, S. DELAURA, E. JONES, K. MANGAN;
Cell. Dynamics Intl., Madison, WI

Abstract: Epilepsy is a neurological condition caused by disturbances in the electrical activity of the brain manifested through multiple etiologies. Over 65 million individuals suffer from epilepsy and one-third of these individuals live with uncontrollable seizures because there are no known pharmacological treatments to date. A portion of this population is accounted for by single-gene epilepsy disorders resulting from mutations within sodium, potassium, or inhibitory ion channels. With recent advances in personalized medicine, there is hope not only for diagnosis but also for treatment options for these individuals. Central to this vision is induced pluripotent stem (iPS) cell technology, which provides a platform to increase our understanding of how single-gene mutations result in disease states. Here we illustrate how human iPS cell-derived cortical neurons can be used to highlight the "disease-in-a-dish" approach to drug development and can act as a springboard to discovering new therapies. We have genetically engineered iPS

cells with single-gene mutations that result in Dravet Syndrome (SCN1A knockout), autosomal-dominant nocturnal frontal lobe epilepsy (KCNT1 P924L) or childhood absence epilepsy (GABRG2 R43Q). Human cortical neurons were derived from these iPS cell lines and the resulting phenotypes were examined by various methods. Here we present morphological data (neurite outgrowth and branching) and functional data (electrophysiological MEA or calcium flux) comparing "healthy" (wild-type) vs. edited (SCN1A, KCNT1, or GABRG2 mutations) neurons illustrating hyperactive phenotypes correlated to the epileptic genotypes. Furthermore, we show examples of selective pharmacology that attenuates these observed "epileptic" phenotypes. The ability to engineer isogenic wild-type and disease-associated alleles by genome editing of human iPSC-derived neurons provides unprecedented access to in vitro models of neurological disorders. Collectively our results showcase how iPSC technology can be leveraged in the personal medicine space.

Title: Altered expression of KCC2 in GABAergic interneuron contributes prenatal stress-induced epileptic spasms in infant rat

Authors: H. KWON[1], *J. KANG[2], H. BAEK[3], J. PARK[3], D. KIM[4];
[1]Med. science, [2]Pediatrics, [3]Physiol., [4]Anat., Chungnam Natl. Univ., Daejeon, Korea, Republic of

Abstract: Long-term stress during pregnancy causes neurologic deficits to offspring with altered gamma-aminobutyric acid (GABA) system in the brain. However, it is not clear how prenatal stress affects the maturing GABAergic interneurons and the resulting abnormalities in infantile

seizures. Here, we showed that prenatal stress alters the maturation of GABA inhibitory system using a seizure model induced by prenatal stress. Prenatal stress with betamethasone or acute immobilization stress (AIS) on gestational day 15 increased the seizure susceptibility to N-methyl-D-aspartate-triggered spasms on postnatal day 15. The expression of GABA was lower in the prenatally stressed group, which compromise the decrease of glutamate decarboxylase 67-immunopositive cells. Prenatal stress markedly decreased the expression of K^+/Cl^- co-transporter (KCC2) in the cortex. GABA induced membrane depolarization demonstrated prenatal stress models had significant higher membrane depolarization compared to control. GABA increased KCC2 expression in cultured cortex-containing slices. Taken together, our results showed that prenatal stress with betamethasone or AIS altered the maturation of GABAergic progenitors and resulted in the lack of GABA input, which in turn, decreased KCC2 expression and lowered seizure threshold. We conclude that delayed GABA excitatory/inhibitory shift would render the cortical neuronal circuit more susceptible to excitatory input in prenatal stress induced seizure.

Title: The role of tonic inhibition in shaping the firing characteristics of cortical pyramidal neurons in the y2R43Q mouse model of absence epilepsy

Authors: *J. A. PFAMMATTER, C. P. MAHANT, M. V. JONES;
Neurosci., Univ. of Wisconsin Madison, Madison, WI

Abstract: Absence epilepsy involves generalized spike-wave discharges (SWDs) concurrent with behavioral arrests. One cause of absence epilepsy is a mutation in the γ2 subunit (γ2R43Q) of the $GABA_A$ receptor. Although the mechanism remains unknown, 'tonic' inhibition (TI), a constant hyperpolarization of neurons by extrasynaptic GABA that regulates neuronal firing, may play an important role. We previously showed that this mutation results in a reduction of $GABA_A$ receptor subunits that mediate TI in the cortex and thalamus of C57Bl6 γ2R43Q knock-in mice (RQ), and these mice lack tonic inhibition in these regions. We also previously showed that low dose ganaxolone, a selective potentiator of δ subunit-containing $GABA_A$ receptors, can exactly restore the TI missing in RQ cortical cells and reduce SWD frequency, and L655,708, an

inverse agonist of α5 subunit-containing $GABA_A$ receptors, can decrease TI in cortical cells of wild type mice (RR) and causes SWDs. We thus hypothesize that layer II/III pyramidal neurons of RQ somatosensory cortex, which lack TI, will have altered firing properties when stimulated with current steps in patch-clamp experiments. We further predict that restoration of TI in pyramidal neurons of RQ mice, with ganaxolone will restore normal firing properties, whereas blocking TI in RR neurons with L655,708 will partially mimic the firing properties in RQ mice. Preliminary results confirm that pyramidal cells in the cortex of RR mice (n=7) have a 6.4±0.4pA (mean±se) tonic current that is reduced to 1.45±0.52pA in RQ cells (n=6; $p \leq 0.012$). Surprisingly, RQ pyramidal cells regularly fired fewer action potentials (maximum 10.2±1.7; n=20) than RR cells (14.8±2.9; n=17; $p<0.19$) in response to current steps ranging from -100 to 300pA, although this result was not significant. Additionally, the duration of action potentials (width at half maximum) trended towards being longer in RR cells (3.98ms) than in RQ cells (2.92ms) at the current which elicited half-maximal spiking ($p<0.092$). Preliminary results are confounded by high cell-to-cell variability, possibly due to heterogeneity of recorded cell types. Ongoing efforts to more effectively compare RR and RQ cells involve paired measurements of cell responses before and after the addition of drug and immunofluorescent categorization of cell types. Ultimately, a better understanding of the role of the loss of TI in pyramidal cell function will help us understand the mechanisms underlying absence epilepsy in patients with compromised inhibition.

Title: Epilepsy and behavioral comorbidities in a zebrafish model for Dravet syndrome

Authors: *B. GRONE, S. C. BARABAN;
Dept. of Neurolog. Surgery, Univ. of California, San Francisco, San Francisco, CA

Abstract: Dravet syndrome (DS) is a catastrophic epilepsy of childhood caused by mutations in SCN1A, a voltage-gated sodium channel. In addition to early-life generalized seizures, comorbid

conditions such as movement disorder, sleep disturbance, anxiety, early fatality and cognitive decline are common. To study the functional consequences of SCN1A mutations, we use zebrafish with a loss-of-function mutation in *scn1lab*, one of two zebrafish *scn1a* gene paralogs. Homozygous *scn1lab*$^{s552/s552}$ mutant larvae exhibit early-life seizures, metabolic deficits, and early death. In order to establish zebrafish as a model for quantifying comorbid conditions in DS, we carried out a battery of *in vivo* assays with *scn1lab*^{s552} mutants between 3 and 6 days post-fertilization (dpf). To study motor activity during a seizure, we used high-speed video imaging with simultaneous EEG recording in head-fixed zebrafish. In mutants (n=8), long-duration ictal events were associated with high-velocity, complex sinusoidal tail deflections >50 degrees and lasting 600-1200 msec; interictal events were associated with briefer tail movement and smaller angle deflections. To study anxiety, we used locomotion tracking to monitor exploratory behavior an open field arena. Mutants exhibited significantly impaired exploratory behavior, with increased time spent freezing and time spent in the periphery. To evaluate nighttime arousal disturbances, we tracked larvae in 96-well plate format for 24 hours. Locomotor activity during night (sleep phase) was higher in mutants compared to controls. To assess cardiac function, we measured heart rate using video recordings. No significant differences in heart rate compared to controls were observed. We also quantified the distribution of onset of fatality, which occurs in the first 14 days postfertilization. Our results demonstrate conserved features of movement disorders, anxiety, sleep disturbances, and early fatality in *scn1lab* mutant zebrafish.

Title: Optogenetic kindling of neocortex elicits seizures

Authors: *E. CELA[1,2,3], A. CHUNG[1], T. WANG[1], P. J. SJÖSTRÖM[1,2];
[1]Neurol. and Neurosurg., Montreal Gen. Hosp., Montreal, QC, Canada; [2]Ctr. for Res. in Neurosci., Montreal, QC, Canada; [3]Integrated Program in Neurosci., Montreal, QC, Canada

Abstract: How seizures arise in the otherwise healthy brain remains poorly understood. One way of addressing this is to unravel the circuit changes that are associated with seizure initiation. To this end, we sought to test the hypothesis that seizures can eventually be initiated in healthy mice solely by repeatedly driving pathological activity in a genetically defined subset of neocortical pyramidal cells. We developed a novel kindling paradigm based on repeated optogenetic stimulation of primary motor cortex (M1). Channelrhodopsin-2 (ChR2) was expressed in M1 of male C57BL/6J mice by stereotactically injecting AAV-CaMKIIa-hChR2-E123T/T159C-p2A-EYFP bihemispherically. After 21 days of recovery and ChR2 expression, animals were kindled by repeatedly illuminating M1 in 3-second-long 50-Hz burst every 48 hours using a 445-nm laser. Animals were monitored by EEG and video during each session. We observed seizures eventually occurring in 6 out of 6 animals after 13 sessions. Seizures were defined as EEG power exceeding background levels by two standard deviations for longer than 3 seconds. We quantified their duration using EEG recordings, and severity using a modified Racine scale. We found that seizure duration ($r=0.52$, $p<0.001$, $n=4$), severity ($r=0.59$, $p<0.001$, $n=4$), as well as the number of seizures ($r=0.48$, $p<0.001$, $n=6$) increased with session, while seizure threshold was decreased ($r=-0.59$, $p<0.001$, $n=4$). We next examined if animals retained their seizure susceptibility after being unstimulated for 36 days. Indeed, after pausing stimulation, seizures had higher Racine scores ($p<0.05$, $n=5$) and lasted longer ($p<0.01$, $n=4$) than sessions preceding the stimulation hiatus. The seizure threshold ($p<0.01$, $n=4$) as well as the number of sessions prior to the first seizure was reduced ($p<0.05$, $n=4$). Finally, preliminary immunohistology for NeuN and GFAP indicated that there was no gross neuronal damage nor appreciable glial activation near the injection site.
In summary, our results show that optogenetic stimulation of a small part of neocortex is sufficient to evoke seizure activity in healthy animals. In line with classical kindling findings, we found an elevated retention of seizure susceptibility in kindled animals, a decrease in threshold for seizure activity, and worsening seizure severity, as well as increased seizure duration over time. These results appear to have arisen in the absence of gross brain damage. We anticipate that optogenetic kindling may be incorporated as a new means to selectively examine the contributions of specific cell populations to epileptogenesis.

Title: Innervation of adult-born dentate granule cells by GABAergic transplants in mice with temporal lobe epilepsy

Authors: *J. GUPTA[1], J. RADELL[1], M. BROMWICH[1], S. GONZALEZ[1], B. W. LUIKART[2], G. AARON[1], J. R. NAEGELE[1];
[1]Biol., Wesleyan Univ., Middletown, CT; [2]Dartmouth Col., Lebanon, NH

Abstract: Medial ganglionic eminence (MGE)-derived GABAergic progenitors transplanted into the dentate gyrus of mice with pilocarpine-induced temporal lobe epilepsy form functional inhibitory synapses onto dentate granule cells (GCs), suppress spontaneous seizures, and improve cognitive impairments (Henderson, Gupta, et al 2014; Hunt et al. 2013; Cunningham et al. 2015). While hippocampal MGE transplants have been shown to synapse with host brain hippocampal neurons, little is known about the neuronal identities of the target cells. Considerable evidence has shown that pilocarpine-induced seizures augment adult neurogenesis in the dentate gyrus, resulting in populations of hyperexcitable, adult-born GCs that hypertrophy, migrate aberrantly, sprout recurrent mossy fibers and form dysmorphic dendrites. In this study, we examined in mice with pilocarpine-induced temporal lobe epilepsy whether hilar transplants of GABAergic interneurons wire selectively with adult-born GCs. Retroviral (pRubi mCherry) labeling was used to identify adult-born GCs at 1, 6 or 12 weeks after status epilepticus. Synaptic inhibition onto these cells by the transplanted interneurons was tested optogenetically in combination with whole cell voltage-clamp electrophysiology and high-resolution images were obtained after biocytin staining. IMARIS 3-D neuron reconstruction software was used to examine the morphology of the adult-born GCs with synaptic connections from the transplants. We found strong transplant-mediated innervation of cells born at 1 week, 6 weeks, and 12 weeks after status epilepticus. The amplitudes of these inhibitory currents correlated with the number of transplant-derived boutons on the recorded granule cells. Innervation by transplant was also associated with changes in dendritic branching pattern as shown by a significant difference in the number of branch points per unit dendritic length (6.32 branch points per 1000 μm dendritic length in cells innervated by transplant vs. 8.15 in cells not innervated by the transplant; $P < .05$). Changes in branching pattern were also revealed by Sholl analysis where neurons that received synaptic innervation from the transplanted interneurons were significantly less branched than non-innervated cells at 20 μm and 30 μm away from their somas ($P < .05$). However, from 120 to 160 microns away from the soma, cells innervated by the transplant were significantly more highly branched than non-innervated cells ($P < .05$). These results indicate the ability of MGE-derived transplanted interneurons to not only provide synaptic inhibition to adult-generated GCs but also lead to alterations in their branching patterns.

Title: Investigating the neuroprotective mechanisms of potential anti-epileptic drug, canabidiol at specific cell-types in healthy and epileptic models

Authors: *A. KHAN[1], T. SHEKH-AHMAD[2], A. KHALIL[2], M. WALKER[2], A. B. ALI[1];
[1]Sch. of Pharm., [2]Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: Non-psychoactive, phytocannabinoids such as Cannabidiol (CBD) are potential anti-epileptic drugs (AED). CBD has given hope for patient groups with uncontrollable epilepsy where other drug treatments have failed, despite the lack of knowledge of the long-term side-effects. To better understand the neuro-protective functions of CBD at identified CNS neurons, we investigated the neuroprotective effects and mechanisms of actions of CBD using in vitro and in vivo models of epilepsy.
Using immunoperoxidase staining the anatomical distribution of two major classes of interneurons, cholecystokinin (CCK) and parvalbumin containing (PV) were determined in healthy and epileptic (post kainic acid) rats.
There was a reduction in the densities of both PV and CCK interneurons, and both cell-types showed distorted morphology in the epileptic model. However, following CBD (100mg/kg) treatment at zero time and 90 mins post status epilepticus, there was a reduction in cell pathology, suggesting that CDB served as a neuro-protective agent. These observations were consistent with electrophysiological whole-cell recordings which showed a decrease in hyper-excitability of principal neurons, whilst selectively enhancing inhibitory interneuron function in the KA and in the Mg2+ free in vitro models of epilepsy.
In summary, the data suggest CBD has a cell-type specific alteration of intrinsic properties of neurons in healthy and epileptic brains. CBD also rescues altered morphological properties of different interneuron subtypes in epileptic brains.

Title: Enhanced output from somatostatin interneurons in malformed cortex

Authors: N. EKANEM[1], N. M. WESTON[1], L. K. REED[1], *K. M. JACOBS[2];
[1]Anat. & Neurobio., [2]Virginia Commonwealth Univ., Richmond, VA

Abstract: Medically-intractable epilepsies are often associated with cortical malformations. One common form is microgyria, having multiple small folds with underlying irregular lamination in place of normal gyri. Neonatal transcranial freeze lesions in rodents mimic this histopathology and the associated epileptiform activity. Using this model, we have previously shown that in malformed cortex, somatostatin interneurons (SS) fire at increased frequencies in response to depolarizing current and have 3X the normal amount of excitatory synaptic input. Here we bred mice to contain Channelrhodopsin selectively in SS in order to examine the level of output from these neurons. We hypothesize that in malformed cortex hyperactive SS contribute to epileptiform activity via synchronization of columnar activity or via network dis-inhibition through their synaptic contacts onto other inhibitory interneurons. Whole cell patch clamp recordings were made in ex vivo slices from layer V pyramidal neurons adjacent to the microgyrus (paramicrogyral region, PMR) or in homologous control cortex. IPSCs were recorded in isolation with glutamate antagonists APV and DNQX in the bath, a high K^+ intracellular solution, and a voltage clamp holding potential of -70 mV. Blue light was applied through a 60X objective centered over the recorded neuron in order to activate the Channelrhodopsin and depolarize SS interneurons. The duration of the light was varied from 0.1 to 2 msec (11 durations) to create an intensity series. Light-evoked IPSCs recorded from pyramidal neurons had significantly larger peaks in malformed compared to control cortex (2-way ANOVA, $p<0.05$, N = 19 control and 14 PMR neurons). With a duration of 2 msec, the light-evoked IPSC had a peak of -167.5±40.5 for control and -510.5±130.4 pA in PMR. Repetitive light stimulation at 50 Hz produced significantly more depression of the IPSC in malformed, compared to control cortex, suggesting an increased release probability. When the light was moved to layer II/III above the recorded neuron, there was no significant difference in the IPSCs produced in PMR compared to control, suggesting that the increased output from SS in malformed cortex is specifically within layer V. Field potential recordings were also made during light activation of SS with 0.2 mM Gabazine ($GABA_A$ antagonist) in the bathing medium. Under these conditions epileptiform activity was evoked after selective stimulation of SS in the

PMR only and not in control cortex. These results suggest that output from SS is enhanced in malformed cortex and contributes to the production of epileptiform activity. Supported by NIH NS054210.

Title: NSAID treatment reverses age-related changes in hippocampal neurogenesis

Authors: ***J. MCGUINESS**[1,2], R. B. SCHEINERT[2,3], V.-C. SCHWINGEL[2], A. RANI[1], A. KUMAR[1], T. C. FOSTER[1], B. K. ORMEROD[2,1];

Abstract: Dysregulated inflammatory signaling could contribute to age-related cognitive decline through effects on hippocampal and olfactory bulb neurogenesis. We tested whether non-steroidal anti-inflammatory (NSAID) drug treatment could reverse age-related declines in neurogenesis and spatial behavior in male Fischer 344 rats. Baseline cognitive ability was assessed in young (4-6 mo; n=32), middle-aged (10-12 mo; n=32), and aged (18-20 mo; n=34) rats using a rapid water maze task. In this task, the rats were trained to locate a visible platform in a single session and then a hidden platform in a single session 3 days later. Strength of learning and memory were tested in probe trials administered immediately and 24h after hidden platform trials, respectively. After the first water maze session, the rats were assigned randomly

to vehicle (200µl of frozen strawberry milk; n=9-11 per age group), rosiglitazone (10mg/kg, BID; n=11 per age group), or indomethacin (2.5mg/kg, BID; n=11 per age group) treatment groups. Beginning a week after treatment, rats were injected once daily over 3 days with bromodeoxyuridine (BrdU, 50mg/kg; i.p.) to label dividing cells and were then trained and tested again using the same rapid water maze protocol (without visible platform trials). After the final probe session, a subset of the rats from each NSAID treatment group was perfused to quantify $BrdU^+$ new and IBA-1^+ microglial cell densities and their phenotypes through the hippocampus, rostral migratory stream (RMS) and olfactory bulb. Because neurogenesis measures were similar between middle-aged and aged rats, we combined these groups into an 'aging group' for subsequent analyses. In young rats, indomethacin ($p < 0.05$) but not rosiglitazone increased new cell number relative to vehicle. In aged rats, both indomethacin ($p < 0.05$) and rosiglitazone ($p < 0.05$) increased new cell number relative to vehicle. New cells in the hippocampus correlated positively with new cells in the olfactory bulb GCL ($p < 0.05$). Young rats outperformed aging rats on hidden platform trials (blocks 2-4; p values < 0.05). Both groups performed similarly on the post-treatment immediate probe trial and aging rats actually outperformed young rats on the 24h probe trial ($p < 0.05$). Our results suggest that short-term NSAID treatment can reverse age-related decreases in neurogenesis.

Title: SST treatment reverses kindling induced changes in adult hippocampal neurogenesis

Authors: *J. A. LEIBOWITZ, G. NATARAJAN, J. ZHOU, M. KING, P. CARNEY, B. ORMEROD;
Univ. of Florida, Gainesville, FL

Abstract: The amygdala kindling model has been used to identify mechanisms and therapeutic strategies for temporal lobe epilepsy (TLE). Hippocampal neural progenitor cell (NPC) proliferation increases 2-to 8-fold and neuronal progeny exhibit aberrant morphologies and connectivity in kindled rats. We have shown that somatostatin (SST) expression driven by AAV5

vector technology blocks epileptogenesis in 70% of rats and have preliminarily shown that SST expression blocks seizure behavior in epileptic rats. To confirm that kindling increases NPC proliferation and neurogenesis, male Sprague Dawley rats (225-250g; n=21) implanted bilaterally with stimulating and recording electrodes into the amygdala were sham or electrically kindled 2x/day to 3 consecutive Racine Grade 5 seizures. They were injected 48h after the final seizure with bromodeoxyuridine (BrdU; 100mg/kg) to label dividing cells and perfused either 4h (n=5-6 per group) or 4w (n=5 per group) later to stereologically estimate total $BrdU^+$ and microglial cell numbers under light microscopy and their phenotypes under confocal microscopy. Significantly more dividing $BrdU^+$ NPCs at 4h ($p < 0.001$) and surviving $BrdU^+$ cells at 4w ($p < 0.05$) were detected in kindled versus sham rats. Kindling upregulated $BrdU^+/GFAP^+/Sox2^+$ Type 1 ($p < 0.05$) but not $BrdU^+/GFAP^-/Sox2^+$ Type 2 NPCs. In these rats, IBA+ microglia number was similar between groups but a greater proportion of $IBA^+/CD11b^+$ microglia ($p < 0.001$) and number of activated ($p < 0.001$) and highly activated ($p < 0.05$) microglia was detected in kindled rats. To test whether SST expression blocked seizure behavior and normalized kindling-induced aberrant neurogenesis, male Sprague Dawley rats were kindled to 3 consecutive Grade 5 seizures and were then injected bilaterally into the CA1 region and dentate gyrus (2µl/site) with pAAV-CBa-GFP control vector (n=5) or pAAV-GFP-SST vector (n=5) to drive SST expression. Three weeks later, rats were given 2-3 test stimulations/week for three weeks, injected with BrdU (100 mg/kg, i.p.) 48h after the final stimulation and perfused 4h later. The average seizure grade was significantly reduced in pAAV-GFP-SST versus pAAV-CBa-GFP rats ($p < 0.05$). Our preliminary data show that pAAV-GFP-SST-treated rats had significantly fewer dividing $BrdU^+$ NPCs than GFP-treated rats ($p < 0.01$) and tended to have fewer Type 1 NPCs ($p = 0.06$) and we are currently quantifying markers of neuroinflammation in these rats. These data support the hypotheses that 1) kindling upregulates Type-1 NPC division, 2) stimulates a neuroinflammatory response and 3) that SST expression may alleviate seizure behavior in epileptic rats by normalizing neurogenesis.

Title: Persistent somatostatin gene expression treats seizures in a subset of rats with experimental temporal lobe epilepsy

Authors: *G. NATARAJAN[1], J. LEIBOWITZ[2], J. ZHOU[2], M. KING[3], B. ORMEROD[3], P. CARNEY[2];
[1]biomedical sciences, neuroscience, [2]Univ. of Florida, Gainesville, FL; [3]Univ. of florida, Gainesville, FL

Abstract: Sustained adeno-associated viral (AAV) vector-mediated neuropeptide expression is a promising therapeutic strategy for drug-resistant temporal lobe epilepsy. Somatostatin (SST) is expressed widely in the hippocampus and interestingly in hilar GABAergic neurons that are vulnerable to death in temporal lobe epilepsy. We previously demonstrated that sustained SST expression prevents the development of limbic seizures during early epileptogenesis. Here we tested whether sustained SST expression is an anticonvulsant in a rat amygdala-kindling model of temporal lobe epilepsy. Rats were electrically kindled until they exhibited 3 consecutive Racine grade 5 seizures. Subsequently, AAV serotype 5 vector driving GFP (AAV5-CBa-GFP) or rat preprosomatostatin and GFP (AAV5-CBa-SST-GFP) gene expression was injected bilaterally into the hippocampal dentate gyrus and CA1 region. Three weeks later, rats were re-tested at periodic intervals using previously effective seizure-evoking intensities. Kindled rats treated with AAV5-CBa-GFP (n=10) continued to consistently exhibit grade 5 seizures upon repeated retesting whereas 6/13 AAV5-CBa-SST-GFP-treated rats were highly refractory to seizures ($p<0.05$). Rats were persistently seizure free even with prolonged stimulus repetition. These preclinical results suggest that SST may be an alternate therapeutic strategy for pharmacoresistant temporal lobe epilepsy. Kindled rats (n=9) also demonstrated a significant learning impairment on reversal trials on the Morris water maze swim task relative to sham-stimulated rats (n=9). Ongoing studies are directed towards testing whether persistent SST expression in kindled rats (n=10) normalizes the observed reversal trial deficits relative to kindled rats treated with GFP (n=12).

Title: Sonic Hedgehog recues impaired neurogenesis associated with kainic acid epileptic effects

Authors: *L. E. GONZALEZ[1], A. H. KOTTMANN[2], D. M. DURAND[1];
[1]Case Western Reserve Univ., Cleveland, OH; [2]Sophie Davis Sch. of Biomed. Med., CUNY, New York, NY

Abstract: Epilepsy has been associated with dysfunction in hippocampal neurogenesis. In rat neurotoxic models increased neurogenesis in acute and sub-chronic conditions followed by a severe decline has been reported. The time-course from increased to decreased neurogenesis is not generalizable across models. In in the KA mouse model of epilepsy a decline in neurogenesis has been detected to occur as soon as 7 days after the KA injection. Thus, Heinrich et al. (J Neurosci. 2006; 26:4701-13) reported a gradual fall in neurogenesis at 1 week and virtual loss of all neurogenesis by 4-6 weeks after the initial seizure episode. Our data confirm a decrease in neurogenesis on the second week after systemic kainic acid injections in mice. We also found a concomitant decline of Shh transcription, Shh protein and the expression of Shh downstream pathway molecules ptc-1, smoothed (smo) and gli-1 on the second and fourth week after KA injections. As the Shh signaling pathway is a major regulator of neurogenesis, the down-regulation of Shh detected in parallel to declined neurogenesis posed the question of whether selective activation of the Shh pathway could rescue neurogenesis in the KA model. Indeed, we found that the down-regulation of Shh pathway and the decreased neurogenesis could both be rescued by systemic administration of SAG (smoothed agonist). Furthermore, activation of Shh pathway reduced seizures frequency and decreased the number of astrocyte infiltrates. The latter effect suggests that Shh in the SGZ favors neural over astroglial generation. Shh has been found to negatively regulate astrocytes and interruption of Shh signaling in postnatal astrocytes by removal of smoothened resulted in reactive gliosis (Garcia et al. J Neurosci. 2010;30:13597-608). This is significant because astrocytes are the mayor cellular source of inflammatory infiltrates and astrogliosis has been directly implicated in the genesis of epilepsy. Several studies suggest that the reduced neurogenesis found in chronic animal models of epilepsy and human temporal lobe epilepsy, can be associated with persistence of spontaneous recurrent motor seizures, memory impairments and depression. Inducing SGZ neurogenesis using Shh and other trophic proteins has been suggested as therapy in the context of depression and can have potential applications in epilepsy.

Title: Brain iron loading impairs manganese metabolism and disrupts GABAergic neurotransmission

Authors: *Q. YE, J. CHANG, J. KIM;
Northeastern Univ., Boston, MA

Abstract: Manganese (Mn) is an essential nutrient for neurological function and emerging evidence suggests that Mn deficiency is significantly associated with epilepsy in both humans and animal models. While Mn and iron share metal transporters for absorption and distribution in the body, disrupted iron homeostasis leads to altered Mn transport. In particular, both humans and mouse models with genetic iron overload exhibit reduced blood Mn levels. However, it is unclear whether iron loading impairs Mn metabolism in the brain. To investigate the role of brain iron loading in Mn-associated brain dysfunction, brain samples from the H67D HFE-mutant mice, a mouse model of brain iron loading, and their control wild-type mice (8-10 wk old) were analyzed for Mn-dependent proteins and neurochemical markers related to the epilepsy. First, H67D mice showed elevated brain iron levels by 20% ($p = 0.001$), as determined by inductively coupled plasma mass spectrometry. Notably, H67D mice displayed decreased Mn levels in the blood by 70% ($p = 0.033$) and in the brain by 7% ($p = 0.011$). Moreover, the activity of mitochondrial superoxide dismutase, an essential Mn-dependent antioxidant enzyme maintaining mitochondrial function, was reduced by 13% ($p = 0.026$). In addition, the expression of mitochondrial complexes decreased by 41-52% ($p < 0.050$) in H67D brains. These results demonstrate impaired Mn transport and Mn-dependent cellular function in H67D mice, which could consequently cause neurochemical alterations related to epilepsy. Since decreased GABAergic signaling contributes to the development of epilepsy, we quantified GABA levels in the brain by HPLC. H67D mice displayed reduced GABA levels in the brain by 32% ($p = 0.041$). In addition, H67D mice showed a 178% increase of GABA-A receptor α2 subunits (GAR2 α) as determined by qRT-PCR ($p < 0.001$), consistent with the findings in the mouse model of temporal lobe epilepsy. We found a significantly increased expression of glutamatergic receptor subunits NR2A (55%, $p = 0.021$) and NR2B (177%, $p = 0.003$) receptors in H67D brain, indicating up-regulation of glutamatergic signaling. This is consistent with findings in epileptic patients who exhibit increased expression of NR2 receptors in the brain. Together, our results demonstrate that brain iron loading impairs Mn metabolism and disrupts GABAergic and glutamatergic neurotransmission, which could predispose the development of epilepsy.

Title: Early-life seizures alter postnatal development of PV interneurons in the auditory cortex

Authors: *Y. J. SONG[1], E. E. DIEL[2], L. T. MASSARO[1], J. J. LIPPMAN BELL[1], H. SUN[1], T. K. HENSCH[2], F. E. JENSEN[1];
[1]Neurol., Univ. of Pennsylvania, Philadelphia, PA; [2]Mol. and Cell. Biol., Harvard Univ., Cambridge, MA

Abstract: Neonatal seizures are associated with long-term cognitive and behavioral deficits, including autism. Our labs have found that pentylenetetrazol (PTZ)-induced neonatal seizures prematurely unsilence thalamocortical synapses and disrupt critical period plasticity in the auditory cortex (Sun et al., in review), indicative of altered excitatory-inhibitory (E-I) balance. Although the inhibitory GABA circuit is initially underdeveloped at birth, E-I balance coincides with the maturation of the inhibitory parvalbumin (PV) interneurons. One marker of increasing PV cell maturity is their association with perineuronal nets (PNN). These PNN-associated PV cells represent the end of the critical period and an attenuation of plasticity (Hensch, 2005). Here we examine whether early-life PTZ seizures further disrupt E-I balance by altering the postnatal maturational profile of PV cells in the primary auditory cortex (A1).
We induced acute seizures in male C57BL/6J mice by daily i.p. injections of PTZ (60mg/kg) from P9-11, with saline-injected littermates used as controls. Mice were sacrificed for immunohistochemistry at P12, 15, 20 and 40 (control: n = 5, 7, 4, 7; PTZ: n = 5, 4, 6, 6, respectively), and evaluated for the number of PV cells with (PV PNN+) and without PNN (PV+ only) in layer 4 of A1. We observe a developmental increase in the number of PV PNN+ cells within layer 4, with the greatest increase occurring between P12 and 15 in both PTZ and control mice ($p<0.05$, P12 vs P15/20/40). However, no difference in the number of PV+ only or PV PNN+ cells is observed at any age between PTZ and control groups ($p>0.05$), indicating that neonatal PTZ-induced seizures do not affect the number of immature or mature PV cells within A1 layer 4. Interestingly, PTZ treated animals exhibit a trend to increased PV gene expression in homogenized A1 collected during the auditory critical period, measures indicative of either cell number changes in other cortical layers, or molecular changes not affecting cell number. We are currently analyzing cell numbers in each cortical layer to evaluate if the RT-qPCR increase can be attributed to changes in cell number. Our combined results suggest a change in PV cell

maturation in A1 following PTZ-induced seizures. This indicates that early-life seizures can alter local inhibitory networks, which may affect plasticity in areas related to language acquisition.

Title: Axonal sprouting in commissurally projecting parvalbumin-expressing interneurons

Authors: *Z. CHRISTENSON WICK, C. LEINTZ, B. HUANG, C. XAMONTHIENE, E. KROOK-MAGNUSON;
Univ. of Minnesota, Minneapolis, MN

Abstract: Reorganization of hippocampal microcircuitry is a hallmark of temporal lobe epilepsy (TLE), the most common form of epilepsy in adults. A detailed examination of hippocampal reorganization is necessary to understand the progression of the disease as well as to identify new potential therapeutic targets. Previous research has shown that *in vivo* on-demand optogenetic stimulation of inhibitory interneurons expressing parvalbumin (PV) is sufficient to suppress seizures in a mouse model of TLE (Krook-Magnuson *et al.*, 2013). Surprisingly, this intervention was capable of attenuating seizures when PV-expressing interneurons were activated ipsilateral or contralateral to the presumed seizure focus, raising the possibility of commissural inhibition in TLE. There are mixed reports regarding commissural PV interneuron projections in the healthy hippocampus, and it was previously unknown whether these connections, if present, are maintained or modified following the network reorganization associated with TLE. Using retrograde tracer and viral vector labeling techniques, we reveal that healthy control mice do indeed possess a population of commissurally projecting hippocampal PV interneurons. Additionally, we show that commissural PV interneuron projections target several subfields of the contralateral hippocampus. In the intrahippocampal kainate mouse model of TLE we see a slight and not statistically significant decrease in PV interneurons labeled with retrograde tracer from the contralateral hippocampus 2 weeks following kainate injection. This

effect does not last, however, and the percentage of commissurally projecting PV interneurons returns to baseline levels already 1 month following kainate injection. Interestingly, by 6 months post-kainate there is a significant increase in retrogradely labeled PV interneurons, indicating long-range inhibitory axonal sprouting. These findings suggest that PV interneurons supply direct inhibition to the contralateral hippocampus, and to our knowledge, are the first report of such long-range inhibitory axonal sprouting.

Title: Complex, dynamic roles for GABAergic interneurons in initiation and maintenance of optogenetically induced seizures

Authors: *S. KHOSHKHOO[1], V. SOHAL[2];
[2]Psychiatry, [1]Univ. of California, San Francisco, San Francisco, CA

Abstract: GABAergic interneurons play critical roles in seizures, but it remains unknown whether these vary across interneuron subtypes or evolve during seizure initiation, propagation, maintenance, and termination. This uncertainty stems from the unpredictable timing of seizures in most models, which limits neuronal imaging or manipulations around the seizure onset. To overcome these challenges, we developed a mouse model for optogenetic seizure induction. Combining this with calcium imaging, we find that seizure onset rapidly recruits parvalbumin (PV), somatostatin (SOM), and vasoactive intestinal polypeptitde (VIP)-expressing interneurons, whereas excitatory neurons are recruited several seconds later. Optogenetically inhibiting VIP interneurons consistently increased seizure threshold and reduced seizure duration. By contrast, inhibiting DlxI12b-labeled PV+ and SOM+ interneurons reduced both seizure threshold and seizure duration, suggesting that these interneurons suppress seizure initiation, but may help maintain ongoing seizures. These results show how an optogenetically-induced seizure model can be leveraged to pinpoint a new target for seizure control: VIP interneurons.

Title: Post natal manipulation of Arx alters cellular physiological properties and transcriptional profiles in Parvalbumin interneurons

Authors: B. JENNY, *E. MARSH, R. RISBUD, D. JOSEPH;
Div. Child Neurol, Childrens Hosp. of Philadelphia, Philadelphia, PA

Abstract: Introduction: ARX is a transcription factor expressed throughout interneuron development. Mutations in ARX lead to a spectrum of neurodevelopmental conditions with epilepsy as a common feature. Arx is important for interneuron development but continues to be expressed postnatally. We have previously begun to determine the anatomical, behavioral, and physiological implications of post natal Arx loss, but the exact physiological changes and transcriptional alterations are unknown. To address this question, we have utilized a conditional Arx mutant mouse (Arx^{cKO}) that results in loss of Arx in post natal parvalbumin (PV) cells and we performed single cell physiology in cultured Arx^{cKO} and WT cells and are performing RNA-seq on isolated mature PV cells.
Methods: To temporally aboragate Arx from PV cells, we crossed a floxed Arx mouse (Arxfl/fl) with a PV-Cre;tDtomato mouse ($PV^{CRE;Tom}$- mice who express the flourescent reporter tDtomato in PV cells),resulting in complete loss of Arx in PV cells from post-natal day (P)14. For single cell recordings we cultured cortical neurons from P0 ArxcKO and $PV^{CRE;Tom}$ mice. Single cell voltage and current clamp recordings of visually identified pyramidal and non pyramidal cells were performed in a HEPES buffer solution using standard protocols. To isolate PV positive interneurons from adult mice (P35-40), we use the MACs dissociator system (Miltyeni Biotec) followed by FACS sorting of the dissociated cortex. Sorted cell RNA was isolated using Trizol and the purified RNA sequenced using the Illumina miSeq platform. Bioinformatic analysis of the RNA seq data will be performed.
Results: Single cell recordings recapitulated the in situ ArxcKO mice recordings. We found a lower frequency of IPSCs at -40 mV in the pyramidal cKO cells. The Arx^{cKO} mean AHP was lower, Rheobase and action potential amplitude higher for the cKO pyramidal cells. In addition, the firing frequency at 60mV above rheobase was lower for cKO as was the EPSC frequency.

But all did not reach statistical significance at this time. Isolation of PV cells resulted in approximately 30,000-40,000 cells per Arx^{cKO} cortex with low RNA yields. RNA-seq experiment is being performed.
Conclusions: We confirm our previous studies showing alterations in the firing and intrinsic properties of Arx^{cKO} pyramidal cells but in cultured neurons. We also can successfully isolate mature PV cells for RNA sequencing to determine what genes are regulated by Arx in the mature neuron. These data will allow us to hypothesize on downstream targets of Arx that could be implemented as an approach to restoring normal function in patients with Arx mutations.

Title: Optogenetic stimulation of principal cells can trigger or dampen ictogenesis.

Authors: *Z. SHIRI[1], F. MANSEAU[2], M. LÉVESQUE[1], S. WILLIAMS[2], M. AVOLI[1]; [1]IPN, McGill Univ. - Montreal Neurolog. Inst., Montreal, QC, Canada; [2]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Seizures in temporal lobe epilepsy can be classified as hypersynchronous (HYP) and low-voltage fast (LVF) according to their EEG onset patterns. Experimental evidence suggests that LVF onset seizures mainly result from the synchronous activity of GABA releasing interneurons while HYP onset discharges are contributed by excessive excitatory neurotransmission as well. In this study, we tested this hypothesis using the optogenetic control of calcium/calmodulin-dependent protein kinase II (CaMKII)-positive principal cells in the entorhinal cortex (EC) of transgenic mice, in the *in vitro* 4-aminopyridine (4AP) model. We found that optogenetic stimulation of CaMKII cells using 20 ms light pulses at 2 Hz for 30 s changed both the onset pattern of spontaneous ictal discharges from LVF to HYP discharges and the predominant high frequency oscillations at ictal onset from ripples to fast ripples. Under similar experimental conditions, stimulating these cells using 1 ms pulses at 1 Hz for 180 s

reduced the frequency and duration of spontaneously occurring ictal discharges in some trials, while completely blocking ictal discharges in others. Our data demonstrate the involvement of principal cells in the initiation of HYP onset ictal events as well as the ability of continuous low frequency stimulation of principal cells to disrupt ictogenesis.

Title: The feasibility of epileptic seizure prediction using intracranial high frequency connectomics

Authors: *F. HAMZEI-SICHANI[1], S. FUERTINGER, 10128[2], M. SPERLING[4], A. SHARAN[4], K. SIMONYAN[3];

Abstract: High frequency oscillations (HFO, 100-500 Hz) in cortical networks have been shown to underlie seizure generation in human intracranial electroencephalographic (iEEG) recordings as well as in in-vitro recordings in various animal models of hippocampal and neocortical epilepsy. HFOs in contrast to other epileptiform discharges such as sharp waves or spikes are the most reliable marker of the epileptogenic area leading to the best surgical outcome when used to define the extent of surgical resections. We assessed the spatiotemporal dynamics of HFOs in pre-ictal, ictal and post-ictal states in contrast to interictal in four patients with intractable epilepsy. Based on band-pass filtered (80-500 Hz) iEEG signals recorded by right fronto-temporo-parietal 8×8 electrode grids, we constructed corresponding functional networks by computing pairwise inter-electrode normalized mutual information (NMI) coefficients for each one-second segment of iEEG data and interpreted the resulting 64×64 NMI matrices as weighted undirected graphs with electrodes representing nodes and NMI coefficients serving as weighted edges. We specifically assessed nodal community dynamics to analyze the temporal evolution of

network topology. Following the concept that seizures can be identified by changes in HFO network community structure, we computed the relative change in HFO partition distance using a sliding window. In all patients, the relative change in the community structure of the interictal state was consistently small, confirming high temporal stability of HFO network partitions during this state. However, network community dynamics started to show critical (> 8%) changes up to 50 s prior to the seizure onset, thus effectively warning against an ensuing seizure. Interestingly, despite widely varied electrographic patterns of cortical activity before the seizure onset, during the electrographic seizure and after seizure termination, the modular dynamics of cortical networks remained remarkably similar. Consequently, a sudden, distinct change in the community structure of the HFO-based dynamic NMI networks was indicative of an imminent epileptic seizure. These findings demonstrate the feasibility of the proposed approach in developing a seizure warning pipeline, based on the concept that electrographic seizures can be characterized by a breakdown of modular structure of HFO networks.

Title: Mossy fiber synapses in the hippocampal CA2 region in temporal lobe epilepsy

Authors: *U. HAUSSLER[1,2], M. JOHNSTON[1], A. KILIAS[3,4,5], P. JANZ[1,2,4], S. TULKE[1,2,4], C. A. HAAS[1,2,5];

Freiburg, Univ. of Freiburg, Freiburg, Germany

Abstract: Temporal lobe epilepsy (TLE) is associated with characteristic neuronal loss in the hippocampal CA3 and CA1 regions and in the hilus and with a dispersion of the dentate granule cell layer. These changes induce structural plasticity, in particular sprouting of mossy fibers (MF) into the dentate molecular layer which is associated with recurrent connectivity that has been described decades ago and intensely investigated. We have recently shown that MF sprouting also affects their projection to the CA2 region in a mouse model for TLE (Häussler et al., 2016, Hippocampus): MF sprout into the CA2 pyramidal cell layer and build aberrant somatic synapses on pyramidal cells. Here we aimed at a more detailed characterization of aberrant MF synapses with respect to their expression of synaptic proteins. In addition, we measured epileptic activity in the CA2 region in a higher spatial resolution than previously. To this end, we performed intrahippocampal kainate injections in adult transgenic Thy1-eGFP mice (M-line, Feng et al., 2008, Neuron), which express enhanced GFP mainly in granule cells and MF, and accomplished immunocytochemistry when recurrent epileptic activity and granule cell dispersion have developed. We localized the CA2 region according to the expression of specific proteins (regulator of G-protein signaling 14 (RGS14) or Purkinje-cell protein 4 (PCP4)) and combined these with the synaptic markers synaptoporin, bassoon, vesicular glutamate transporter 1 (vGlut1) and glutamic acid decarboxylase (GAD). Identification and quantification of synapses was performed with Imaris-based 3D reconstruction. In addition, in a subset of mice we implanted high resolution neural probes for *in vivo* recordings into the CA2 region to measure pyramidal cell firing and epileptic activity. We show that MF synapses in the CA2 region of the kainate-injected hippocampus express the synaptic proteins synaptoporin and bassoon which is in favor of a functional synaptic apparatus in the aberrant synapses. Interestingly, they develop a dual phenotype with expression of vGlut1 as well as GAD indicating that intrinsic compensatory processes have taken place that may aim at reducing overexcitation. Nevertheless, CA2 shows strong epileptic population discharges as well as multi-unit firing pointing towards an active contribution to epileptic activity. Title: *In vivo* multi-layer calcium imaging of elastic cortical seizure progression

Authors: *M. WENZEL, J. P. HAMM, D. S. PETERKA, R. YUSTE;
Columbia Univ. / Biol. Sci., New York, NY

Abstract: Mapping the fine details of epileptic seizure progression is key to understand the pathophysiology of epilepsy. Yet, the in vivo dynamics of seizure progression in densely labeled neural populations have remained unknown. We combine fast in vivo two-photon calcium imaging (30-Hz) with field electrophysiology to map neocortical seizure spread at cellular resolution in a mouse model of acute pharmacological seizures. We find strikingly reliable recruitment of local cortical cell populations, which is appreciable even at the single cell level. Glass microprism assisted multilayer imaging reveals that this reliability holds true across the cortical column. Further, we uncover layer-specific temporal delays during the lateral spread of ictal activity, suggesting an initial supra-granular cortical invasion followed by deep layer recruitment. Intriguingly, despite the same propagation pathways, successive seizures show pronounced compression or expansion in time. We propose an epilepsy circuit model resembling an elastic meshwork wherein ictal progression faithfully follows preexistent neural pathways but can flexibly vary in time.

Title: Role of potassium/chloride co-transporter (KCC2) in 4 aminopyridine (4-AP) induced epileptiform activity

Authors: *O. C. GONZALEZ[1], T. L. MYERS[2,1], J. B. STEIN[2], G. P. KRISHNAN[1], S. HAMIDI[3], M. AVOLI[3], M. BAZHENOV[1];
[1]Dept. of Med., UCSD, La Jolla, CA; [2]Dept. of Cell Biol. and Neurosci., Univ. of California, Riverside, Riverside, CA; [3]Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: 4-Aminopyridine (4-AP)-induced epileptiform activity is a well-established model of epilepsy. 4-AP increases neuronal excitability by reducing outward voltage-gated potassium currents (e.g., A and D-currents) leading to increased release of transmitters at both inhibitory and excitatory terminals. Recent findings point to the involvement of the potassium/chloride co-transporter (KCC2). In this study, we used 60 channel multielectrode array recordings to characterize spatio-temporal patterns of the epileptiform activity induced by bath application of 4-AP to acute mouse hippocampal brain slices. At low concentrations of bath applied 4-AP (25 – 75uM) we observed interictal spikes characterized by bursting at low frequencies (~1 Hz). At higher concentrations (100 – 200uM) we observed both ictal and interictal events, with ictal events characterized by synchronized activity in the frequency range of 10 – 15 Hz. In all cases, the CA3 subregion of the hippocampus appeared to have the largest activity as compared to CA1 and dentate gyrus (DG). Upon application of the KCC2 antagonist, VU0240551, the higher concentrations of 4-AP were no longer able to generate ictal activity, however the interictal activity remained relatively unchanged at all concentrations. These results are consistent with our past studies of the cortical epileptiform activity and support the hypothesis that in 4-AP conditions the increased release of GABA leading to activation of $GABA_A$ receptors and intracellular Cl^- overload activates KCC2 which then triggers extracellular K^+ increase. This initiates ictal activity. KCC2 works to extrude both Cl^- and K^+ from the intracellular medium, and has been shown to be sensitive to changes in the intracellular Cl^- concentrations. We further explored this hypothesis in a biophysically realistic conductance-based network model including excitatory and inhibitory neurons with dynamic ion (K^+, Na^+, Ca^{2+}, Cl^-) concentrations. In our model, under normal conditions, an increase in intracellular Cl^- for a brief period (5s) in both excitatory and inhibitory neurons resulted in ictal-like activity. In accordance with our hypothesis, reduction of the KCC2 co-transporter prior to the increase in intracellular Cl^- in the model was able to prevent seizures. Overall, we show that (1) development of interictal and ictal activity in the hippocampus is dependent on 4-AP concentration, (2) reduction of KCC2 co-transporter activity prevents the generation of 4-AP induced ictal activity in the hippocampus. Our study provides further evidences for the critical role of the KCC2 co-transporter in the generation 4-AP induced epileptiform synchronization.

Title: Scale free dynamics in human epileptogenic brain tissue

Authors: *S. MOY[1], A. BRAGIN[1], I. FRIED[2], J. ENGEL, Jr.[1], R. STABA[1], S. WEISS[1];
[1]Neurol., [2]Neurosurg., UCLA, Los Angeles, CA

Abstract: Scale-free dynamics, with a power spectrum following $P \propto f^{-\beta}$ are found in many complex processes in nature. We asked if scale free dynamics were modulated in epileptogenic brain tissue. We analyzed data from 13 patients with mesial temporal or neocortical epilepsy who had been implanted with intracranial clinical depth electrodes for the purpose of localizing the seizure onset zone. We examined the power law relationships of power spectral density for the inter-ictal recordings from each macroelectrode contact in all of our subjects. Overall, 664 out of 780 macroelectrode recordings exhibited a clear power-law relationship in the power spectral density (R-sqaured > 0.85). We found that among these macroelectrode recordings, the slope of the power law (β) was steeper in the non seizure onset zone channels (-3.2291 ± 0.6262) than the seizure onset zone channels (-3.0512 ± 0.6152) (unpaired two-tailed t-test, n = 664, p = 0.0255), indicating that physiological mechanisms specific to the seizure onset zone influence scale-free dynamics. In macroelectrode recordings we also determined the probability distribution of the size of negative deflections in the EEG. While we observed power-law relationships in these negative deflections, β was less than -1.5, suggesting that these areas of the brain were not operating at criticality. We did not observe any difference between the slopes of the seizure and non seizure onset zones in the range of the power law slopes. Future work will determine whether or not certain areas in the epileptic brain function at criticality, and whether or not criticality is found exclusively outside the seizure onset zone.

Title: Seizures and sugar, a dietary trigger?

Authors: *K. A. SALVATI[1], P. DAVOUDIAN[1], P. M. KLEIN[1], R. P. GAYKEMA[2], D. R. WYSKIEL[1], M. P. BEENHAKKER[1];
[1]Dept. of Pharmacol., [2]Dept. of Anesthesiol., Univ. of Virginia, Charlottesville, VA

Abstract: The link between diet and epilepsy remains contentious and the mechanisms through which diet modulates seizures are not well elucidated. Recent evidence suggests that diets leading to low blood-glucose precipitate seizures associated with absence epilepsy. Absence epilepsy is a non-convulsive seizure disorder characterized by a sudden arrest of consciousness and 3-5Hz spike-and-wave discharges (SWDs) in the electroencephalogram (EEG). SWD generation involves thalamocortical circuits comprised of neurons within the reticular thalamic nucleus, primary thalamic nuclei and the cortex. Herein, we investigate how hypoglycemia alters thalamocortical (TC) circuit activity. We first demonstrate in two rodent models of absence epilepsy, the DBA/2J mouse and the WAG/Rij rat, that hypoglycemia increases SWD occurrence (127%, $p<0.001$; 51%, $p = 0.025$) and duration (36%, $p=0.002$; 7.5%, $p=0.18$) after a 16 hour fast. Seizure exacerbation was associated with decreased blood glucose levels (18% drop, $n=10$, $p=0.29$; 28% drop, $n=11$, $p<0.001$) and increased ketone bodies (270% increase, $n=12$, $p<0.001$; 53% increase, $n=6$, $p=0.001$), in mice and rats, respectively. To determine whether ketone bodies, an alternative energy substrate, affect SWD activity, we measured SWD occurrence and duration following injection of insulin. The injection lowered blood glucose (71% decrease, $n=6$) but did not significantly change ketone body levels ($n=6$). Nonetheless, insulin injection increased SWD occurrence (139%, $p=0.043$) in WAG/Rij rats, thus suggesting that SWD modulation occurs specifically via a drop in blood glucose. *In vitro* current- and voltage-clamp recordings suggest hypoglycemic conditions shift TC firing activity from tonic spingle-spike firing to seizure-associated burst mode in response to a low-glucose perfusate. One potential molecular mechanism conferring glucose sensitivity to TC neurons is the ATP-sensitive potassium channel (K_{ATP}). Immunohistochemistry, *in situ* hybridization and qPCR confirm expression of K_{ATP} channels in TC neurons. Moreover, patch-clamp recordings from TC neurons using K_{ATP} channel modulators demonstrate functional K_{ATP}-channel expression in the thalamus. We are currently assessing whether modulation of K_{ATP} channels mediate glucose-dependent absence seizure expression. In sum, we demonstrate that hypoglycemia modulates

thalamocortical circuits likely involved in absence seizure generation. These findings further support the hypothesis that environmental factors, like diet, influence the occurrence of epileptic activity in the brain.

Title: Insult to injury: A new model of epileptiform activity in primate cortex?

Authors: *R. T. BORN[1,2], C. GOMEZ-LABERGE[1], T. S. HARTMANN[1], J. J. NASSI[1,3], A. R. TROTT[1];
[1]Harvard Med. Sch., Boston, MA; [2]Ctr. for Brain Sci., Harvard Univ., Cambridge, MA; [3]Inscopix, Inc., Palo Alto, CA

Abstract: Multi-electrode arrays have seen increasing use in both nonhuman primates and humans. One of the most popular devices is the "Utah Electrode Array" (UEA), which consists of a 10-by-10 grid of ~1 mm long electrodes spaced 0.4 mm apart. In order to overcome the surface resistance of the brain, these arrays are typically inserted using a pneumatic piston that applies 15-20 psi of pressure over ~200 ms. This insertion is a traumatic procedure known to be accompanied by microhemorrhages and ultimately to lead to reactive gliosis around the electrodes (Fernandez et al. 2014). In our experience, inserting UEAs into primary visual cortex (V1) of macaque monkeys (n=5) has *never* resulted in abnormal activity, and the responses of the single- and multi-unit activity have been consistent with the abundant literature on V1, including basic receptive field properties, like orientation tuning, and higher order properties such as feature-matched surround suppression (Trott & Born 2015). However, when we performed a second manipulation—the inactivation of feedback from V2/V3 by cortical cooling—we unmasked a latent propensity for epileptiform activity on the UEA in three of three animals. Critically, we have extensive experience (9 monkeys) in which we used the same method of inactivating V2/V3 with "cryoloops" but recorded from multiple early visual areas with single

microelectrodes; in none of these cases did we observe abnormal activity. It was only when we combined UEAs with feedback inactivation that epileptiform activity occurred. In two of the three animals, we recorded normal activity from the V1 UEA for many days *prior* to cooling, but then observed epileptiform activity within minutes of initiating the first cooling session. In these animals, the events terminated shortly following the cessation of cooling, and in all three animals they became less frequent over the course of weeks to months; none ever generalized beyond the confines of the array, and receptive field properties returned to "normal" afterwards. We offer three observations. First, the ability of feedback inactivation to trigger epileptiform activity is consistent with our previous characterization of the role of feedback in surround suppression (Nassi et al. 2013, 2014). Second, the massive data sets acquired from the UEAs for months prior to, immediately before, during and after the initiation of epileptiform activity may prove useful for testing dynamical models of epilepsy (e.g. Truccolo et al. 2011). Finally, our results suggest that the trauma associated with UEA implantation does predispose to abnormal cortical activity that may be revealed by subsequent events that lower cortical inhibition.

Title: How activation of sensory regions can promote propagation of adjacent focal neocortical seizures

Authors: ***S. S. HARRIS**[1], L. BOORMAN[2], A. KENNERLEY[2], P. G. OVERTON[2], Y. ZHENG[3], T. H. SCHWARTZ[4], J. BERWICK[2];
[2]Psychology, [1]Univ. of Sheffield, Sheffield, United Kingdom; [3]Sch. of Systems Engin., Univ. of Reading, Reading, United Kingdom; [4]Neurolog. Surgery, Weill Cornell Med. Col., New York, NY

Abstract: Understanding how seizures propagate across the brain is important to informing ictal symptomatology and improving treatment strategies in pharmacoresistant focal epilepsy. Converging evidence suggests that propagation of focal epileptiform events is restrained by feed-forward inhibition, although the circumstances and processes which result in failure of the

inhibitory restraint remain poorly understood. Previous work by our laboratory and others has indicated sensory adaptation during repetitive stimulation to result in a reduced efficacy of inhibition and attributed this to activity-dependent depression of inhibitory synapses, a mechanism also recently suggested to play a key role in seizure propagation. We therefore hypothesised that the inhibitory restraint which opposes epileptiform discharge propagation might be modulated by local cortical processing to repetitive exogenous stimuli. To test this, we exploited our established multi-modal methodology to examine neural and hemodynamic responses in cortex during physiological stimulation and recurrent focal acute seizures, and our mathematical model that allows decomposition of evoked LFPs into excitatory and inhibitory components. Two multi-channel depth electrodes were implanted into visual and adjacent vibrissal cortex of the urethane-anesthetized rat, the latter loaded with 4-aminopyridine (4-AP, 15mM, 1microliter) for induction of recurrent focal seizures. 4-AP was infused into visual cortex at a depth of 1500micrometers (5min, 0.2microliters/min) after 280s pre-infusion baseline recording. High-resolution spatial measures of oxygenated, de-oxygenated and total haemoglobin concentration were obtained using optical imaging spectroscopy. Whisker stimulation (16s, 5Hz, 1.2mA) was delivered at two different time-points (1000 and 1500s) following 4AP infusion and responses compared to controls to determine the effect of nearby epileptic activity on sensory processing and whether ictal propagation is actively promoted by nearby sensory stimulation. Laterolaminar properties of epileptiform activity and resultant neurovascular coupling processes during the horizontal spread of epileptic activity were concurrently assessed using a suite of analysis techniques. Our findings provide novel evidence that sensory stimulation can promote the propagation of focal acute seizures in adjacent cortex into neighbouring sensory-activated cortex, and indicate complex effects on sensory processing in the ictal penumbra. Our results may have important implications for our understanding of epileptic network properties and the localisation of epileptic foci.

Title: Functional connectivity analysis of interictal neuronal activity

Authors: *K. P. LILLIS, T. JACOB, K. STALEY;
Neurol., Harvard Med. Sch. Dept. of Neurol., Charlestown, MA

Abstract: The rapidly developing field of connectomics in neuronal microcircuits can be broadly divided into two categories: anatomical connectomics and functional connectomics. Anatomical synapses can be mapped at a high spatial resolution, but throughput is low and tissue must be fixed. Furthermore, although maps of anatomical synapses can be created with a high degree of certainty, they do not necessarily predict network function: Other factors (e.g. ion channel density) contribute to determining how neurons synchronize and propagate activity. Functional connectivity can be measured in living tissue by analyzing correlated activity in populations of neurons. In previous work, we have demonstrated that functional connectivity changes dynamically with network state. For example, pre-ictal disinhibition unveils scale-free functional network connectivity in seizing brain slices (Lillis et. al. 2015). Thus, functional connectivity does not necessarily directly reflect anatomical connections - rather, it is a level of abstraction for quantifying network output. Here, we used high-sensitivity, red-shifted, genetically encoded calcium indicators (GECIs) to analyze functional connectivity, in spontaneously epileptic organotypic hippocampal slice cultures, during interictal periods of relatively low activity. By imaging sparsely-expressed fluorescent proteins using low-magnification objectives, we were able to record from an entire hippocampal slice culture with single-neuron resolution and single action potential sensitivity. Furthermore, interneurons were labelled by co-expression of green fluorescent protein in DLX-expressing cells. For each of ~500 neurons imaged per recording, an output map was computed by identifying “follower neurons” that activated within 100ms of the index neuron. Organotypic brain slice cultures have no external connectivity and exhibit robust sprouting. Thus computing output maps provides the data to generate input maps for all visualized neurons. Using these data we quantify functional network architecture to look at 1) input maps for interneurons vs principal cells, 2) the relationship between input and output maps, 3) the spatial distribution of functional connections. 4) connectivity vs. age and epilepsy. Preliminary data suggest that, with the higher sensitivity GECIs used in this study, small-world network structure is apparent in “resting state” calcium imaging data. Although this approach identifies connections based on correlation, rather than causation, it represents a stride towards the ultimate goal of functional network mapping in living tissue.

Title: Computational models of ictogenesis: synaptic depression, recovery, and connectivity

Authors: *T. JACOB, K. STALEY;
Neurol., Massachusetts Gen. Hosp. Dept. of Neurol., Charlestown, MA

Abstract: Objective: The events that transpire as an epileptic network transitions from a non-seizing state to a seizure, i.e. ictogenesis, are enigmatic and very difficult evaluate experimentally. We have created a distributed network model of the CA3 region of the hippocampus that exhibits both interictal spikes and spontaneous seizures. In our simulations, we can record any neuronal or network parameter and study how it changes during ictogenesis. We can then vary parameters of interest to test their influence on ictogenesis. Methods: Our model has a layer of 100 x 100 pyramidal cells, interspersed with a 20 x 20 array of interneurons. The neurons are based on a MacGregor single-compartment model. Every neuron is connected to a neighborhood of surrounding neurons, using several different strategies for synaptic connectivity. Synapses were designed to undergo activity-dependent short-term depression and recovery. The amount of glutamate released at a synapse depends on: 1) probability of release of a glutamate vesicle and 2) the number of releasable glutamate vesicles currently available at the synapse. Both spontaneous release and activity dependent release of glutamate are supported by the model. We also model release of GABA at inhibitory synapses. In this presentation, we report 1) the nature of ictal activity in this network 2) the role that network connectivity plays in seizure generation Results: We found that 1) seizures were comprised of traveling waves whose genesis was strongly dependent on the network distribution of synaptic depression and recovery, and the region within this pattern where ictal activity began 2) small world connectivity increased the probability of ictogenesis, compared to a network connected uniformly. Small world connectivity increased seizure probability by increasing the likelihood of sufficient activity in an ictogenic region of a permissive pattern of synaptic depression and recovery. However, external inputs to uniform networks in ictogenic regions could also generate seizure activity. We are currently investigating scale free connectivity in our network.

Title: Seizing the brain with inhibition and silencing it with excitation

Authors: *L. YEKHLEF[1,2], G. BRESCHI[2], S. TAVERNA[1];
[1]Div. of Neurosci., San Raffaele Scientific Inst., Milano, Italy; [2]Inst. Italiano di Tecnologia, Genoa, Italy

Abstract: In patients suffering from temporal lobe epilepsy (TLE), the physiopathology of ictogenesis phenomena associated with tonic-clonic seizures is still under extensive investigation. In particular, the role of the different cortical populations is not well understood. We combined optogenetic stimulation and whole-cell patch-clamp recordings in mouse brain slices to dissect the role of glutamatergic neurons and GABAergic interneurons, prior to and during the course of seizure-like events (SLEs) pharmacologically induced in the medial entorhinal cortex. Channelrhodopsin-2 (CHR2) was first expressed under the control of promoters for specific markers of either of the two most common subtypes of GABAergic interneurons, parvalbumin (PV) and somatostatin (SOM). Alternatively, CHR2 was expressed in principal glutamatergic cells (PCs) under the promoter of the synaptic vesicular transporter VGlut2. Direct optogenetic activation of GABAergic interneurons was highly effective in triggering both interictal and ictal discharges which closely replicated analogue events occurring spontaneously. SLEs were associated with a relatively high increase in extracellular potassium concentration and were strongly shortened during extracellular perfusion with the $GABA_A$ receptor antagonist gabazine. Selective PC photostimulation also induced tonic-clonic discharges; however, while interneuronal activation failed to stop or shorten the progression of ictal events, photostimulation of PCs was surprisingly very functional in abolishing ongoing SLEs thanks to a substantial depolarization block effect. Our results suggest that GABAergic interneurons are instrumental in initiating, but ineffective in terminating seizures in the medial entorhinal cortex. Conversely, selective photostimulation of glutamatergic PCs paradoxically blocks the progression of ictal discharges.

Title: Optogenetic identification of neural circuits involved in the initiation of nerve agent-induced seizures.

Authors: *J. W. SKOVIRA, D. L. SPRIGGS, J. L. WINKLER, C. E. KAROLENKO, K. M. BOWENS;
US Army Med. Res. Inst. of Chem. Def., Aber Prov Grd, MD

Abstract: Seizures induced by organophosphorus nerve agents, such as soman, are believed to be initiated through overstimulation of the cholinergic system. The substantia innominata (SI) provides the principal cholinergic input to structures known to be highly sensitive to generating seizure activity (piriform cortex and basolateral amygdala). Using classical techniques, such as lesioning or direct injection of drugs, it is difficult to study highly specific neuronal cell types within heterogeneous populations, such as the cholinergic cells of the SI and their projections. Using an optogenetic approach this proof-of-principle study examined whether inhibition by illumination of cholinergic neurons or their projections during seizure onset can modulate the spatial and/or temporal extent of seizure activity. Adult male Long Evans-Tg (ChAT-Cre) rats were surgically prepared 21 days prior to the experiment with cortical screw electrodes to record brain electrocorticograms. An intracranial injection was then made to transduce SI cholinergic neurons using a Cre-inducible recombinant adeno-associated virus vector carrying the Halorhodopsin gene. Optic fiber segments were implanted bilaterally into the SI, piriform cortex, or basolateral amygdala. The indwelling fiber segments were coupled to a DPSS laser (590 nm) during experimentation. Animals received HI-6 (125 mg/kg, IP) 30 min prior to soman exposure (180 µg/kg, SC). Additionally, animals received atropine methyl nitrate (2 mg/kg, IM) at 1min post-exposure followed by 2-PAM (25 mg/kg, IM) + atropine sulfate (0.5 mg/kg, IM) at 5 min after the onset of seizures to reduce toxic signs and increase survival without affecting seizure activity. Following seizure onset cholinergic SI neurons or their projections to the piriform cortex or amygdala were illuminated and electrocortical activity was monitored. Our results show that illumination of cholinergic SI neurons or their projections to sensitive brain areas modulates seizure activity following soman exposure. These results are the first to show that cell type specific manipulation using optogenetics following nerve agent exposure can influence seizure activity and indicate the specific involvement of SI cholinergic neurons early following soman-induced seizures.

Title: Multimodal (CCEP and tractography) approach to localize epileptogenic cortex

Authors: ***L. ENTZ**[1], L. HALASZ[1], D. FABO[1], E. TOTH[1], I. ULBERT[2], L. EROSS[1];

Abstract: Surgery is the most effective therapeutic option for patients with drug resistant focal epilepsy however 40% of operated extratemporal epilepsy patients do not remain seizure free in the long term. In this study, we correlated the results of cortico-cortical evoked potentials (CCEP) mapping with the results derived from probabilistic tractography measurements in order to revel the epileptogenic cortex. Novel non-invasive mapping methods are needed in the future to substitute invasive surgical methods in order to find the epileptogenic cortex.
One patient with refractory epilepsy was implanted with subdural electrodes prior surgical resection. CCEP mapping was performed using bipolar stimulation (10ma, 0.5Hz, 0.2us). Every neighboring electrode pairs were stimulated while the evoked potentials were recorded on the remaining electrodes. An expert neurologist reviewed the ictal EEG to find those electrodes which were involved in seizure onset and early (10 ms) spread. Midpoints between stimulation electrode pairs were selected as seed regions and every recording electrode was selected as a target region for probabilistic tractography. We correlated the zscore of the CCEP amplitudes and mean connectivity values of prob.tractography between the stimulated and the recording electrodes.
We were able to perform probabilistic tractography measurements between desired electrode contacts and established an automated method to run measurements between every stimulated and recorded contact. From 10 stimulations, 5 correlated significantly with the results of tractography using amplitude cross correlation. The significantly correlated stimulations were over ictal areas except one and just one ictal stimulation did not correlate significantly with the tractography. If the CCEPs can reveal effective connections underlying seizure networks, and

prob.tract. shows the white matter projections the combination of these two method can facilitate to survey the expansivity of the ictal network.

Title: Ventral medial hypothalamus <VMH> and its role in control of spasms.

Authors: *C.-R. CHERN, L. VELISEK;
Dept. of Cell Biol. and Anat., New York Med. Col., VALHALLA, NY

Abstract: Ventral Medial Hypothalamus (VMH) is a part of the hypothalamic network and together with the Arcuate Nucleus (ARC) and Lateral Hypothalamus (LH) projects to the Paraventricular Nucleus (PVN; directly or indirectly). PVN in turn regulates the hypothalamo-pituitary-adrenal (HPA) axis. In our previous research, we observed specific seizure phenotype in rats after microinfusion of a $GABA_A$ receptor agonist, muscimol into the PVN. In this project, we determined the role of VMH in the control of spasms by functional activation with bicuculline (a $GABA_A$ receptor antagonist) microinfusion or by functional inhibition with muscimol microinfusion into VMH. We used a rat model of Infantile Spasms (IS). This model uses infant rats prenatally primed with betamethasone, in which spasms are triggered with N-methyl-D-aspartic acid. We evaluated latency to onset of the spasms and the number of spasms as a response to microinfusions of muscimol, bicuculline or vehicle into VMH. There was no significant difference in the latency to onset of spasms or in the number of spasms between control (vehicle-microinfused) and muscimol-microinfused animals. However, we found that with bilateral infusion of $GABA_A$ receptor antagonist, bicuculline, 50% of animals did not develop spasms during the observation time and the remainder experienced a significant delay to onset of fully developed spasms. Our data show that VMH participates in control of experimental spasms indicating a possible role of medial hypothalamus for pathogenesis of infantile spasms. To further investigate these hypothalamic connections we are currently examining an additional structure, the dorsal medial hypothalamic nucleus, which also has direct connection to the PVN.

Title: Silencing of nigrotectal projections is sufficient to recapitulate the anti-seizure effects of substantia nigra inactivation in diverse experimental models of seizures

Authors: *E. WICKER[1], V. BECK[1], C. SOPER[1], C. KULICK[1], P. N'GOUEMO[2], P. FORCELLI[1,2];
[1]Pharmacol. and Physiol., [2]Interdisciplinary Program in Neurosci., Georgetown Univ., Washington, DC

Abstract: The potent anticonvulsant effect of pharmacological inhibition of the substantia nigra pars reticulara (SNpr), originally identified in the early 1980s by Gale and colleagues, has long been hypothesized to function by disinhibition of the deep and intermediate layers of the superior colliculus (DLSC). The SNpr is a principle source of GABAergic inhibitory input to the DLSC, and consistent with this hypothesis, activation of DLSC is also potently anticonvulsant. Selective targeting of nigrotectal projections (to the exclusion of projections from SNpr to other regions such as thalamus or pedunculopontine nucleus) was not achievable using pharmacological approaches. The advent of optogenetics has enabled direct targeting of this pathway, and thus direct testing of the DLSC disinhibition hypothesis. We have previously reported that optogenetic stimulation of the DLSC is potently anticonvulsant in various models of seizures and epilepsy (Soper et al., 2016). Here, we employed intraperitoneal injection of pentylenetetrazole (which can trigger both forebrain and hindbrain seizures), focal microinjection of bicuculine into the “area tempestas” (to trigger forebrain seizures), intraperitoneal injection of gamma butyrolactone (to trigger absence/spike-and-wave-like seizures) and by auditory stimulation (to trigger generalized tonic-clonic seizures in genetically epilepsy-prone rats (GEPR-3s)). Rats were injected with an AAV coding for the inhibitory opsin, ArchT, into the SNpr and fiber optics were implanted either into SNpr (to silence cell bodies) or within the DLSC (to silence nigrotectal terminals). We found that inhibition of either SNpr cell bodies or the nigrotectal terminals with either unmodulated light or 100Hz pulsed light were effective at reducing seizure severity in all models we examined. Interestingly, the magnitude of seizure suppression was similar between sites of optogenetic silencing. These data show that selective suppression of the nigrotectal pathway is sufficient to account for anticonvulsant effects achieved by inhibition of

the SNpr. The enhanced specificity provided by this approach may further enhance the translational utility and our understanding of this endogenous seizure suppressive circuit.

Title: Mapping seizure spread during status epilepticus at a single neuron resolution

Authors: *J. KAPUR[1], N. DABROWSKA[2], S. JOSHI[2], J. WILLIAMSON[2];
[1]Dept Neurol., Univ. Virginai Hlth. Sci. Ctr., Charlottesvle, VA; [2]Univ. of Virginia, Charlottesville, VA

Abstract: Seizures propagate from a focus to multiple brain structures, but the neuronal circuits activated during this process are poorly understood. We characterized the temporal changes in the activation of brain regions during prolonged seizures of status epilepticus (SE).
We used TRAP (targeted recombination in activated population of neurons) mice to visualize the brain areas activated during SE. In these mice cfos, which is an immediate early gene that is activated by neuronal activity, regulates the expression of estrogen receptor-tagged Cre recombinase. Administration of 4-hydroxytamoxifen (4OHT) to the mice following a stimulus leads to nuclear translocation of Cre and induction of a reporter protein tdTomato in the population of active neurons. Because the activation of cfos is transient and metabolism of 4OHT is rapid, this strategy allows visualization of active neurons in a restricted window of time (1 hr prior to 4OHT administration). SE was induced by continuous hippocampal stimulation (CHS) for 60 min and cohorts of mice were treated with 4OHT at different times following end of the stimulation. The mice were perfused and brains were processed with passive clarity tissue clearing technique (PACT) 7 days following SE. Images were acquired on a Zeiss 780 confocal microscope.
Mice that underwent electrode implantation only did not show much activation, tdTomato expressing neurons were mostly seen in the ipsilateral hippocampus surrounding the tip of the

electrode. CHS for 60 min induced SE in mice, the continuous seizure activity typically lasted for 120-180 minutes, after which there was low frequency, arrhythmic spike-wave discharges lasting 60-90 minutes. In the mice treated with 4OHT 60 min after the end of stimulation (1st hour of SE), activated neurons were present mostly in the ipsilateral and contralateral hippocampus: dentate gyrus, CA1, CA3 pyramidal layer, lateral entorhinal cortex, olfactory cortex and cingulate gyrus. With the progression of seizures, activated neurons were also detected in the subiculum, lateral entorhinal cortex, olfactory bulbs, and lateral septum in the mice given 4OHT 2 and 3 hr after the end of stimulation, that is during the 2nd and 3rd hour of SE. The number of activated neurons reduced in the 4th hour of SE.
These studies showed that seizures initiate in the hippocampus and there is recruitment of septal and cortical regions with the progression of seizures. In conclusion, TRAP mice combined with brain clarification and advanced microscopy provide a novel tool to map seizure activity at a single cell level.

Title: Disruptions of intrinsic functional connectivity during epileptogenesis in a mouse model of temporal lobe epilepsy

Authors: *H. LEE, S. JUNG, P. LEE, Y. JEONG;
Dept. of Bio and Brain engineering, Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Patients with epilepsy suffer from various cognitive and psychiatric symptoms such as learning and memory impairments, emotional instability, and social behavior deficits. Recent fMRI studies on temporal lobe epilepsy (TLE) reported that alteration of resting-state functional connectivity is associated with these symptoms. One recent study using mice reported that these social behavior deficits and related abnormal cortical activity appeared even in the latent period of epilepsy when epileptogenesis occur. Understanding the changes in the latent period is critical for early diagnosis and management of TLE. In this study, we investigated the alterations of resting-state functional connectivity during the latent period in pilocarpine-induced TLE mouse model using intrinsic optical signal imaging (IOSI). This technique can monitor the changes of local hemoglobin concentration by neuronal activity and can be used for investigating the large-

scale brain intrinsic networks. After seeding on anatomical region of interests (ROI) and calculating the correlation coefficients at each ROI, we built functional correlation matrix and functional connectivity maps in latent and chronic period of epilepsy. We observed significant decreased interhemispheric functional connectivity in frontal, temporal and visual cortex in both periods. We also found that the spectral features of low-frequency oscillations are changed in certain cortical regions in both latent and chronic period. These results show that the even there is no seizure events during the latent period, the change of functional connectivity is ongoing. This finding could help to understand the epileptogenesis and can be used for early biomarker.

Title: Interictal spikes: Hallmark of the ictal onset zone or the epileptic network?

Authors: *E. BAIRD-DANIEL[1], H. MA[1,2], A. G. S. DANIEL[1], M. ZHAO[1,2], J.-Y. LIOU[3], T. H. SCHWARTZ[1,2];
[1]Neurolog. Surgery, Weill Cornell Med. Col., NEW YORK, NY; [2]Brain and Mind Res. Inst. Brain and Mind Res. Inst., New York, NY; [3]Columbia Univ., New York, NY

Abstract: Whether interictal spikes (IIS) arise from the ictal onset zone (IOZ) or the extended epileptic network as well as the etiology and function of IIS are widely debated. Using *in vivo* wide-field bihemispheric calcium imaging we were able to map the onset site of IIS throughout the ipsilateral and contralateral hemisphere in a model of focal neocortical epilepsy. An ictal focus was created via local unilateral injection of 4-aminopyradine (4-AP, 500nl, 15mM) in adult SD rats under isoflurane anesthesia. Ictal events and IIS were recorded through bilateral LFP measurements and simultaneous wide-field calcium imaging. We found that after 4-AP injection, 93.65% of IIS initiated from the contralateral hemisphere (mirror focus). After focal blockade of inhibition with local injection of bicuculline methiodide (BMI, 500nL, 5mM), a GABA antagonist, into the contralateral mirror focus the IIS initiation site switched from the contralateral mirror focus to the 4-AP IOZ, with 91.43% of IIS now occurring ipsilaterally. In a separate group of animals, we injected BMI ipsilaterally ~4mm posterior to the 4-AP injection site, after which we observed that the majority (95.23%) of IIS once again initiated from the

contralateral mirror focus. Consequently, our results suggest that IIS initiation is mediated by GABA-ergic cells in the epileptic network. Suppression of network interactions creates an environment for IIS to arise from the IOZ. This finding suggests that under certain circumstances IIS arise not form the IOZ but the epileptic network, particularly the contralateral hemisphere.

Title: Spatial organization of neural field activity at multiple scales increases during human seizures

Authors: *L.-E. MARTINET[1], G. FIDDYMENT[3], O. J. AHMED[4], E. N. ESKANDAR[2], S. S. CASH[1], M. A. KRAMER[3];
[1]Dept. of Neurol., [2]Massachusetts Gen. Hosp., Boston, MA; [3]Boston Univ., Boston, MA; [4]Univ. of Michigan, Ann Harbor, MI

Abstract: Epilepsy is a complex multiscale disease, extending spatially from microscopic synapses to macroscopic behavioral manifestations. Seizures - the hallmark of epilepsy - exhibit multiscale spatiotemporal dynamics that remain incompletely understood. Here we study the properties of focal seizures using a unique data set of multiscale recordings from microscopic (10x10 grid, 0.4 mm spacing microelectrode array - MEA) and macroscopic (8x8 grid, 10 mm spacing) subdural electrode arrays implanted in patients with pharmacoresistant epilepsy. We find voltage waves propagating along the brain surface in the local field potential (LFP) recorded with the MEA, as well as in the invasive electroencephalogram (ECoG) recordings. To investigate the spatio-temporal coupling between those two scales, we measure the coherence between pairs of electrodes, both within the micro-electrode array and between micro- and

macro-scale. We find that coherence increases during seizure at all scales and that the increase is larger locally at the macro-scale. The group delay between electrodes identifies the presence of planar travelling waves. We find within both the micro- and macro-scale an increased number of waves - and increased consistency of these waves - as seizures generalize. We also show that the direction of propagation is consistent between spatial scales and from seizure to seizure for a given patient. Overall, these results suggest that the spatio-temporal organization of neural populations within and between spatial scales increases during seizure. We hypothesize that this effect may be due to the local circuit activity at the microscopic scale becoming more strongly influenced by macroscopic ictal propagation. We test this hypothesis using a multiscale mean-field model simulating both ECoG and LFP activity. We show that the presence of a slowly diffusing extra-cellular ionic effect can account for a change of spatio-temporal regime during seizure, from a non-organized state to an organized state where activity propagates through consistent waves. A deeper understanding of ictal spatio-temporal dynamics within and between scales may have clinical implications, such as the development of tailored surgical interventions or improved guidance for stimulation induced seizure interruption.

Title: Observations of high-frequency oscillations at human seizure onset from microelectrode array recordings.

Authors: ***J. NADALIN**[1], L.-E. MARTINET[3], G. FIDDYMENT[2], E. N. ESKANDAR[4], C. J. CHU[3], S. S. CASH[3], M. A. KRAMER[1];

Abstract: Human seizures are characterized by rhythmic activity that spans a wide range of frequencies. High frequency oscillations (HFO, >80 Hz) have been widely reported as a spatial and temporal signature of seizure onset. However, many aspects of HFO remain unknown, including the mechanisms that govern HFO, why HFO occurs before a seizure and its causal relation with a subsequent seizure, and whether interventions should target HFO. Here, we examine the features of HFO from microelectrode array (10x10 grid, 0.4 mm spacing) recordings in four human patients with pharmacoresistant epilepsy. We characterize the spatiotemporal dynamics of the HFO, and the evolution of these dynamics during seizure onset. Preliminary results suggest that cross-frequency coupling between fast and slow frequencies occurs, with the temporal localization of high frequency oscillations occurring in the troughs of lower frequency oscillations. Previous work suggests that HFO evolve in patterns of spreading waves of activation, with each wave initiated by activity within a localized cortical region. Here we analyze the spatial organization of the microscopic spatial dynamics of HFO and propagation of activity. A deeper understanding of HFO at human seizure onset promises new insight into the mechanisms of human seizure onset, and possibly treatment.

Title: Differential roles of somatic inhibition in inter-ictal and ictal discharges in a focal cortical seizure model

Authors: *V. MAGLOIRE, J. CORNFORD, D. M. KULLMANN, I. PAVLOV;
UCL Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: GABA(A) receptor blockers trigger seizures while GABAergic drugs are commonly used to treat epilepsy, implicating a failure of the inhibitory system as one of the main causes of epileptic discharges. However, GABAergic interneurons constitute a diverse neuronal population, and the specific contribution of different subtypes of interneurons to the generation and maintenance of epileptic activity remains unclear. Accumulating evidence suggests that GABAergic signalling may, in some circumstances, even facilitate epileptiform activity. Here, we focused on the role of parvalbumin-positive (PV^+) interneurons, which mainly provide fast perisomatic inhibition, in the generation of spontaneous epileptiform discharges *in vivo* in a mouse model of focal cortical seizures. Acute injection of pilocarpine (3 M, 0.2-0.4 μl) into the visual cortex induced either brief inter-ictal bursts (100-500 milliseconds), or ictal-like discharges lasting several seconds. We used closed-loop optogenetic stimulation in combination with a wireless EEG recording system and automated seizure detection to deliver laser-generated light pulses through an optic fibre positioned close to the pilocarpine injection site. Channelrhodospin-2 (ChR2) was selectively expressed in PV^+ interneurons, enabling us to activate PV^+ cells during detected pathological discharges. Optogenetic activation of PV^+ interneurons during periods of inter-ictal like activity facilitated their generation (the last inter-event interval during 10s-long photostimulation was 21 ± 2% shorter than that during the baseline, mean ± SEM, $p<0.01$, n=8 mice) following an initial transient suppression (the first IEI increased by 79±9% compared to baseline, $p<0.05$, n=11 mice). In contrast, ictal-like activity was suppressed by closed-loop photostimulation of PV^+ interneurons. The duration of discharges was reduced by 35 ± 7% (from 3.35 ± 0.57 s to 1.99 ± 0.34 s, n=8, $p<0.05$). To investigate the temporal relationship between somatic inhibition and its ability to attenuate ictal-like activity, we delayed (by 0.5, 2 or >2 s) the delivery of the light pulse after event detection. While photo-activation of PV^+ interneurons 0.5 s into ictal-like events reduced their duration, a delay of 2s and more significantly prolonged the duration of seizure-like discharges (by 34 ± 6%, $p<0.05$, n=5 mice). Thus, we infer that increased activation of perisomatic-targeting interneurons has both pro- and anti-epileptic action depending on the network state. In addition, the use of optogenetic stimulation of PV^+ interneurons to suppress ictal-like discharges is restricted to a narrow time window after the event onset.

Title: Epilepsy-associated mutations of Nedd4-2 in regulating neuronal network activity

Authors: *J. ZHU, K. A. JEWETT, N.-P. TSAI;
Mol. and Integrative Physiol., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Epilepsy affects more than 300,000 children under the age of 15 in the United States, according to the Centers for Disease Control and Prevention (CDC), and genetic mutation is an important contributing factor. It is widely accepted that the alterations in activity, composition or distribution of ion channels caused by genetic mutations contribute to the onset of epilepsy. DNA sequencing and analysis performed as part of a worldwide research study called Epilepsy 4000 (Epi4k) recently revealed 329 *de novo* mutations in patients with epilepsy. Among those genes identified, Neural precursor cell Expressed Developmentally Down-regulated 4-like (*Nedd4-2*), was specifically noted. *Nedd4-2* encodes a ubiquitin E3 ligase that has high affinity in ubiquitinating and degrading ion channels. Furthermore, three missense changes in *Nedd4-2* have also been identified in families with epilepsy. Despite these discoveries, the mechanisms by which Nedd4-2 is associated with epileptogenesis are completely unknown. Recently, our lab identified the major subunit (GluA1) of an ionotropic glutamate receptor, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor, as a novel substrate of Nedd4-2. Because reduction of the AMPA receptor is known to be critical for leveling down neuronal excitability, and a high level of GluA1 is associated with pediatric epilepsy, our findings led to the *central hypothesis* that Nedd4-2 down-regulates neuronal excitability through ubiquitinating and degrading GluA1. We applied genetic mouse models, electrophysiological and biochemical approaches to investigate the functions of Nedd4-2. With a genetic mouse model, *Nedd4-2*^{andi} mice, in which the predominant form of Nedd4-2 in the brain is deficient, we first found that Nedd4-2 is involved in the regulation of neuronal network excitability. Subsequently our data also indicated that the epilepsy-associated mutations of Nedd4-2 impair its function of degrading GluA1. Our findings reveal the potential link by which Nedd4-2 regulates neuronal excitability. Our continuing study will improve our understanding of 1) protein ubiquitination in neurophysiology, 2) AMPA receptor dynamics and 3) Nedd4-2-associated epilepsies.

Title: Preclinical *In vitro* prediction for the seizure-inducing side effects of drugs

Authors: ***M. GAO**[1], K. SATO[2], Y. IKEGAYA[1];
[1]Pharmaceut. Sciences, The Univerity of Tokyo, Tokyo, Japan; [2]Natl. Inst. of Hlth. Sci., Tokyo, Japan

Abstract: Epilepsy is a brain disorder marked by recurring seizures. To date, various triggers of seizures have been identified, among which one possible cause is the side effects of drugs. During the preclinical research process of drug development, animal testing is widely used to help screen out the dangerous side effects of drugs. However, it remains hard to predict the seizure-inducing side effects of drugs within this process. Here, we developed an *in vitro* system to monitor the effects of drugs on neuronal activities to detect the seizure-inducing effects. Acute brain slices of mice were applied with drugs in different concentrations, while the local field potential (LFP) of alveus near hippocampal CA1 region being recorded by the 64 channel multi-electrode. Using this system, we tested 12 kinds of drugs that have been reported with seizure-inducing effects to various degrees, including picrotoxin, theophylline, aspirin, enoxacin, oseltamivir, cimetidine, diphenhydramine, ketamine, methamphetamine, diazepam, imipramine and dextran. As a result, drugs reported with high risks of triggering seizures, including picrotoxin, theophylline, enoxacin and diphenhydramine, stably caused abnormal firing in neuronal networks, as was shown by the abrupt changes in amplitudes of LFP, while other drugs showing limited influence. By conducting analysis on the LFP data of different drugs, it was possible to collectively evaluate the risks of seizure-inducing. Therefore, this system seems to be a useful and sensitive tool in the preclinical research process of drug development for seizure-inducing side effect prediction, and might serve as an alternative method of inducing *in vivo* animal testing.

Title: Dynamic Causal Modelling of GRIN2A-related epileptic abnormalities in sleep

Authors: *M. HEILBRON[1], R. E. ROSCH[1], K. J. FRISTON[2];
[1]Inst. of Neurol., Univ. Col. London, London, United Kingdom; [2]Wellcome Trust Ctr. For Neuroimaging, London, United Kingdom

Abstract: Mutations in the GRIN2A gene - encoding the 2A subunit of the human NMDA receptor - have recently been identified as a major genetic cause for a group of related conditions along the childhood epilepsy-aphasia spectrum. For many patients, language regression and delay, rather than seizures, are the dominant symptoms. However, the EEG of patients within this disease spectrum characteristically shows epileptiform activity with a centro-temporal focus that is strongly enhanced in NREM sleep. This sometimes results in near-continuous epileptiform discharges during slow wave sleep, yet the exact role of sleep and its interaction with NMDAR, remain unknown. According to one hypothesis, epileptiform discharges are hypersynchronous 'perversions' of normal sleep activity, generated by an excitation-inhibition imbalance in the thalamocortical sleep circuit. However, evidence for the hypothesis from human patients has been limited.
Dynamic Causal Modelling (DCM) is an analysis framework that fits generative neuronal models to empirical data. Using Bayesian estimates of model evidence, DCM also allows for direct comparison of competing hypotheses cast in terms of neural models. Recently, it has been applied to identify causative synaptic changes underlying neural signatures of anaesthesia and seizure propagation from EEG. In this study, we apply DCM to invert a network model of relevant thalamic and fronto-temporal nodes for a single patient with a known *GRIN2A* mutation and age-matched controls: Here, cross-spectral densities across sleep stages and epileptiform paroxysms are modelled with coupled neural mass models and differences in the spectral composition of the EEG signal explained with variations in a limited set of model parameters. Inversion over different competing models allows the evaluation of evidence for competing hypotheses regarding the interactions of sleep and seizure mechanism. We specifically tested whether there was evidence for effective connectivity changes between two bilateral perisylvian sources with or without hidden thalamic source.
Through model inversion DCM analysis yields a fully parameterised forward model, explaining the observed changes in EEG output in terms of synaptic changes in a simplified corticothalamic network. This reveals interactions between (i) the sleep-stage specific transitions through parameter space, and (ii) paroxysmal abnormalities underlying ictal discharges. These findings offer a network-level mechanistic description of sleep-related EEG abnormalities in a patient with a known *GRIN2A* mutation, providing a bridge between molecular pathology and network level observations.

Title: Modulation of thalamic neuronal activity during focal limbic seizures differs by thalamic subnucleus

Authors: *L. FENG[1,2], J. MOTELOW[1], W. BICHE[1], C. MCCAFFERTY[1], N. SMITH[1], M. LIU[1], Q. ZHAN[1], R. JIA[1], A. DUQUE[3], H. BLUMENFELD[1,3,4];

Abstract: Impaired consciousness in temporal lobe seizures has a major negative impact on quality of life. Previous work has identified the thalamus, particularly the intralaminar nuclei, as a key subcortical arousal region that plays a critical and unique function in regulating arousal, attention and goal-directed behavior. There is also growing evidence that the anterior nucleus of the thalamus (ANT) may have a role in the propagation of seizure activity due to its direct connectivity with the hippocampus. Additionally, relay nuclei such as the ventral posteromedial nucleus of the thalamus (VPM) may play a role in the formation of corticothalamic oscillations. To better understand possible mechanisms and effects in different thalamic subnuclei during focal seizures, we performed separate multiunit recordings in the intralaminar central lateral nucleus of the thalamus (CL), ANT, and VPM in an anesthetized rat model of focal limbic seizures. We found that during focal limbic seizures, the multiunit activity (MUA) in the CL region decreased obviously after seizure initiation, while the ANT demonstrated increasing MUA during the ictal period. In both regions, MUA recordings showed that neuronal firing slowly recovered during the postictal period. In the VPM, the occurrence of spindle waves was markedly increased during seizures. Furthermore, we acquired juxtacellular recordings in the CL thalamus to investigate single neuron activity changes during focal seizures. We found that single neurons in the CL thalamus fired regularly prior to hippocampal seizure initiation, but markedly decreased almost immediately after the seizure began. Firing rates slowly recovered during the postictal period and resumed normal firing after variable intervals. Most neurons in CL fired with a burst pattern during seizures, but fired single spikes during baseline and after recovery. These findings suggest that different subnuclei of the thalamus may play different functional roles during focal seizures, including seizure propagation, cortical inhibition, and formation of slow oscillations. At the cellular level, reduced firing rates and a burst firing mode

for identified CL neurons were recorded during focal limbic seizures. Burst firing has been previously described in thalamic neurons in states such as sleep or deep anesthesia. These results suggest depressed arousal of the CL region of the thalamus, which may suppress the activity of the cortex. Further work is needed to characterize activity patterns in other major thalamic regions. Decreased subcortical arousal could be a critical mechanism for loss of consciousness in focal temporal lobe seizures.

Abstract: Impaired consciousness during the ictal and postictal states is a major component of morbidity and mortality in epilepsy. The use of deep brain stimulation (DBS) to improve consciousness during and after seizures would represent an alternative therapeutic resource for patients suffering from medically and surgically refractory epilepsy, with a significant impact on their quality of life. To explore this, our lab has developed and uses a rodent model of limbic seizures that reproduces the human electrophysiological and behavioral manifestations associated with loss of consciousness in temporal lobe epilepsy. Some of our recent work has shown that dual-site stimulation of the thalamic intralaminar central lateral nucleus (CL) and pontine nucleus oralis (PnO) applied bilaterally during seizures restored normal-appearing

cortical electrophysiology and markedly improved behavioral arousal in this rodent model. Here we have focused on further investigating the effect of this dual-site stimulation on behavior. We implement an operant behavioral task to assess performance during and after focal seizures and evaluate the cognitive improvements provided by DBS. The task involves responding at an instrumental port (nose-poking) toactivate an adjacent reward port, where rats can collect liquid sucrose rewards when signaled by a stimulus. During successive training sessions, animals show increased percentage of rewards collected, decreased response times, and increased selectivity in responding. After training is completed, we implant electrodes bilaterally in CL and PnO, and unilaterally in the hippocampus and lateral orbitofrontal cortex. Following recovery, animals are reevaluated and, if necessary, retrained in the task until they accomplish optimal baseline performance. Seizures are induced by brief 2 second hippocampal stimulation at 60 Hz in some of the trials within a session. We then stimulate bilateral CL at 100 Hz and PnO at 50 Hz at varying current intensities during and after seizures while synchronously recording electrophysiology and behavior. Task performance was impaired during seizures. Further work is needed to determine the degree of improvement in performance obtained with the dual site stimulation during the ictal and postictal periods. We expect the results that we can obtain through the implementation of our experiments to yield substantial information that will further elucidate the potential benefits of using multi-site DBS to improve consciousness in patients with refractory epilepsy, accelerating the translation of preclinical data into the development of a clinical therapeutic resource.

Title: Mechanisms of absence seizures investigated by relating hemodynamics, electrophysiology, and behavioral severity in an awake rodent model

Authors: *C. P. MCCAFFERTY[1], A. KUNDISHORA[1], J. SAMPOGNARO[1], E. JOHNSON[1], W. ISLAM[1], P. VITKOVSKIY[1], P. ANTWI[1], N. SMITH[1], A. MORAWO[1], J. XU[1], M. GALARDI[1], H. BLUMENFELD[1,2,3];
[1]Neurol., [2]Neurobio., [3]Neurosurg., Yale Univ., New Haven, CT

Abstract: Absence seizures, consisting of behavioral arrest and concurrent EEG spike-and-wave discharges, are the most common type of generalized epilepsy. They are the defining symptom of childhood and juvenile absence epilepsy, which are associated with learning difficulties, behavioral disorders and other cognitive impairments. The neural activity underlying absence seizures has yet to be comprehensively characterized, a development that is imperative given the lack of improvement in first-line therapeutics over the past 50 years. Experimental absence seizures have hitherto been studied primarily in anesthetized or neurolept-sedated animals, introducing a difference in arousal state from the clinical condition that may explain discrepancies observed in hemodynamic responses. Consequently, a protocol allowing electrophysiological, hemodynamic and behavioral measurements during unadulterated absence seizures is needed. Further, recent evidence suggesting inter-seizure variation in the degree of behavioral arrest calls for the investigation of arousal and behavioral correlates of consciousness during experimental absence seizures. We developed a head-fixation protocol for Genetic Absence Epilepsy Rats from Strasbourg (GAERS) that minimized stress and allowed expression of seizures. Local Cerebral Blood Flow (CBF) and neuronal activity was thus measured during true absence seizures using combined laser Doppler flowmetry, local field potential and multiunit activity (MUA) recordings. CBF, in multiple cortical regions, increased by ~5% within the first 2 seconds of seizure before decreasing to 95% of pre-seizure baseline over the next ~5s. These changes were accompanied by similar changes to the root-mean-squared amplitude of local MUA in deep layers of the cortex, which initially increased to ~120% of baseline before gradually decreasing to ~90%. These changes are in line with blood oxygen level dependent functional magnetic resonance imaging (BOLD-fMRI) changes in human absence seizures and completely contrast with prolonged increases in CBF, BOLD, and local neuronal activity in sedated animal models. These data strongly suggest that hemodynamics of absence seizures are qualitatively altered by sedation, and therefore that mechanisms of absence seizures should be studied in undrugged models. This head fixation method has been successfully adapted for fMRI, to allow multi-modal assessment of hemodynamics. EEG properties of these seizures will be used to relate hemodynamics and neural dynamics to behavioral correlates of similar events, elucidating the neural and blood flow mechanisms underlying variations in seizure severity.

Title: The role of respiration and brain alkalosis in adult Naked Mole-Rats seizure

Authors: ***M. ZIONS**[1], T. DZEDZITS[1], D. THEVALINGAM[1], D. P. MCCLOSKEY, 07016[2]; [1]CUNY CSI, Staten Island, NY; [2]CUNY CSI, Staten Island, NJ

Abstract: Adult African naked mole-rats demonstrate robust epileptic seizures under conditions which are likely to induce brain alkalosis, including hyperventilation. The purpose of the current study was to establish appropriate methodology to measure respiration rate in this species, and to determine the alkalosis threshold for hyperexcitability in vitro. We first compared pulse oximetry (Starr Life Sciences), piezoelectric sensors (PVDF wire, Pinnacle EEG), manual counting on slow-motion video, and Eulerian video movement magnification (MIT, CSAIL) to measure respiration rate in freely moving naked mole-rats. The pulse oximetry system reported frequent loss of signal with throat and collar sensors, likely due to the failure of infrared signal penetration through the heavy musculature in the naked mole-rat neck. Better results were obtained with a clip on animals' thighs. Piezo sensors connected to a voltage divider and recorded on an EEG system detected diaphragm movement, but at this time a finer resolution is still needed. High-speed video recorded at 480 frames per second permitted manual counting but with difficulty. Eulerian magnification and visual filtering applied in MATLAB exaggerated ribcage motion and greatly assisted manual counting, and shows promise for measuring laboratory animal respiration if movement is sufficiently restricted. We then recorded epileptiform activity in vitro using extracellular electrodes in naked mole-rat hippocampal slices to manipulate pH. Most slices recorded showed a measurable spontaneous epileptiform burst discharge in area CA3 under routine recording conditions and normal ACSF. When ACSF pH was elevated from 7.4 to ~7.6 through the addition of bicarbonate, bursting frequency increased, indicating a more rapid turnover in the burst-generating mechanism. When carbogen delivery to the slice was removed for 15 minutes and then restored, bursts grew significantly in amplitude and duration, indicating greater recruitment of the excitatory network in burst activity during relative shifts in local pH. Together, these findings suggest that naked mole-rats can provide an excellent model system for understanding the mechanisms of alkalosis-induced hyperexcitability in febrile seizures and similar disorders.

Title: Synaptic protein alterations during the acute, sub-acute, and chronic inflammatory response following status epilepticus (SE)

Authors: *U. AVDIC[1,2], M. AHL[2], D. CHUGH[2], I. ALI[2], C. EKDAHL CLEMENTSON[2];
[1]Lund Univ., Malmö, Sweden; [2]Clin. Sci., Div. of Clin. Neurophysiol., Lund, Sweden

Abstract: Synaptic transmission is modulated by synaptic adhesion molecules. Altering the expression of these synaptic proteins may be a new way to "tune" the synaptic activity, both excitatory and inhibitory, and dampen hyperexcitability in epilepsy. The objective of this study was to evaluate the expression of some key synaptic adhesion molecules and synaptic proteins acutely (6h and 24h), sub-acutely (1w), and chronically (4w) following temporal status epilepticus (SE) in rats. We also studied whether protein expression was different in rats that developed spontaneous seizures (epileptogenesis) after SE compared to those with only acute symptomatic seizures until day of perfusion (seizures occurring within 1 week after a brain insult).
Adult male Sprague Dawley rats underwent electrically-induced temporal SE. Electrode-implanted rats with no stimulation served as controls. Animals were continuously video and EEG-monitored. They were sacrificed 6h, 24h, 1w, and 4w post-SE. Brains were removed, sub-divided into cortical, subcortical and hippocampal tissue (ipsi- and contralateral to epileptic focus), and processed for western blot analysis.
In the acute phases (6h and 24h) following SE, we detected a small decrease in the cortex of PSD-95, a scaffolding protein found predominately on excitatory synapses, which may represent an acute reaction to the seizure insult. At 1week, when the vast majority of animals had experienced acute symptomatic seizures, protein changes manifested in the hippocampus with decreased expression of both postsynaptic proteins PSD-95, gephyrin (scaffolding protein found on inhibitory synapses), NL-1 (adhesion molecule in excitatory terminals), and the presynaptic protein synapsin II. This decrease was not sustained 4 weeks post-SE, neither in rats with only acute symptomatic seizures nor in epileptogenic rats that experienced spontaneous recurrent seizures. Instead, we observed 4 weeks post-SE a decrease in the excitatory adhesion molecule N-cadherin in the hippocampus of rats that had become epileptogenic compared to rats with only acute symptomatic seizures.

These results demonstrate synaptic protein changes within the temporal epileptic focus 1 week following temporal SE, at both excitatory and inhibitory synapses, without spread to other cortical/sub-cortical structures. However, these changes were transient. Instead, we found the adhesion molecule N-cadherin to be decreased in the hippocampus specifically in rats that experience spontaneous epileptic seizures, in addition to the initial SE insult 4 weeks post-SE. Further analyses will be needed to verify whether this decrease may predict epileptogenesis.

Title: Levetiracetam prophylaxis ameliorates seizure epileptogenesis after fluid percussion injury

Authors: *Y.-H. CHEN[1], B. J. HOFFER[2];
[1]Tri-Service Gen. Hospital/National Def. Medi, Taipei City, Taiwan; [2]Dept. of Neurosurg., Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Abstract: To determine whether post-traumatic seizure severity would be affected by the interval between seizures and head injury, we measured seizures after various times with or without fluid percussion brain injury (2atm fluid percussion injury; FPI). To determine efficacy of anti-seizure medication, we also determined if levetiracetam (LEV) would alter the relationship between injury and subsequent seizures. Early post-traumatic seizures were induced by Kainic acid (KA) at one week after 2atm fluid percussion injury (FPI) in one group (FPI-ES). Seizures were induced at two weeks after FPI by KA in another group (FPI-LS). In addition, one group had induced seizures by KA without FPI, (sham-ES). Finally one group of animals received the antiepileptic agent (levetiracetam) infusion for one week after FPI and then had seizures induced by KA (FPI-LEV-ES). We measured seizure onset time, ictal duration and severity of seizures using a modified Racine's scale. Histopathological changes in the

hippocampus CA1 region were also analyzed. Severity of seizures were increased in the FPI-ES group compared with sham-ES animals. Severity was also enhanced in early post-injury seizures induced by KA (FPI-ES vs. FPI-LS); this exacerbation of seizure severity could be ameliorated by levetiracetam infusion (FPI-ES vs. FPI-LEV-ES). Neuronal degeneration in CA1 was more severe in the FPI-ES group and this degeneration was also diminished by LEV. We conclude that early post injury seizures exacerbate susceptibility and severity of post traumatic seizures and increase neuronal degeneration in the CA1 layer of hippocampus. These changes are partially reversed by LEV infusion after FPI.

Title: Effects of glucose and 2DG concentration on epileptiform activity in the hippocampus

Authors: Y. PAN[1], T. SUTULA[1], *P. A. RUTECKI[1,2];
[1]Neurol., Univ. of Wisconsin, Madison, WI; [2]William Middleton Mem. VA Hosp., Madison, WI

Abstract: In vitro brain slice preparations are typically bathed in artificial cerebral spinal fluid (ACSF) with glucose concentrations between 10-20 mM. These concentrations are relatively high compared to the in vivo conditions as lack of cerebral vascular autoregulation in slices requires higher glucose concentration to support diffusion-dependent delivery to achieve physiological concentrations of 2.5-4.4 mM. In rat hippocampal slices, we evaluated the effects of glucose concentration on the rate of epileptiform bursting produced by elevating the extracellular potassium concentration to 7.5 mM and also evaluated the effects of the glucose analogue and glycolytic inhibitor 2D-deoxyglucose (2DG) in suppressing the bursting rate relative to the glucose concentration. Extracellular recordings were made from the CA3 region and the burst frequency was measured in various concentrations of glucose and glucose with added 2DG. Whole-cell voltage clamp recordings from CA3 neurons were made to assess spontaneously occurring EPSCs.
Elevating the glucose to 20 mM from a control level of 10 mM did not alter burst frequency. Also there was no change in lowering the glucose concentration to 5 mM, but 2.5 mM glucose decreased the burst rate by 57%, and 1 mM glucose resulted in cessation of bursting. ACSF with

5 mM glucose and 2.5 mM 2DG decreased the bursting rate 42% with minimal additional reduction in burst frequency produced by 5 mM 2DG (49%). When 2.5 mM 2DG was added to slices bathed in 2.5 mM glucose and 7.5 mM extracellular potassium, the bursting rate decreased by 56%.
2.5 mM glucose decreased the frequency but not amplitude of sEPSCs in control 3.5 mM extracellular potassium, suggesting a presynaptic effect of reducing glycolytic flux. In the presence of 10 mM glucose, 10 mM 2DG has effects on sEPSCs in 7.5 mM but not at 3.5mM extracellular potassium implying that activity is required for 2DG uptake and glycolytic inhibition.
Combinations of reduced glucose and 2DG have synergistic effects in suppressing epileptiform bursts in the hippocampus and demonstrate anticonvulsant actions of reduced glycolytic flux and glycolytic inhibition on epileptic network synchronization that likely contributes to anticonvulsant efficacy of 2DG in multiple acute and chronic rodent models of seizures and epilepsy.

Title: Regulation of kindling epileptogenesis by hippocampal toll-like receptors 2

Authors: ***S. MEDEL-MATUS**, E. MINAKOVA, D. SHIN, R. SANKAR, A. MAZARATI; Pediatric Neurol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Toll-like receptors (TLR) are key components of innate immunity that recognize pathogens and molecules related to cellular dysfunction under conditions of various stressful stimuli, including seizures. Seizures result in increased expression of TLR type 2 (TLR2) and 4 (TLR4) by microglia. While the involvement of TLR types 3 and 4 in ictogenesis and epileptogenesis has been well established, the role of TLR type 2 (TLR2) has been sparsely

explored. The goal of this study was to determine whether TLR2 signaling has modulatory effects on seizures in an animal model of limbic epilepsy-hippocampal rapid kindling. A TLR2 agonist, lipoteicoic acid (LTA, 50 μg, n=8), LTA antibody (LTA-A, 1 μg, n=8) or normal saline (control, 1 μl, n=8) were administered daily over 3 consecutive days, unilaterally into ventral hippocampus of 50 days-old male Wistar rats. Thirty minutes after the last injection, the animals were subjected to kindling (sixty 10-s trains delivered every 5 min; train parameters: 20 Hz, 1 ms pulse duration, square wave monophasic stimuli, 50 μA above afterdischarge threshold [ADT]). ADT and afterdischarge duration (ADD) were gauged before the treatments, 10 min before and 24 hrs after kindling. Kindling progression was analyzed by calculating the number of stimulations required for the development of focal and secondary generalized complex partial seizures. Neither LTA, nor LTA-A affected baseline afterdischarge properties. LTA had no effects on kindling progression. However, LTA-A significantly delayed the occurrence of behavioral seizures (number of stimulations to reach the first behavioral seizure [focal: LTA-A 6.5±1.13, saline 1.62±0.26, $p<0.001$; generalized: LTA 50.25±6.13, saline 25.25±2.67, $p<0.01$]). In addition, LTA-A prevented kindling-induced decrease of ADT (before kindling: 0.76±0.07 mA; after kindling saline: 0.17±0.03 mA; LTA-A: 0.53±0.07 mA, $p<0.001$) and increase in ADD (before kindling: 30.42±1.54 s; after kindling saline 53.63±5.15 s; LTA-A: 26.25±4.38 s, $p<0.001$). The results suggest the involvement of TLR2 in kindling epileptogenesis and kindling-induced increase of seizure susceptibility.

Title: Attenuation of the changes in the expression of BDNF and cfos in adult mice brain undergoing kindling: implications for antiepileptogenic properties of novel antiepileptic compound isoxylitones [E/Z]

Authors: *S. U. SIMJEE[1,2], N. ASHRAF[1], F. SHAHEEN[1], M. I. CHOUDHARY[1,2], A. RAHMAN[1,2], S. U. A. SHAH[1];
[1]HEJ Res. Inst. of Chemistry, Dr. Panjwani Ctr. For Mol. Med., Karachi, Pakistan; [2]Dr. Panjwani Ctr. for Mol. Med. and Drug Res., Karachi, Pakistan

Abstract: Purpose: For the development of new drugs for untreatable epilepsy, it is necessary to clarify the basic pathophysiology involved and find the target site. Immediate early genes such as c-fos followed by expression of brain-derived neurotrophic factor (BDNF) have been evidenced as initial important phenomena in the cascade of molecular systems that develop and complement the neuronal excitation to long-term neuronal plasticity. Both have drawn much attention as a potential therapeutic target for epilepsy. In the present study we have focused on the expression of BDNF and c-fos as a target of novel antiepileptic compound *isoxylitones* [(*E*/*Z* isomeric mixture] in the model of epileptogenesis. **Methods**: Kindling was induced by pentylenetetrazole. Levels of mRNAs and protein for BDNF and c-fos were analyzed in brain samples of mice using RT-PCR and Immunohistochemistry. **Results:** After the generalized grade 5 seizures, induced by chemical kindling, increased expression of BDNF and c-*fos* mRNA and protein was detected in amygdala, cortex, hippocampus and thalamus compared to normal group. In contrast, the treatment of isoxylitones not only retards the development of epileptogenesis but also exhibited a marked reduction in BDNF and c-*fos* levels. Furthermore, the test compound was more effective compared to diazepam since it did not produced neuro- or muscular toxicity. **Conclusion:** The present data suggests that isoxylitones act at the underlying molecular mechanism to control the seizure pattern, such as the suppression of BDNF and c-fos in various key regions of brain. These results further point out the significance of BDNF and c-fos as a target to modify epileptogenic process and to develop antiepileptogenic treatments. Further investigations to explore the mechanism of action of these compounds are under process.

Title: Resected human hippocampal tissue as a platform for testing novel treatments

Authors: *J. M. WICKHAM[1], R. VIGHAGEN[1], J. BENGZON[2], L. H. PINBORG[3], D. P. D. WOLDBYE[4], M. ANDERSSON[1], M. KOKAIA[1];
[1]Lund Univ., Lund, Sweden; [2]Univ. Hosp., Lund, Sweden; [3]Univ. Hosp., Copenhagen, Denmark; [4]Univ., Copenhagen, Denmark

Abstract: Epilepsy is a devastating disease and effects about 1% of the general population. Today symptomatic relief is given with anti-epileptic drugs but in 30 % of the patients the drugs

are ineffective. Preclinical research use animal-models to mimic the disease in humans. But due to the complexity of the disease it has proven difficult to translate the findings and new treatments from the animal-models to the human form of the disease. The consequence of this is seen in clinical trials that fail even if the preclinical results looked promising. Some of the drug-resistant patients will undergo surgery to resect the area where the epileptic focus is located. The surgery is usually successful and if the tissue can be resected in one intact piece it can be sliced and the neurons, as well as the neural networks, studied acutely with electrophysiology. The aim for our study was to take advantage of this unique opportunity and create a step in between the preclinical animal-models and the clinic. By creating a platform based on the resected brain tissue from patients with epilepsy to test promising novel treatments and drugs before forwarding them to clinical trials. When the tissue is resected it is carefully moved to our lab, cut into slices and kept in an acute state by interface incubation with oxygenised air above and artificial cerebrospinal fluid (aCSF) below the slice for up to 48h. Electrophysiological patch clamp recordings were performed on individual cells in the granular cell layer in the dentate gyrus at 3h, 24h and 48h time points. To evoke epileptiform activity the slices were perfused with 0 Mg aCSF as well as 0 Mg + 4AP aCSF during electrophysiological recording. Our results show that the intrinsic properties of the cells do not change from 3h to 48h of incubation. We have recorded spontaneous epileptiform activity in normal aCSF as well as 0 Mg aCSF. However this epileptiform activity occur in between long periods of normal activity and is therefore not reliable enough to function as a test-platform. By perfusion of 0 Mg + 4AP aSCF we recorded robust epileptiform activity with a constant occurrence of epileptiform events. By showing that it is possible to keep the slices for up to 48h it enable us to perform more recordings and gather more data in the acute tissue condition. This combined with the robust and constant occurrence of epileptiform events during perfusion of 0 Mg +4AP aCSF is the key for a test platform. By enabling a way of testing novel treatments in human brain tissue before moving on to clinical trails time, money and animals can be saved. The resources can be directed into the treatments that actually function in the human brain and the ones that do not can be sorted out in an early stage.

Title: Comparative study in two rodent species of the efficacy of anticonvulsant substances in the 6 hz psychomotor seizure test

Authors: *E. ESNEAULT, G. PEYON, E. SABLÉ, V. CASTAGNÉ;
Porsolt, Le Genest St Isle, France

Abstract: The 6-Hz test was originally described as a model of psychomotor seizure characterized by differing sensitivity to Phenytoin and Levetiracetam. Usually performed in the mouse, this screening test is recommended for identifying potential new anticonvulsant substances against partial seizures. The aim of the present study was to evaluate the utility of adapting this test in the rat. We first compared the effects of increasing current intensities for inducing seizures in the mouse and in the rat, followed by the evaluation of the pharmacological profile of anticonvulsant substances in both species. Mice or rats were manually restrained and an electrical stimulation was administered via corneal electrodes connected to a constant current shock generator. The seizure was characterized by the presence or absence of forelimb clonus immediately after electrical stimulation. Following the evaluation of their anticonvulsant effects, the possible adverse effects of drugs were evaluated by measuring locomotion. In the rat, the forelimb seizure score was intensity-dependently increased and seizures were observed in all the animals tested at 44 mA. The seizures were of lower magnitude in the mouse and they were not observed in all mice stimulated at 44 mA. Levetiracetam clearly decreased the forelimb seizure score over the dose-range 100-300 mg/kg in both species without affecting locomotor activity. Valproate displayed anticonvulsant activity at 200 mg/kg and fully protected both species at 300 mg/kg, a dose producing sedative effects in the mouse. Lamotrigine partially antagonized forelimb seizure from 10 to 60 mg/kg in the mouse and from 30 to 60 mg/kg in the rat, but induced clear motor impairments at the high dose in both species. Behavioral toxicity characterized by seizures was observed with lamotrigine at 100 mg/kg in the mouse. Phenytoin showed slight anticonvulsant activity at 10 mg/kg in the mouse and 30 mg/kg in the rat but the effects were not confirmed at higher doses. Although the magnitude of seizures was differed in the mouse and the rat for a given current intensity, the pharmacological profile of anticonvulsant substances in the 6 Hz test was very close in both species. Dose-dependent efficacy of Levetiracetam and Valproate was observed in the absence of clear efficacy of Phenytoin. Lamotrigine also showed anticonvuslant activity, even if the effective dose was close to the toxic dose. The 6 Hz test in the rat can therefore be useful as a screening model prior to follow-up models of partial seizures usually performed in the rat, such as the amygdala kindling or the pilocapine model of spontaneous recurrent seizures.

Title: Rapid astrocyte morphology changes support epileptic activity

Authors: *S. ANDERS[1], M. K. HERDE[1], D. MINGE[1], T. DESHPANDE[1], B. BREITHAUSEN[1], A. BOEHLEN[1], P. BEDNER[1], C. STEINHÄUSER[1], C. HENNEBERGER[1,2,3];
[1]Inst. of Cell. Neurosciences, Univ. of Bonn Med. Sch., Bonn, Germany; [2]UCL Inst. of Neurol., UCL, London, United Kingdom; [3]German Ctr. for Neurodegenerative Dis. (DZNE), Bonn, Germany

Abstract: Astrocytes actively contribute to the functioning of neuronal networks. Their close contact to thousands of neurons enables them to modulate and maintain neuronal function effectively by, for example, buffering potassium and glutamate clearance. A disruption of this spatial relationship could be of pathophysiological significance. Indeed, astrocyte dysfunction and long-term morphology changes have been implicated in numerous diseases including epilepsy. How rapid astrocyte morphology is altered by the onset of epileptiform activity and to what degree this contributes to aberrant network activity is largely unknown. Combining established protocols of hippocampal epileptogenesis, electrophysiology and two-photon excitation fluorescence microscopy allowed us to monitor astrocyte morphology changes during the induction of epileptiform activity in acute rodent hippocampal slices. Analysis revealed that small and medium-sized astrocyte processes shrink acutely within minutes after epileptiform discharges appeared in the CA1 region. Importantly, similar astrocyte morphology changes were also detected 30 minutes after induction of status epilepticus *in vivo* by intracerebral kainate injection. *In vitro*, these astrocyte morphology changes outlasted the induction of epileptiform activity, persisted after pharmacological termination of epileptic activity by TTX and were sensitive to inhibition of Rho-associated protein kinase (ROCK, Y-27632). Interestingly, ROCK inhibition also reduced epileptiform activity, indicating that rapid astrocyte morphology changes support epileptic activity. A modification of glutamatergic or GABAergic synaptic transmission

did not underlie the proconvulsive effect of astrocyte morphology changes. Instead, we observed that intracellular diffusion in astrocytes and diffusion between astrocytes via gap junctions were significantly decreased in parallel to morphology changes. The reduced astrocyte gap junction coupling is likely a consequence of reduced intracellular diffusion because no change of connexin 43 and 30 expression and phosphorylation was observed. Thus, astrocytes respond to epileptic activity with morphology changes on a time scale of minutes, which reduces intra- and intercellular diffusion in the astrocyte network and supports further epileptic activity. Current experiments investigate the mechanism (e.g. potassium buffering and glutamate uptake) linking acute astrocyte morphology changes and the maintenance of epileptiform activity.

Title: Association of ELAVL2 and PTPRD genes with epilepsy in purebred Chinese Crested Dogs

Authors: *A. L. SINIARD[1], I. S. PIRAS[1], M. KRUG[2], B. BALLIF[2], L. SHAFFER[2], V. ZISMANN[1], J. TRENT[1], M. J. HUENTELMAN[1];
[1]Tgen, Phoenix, AZ; [2]Pawprint Genet., Spokane, WA

Abstract: We performed a genome-wide case-control study in a sample of epileptic Chinese Crested Dogs and matched controls to investigate the contribution of genetic variants to the high epilepsy risk in the breed. The genotyping was performed using the Canine HD Whole-Genome Genotyping BeadChip (Illumina). After quality controls, we obtained a dataset of 27 cases and 38 controls (Call Rate > 80%) for a total of 106,392 informative autosomal SNPs. Association analysis at the SNP level was conducted using PLINK running a logistic regression including age, gender and correcting for population stratification. Quality of candidate SNPs detected was further assessed by visually inspecting the genotype cluster plots. None of the SNPs analyzed reached genome-wide significance (P = 4.7E-07). However, at nominal significance levels we observed 7, 15 and 2 SNPs with P < 0.001 in the additive, dominant and recessive models, respectively. Among the top genes we observed KHRDBS3, ELAVL2, TCF25, DEF8, PTPRD, RNF25, GALNT10, DPYD, ATAD2 and WDYHV1. The association test was rerun for the

SNPs located in the most potentially biologically relevant genes for epilepsy (KHRDBS3, ELAVL2 and PTPRD) with additional samples not included in the GWAS due to call rate, for a total of 4 or up to 9 additional samples depending on the SNP. The results confirmed the significance for the SNPs located in PTPRD and ELAVL2 (P = 9.9E-05 and P = 9.9E-05, respectively). The results for the variant located in KHRDBS3 were not considered due to the low quality of the additional samples for that particular SNP. Our preliminary results suggest the involvement of variants located in ELAVL2 and PTPRD with epilepsy in the Chinese Crested Dog breed. ELAVL2 is highly expressed in hippocampal CA3 pyramidal neurons and hilar interneurons. It has also been reported in animal models that Elavl2 protein level in the hippocampus is acutely down regulated after a kainic acid induced seizure in the hippocampal CA3 region. PTPRD was detected suggestively significant in a GWAS investigating the association with remission of seizures after starting treatment in 889 newly treated patients. We also observed 2 SNPs located in ADAM23 (P = 0.0012), a gene previously associated with idiopathic epilepsy in 4 different dogs breeds. Due to our limited sample size, the results are not significant at the genome-wide level after correction for multiple testing. A larger sample size will help to confirm the results; however, the biological significance of some of the top genes justifies a potential role of these variants in epilepsy in the Chinese Crested Dog.

Title: Tumor-associated epilepsy in a mouse model of malignant glioma.

Authors: *E. STOLL[1], C. GANDARA DE SOUZA[2], V. AFFLECK[2], J. STOCKTON[3]; [2]Inst. of Neurosci., [3]Undergraduate Programme in Biomed. Sci., [1]Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Glioma is the most common form of adult-onset primary malignant brain tumor, affecting approximately 4 per 100,000 people and representing 81% of all malignant brain

tumors. Low-grade gliomas commonly manifest with a seizure, in approximately 75% of cases; high-grade gliomas, called glioblastomas, are associated with seizures in 29-49% of cases (Ostrom *Neuro Oncology* 2014, CBTRUS *Statistical Report* 2009). Tumor-associated epilepsy (TAE) significantly impacts on the quality of life of these patients.

Initiating events underlying TAE are not well-understood, but are thought to include mass effect during tumor growth, with attendant increases in intracranial pressure; loss of interneuron populations; aberrant potassium ion channel expression within neurons, leading to depolarizing not hyperpolarizing responses to GABA signals; excess glutamate release by the tumor or altered responses of cells to this neurotransmitter; alterations in gap junctions between cells; altered cation buffering by glial cells or altered glial excitability; pH shifts due to the acidic environment created by tumour cells; or localised disruption of neural networks near the tumor (Cowie & Cunningham *Epilepsy & Behavior* 2014).

An animal model of malignant glioma which demonstrates tumor-associated epilepsy may help to elucidate the underlying mechanisms for this phenomenon, although few characterised models are available (Kirschstein & Kohling *J Neurosci Methods* 2015). Recently, a syngeneic mouse model of glioma has been developed which reproduces the histopathological and clinical characteristics of human glioma on a wild-type background (Mikheev et al. *Aging Cell* 2009). We observe that 26% of these animals manifest seizures, thereby providing a highly reproducible context in which to evaluate mechanisms underlying TAE.

In this study, we conducted histological analysis in seizing and non-seizing animals to discern cellular and molecular features associated with this phenotype. Animals with seizures do not have significantly larger tumor size or greater infiltration of brain areas, nor do they demonstrate significant changes to interneuron population size in the ipsilateral peri-tumoral region, although some cellular disorganisation is observed. Future studies will address mechanisms underlying TAE by using Utah Arrays to record single-unit activity and field potentials across tissue sections containing both tumoral and peri-tumoral regions, while pharmacologically manipulating glutamate, GABA, and gap junction signalling.

Title: A model of bilateral subcortical band heterotopia created by *In utero* electroporation with a triple electrode probe

Authors: *S. SAHU[1,2], E. BUHLER[3,2], Y. CHAUVIN[1,2], A. REPRESA[1,2], J.-B. MANENT[1,2]; [1]INMED, INSERM U901, Marseille, France; [2]Aix Marseille Univ., Marseille, France; [3]INMED, PPGI, Marseille, France

Abstract: Experimental subcortical band heterotopia (SBH) can be modeled in rats by knocking down Dcx in embryonic brains using in utero electroporation and RNA interference. These Dcx-KD rats display altered neocortical excitability, resulting in an increased propensity for convulsant induced seizures at juvenile ages and spontaneous focal, absence-like seizures in adulthood. These rats however harbor a band heterotopia located in a single hemisphere (unilateral), unlike most human patients harboring bilateral and symmetrical SBH. Also, spontaneous seizures were rarely observed before 5-6 months of age in unilateral Dcx-KD rats, while epilepsy usually begins between childhood and infancy in most patients with SBH. To overcome these limitations and increase the strength and relevance of experimental SBH regarding the human situation, we recently introduced a novel rat model with bilateral SBH. This rat model is generated via in utero electroporation by utilizing a triple electrode configuration enabling simultaneous electroporation of the two brain hemispheres (bilateral) instead of a single hemisphere in the conventional settings. Histological analyses revealed the presence of widespread band heterotopia in both hemispheres of Dcx-KD rat brains. Telemetric EEG recording at different age (1-6 months) showed that rats with bilateral SBH develop spontaneous recurrent spike-and-wave discharges at early ages. Furthermore, whole cell voltage clamp recordings on acute juvenile neocortical slices revealed an increased ongoing glutamatergic synaptic activity and the occurrence of spontaneous network driven activities in the cortex overlying SBH. Our preliminary results indicate that this novel model could be useful to study the mechanisms leading to spontaneous epilepsy in an experimental context more relevant to the clinical situation seen in humans.

Title: Interneuronopathy in a non-genetic animal model of infantile spasms

Authors: *A.-M. KATSAROU[1], S. L. MOSHÉ[1,2,3], A. S. GALANOPOULOU[1,2];
[1]Saul R. Korey Dept. of Neurology, Lab. of Developmental Epilepsy, [2]Montefiore/Einstein Epilepsy Center, Dominick P. Purpura Dept. of Neurosci., [3]Dept. of Pediatrics, Albert Einstein Col. of Med., Bronx, NY

Abstract: **Background:** West syndrome is an age-specific type of severe epilepsy of infancy, which manifests with characteristic seizures, infantile spasms (IS), and poor prognosis. Numerous structural, metabolic or genetic etiologies have been linked to IS. Interneuronopathy, a dysfunction or abnormal migration of interneurons, has been associated with certain genetic etiologies of IS. We have developed a non-genetic animal model, the multiple-hit rat model of infantile spasms due to an acquired structural lesion, to investigate further the pathogenesis of West syndrome.
Objective: Here, we investigate if interneuronopathy is a feature of IS of acquired etiologies. We focused on parvalbumin-immunoreactive (PRV-ir) GABAergic interneurons, which comprise almost half of the GABAergic cortical interneurons, and investigated whether they are selectively reduced in the cerebral cortex of multiple-hit rats with IS.
Methods: Postnatal day (PN) 3 Sprague-Dawley male rats received right intracerebral injections of Doxorubicin and Lipopolysaccharide followed by systemic p-chlorophenylalanine on PN5 (herein called DLP rats). On PN20, rats were subjected to transcardiac perfusion and brains were frozen for histology. PN20 male control rats were also used. Coronal brain cryosections (40μm) were stained with a primary mouse anti-PRV antibody (SIGMA, St Louis, MO). PRV-ir cells (cells/mm^3) from all layers of the left or right sensory (S1, S2) cortex and cortical volumes were counted in 8 DLP and 7 control rats, blinded to treatment allocation. Median test was used for statistical comparisons.
Results: In the left sensory cortex, cortical thickness of DLP rats was reduced only to 91.8% of controls (P=0.0553), yet there was a preferential reduction in the densities of PRV-ir interneurons in DLP rats (median=1006.94 cells/mm^3) compared to controls (median=1973.27 cells/mm^3) (P=0.0062). In the right sensory cortex of DLP rats, there was a significant reduction in cortical thickness (57.2% of controls, P=0.01) but no further selective reduction in PRV-ir cell densities.
Discussion: In the right sensory cortex, the induced lesion is not cell-type specific, manifesting as severe cortical thinning. In the contralateral cortex, however, there is preferential loss of PRV-

ir interneurons. Interneuronopathy can be a feature of certain acquired etiologies of IS extending beyond the borders of the primary structural lesion.

Title: Novel chemo-optogenetic model of inducible epileptic seizures

Authors: ***R. MITELMAN**[1], D. R. LEVY[1], L. POTHMANN[2], H. BECK[2], I. LAMPL[1], O. YIZHAR[1];
[1]Neurobio., Weizmann Inst. of Sci., Rehovot, Israel; [2]Dept. of Epileptology, Exptl. Epileptology and Cognition Res., Univ. of Bonn Med. Ctr., Bonn, Germany

Abstract: Epilepsy, one of the most common and devastating neurological disorders, is manifested by synchronized neuronal seizures that typically begin as a local-circuit phenomenon and rapidly spread to remote brain regions, impairing cognition, motor functions and sensory perception. Better understanding of the pathophysiology of seizure onset, propagation and changes in excitation/inhibition (E/I) balance is required for the development of new therapeutic approaches. However, current animal models suffer major weaknesses rendering them less suitable for these purposes. Reliable models of epilepsy (e.g., pilocarpine), lack a method for seizure induction, whereas reliable seizure models (e.g., PTZ induced seizure), require radical interventions in the network activity. We have developed a novel chemo-optogenetic model that allows light inducible seizures, with high reproducibility at a defined cortical locus. In this model we used AAV stereotactic injections to express an inhibitory chemogenetic tool (hM4D) along with channelrhodopsin-2 in GABAergic interneurons of the medial prefrontal cortex. Application of the synthetic ligand of hM4D Clozapine N-oxide (CNO) silenced GABAergic neurons, as we demonstrated by acute brain slice recordings. Importantly, systemic application of CNO in non-anesthetized mice initiated a global seizure within a few minutes, as expected by silencing the inhibitory population of neurons. Paradoxically, when the same population of inhibitory cells was optogenetically activated days later, prolonged epileptic activity also developed, lasting minutes after the light was terminated. We also observed spontaneous epileptic activity in some of the animals. Strikingly, systemic pre-treatment of these mice with

Bumetanide, a blocker of NKCC1 transporters, attenuated the optogenetically-induces seizures. NKCC1 pumps chloride into the cells and is not expressed in healthy adult neurons. Therefore, our results suggest that seizure-associated re-expression of NKCC1 in neurons raises GABA reversal potential, making these synapses less inhibitory or even excitatory. In summary, this novel model combines the advantages of both a chronic epilepsy model, as the animals show spontaneous epileptic activity, and an acute seizure model, with inducibility by optogenetic activation of GABAergic neurons. Seizures are likely to result from a shift of GABA reversal potential, rendering the network more excitable. This inducible model allows highly controlled testing of the underlying cellular and network mechanisms of seizures, such as changes in the E/I balance and their spatiotemporal propagation pattern.

Title: Status epilepticus induced by pentylenetetrazol and lithium-pilocarpine increases cell proliferation in the developing rat cerebellum

Authors: *E. VELAZCO[1], I. ZAMORA BELLO[2], A. A. PUIG LAGUNES[2], L. BELTRAN PARRAZAL[2], C. A. PEREZ ESTUDILLO[2], C. MORGADO VALLE[2], M.-L. LOPEZ MERAZ[2]; [1]Ctr. De Investigaciones Cerbrales, Xalapa, Mexico; [2]CENTRO DE INVESTIGACIONES CEREBRALES, UNIVERSIDAD VERACRUZANA, XALAPA, Mexico

Abstract: Evidence supports that *status epilepticus* (SE) promotes neuronal proliferation and differentiation in the adult and developing rodent hippocampus. However, the effect of SE on other neurogenic brain regions, such as the cerebellum, has been less explored. The goal of this research was to determine whether SE induced by pentylentetrazole (PTZ) and lithium-pilocarpine (Li-Pilo) increases cell proliferation in the developing rat cerebellum. SE was induced in fourteen-days-old (P14) Wistar rat pups (both sexes). PTZ-induced SE was produced by injection of 55 mg/kg (n=6); Li-Pilo SE was induced by given 3 mEq/kg lithium chloride on the day before the induction of SE with 100 mg/kg pilocarpine hydrochloride. Control animals were given an equal volume of saline or lithium chloride followed by saline, respectively. One h

after SE and the following day, rats were injected intraperitoneally with 5-bromo-2-deoxyuridine (BrdU, 50mg/kg). Seven days following SE, rats were anesthetized and transcardially perfused with 4% phosphate-buffered paraformaldehyde; control rats were processed similarly. Subsequently, the cerebellum was removed and cut (40-µm-thick sagittal sections) in order to perform peroxidative immunohistochemistry to detect BrdU in the cerebellar vermis. This protocol allowed to quantify the number of cells that incorporated BrdU (BrdU+), indicative of cell proliferation, in the granular layer of the vermis. Data were analyzed by a Student *t* test. Results showed a significant increase in the number of cerebellar BrdU+ cells after SE induced by PTZ (121 ± 5.5) or Li-Pilo (98 ± 4) when compared with the control group (77 ± 3.4 and 70 ± 3.2, respectively). PTZ-induced SE increased the number of BrdU+ cells specifically in the lobules II (81.5 ± 10.5), III (122 ± 17.5), VIb (165 ± 17.2), VIc (161 ± 24.8), VIII (179 ± 14.4), IXa (108 ± 10) and IXb (176 ± 14.3) when compared with the control group (49 ± 7.8, 73 ± 9.4, 80 ± 15.4, 11.5 ± 96, 93 ± 8.2, 11.9 ± 73 and 82 ± 10.4 respectively). Li-Pilo-induced SE increased the number of BrdU+ cells in the lobules II (67 ± 4.3), V (100 ± 11.3), VIc (151 ± 13.5), VII (130 ± 11.1) and X (87 ± 10.1) compared with the control group (44 ± 8.5, 67 ± 7.3, 14.7 ± 86, 92 ± 8.2 and 56 ± 7, respectively). In conclusion, SE induced in the developing rat by different experimental models increases cell proliferation in the granular layer of the cerebellar vermis.

Title: Interictal and ictal involvement of the anterior nucleus of the thalamus in a non-human primate model of mesial temporal lobe epilepsy

Authors: A. SHERDIL, Jr[1,3], S. CHABARDES[2], A. DAVIN, Jr[2,3], S. MICHALLAT[2], O. DAVID[2,3], *B. Y. PIALLAT, PhD[4,3];

Abstract: Mesial temporal lobe epilepsy (mTLE) consists in a paroxysmal neuronal synchronous hyperactivity within the temporal lobe, especially in the hippocampus (Hc). Because this structure is part of the Papez circuit, we hypothetize that the ictal activity would propagate through the various structures of the Papez circuit, namely the anterior nucleus (AN), what would contribute to ictal activity maintenance. To verify the involvement of AN in mTLE, we recorded the neuronal activity of AN during mTLE on epileptic monkeys. In 4 monkeys (M1 to M4), penicillin (1950-2600 UI) was injected into the Hc, on demand, at the speed of 2μL/min) using a mechanical pump connected to a Hamilton syringe, to induce the mTLE for about five hours. Temporal seizures were monitored using one Hc quadripolar macro-electrode. The AN activity was studied using a chronic implanted macroelectrode to record local field potentials in M1-3 and using a microelectrode with a recording chamber in M4. For each neuron, we calculated the mean firing rate and evaluated the type of firing pattern (rhythmic oscillatory, irregular or regular) during interictal and ictal periods. All monkeys exhibited the first ictal spike during the penicillin injection about 3 min after the beginning of the injection and the first seizure appeared during the first 30 min. The duration of seizures was of about 30s (29.3 ± 1.2 s from M2, with 3-4 seizures by 20min for 4 hours). Seizures were associated with behavioral effects, including salivation, tongue automatisms, chewing and highly frequent orofacial movements. In M1-3, we observed, within the AN, the occurrence of an ictal activity synchronized with all mTLE ictal events recorded in Hc. For all seizures, time frequency analysis showed the same frequency composition in the Hc and the AN, with, in M1, a significant oscillation at 40Hz in the AN for few seconds at the end of seizures. In M4, 8/30 AN recorded neurons showed a significant increase of firing rate time locked to the Hc interictal spikes and during the Hc seizures. We also observed that Hc interictal spikes induced, 80 to 200 ms after, significant biphasic evoked potentials within the AN region. These data show that AN neurons are indeed involved during mTLE seizures. This confirms, in non-human primate, that AN could be a good target for therapeutic neuromodulation.

Title: Ethanol inhibits cooling-induced spinal seizures

Authors: *N. L. DALO[1], J. C. PIÑA-CRESPO[2];
[1]Univ. Centroccidental Lisandro Alvarado, Iribarren, Venezuela, Bolivarian Republic of; [2]Basic Sci., Univ. Centroccidental Lisandro Alvarado, Barquisimeto, Venezuela, Bolivarian Republic of

Abstract: The isolated spinal cord is capable of generating patterns of tonic-clonic seizures similar to those observed in intact animals and paroxysmal seizure-like activity could be induced by cooling the isolated spinal cord; an experimental model of seizures that depends on release of excitatory amino acids (EAA)**.** We examine whether clinically relevant doses of ethanol can prevent the onset and severity of spinal seizures. Tonic-clonic seizures of spinal origin were generated by sudden cooling to 7 ºC of the isolated spinal cord-hindleg preparation of toads. The characteristic phases of seizures and their intensity were assessed by recording muscle contractions. The onset and duration of seizures were measured 45 min after intralymphatic administration of ethanol at doses of 1.5, 2.5 and 5 g/kg diluted to 10% with Ringer solution. The tonic phase of seizures was effectively shortened or eliminated in a dose dependent manner when ethanol was given at 1.5 and 2.5 g/kg. At doses of 5 g/kg ethanol abolished all phases of seizures. The latency of seizure onset was enhanced by 71% and 145% at ethanol doses of 1.5 and 2.5 g/kg, respectively. The effect of ethanol on the pattern of seizures was compared with that of known antagonists of EAA receptors. We concluded that ethanol inhibition of the tonic phase was linked to inhibition of NMDA receptors, while inhibition of the clonic phase of seizure was due to its blocking action on AMPA receptors; on the other hand, its effect on the latency of seizure onset resembled that of drugs that enhance $GABA_A$ receptor activity.

Title: Mitochondrial translocation of high mobility group box 1 facilitates LIM kinase 2-mediated programmed necrotic neuronal death

Authors: H.-W. HYUN, A.-R. KO, J.-E. KIM, *T.-C. KANG;
Col. Med, Hallym Univ., Chunchon, Korea, Republic of

Abstract: High mobility group box 1 (HMGB1) acts a signaling molecule regulating a wide range of inflammatory responses in extracellular space. HMGB1 also stabilizes nucleosomal structure and facilitates gene transcription. Under pathophysiological conditions, nuclear HMGB1 is immediately transported to the cytoplasm through chromosome region maintenance 1 (CRM1). Recently, we have reported that up-regulation of LIM kinase 2 (LIMK2) expression induces HMGB1 export from neuronal nuclei during status epilepticus (SE)-induced programmed neuronal necrosis in the rat hippocampus. Thus, we investigated whether HMGB1 involves LIMK2-mediated programmed neuronal necrosis, but such role is not reported. In the present study, SE was induced by pilocarpine in rats that were intracerebroventricularly infused with saline, control siRNA, LIM kinase 2 (LIMK2) siRNA or leptomycin B (LMB, a CRM1 inhibitor) prior to SE induction. Thereafter, we performed Fluoro-Jade B staining, western blots and immunohistochemical studies. LIMK2 knockdown effectively attenuated SE-induced neuronal death and HMGB1 import into mitochondria accompanied by inhibiting nuclear HMGB1 release and abnormal mitochondrial elongation. LMB alleviated SE-induced neuronal death and nuclear HMGB1 release. However, LMB did not prevent mitochondrial elongation induced by SE, but inhibited the HMGB1 import into mitochondria. The efficacy of LMB was less effective to attenuate SE-induced neuronal death than that of LIMK2 siRNA. These findings indicate that nuclear HMGB1 release and the subsequent mitochondrial import may facilitate and deteriorate programmed necrotic neuronal deaths. The present data suggest that the nuclear HMGB1 release via CRM1 may be a potential therapeutic target for the programmed necrotic neuronal death induced by SE.

Title: Environmental enrichment reduces seizure frequency in adolescent rats prone to sound-induced seizures

Authors: *M. C. ZRULL, D. I. ALEWEL, H. C. SKINNER, S. L. SANTIAGO, H. L. JOHNSON, S. J. SNOUSE, T. J. ARNOLD;
Psychol, Appalachian State Univ., Boone, NC

Abstract: Environmental enrichment (EE) promotes brain plasticity through interaction with objects and conspecifics and can protect from results of brain damage as well as mitigate severity of deficits after brain injury. Seizures, which involve abnormal neural activity that may generalize and provoke convulsions, produce brain injury with each event leading to more severe epilepsy in the future. We examined the effects of EE on audiogenic seizure (AGS) frequency and severity using a model of acquired recurrent AGS through adolescence. One group of AGS-prone Long Evans rats (n=21) lived in standard cages and received EE for 1.5-h 18 times from postnatal day (pnd) 32 to 60, and a control group of AGS-prone rats (n=18) remained in standard cages, received no EE, but were picked up periodically to control for handling. For all rats, 12 audiogenic responses (AGRs) were induced with 120 dB broadband noise on the same schedule between pnd 32 and 62. Severity of the seizure disorder was measured as latency to AGRs (wild running, shorter is more severe), and intensity of AGSs was measured as the duration of clonus (longer is more intense). When regressed on EE condition and induction session, 11% of the variance AGR latency was explained (p<.05) with latency decreasing by 52% for control and by 26% for EE rats exhibiting AGRs. Similarly, 8% of the variance in AGS duration was explained by the regression on EE and induction (p<.05) with seizure duration remaining unchanged across inductions for control and decreasing slightly (-6%) for EE rats exhibiting AGSs. While 86% of controls had seizures at the final inductions, only 50% of EE rats exhibited AGSs at these inductions (p<.05). One hour after the final induction, seizure-prone rats were sacrificed and brains were processed to visualize a neural activity marker, c-fos protein, in the lateral amygdala (LA), which is a critical relay in the network allowing anomalous excitation to reach the forebrain. EE brains revealed an increase of neural activity of 954% over baseline while control LA showed an increase of 509%. While not changing the rate of AGR occurrence or intensity of seizures when they occurred, EE did reduce the number of seizures experienced. The LA data are intriguing with EE enhancing rather than suppressing LA activity evoked by AGR induction as the behavioral data might predict; however, the activity may be of inhibitory interneurons and bares further investigation. Particularly during the critical developmental period of adolescence,

EE may provide a relatively simple, benign, non-invasive alternative to pharmacological or surgical treatment for seizure disorder, which may produce unintentional brain injury.

Title: Functional integration of transplanted MGE-derived interneurons within hippocampal circuits revealed using optogenetics

Authors: *J.-Y. HSIEH, S. BARABAN;
Neurolog. surgery, UCSF, San Francisco, CA

Abstract: Interneuron-based cell therapy has gained an increasing amount of attention owing to its promising potential to rectify diseased neural networks, including epilepsy. Our previous work showed that transplanting embryonic GABA progenitors, derived from the medial ganglionic eminence (MGE), into epileptic mice suppresses spontaneous seizures and improves learning behavior (Baraban et al. PNAS 2009; Hunt et al. Nat. Neurosci. 2013). It is thought that the therapeutic effect results from synaptic integration of these cells in host circuits. However, details underlying integration of MGE-derived interneurons have yet to be fully explored. Here, by employing optogenetic and electrophysiological approaches, we further investigated the properties of grafted interneurons and the functional impact of them on local circuits in a cell-type specific manner. Embryonic MGE cells were transplanted into the hippocampus of WT mice at postnatal day 2. ChR2-eYFP was expressed in MGE-derived donors driven by GAD2-, or PV- or SST-Cre. We first characterized intrinsic properties of MGE-derived interneurons starting at 30 days after transplantation, and found that they share common attributes with their corresponding types of native interneurons. We then focused on the postsynaptic connections between MGE-derived interneurons and native pyramidal cells; spontaneous IPSC frequency and the kinetics of light-evoked IPSCs were analyzed. As expected, IPSC frequency was increased in regions containing transplanted MGE-derived interneurons. In all cases, optogenetic activation of MGE-derived ChR2-expressing interneurons evoked IPSCs on native pyramidal neurons with normal kinetics; light-evoked IPSCs were blocked by the subsequent addition of gabazine (a

GABA receptor antagonist). Next, we explored the impact of excessive activation of grafted interneurons on native pyramidal neurons. We used input-output curves to probe changes in excitability and in the dynamic range of spiking upon synchronized interneuron activation. Optogenetic activation of MGE-derived ChR2-expressing interneurons in the vicinity of a native pyramidal cell right-shifted its I-O curve. This parallel shift suggests that MGE-derived interneurons alter the circuit by simply imposing an inhibitory shunt to pyramidal cell activation and not affecting the gain (slope) or the dynamic range (max frequency). Taken together, our results show that MGE-derived interneurons functionally integrate into host circuits in a cell-type specific manner, and that even with excessive activation transplanted cells do not alter host circuit function in a non-specific, nor deleterious, manner.

Title: 1400W, a highly selective inducible nitric oxide synthase inhibitor is a potential disease modifier in the rat kainate model of temporal lobe epilepsy

Authors: *T. THIPPESWAMY[1], S. PUTTACHARY[2], S. SHARMA[2], S. VERMA[2], Y. YANG[2], M. R. E. PUTRA[2], A. THIPPESWAMY[2], L. DIUO[2];
[1]Dept. of Biomed. Sci., [2]Iowa State Univ., Ames, IA

Abstract: *Status epilepticus* (SE) initiates epileptogenesis to transform normal brain to epileptic state which is characterized by spontaneous recurrent seizures (SRS). Prior to SRS, progressive changes occur in the brain soon after SE, for example, loss of blood-brain barrier (BBB) integrity, neuronal hyper-excitability (epileptiform spiking), neuroinflammation [reactive gliosis, high levels of reactive oxygen/nitrogen species (ROS/RNS)], neurodegeneration and synaptic re-organization. Our hypothesis was that modification of early epileptogenic events will alter the course of disease development and its progression. We tested the hypothesis in the rat kainate model of chronic epilepsy using a novel disease modifying drug, 1400W, a highly selective inhibitor of inducible nitric oxide synthase (iNOS). In an *in vitro* mouse brain slice model, using a multi-electrode array system, co-application of 1400W with kainate significantly suppressed kainate-induced epileptiform spiking. In the rats, *in vivo*, four hours after the induction of SE with kainate, 1400W (20 mg/kg, i.p.) was administered twice daily for three days to target early events of epileptogenesis. The rats were subjected to continuous (24/7) video-EEG monitoring,

remotely, for six months from epidurally implanted cortical electrodes. The 1400W treatment resulted in >90% reduction in SRS when compared to the vehicle-treated control group (257±113 versus 19±10 episodes) during the six month period. Immunohistochemistry (IHC) of brain sections at seven day and six month revealed a significant reduction in; reactive astrogliosis and microgliosis (M1 type), extravascular serum albumin (marker for BBB leakage) and neuro-degeneration in the hippocampus, amygdala and entorhinal cortex in the 1400W-treated rats when compared to the vehicle control. In the seven day group, hippocampal Western blots revealed downregulation of inwardly-rectifying potassium (K_{ir} 4.1) channels and glutamate transporter-1 (GLT-1) levels in the vehicle group, and 1400W treatment partially reversed K_{ir} 4.1 levels, however, GLT-1 levels were unaffected. In the six month group, a significant reduction in mossy fiber staining intensity in the inner molecular layer of the dentate gyrus was observed in the 1400W-treated group. Overall these findings demonstrate that 1400W potentially modifies epileptogenesis and the severity of the chronic epilepsy.

Title: Chronic branched-chain amino acid ingestion aggravates hilar neuronal loss in a rodent model of temporal lobe epilepsy

Authors: S. E. GRUENBAUM[1], R. DHAHER[2], A. RAPUANO[3], A. TANG[2], *T. EID[2];
[1]Dept Anesthesiol., [2]Dept Lab. Med., [3]Dept Neurosurg., Yale Univ., New Haven, CT

Abstract: Introduction: The branched chain amino acids (BCAAs) valine, leucine, and isoleucine are essential amino acids that are diet-derived. There is increasing evidence to suggest that BCAAs are critical for several functions in the brain, including glutamate synthesis (and thus glutamine and GABA synthesis), intracellular signaling, immune modulation and mitochondrial health. However, there are conflicting data on the role of the BCAAs in the pathophysiology of brain disorders such as epilepsy. The objective of this study was to determine the effects of chronic BCAA ingestion on hilar neuronal loss in a rodent model of mesial temporal lobe epilepsy (MTLE). **Methods:** Sixteen rats were randomly divided into two groups: 8 rats drank a 4% aqueous solution of all three BCAAs (BCAA group) *ad libitum* for 31 days, and the other 8 rats drank regular water (control group) for the same period. After 10 days of

drinking, a microinjector was surgically implanted in the right dentate gyrus to continuously infuse the glutamine synthetase inhibitor methionine sulfoximine (MSO) for 28 days. After 31 days of drinking, rats were perfused transcardially with 0.9% NaCl followed by 4% formaldehyde in phosphate buffer. The brains were removed and fixed, sectioned on a Vibratome at 50-µm thickness, and were mounted on a gelatin-coated slides and stained with NeuN. Neuron counts in the hilar region were performed ipsilateral to the infusion site using a stereological technique. **Results:** Rats in the BCAA group had 37% fewer neurons in the dentate hilus than the control group ($5.8 \times 10^{-4} \pm 6.8 \times 10^{-5}$ vs $8.9 \times 10^{-4} \pm 5.6 \times 10^{-5}$ cells respectively, $p<0.01$). **Conclusions:** This study demonstrates that chronic ingestion of BCAAs aggravates hilar neuronal loss in a rodent model of MTLE. This study gives important insight into how BCAAs may affect neuronal viability. Although the role of BCAAs in seizure formation is unknown, these results suggest that BCAAs may play an important role in neurochemical modulation and neurotoxicity.

Title: Effect of chronic seizures on the functional integration of adult born neurons

Authors: A. KALININA, J. CARR, H. TURNER, H. LEHMANN, *N. M. FOURNIER; Dept. of Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Adult neurogenesis is a developmental process encompassing the birth of new neurons and their integration into the existing neuronal circuitry. As new neurons begin the process of integration, they pass through a transient period of heightened plasticity, which is called the critical period. This period lasts ~2 to 4 weeks in rats, and it is during this time that newborn cells are more excitable than their mature counterparts enabling these new neurons to play a key role in supporting hippocampal functions, such as spatial learning and memory. However, with aberrant stimulation, this critical period might be significantly compressed resulting in adult-born neurons integrating and becoming functionally quiescent at earlier time points. To test this possibility, we examined the impact of chronic seizures on the temporal progression of network

integration of new neurons. We labeled dividing cells with the proliferation marker BrdU before commencing with pentylenetetrazole (PTZ) kindling for a period of 1 or 2 weeks. To examine integration and activity of newborn and mature neurons, we examined for the expression of immediate early gene markers of neural activity (IEGs: Fos and Zif268) following 30-minute exposure to novel spatial environment. As expected, exploration of a novel environment significantly increased the number of Fos+ and Zif268+ cells in the dentate gyrus of non-kindled controls. In contrast, rats that received 1 or 2 weeks of PTZ kindling showed fewer Fos+ and Zif268+ cells in the dentate following exposure to the novel environment. Preliminary co-localization analysis showed that significantly fewer BrdU+ cells were activated following exploration of the novel environment in kindled rats compared to non-kindled controls. These findings raise the possibility that chronic seizures might interfere in the ability of new neurons to integrate and functionally participate in behavioural circuits. We are currently assessing the effect of longer durations of kindling on network integration of adult-born neurons as well as examining the role of GABA signaling in regulating the plasticity of new neurons in the epileptic brain.

Title: Dentate granule cell hyperactivity contributes to cognitive comorbidities in temporal lobe epilepsy

Authors: ***J. B. KAHN**[1], C. YUE[4], H. TAKANO[4,2], D. A. COULTER[1,3,4];
[1]Neurosci., [2]Neurol., [3]Pediatrics, Univ. of Pennsylvania, Philadelphia, PA; [4]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Although epilepsy management focuses on ameliorating seizure activity, patients must cope with a host of complicated cognitive comorbidities, which many patients find more detrimental to daily life than the seizures. However, the neural mechanisms mediating these

cognitive impairments in temporal lobe epilepsy (TLE) are not well defined. The dentate gyrus (DG) is fundamental for cognitive functions in the hippocampus, a structure that TLE seizures highly activate, particularly pattern separation. Pattern separation is mediated by remarkably sparse activation in the DG's granule cells (DGCs). Sparse DGC activation has a secondary effect: the DG limits cortical input to the hippocampus and acts like a "gate," the failure of which may contribute to the excessive cortical-hippocampal activity underlying TLE seizures. Our laboratory previously found a more than 10-fold increase in DGC activation patterns following epilepsy onset in our TLE mouse model. In this study, we used Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to hyperactivate DGCs in otherwise normal mice to isolate the potential cognitive consequences on a hippocampal memory task. In the spatial object recognition (SOR) task, mice are exposed to 3 objects; 24 hours later, one object is moved, and the amount of time the mice explore the displaced object (DO) reflects if the mice recognize a change in their spatial environment. Wild type mice performed well on the SOR task, spending significantly more time exploring the DO compared to the non-displaced objects (NDOs). However, epileptic mice failed to discriminate. Mice that received viral injections of the excitatory DREADD to the dorsal DG were given either saline or CNO injections i.p. 1 hour before the SOR testing trial. The saline group successfully discriminated between the DO and NDOs, while the CNO group failed to discriminate. hM3D-receiving mice were a transgenic line in which fos drives expression of tdTomato when tamoxifen is present, called Fos Targeted Recombinase in Active Populations (FosTRAP). FosTRAP is an inducible, permanent marker of activity, providing a "snapshot" of the number of DGCs that were recruited during the behavior, and confirming that CNO did not induce seizure-like activity. Voltage sensitive dye recordings in slices confirmed that CNO increases the number of DGCs that fire in response to stimulation. These data collectively suggest that DREADD-driven hyperactivation of the DGCs was sufficient to compromise behavioral performance. Thus, DGC hyperactivation may be a critical factor in TLE cognitive comorbidities.

Title: Transcriptome profile of the dentate gyrus and CA3 in the pilocarpine model of temporal lobe epilepsy

Authors: *A. MATOS[1], A. VIEIRA[1], A. CANTO[1], C. ROCHA[1], V. PASCOAL[2], B. CARVALHO[1], R. GLIOLI[1], I. LOPES-CENDES[1];

Abstract: It is well known that gene expression profile of specific tissue provides relevant biological information about molecular mechanisms potentially involved in complex biological phenomena. Gene expression in different subset of cells, it is important to take sub-regional specificities, especially in the CNS. The aim of this study was to analyze and correlate gene expression profile using next generation sequencing technology in different sub-regions of the dentate gyrus (DG) and *Cornu Ammonis* 3 (CA3) in an animal model of temporal lobe epilepsy induced by pilocarpine. Male Wistar rats were injected with methyl-scopolamine (1 mg/kg) thirty minutes before of the systemic injection of pilocarpine hydrochloride (320 mg/kg) to reduce peripheral cholinergic side effects. Four hours after the administration of pilocarpine diazepam was administrated (4 mg/kg) in order to stop seizures. Control rats were injected with saline after methyl-scopolamine injection. Fifteen days after induction, rats were euthanized (n=4) and brains were processed for laser microdissection. Dorsal and ventral DG, and dorsal, intermediate and ventral CA3 were collected from each rat. RNA sequencing was performed in an Illumina Hiseq® platform. Sequences were aligned and quantified with the TopHat/DESeq2 pipeline for total RNA. Gene ontologies were analyzed with the MetaCore® software. We found a total of 969, 308, 2624, 1731 and 1278 genes differentially expressed ($p<0.05$) when comparing control and pilocarpine rats for the dDG, vDG, dCA3, iCA3 and vCA3 respectively. Gene ontology analysis indicates a predominance of inflammation related molecules among the genes found to be upregulated and synaptic transmission in genes found to be downregulated in both dDG and vDG. In addition, in the dDG there was a significant downregulation of gene in the calcium transport network, as well changes in expression of various genes involved in neuropeptides signaling, potassium and sodium transport. In dCA3 we observed upregulation of genes related to cytoskeleton remodeling and cell cycle. In iCA3 we identified upregulation of genes involved in oligodendrocyte differentiation in adult stem cells. In vCA3 there was downregulation of glutamatergic neurophysiological process, and upregulation of genes related to regulation of G1/S transition. The present data indicates region specific molecular mechanisms taking place in the hippocampus sub-regions of an animal model of temporal lobe epilepsy induced by pilocarpine. The transcriptome data suggest an interaction among several molecular components leading to epileptogenesis in this animal model that displays widespread hippocampal damage.

Title: Reciprocal effect in different stages of amygdaloid kindling and forced swim test over convulsive activity and depression-like behaviour

Authors: *D. U. GONZALEZ-MENDEZ, A. DÍAZ-JIMÉNEZ, J. D. AYALA-RODRÍGUEZ, B. A. GARAY-CORTES, R. FERNÁNDEZ-MAS, A. VALDÉS-CRUZ;
Neurociencias, Inst. Nacional De Psiquiatria Ramon De La Fuen, Ciudad DE Mexico, Mexico

Abstract: It has been seen a high incidence of depression in patients with temporal lobe epilepsy but the biologic nature of this relationship has been poorly understood. Furthermore, there is a controversy if depression is being developed in early stages of epileptogenesis or if a depressive state during epileptogénesis allows the epilepsy easier to installate. The aim of the present study was to analyse the effect of different stages of amygdaloid kindling (according to Racine's scale) over the induced depression by forced swim test (FST) and the presence of this one over the development of epilepsy. We used male Wistar rats: 8 rats were separated in order to have a control FST group and they only did the FST. 24 rats were implanted with a tripolar electrode placed in basolateral left amygdala, these animals were divided in 4 groups: Sham group (Sham), rats implanted but with any stimulation, manipulated for 6 days and subjected to FST between manipulation days 3 and 4; control kindling (control K); kindling stage 2 + FST (K2+FST), animals subjected to FST in stage II; and kindling stage 5 + FST (K5+FST), animals subjected to FST in stage V. In last 3 groups the rats were daily stimulated until achieve the stage V for 5 days. To kindling, we analysed: number of stimuli to reach stage V, permanence, spikes, frequency spikes and duration for each stage. It was also compared the initial and final threshold to trigger spikes and seizures. To FST, we analysed the time that the animal showed immobility, swimming and climbing. In kindling, there was an increase in K2+FST in comparison to control K in number of days to achieve the first seizure ($p<0.015$), permanence of stage 3 ($p<0.021$), number of spikes in stage 4 ($p<0.036$), and spikes frequency in stage 2 ($p<0.03$), stage 3 ($p<0.002$) and stage 5 ($p<0.001$), whereas there was a reduction in seizure duration in stage 4 ($p<0.019$). In addition, there was a reduction between initial threshold and final threshold to trigger spikes ($p<0.001$) and seizures ($p<0.004$) for control K, and a reduction in final threshold to trigger spikes $p<0.037$) for K5+FST. In FST, immobility showed a reduction in K2+FST ($p<0.022$) and Sham ($p<0.008$) in comparison to control FST as well as a reduction in comparison to K5+FST (K2+FST ($p<0.008$) and Sham ($p<0.003$)). In swimming, there was a

reduction in K2+FST ($p<0.013$) in comparison to control FST. By last, in climbing was a reduction in K5+FST ($p<0.001$) in comparison to Sham. The results suggest that FST interferes with the normal establishment of kindling and susceptibility of seizures in early stages but causes more severe seizures and partial seizures and discrete damage in amygdala affects the installation of depression-like behaviour.

Title: Electrical seizure threshold measurement in mu opioid receptor knockout mice

Authors: *T. N. FERRARO[1], G. A. DOYLE[3], W. H. BERRETTINI[3], R. J. BUONO[2];
[1]Dept Psychiatry, [2]Biomed. Sci., Cooper Med. Sch. of Rowan Univ., Camden, NJ; [3]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Several lines of evidence support a relationship between opioid neurotransmission and seizure susceptibility or epilepsy. Preclinical studies document that endogenous opioid peptides and prototypical opioid drugs alike can mediate both pro- and anti-convulsant effects. Clinical reports document that seizures may be elicited as an adverse side effect of opioid agonists including morphine and meperidine, as well as the opioid antagonists naloxone and naltrexone. Moreover, genetic association studies provide suggestive evidence that variants in *OPRM1*, the gene that encodes the mu opioid receptor, influence the risk for developing epilepsy in humans. To further elucidate the role of endogenous opioids in regulating the expression of seizure activity, we measured electrical seizure threshold in strains *Oprm1* knockout (MuKO) mice in which the null allele was transferred to both C57BL/6J (B6) and DBA/2J (D2) genetic backgrounds. Allelic transfer was accomplished with a backcross breeding strategy involving use of the neomycin cassette insert sequence, together with an *Oprm1* sequence spanning the gene promoter and exon 1, as selection markers. Heterozygous MuKO mice were brother –sister mated after 10 backcross generations to produce homozygous null *Oprm1* mice for this study. MEST was measured in 8-10 week old mice by administering a single daily electrical stimulus (via earclip electrodes) with a constant current electroshock unit (Ugo Basile, model 7801). The

starting current was 20 mA (MuKO-D2) or 40 mA (MuKO-B6) and the current level was increased 1 mA per day. Seizures were scored as focal, generalized or maximal (i.e. tonic extension of hind limbs). Whereas the stimulus current was increased with each daily trial, stimulus frequency (60 Hz), pulse width (0.4 ms), and duration (0.2 s) remained constant. Testing revealed that MuKO-B6 mice have a significantly lower MEST compared to parental B6 mice, with similar results obtained for females and males. On the other hand, there is no significant difference in MEST between MuKO-D2 and parental D2 mice, possibly due to a floor effect mediated by the D2 genetic background. Consistent with prior studies, B6 females were found to have a lower seizure threshold than B6 males; this difference is not observed in D2 mice. Overall, we conclude that the mu opioid receptor is involved in regulating seizure threshold in certain strains of mice, and that molecules involved in opioid neurotransmission represent potentially viable targets for developing new epilepsy pharmacotherapies.

Title: Neurochemical and behavioral effects of chronic stress in a mouse model of temporal lobe epilepsy

Authors: *J. B. DE ROSS[1,2], N. K. LEIBOLD[2], V. K. MENDOZA[2], G. F. BUCHANAN[2]; [1]Univ. of Sao Paulo, Ribeirao Preto, Brazil; [2]Neurol., Univ. of Iowa, Iowa city, IA

Abstract: Depression is one of the most frequent comorbidities in patients with temporal lobe epilepsy (TLE). It is suggested that these conditions have a bidirectional relationship, however, the mechanisms underlying this association are poorly understood. It is known that chronic stress worsens epileptogenesis and seizure outcome, although the possible vulnerability of the epileptic brain to chronic stress has not been properly addressed. Deficits in serotonin (5-HT) and dopamine (DA) neurotransmission may be involved in both conditions and can predispose

individuals to both seizures and depressive symptoms. Thus, with this work we aimed to investigate some of the behavioral and neurochemical aspects of the relationship between depression and epilepsy and how the epileptic brain responds to chronic stress. Adult male C57BL/6J mice with 6 weeks of age were subjected to the pilocarpine-status epilepticus model of TLE (PILO) or saline treatment (CTRL), and were implanted with EEG electrodes and microdialysis cannulae directed toward the hippocampus. Once the pilocarpine-treated animals developed spontaneous recurrent seizures, half of the animals in each treatment group were subjected to an unpredictable chronic mild stress (UCMS) paradigm and the other half of each group underwent sham housing. All animals were then evaluated for stress hormone levels, exploratory activity, depressive-like behavior, $5HT_{1A}$ receptor function and changes in 5-HT and DA release after intrahippocampal citalopram administration. Prior to the UCMS paradigm, PILO animals presented with higher corticosterone levels and hyperlocomotion, compared to CTRL. After UCMS, PILO animals spent less time at the center of the open field, showed an enhanced immobility time in the tail suspension test, reduced food intake, a blunted hypothermic response to 8-OH-DPAT injection and a reduction in 5-HT and DA release in the hippocampus after local citalopram perfusion. These data indicate that chronic seizures seem to enhance stress hormones levels in mice, which in turn, show a more prominent depressive-like phenotype and reduced monoamine release in the hippocampus after chronic stress. In conclusion, this study corroborated our hypothesis that the epileptic brain is more vulnerable to detrimental effects of stress, mechanism that may underlie the high prevalence of depression among TLE patients. Further examination into the underlying mechanisms of these changes is underway.

Title: Continuous spike-waves during slow-wave sleep (CSWS) in a mouse model of focal cortical dysplasia (FCD)

Authors: *C. ZHOU, Q.-Q. SUN, W. YANG, C. ZHANG, D. PETRUS;
Zoology and Physiol., Univ. of Wyoming, Laramie, WY

Abstract: Objective To examine if mice with focal cortical dysplasia (FCD) develop chronic spontaneous epileptic seizures and if so, what are the key EEG features in comparison to that reported in similar clinical conditions. **Methods** Unilateral single freeze lesions to the S1 region (SFLS1R) were made in postnatal day 0–1 pups to induce a neocortical microgyrus in the right cortical hemisphere. Continuous 24 hour recordings with screw-free intracranial EEG electrodes and a battery of behavioral tests were performed in adult SFLS1R and sham control mice to assess neurological status. **Results** 88% (30/34) of SFLS1R and 0% (0/11) of control, age matched mice developed chronic spontaneous ictal-spikes (IS). 20 of the 30 SFFLS1R mice with IS activities exhibited highly frequent, persistent and repeatable spontaneous electrographic seizures that occurred predominantly during the NREM sleep. The epileptic discharge pattern closely resembled the pattern of continuous spike-waves during slow-wave sleep (CSWS) of the human epileptic syndrome described as an electrical status epilepticus during slow wave sleep (ESES). Electrographic seizures were strongest in the right S1 region though generalized to contralateral cortex, hippocampus and thalamus, and were associated with significant cognitive and behavioral deficits. Seizures were temporarily alleviated by ethosuximide treatment or optogenetic activation of cortical S1 GABAergic neurons. **Interpretation** This is the first report of a FCD model displaying chronic CSWS/ESES type EEG seizures. Further characterization of the abnormal corticocortical and corticothalamic oscillations in this model may lead to a better understanding of the mechanisms and treatment of CSWS/ESES in humans.

Title: Cortical hyperexcitability and loss of local field potential synchrony in a mouse model of focal cortical dysplasia

Authors: *A. J. WILLIAMS, W. YANG, C. ZHOU, Q.-Q. SUN;
Dept Zool & Physiol, Univ. Wyoming, Laramie, WY

Abstract: Focal cortical dysplasias (FCDs) are a common cause of brain seizures and are often associated with intractable epilepsy. Here we evaluated aberrant brain neurophysiology in an *in vivo* mouse model of FCD induced by neonatal freeze lesions (FLs) to the right cortical hemisphere (near S1). Linear multi-electrode arrays were used to record extracellular potentials from cortical and subcortical brain regions near the FL in anesthetized mice (6-9 months old) followed by 24h cortical EEG recordings in awake animals. Results indicated that FL animals exhibit a high prevalence of spontaneous spike-wave seizure discharges, predominately during sleep (EEG), and a reduced threshold for burst-suppression activity under general anesthesia (extracellular recordings, 0.5-3.0% isoflurane). Brief periods of burst activity in the local field potential (LFP) included an increase in theta-alpha spectral peaks (4-12 Hz) on a background of low-amplitude delta activity (1-4 Hz). Burst activity was more prominent in the superficial vs. deep cortical layers, was associated with an increase in spontaneous spiking of cortical neurons, and was highly synchronized in control animals across both cortical and subcortical layers (average cross-correlation values ranging from +0.73 to +1.0) with minimal phase shift between electrodes and strong signal coherence below 20 Hz. However, in FL animals, cortical vs. subcortical LFP signals were strongly out of phase with significantly lower cross-correlation values compared to controls (average values of -0.1 to +0.5, $P<0.05$ between groups). In particular, a marked reduction in the level of synchronous LFP activity was observed the closer the recording electrodes were to the FL (Pearson's Correlation = 0.525, $P<0.05$). In summary, these studies indicate the presence of altered extracellular signal patterns near the site of cortical FLs that may disrupt the synchronous flow of information between cortical and subcortical brain regions. Cortical FLs were also associated with an increased pattern of hyperexcitable burst activity that may represent an altered level of excitation to inhibition in the FL brain contributing to the associated spike-wave seizure discharges observed in these animals.

Title: Comparison of tetanus toxin rat models for gene therapy for focal neocortical epilepsy

Authors: *E. CHABROL, A. SNOWBALL, A. LIEB, R. C. WYKES, S. SCHORGE, M. C. WALKER, D. M. KULLMANN;
UCL, London, United Kingdom

Abstract: Focal neocortical epilepsy is frequently resistant to medication, and surgical resection is rarely feasible, often because of proximity to eloquent cortex. New treatment options are therefore needed.
We reported successful lentiviral-mediated gene therapy in a rat model of focal motor epilepsy (Wykes et al., 2012). Tetanus toxin (TeNT) injected into the motor cortex elicited frequent, brief (<1 s), spontaneous bursts of high frequency epileptiform EEG activity, which lasted over 1 month, and at higher doses were accompanied by focal and occasionally secondarily generalized motor convulsions. Seizures were suppressed by lentiviral overexpression of the potassium channel Kv1.1, which causes a reduction in neuronal excitability and neurotransmitter release. Although gene therapy was effective against focal motor epilepsy, it is not known if this can be generalized to epilepsy arising in other brain areas, which is important for clinical translation. We implanted rats with wireless EEG transmitters (Open Source Instruments, Inc), which permit continuous monitoring. TeNT injected into the rat visual cortex was followed within 3-4 days by the occurrence of spontaneous seizures lasting 30-80 seconds and occurring approximately 10 times a day for as long EEG recordings were performed (>1 month). Importantly, these seizures were well tolerated with minimal morbidity. Simultaneous video recordings showed frequent generalization. TeNT in visual cortex leads to longer and less frequent seizures than TeNT in motor cortex. Although the motor cortex TeNT model resembles epilepsia partialis continua, an especially refractory form of epilepsy, the seizures in the visual cortex model are more typical of secondarily generalized seizures.

Title: Differential seizure susceptibility and postictal cardiorespiratory outcomes depending on vigilance state and genetic ablation of serotonin neurons

Authors: *B. S. PURNELL[1,2], K. CLAYCOMB[3], S. KRUSE[1], G. F. BUCHANAN[1,2]; [1]Neurol., [2]Interdisciplinary Grad. Program in Neurosci., Univ. of Iowa, Iowa City, IA; [3]Neurol., Yale Sch. of Med., New Haven, CT

Abstract: Amongst neurological conditions SUDEP, or sudden unexpected death in epilepsy, is second only to stroke in terms of years of potential life lost. Due to the unforeseen nature of SUDEP it is difficult to determine its antecedents; however, we know that SUDEP usually occurs at night and follows a generalized tonic-clonic seizure. What makes the seizures which precede SUDEP different from those that epilepsy patients suffer with more regularly is poorly understood. Using maximal electroshock seizures (MES) we have previously demonstrated that vigilance state can alter parameters such as seizure likelihood, severity, respiration and survivability. We have also shown using MES that modifications to the serotonin system can alter seizure outcomes. MES experiments are limited by the fact that MES is an acute model of seizures in a seizure-naïve brain which has not undergone the changes in excitability which characterize epilepsy. In this investigation we assessed whether the changes to seizure susceptibility and postictal cardiorespiratory outcomes which were seen in the MES model would extend to two models of epilepsy: amygdala kindling and pilocarpine-temporal lobe epilepsy. In the amygdala kindling group wildtype (WT) mice and mice lacking central serotonin neurons (*Lmx1b*$^{f/f/p}$) were implanted with EEG, EMG and EKG electrodes as well as a bipolar electrode in the right basolateral amygdala. Mice were kindled with twice daily stimulations (80-240 mA, 1 ms biphasic square wave, 1 s, 60 Hz). Once fully kindled, seizures were elicited during rapid eye movement sleep (REM), non-rapid eye movement sleep (NREM) and wakefulness. Seizures and cardiorespiratory sequelae were characterized using EEG, EMG, EKG, and plethysmography recordings. In the temporal lobe epilepsy group status epilepticus was induced using pilocarpine resulting in subsequent spontaneous seizures. These animals were monitored via plethysmograph, EKG, EEG and EKG to determine the vigilance state and cardiorespiratory outcomes of the spontaneous seizures. In both WT and *Lmx1b*$^{f/f/p}$ mice seizures induced by amygdala kindling during NREM resulted in an increase in respiratory rate variability and an increased occurrence of apneas. Seizures were rarely inducible during REM in WT mice but were more readily induced during REM in *Lmx1b*$^{f/f/p}$ mice. Spontaneously occurring REM seizures were rare in the WT mice but were more frequent in the *Lmx1b*$^{f/f/p}$ mice. This data suggests that seizures occurring during sleep can have adverse effects on respiration which may result in death. Also, this investigation implicates serotonin in the vigilance state dependent nature of seizure susceptibility and severity.

Neurologico C.Besta, Milano, Italy; [8]Italian Inst. of Technol. and Univ. of Genova, Genova, Italy; [9]San Raffaele Scientific Inst. and Vita Salute Univ., Milano, Italy

Abstract: Synapsins (Syns) are a family of synaptic vescicle-associated phosphoproteins involved in synaptic development, function and plasticity (Cesca et al., 2010). Mice with deletion of the Syn I,II and III genes (triple knock-out, TKO) are a validated model of epilepsy (Boido et al., 2010; Ketzef et al., 2011), with spontaneous and evoked seizures which start to occur around two months of age (Cambiaghi et al., 2013). The lack of synapsins in these mice was shown to generate specific alterations at excitatory and inhibitory synapses (Ketzef et al., 2011; Farisello et al., 2013) and hippocampal hyperexcitability (Boido et al., 2010) at both the pre-symptomatic and symptomatic ages.

We investigated the presence of alterations of neocortical network excitability at presymptomatic ages. We focused on the synchronous, low frequency (<1 Hz) propagating network activity recorded in cortical slices with extracellular electrodes, shown to correspond to the up- and down-states detected in individual pyramidal neurons (Sanchez-Vives & McCormick, 2000). This activity has been proposed to be the slice counterpart of the slow oscillations observed with intracellular and EEG recordings during sleep, anesthesia, and some phases of quiet wakefulness. We studied the occurrence of up-states in somatosensory cortex slices from age-matched C57BL/6J wild type (*wt*) and TKO mice (P24-P36) using microelectrode array recordings of extracellular voltage. Up-states had significantly higher frequency in TKO mice. We also measured their layer of origin, duration, amplitude and power spectral density, as well as their apparent spatial extension and propagation velocity. Up-states appeared to originate with larger

probability in supragranular layers in *wt*, but with more homogeneous probability across layers in TKO; similarly, the total power of activity was generally maximal in supragranular layers in *wt* mice, while in TKO mice in a substantial fraction of cases maximum activity was observed in granular or infragranular layers. Up-state duration and spatial extent were similar in *wt* and TKO mice. Overall, this study shows the presence of altered neocortical network excitability in TKO mice at presymptomatic ages.

Title: Age-dependent susceptibility to seizure and neuronal loss in rat soman model

Authors: F. ROSSETTI[1], M. F. STONE[2], M. C. MOFFETT[2], T. M. TURNER[2], L. S. NAIDU[2], *B. MARRERO-ROSADO[2], C. R. SCHULTZ[2], L. A. LUMLEY[2];

Abstract: Introduction: *Status epilepticus* (SE) occurs at double the rate in those over 65 years of age. Although epilepsy increases with age, few studies have evaluated the development of epilepsy in aged rats. We recently observed that aged rats exposed to the chemical warfare nerve agent soman (GD) are more sensitive to the lethal effects of GD compared to adult rats. Aged rats have loss of hippocampal interneurons, and reduced inhibition may increase excitability, which may lead to increased susceptibility to development of seizures. We currently report on the effects of GD exposure in adult and aged male rats on seizure activity and neuronal loss. Methods: Male F344 adult (2 months old) and aged (18 months old) rats were implanted with telemetry devices for monitoring EEG, temperature and activity. Rats were exposed subcutaneously (sc) to equitoxic doses (88 and 66 μg/kg, respectively) of soman (GD) and treated 1 min later with standard medical countermeasures (atropine sulfate and oxime HI-6) and 30 min after seizure onset with the anticonvulsant diazepam. Rats were monitored continuously for the development of SE and early recurrent seizures (eRS) in the first 3 days, as well as the

development of spontaneous recurrent seizures (SRS) until 60 days after exposure, and performance was assessed in a radial arm maze. Results: Although aged rats received a lower dose of GD compared to adult rats, aged rats tended to have a shorter onset to SE, spend more time in SE+eRS, have an earlier onset of SRS, and have a greater number of SRS. Both young adult and aged rats exposed to GD that developed seizures had an equally significant reduction in density of glutamic acid decarboxylase 67 (GAD-67), a marker of GABAergic interneurons, in the basolateral amygdala and piriform cortex. Aged rats tended to have less GAD-67 cells than young adult rats, mainly in the hippocampus and amygdala. Both young adult and aged rats tended to have reduced GAD-67+ cells in the dentate gyrus of the hippocampus. However, the reduction was higher in aged rats compared to young adult rats. Conclusion: Clearly, the sensitivity to GD exposure is age-dependent. Aged rats are highly susceptible to the effects of soman on SE, SRS or the development of epilepsy and consequent brain pathology. *Disclaimer* The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government. Title: Cardiorespiratory dysfunctions and sudden death in two mouse models of intractable epilepsy

Authors: A. M. BARD, N. SAHAI, S. M. HANNA, J. SKIBO, A. ROY, J. RAMIREZ, K. J. MILLEN, *F. K. KALUME;
Ctr. for Integrative Brain Res., Seattle Children's, Seattle, WA

Abstract: Sudden unexpected death in epilepsy (SUDEP) is the most common type of death in people with intractable epilepsies. These include epilepsy associated with focal cortical dysplasia (FCD) and Dravet syndrome (DS). FCD is a developmental disorder with early childhood onset marked by regional brain malformations and intractable seizures. FCD type IIa has been linked

with gain-of-function mutations in *PIK3CA, a* gene involved in development and cancer. Conversely, DS is a treatment-resistant epilepsy with infantile-onset and elevated SUDEP rates. DS is often caused by loss-of-function mutation in *SCN1A*, the gene encoding Na_V 1.1 channels. SUDEP is caused by cardiovascular dysfunctions. We conducted dual examinations of cardiac and respiratory functions during interictal, ictal, and post-ictal periods to identify and compare signs of SUDEP susceptibility in a mouse model of FCD (carrying a gain-of-function mutation in Pik3ca) and that of DS (harboring a heterozygous knock-out of Scn1a). Video-EEG-ECG and whole body plethysmograph were recorded from these mutant mice and controls using fine silver EEG, ECG and EMG electrodes. Signals were acquired on a Power Lab 8/35 using LabChart Software 8.0 (AD Instruments). In DS mice, our previous studies showed a substantial suppression of resting heart rate variability, increased frequency of AV blocks, and no change in resting heart rate (HR). In these studies, we observed suppressed respiratory responses to hypercapnia (60 ± 8 %), hypoxia (48 ± 5 %), and anoxia (31 ± 6 %) in DS mice (n=6) compared to WT (n=9). In addition, these mice exhibited concurrent transient bradycardia and bradypnea during the tonic phases of thermal generalized tonic clonic seizures. Mice carrying DS-causing mutation in GABAergic interneurons alone, not excitatory neurons, revealed similar ictal and interictal dysregulations of cardiorespiratory functions. In FCD mice (n=6), resting interictal recordings also showed a decreased in HRV, but accompanied with increase in HR and absence of AV blocks. Respiratory recordings showed reduced respiratory responses to hypercapnic (80 ± 9 %), hypoxic (60 ± 8 %), and anoxic (30 ± 7 %) conditions compared to controls (n=6). Furthermore, PTZ-induced seizures caused less severe physiological abnormalities than to those of DS mice. These results suggest that regardless of the etiology of epilepsy, seizures cause similar cardiorespiratory dysfunctions leading to SUDEP. GABAergic interneurons are implicated in the mechanisms of SUDEP. Understanding the cellular and network mechanisms underlying these physiological dysfunctions may lead to better therapeutic methods for SUDEP prevention.

Title: Effect of growth hormone on status epilepticus induced by lithium-pilocarpine in adult rats

Authors: *I. ZAMORA-BELLO[1], E. VELAZCO CERCAS[1], A. PUIG LAGUNES[1], L. BELTRAN PARRAZAL[1], C. MORGADO VALLE[1], I. SANTIAGO ROQUE, 91010[2], E. JUAREZ AGUILAR, 91010[3], M. LOPEZ MERAZ[1];

Abstract: It has been reported that growth hormone (GH) facilitates epileptogenesis induced by electrical kindling in mice. However, some kinases implicated in GH signaling pathways, such as ERK and PI3K, are associated with pro- and anti-convulsant effects. The goal of this study was to evaluate the effect of intracerebroventricular administration of GH on *status epilepticus* (SE). Adult Wistar male rats were implanted with a guide cannula into the right ventricle and GH was injected at different amounts (70, 120 y 220 ng) for 5 days using artificial cerebrospinal fluid as a vehicle. SE was induced by the lithium-pilocarpine model (3 mEq/kg and 30 mg/kg, respectively) 24 h after the last administration of GH. Rats were injected with diazepam (10 mg/kg) one hour after the SE onset. Seizure severity was evaluated with the Racine´s scale. Data were analyzed by a proportions test or one-Way ANOVA followed by a Tukey post-hoc test. All rats (100%) injected with 120 ng of GH required a greater number of injections of pilocarpine (2.7 ± 0.8) to develop SE compared with the other GH groups ([0%] 1 ± 0.8 for 70 ng GH and [20%] 1.2 ± 0.7 for 220 ng GH) and the vehicle group ([16.6%] 1.2 ± 0.4). The latency to the first generalized seizure stage IV/V (79.3 ± 7.2 min) and SE (84.1 ± 6.8 min) was higher in the group of 120 ng GH when compared with the 70 ng GH (49.6 ± 10.2 min and 55.6 ± 9.7 min, repectively), 220 ng GH (43.2 ± 20.4 min and 47.4 ± 19.2 min, respectively) and the vehicle (42.9 ± 13.7 min and 49.2 ± 12.2 min, respectively) groups. No differences in the duration of SE or generalized seizures as well as in the number of generalized seizures stage IV and V were observed between the experimental groups. In conclusion, the subchronic administration of GH showed an anticonvulsant effect against lithium-pilocarpine-induced SE.

Title: The role of hippocampal oxygen levels in the development and expression of epilepsy in two models: intrahippocampal kainate and perforant path electrical stimulation.

Authors: *M. D. WOLFF, M. SCANTLEBURY, G. C. TESKEY;
Univ. of Calgary, Calgary, AB, Canada

Abstract: *Rationale:* We recently determined in the kindling model of focal seizures, that following the cessation of brief electrographic seizures, a long-lasting, severe hypoxic event occurs in the brain regions involved in the electrographic seizure. For example, local tissue oxygenation drops below 10 mmHg and remains at a severe hypoxic level for over an hour in the hippocampus. We reasoned that given this severe and long-lasting change in oxygen levels following a brief ictal event, there might also be changes in local oxygen levels during the induction of epilepsy; these changes in turn may account for the development of chronic epilepsy in rodent models. Current animal models of epilepsy employ the use of either electrical stimulation or a chemoconvulsant in order to induce spontaneous recurrent seizures (SRS) in rodents. Our aim was to conduct a head-to-head comparison of both models with the goal to prevent status epilepticus, limit lethality, and ultimately produce self-generating seizures in a rodent. We hypothesized that during the induction of epilepsy, there will be drastic changes in hippocampal oxygen levels. *Methods:* A sub-anesthetic dose of urethane was administered before the induction protocols in order to sequester electrical activity to the temporal lobes and prevent generalized status epilepticus. In the intrahippocampal kainic acid model, kainic acid was infused directly into the rat ventral hippocampus. In the electrical stimulation model, a 24-hour stimulation protocol of the perforant path was used (Norwood et al. 2010). In both groups, oxygen levels and EEG were recorded in dorsal hippocampus throughout the first 24 hours. Immediately after the 24-hour induction period, rats were transferred to a 24/7 video-EEG monitoring unit. Hippocampal EEG was monitored continuously for 4-6 weeks. Once per week oxygen recordings were taken alongside EEG to look for spontaneous seizure-induced hypoxia. *Analysis:* Several dependent measures were recorded and analyzed. Firstly, we analyzed EEG to look at the frequency, duration, and severity of seizures starting from the first day post-induction. We also analyzed oxygen levels post-induction in order to determine if frequent episodes of post-ictal hypoxia were related to the development of SRS. *Significance:* This study will advance our current understanding of epilepsy models. In addition, we hope to uncover the role that oxygen may play towards the development of SRS in these models. These discoveries may lead to the development of new treatments or preventative strategies for people with epilepsy.

Title: Gamma event coupling as a measure of functional connectivity during epileptogenesis

Authors: *L. LI[1], J. ALMAJANO[1], J. ENGEL, Jr[1,2,3], A. BRAGIN[1,2];
[1]Neurol., [2]Brain Res. Inst., Univ. of California Los Angeles, Los Angeles, CA; [3]Neurobio. and Psychiatry and Biobehavioral Sci., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: **Rationale:** Epilepsy is one of the most serious neurological diseases and it is becoming increasingly apparent that epileptic activity may cause alterations of local and distant functional connections within neuronal networks. However, whether, and what types, of connectivity reorganization can lead to epilepsy after potentially epileptogenic brain lesions, is unknown. This study aims to investigate if coupling of local field potentials (LFP) in the gamma band range (30-55Hz) changes after kainic acid (KA) lesions of hippocampus and neocortex and, if so, whether these changes correlate with the process of epileptogenesis. **Methods:** Experiments were conducted on adult male Sprague-Dawley rats (n = 21). 16 tungsten microelectrodes (50 um outer diameter) and screw electrodes were implanted 1 week in symmetrical sites of prefrontal cortex, motor cortex, hippocampus and thalamus**.** KA was injected either in the left anterior hippocampus or left neocortex. Two-month continuous EEG recordings were performed with sampling frequencies from 1k to 10k Hz. Maxima for gamma activity waves were detected and Shannon entropy was applied to determine the functional connectivity between different brain regions as peri-event histograms for each pair of channels. Connectivity index (**CI**) represented by normalized Shannon entropy values between areas of interest, was then compared to distinguish the connectivity differences between rats that developed seizures within two months after brain lesioning, and rats that did not. **Results:** An overall decrease in regional connectivity was observed in both groups after two-months of recordings, compared to the baseline. We observed a decreased **CI** in rats without seizures, between the peri-lesion site and the left prefrontal cortex as well as the right thalamus, and an increased **CI** between the peri-lesion site and right prefrontal cortex, right hippocampus and left thalamus**,** forming a balanced gamma event coupling strength between the left and right sides of the brain. Rats with seizures showed a decreased **CI** between the lesion site and most of the ipsilateral regions, and an increase **CI** between the lesion site and contralateral regions, revealing a shift of gamma event coupling strength to the opposite site of the lesion. **Conclusion:** Our

results indicate **CI** changes after local epileptogenic lesions of specific brain areas. Spatial reorganization of functional connectivity of the perilesional area with local and remote networks was different in animals that did, and did not develop epilepsy. Patterns of gamma event coupling changes could be biomarkers for prediction of epilepsy in patients after potentially epileptogenic brain injury.

Title: Sudep and functional remodeling of vagal complex activity in a mouse model of temporal lobe epilepsy

Authors: *I. DERERA[1], B. P. DELISLE[1,2], B. N. SMITH[1,2];
[1]Univ. of Kentucky, Lexington, KY; [2]Univ. of Kentucky, Epilepsy Ctr., Lexington, KY

Abstract: Sudden unexpected death in epilepsy (SUDEP) is the most common cause of death in individuals with refractory epilepsy and has been associated with disturbances in cardiorespiratory function and autonomic nervous system (ANS) imbalance. GABAergic neurons of the nucleus tractus solitarius (NTS) of the brainstem dorsal vagal complex are essential modulators of parasympathetic tone. Studies of genetic models of epilepsy suggest that ANS dysfunction coincides with SUDEP susceptibility, but this has not been investigated in models of temporal lobe epilepsy (TLE), the most common epilepsy type. This study investigated cardiac function and activity of GABAergic NTS neurons in the vagal complex in the pilocarpine-induced status epilepticus (pilo-SE) model of TLE. Pilocarpine (281 mg/kg) was administered to 5-6 week old mice to induce SE and eventual development of TLE. GIN mice were split into 3 groups to assess survival rates, in vivo electrocardiography (ECG), and *in vitro* electrophysiology of GABAergic NTS neurons at several times post-SE. Pilocarpine-treated mice displayed a 30% survival rate (versus 100% for vehicle-treated controls) by 150 days post-SE. Heart rate was increased and heart rate variability was decreased by 12 weeks post-SE relative to age-matched control mice. For electrophysiological recordings from identified GABAergic NTS neurons, coronal brainstem slices were taken at 1, 6, and 12 weeks post-SE. Significant increases in spontaneous action potential and EPSC frequency ($p<0.05$) were

detected 1, 6, and 12 weeks post-SE. Miniature EPSC frequency was increased relative to controls at 12 weeks post-SE, but not at 1 and 6 weeks. Blockade of ionotropic glutamate receptors significantly reduced spontaneous action potential frequency to levels similar to controls at 6 and 12 weeks post-SE. These results suggest long-term changes in cardiac function develop in conjunction with increased synaptic excitability of GABAergic NTS neurons after pilo-SE, which could contribute to autonomic dysregulation, cardiorespiratory collapse, and SUDEP. Future studies will determine if increased excitability of GABAergic NTS neurons underlies increased susceptibility to depolarization block and spreading depression in the NTS of mice with TLE.

Title: Malfunction of beta-catenin pathways leads to infantile spasms and seizures

Authors: *A. PIRONE, J. ALEXANDER, L. ANDRESEN, C. DULLA, M. JACOB;
Dept. of Neurosci., Tufts Med. Sch., Boston, MA

Abstract: Infantile Spasms (IS) is a catastrophic childhood epilepsy syndrome, characterized by neonatal flexion-extension motor spasms, which progress to chronic seizures and cognitive deficits in later life. The underlying molecular and functional changes that cause IS are poorly defined and animal models remain sparse. Genetic screens of individuals with IS have identified multiple risk genes, several of which are predicted to alter β-catenin pathways. β-catenin has dual roles in the N-cadherin synaptic adhesion complex and the canonical Wnt signaling pathway- both are critical for the normal formation and function of brain circuits. Tests for a link between malfunction of β-catenin pathways and IS are lacking. Here, we show that mice with conditional deletion in neurons of adenomatous polyposis coli protein (APC cKO), the major negative regulator of β-catenin levels, leads to excessive β-catenin and most of the features of human IS. Compared with wild-type littermates, neonatal APC cKOs exhibit flexion-extension motor spasms and abnormal electroencephalographic (EEG) activity. Cortical hyperexcitability is also indicated by increased spontaneous and evoked excitatory electrical activity in layer 5 pyramidal neurons at postnatal day 9, the age of peak spasm intensity. At adult ages, APC cKOs

display spontaneous behavioral seizures and abnormal EEGs. Further, we show that our novel mouse model with conditional overexpression of β-catenin that lacks the degradation domain (β-cat cOE) also leads to excessive β-catenin levels and IS-like phenotypes (neonatal spasms and chronic seizures). Both APC cKO and β-cat cOE mice show increases in synaptic spine density, abnormal plasticity of excitatory synapses, and changes in circuit connectivity. In particular, cortico-striatal connections are altered in our two different genetic mouse models of IS. Our data provide the first *in vivo* evidence for a novel molecular etiology of IS that is centered on aberrant β-catenin networks. Defining new molecular targets is essential for developing novel and effective therapeutic interventions to ameliorate IS and seizures.

Title: Seizure-induced brainstem hypoxia's involvement in sudden unexpected death in epilepsy

Authors: ***A. K. WALL**[1,4], J. S. FARRELL[2,4], G. C. TESKEY[3,4];
[2]Neurosci., [3]Cell Biol. and Anat., [1]Univ. of Calgary, Calgary, AB, Canada; [4]Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Sudden unexpected death in epilepsy (SUDEP), which occurs when an individual dies with no identifiable cause of death, is the leading cause of death directly related to epilepsy. Recent clinical research suggests that SUDEP results from a failure to breathe during or following a seizure, but the mechanism behind this failure is unknown. We have recently discovered a period of local tissue hypoxia (< 10mmHg), that occurs during and following a seizure in the brain areas involved in the seizure which is severe enough to cause behavioural dysfunction. This seizure-induced hypoxia provides a potential mechanism for the breathing failure that leads to death in cases of SUDEP; seizure activity invades brainstem breathing centers leading to local hypoxia, cellular/synaptic dysfunction of breathing centers, breathing failure, and death.
We hypothesized that seizure activity would propagate from the hippocampus to brainstem breathing centers, leading to severe hypoxia in this region preceding breathing failure and death. To investigate we administered intra-hippocampal kainic acid to adult male mice to induce seizures and death. Following kainic acid administration we continuously recorded seizure

activity, brainstem oxygen levels, breathing, and heart rate in awake, freely moving mice. Seizure activity in brainstem breathing centers was measured from chronically implanted bipolar electrodes. Tissue oxygen levels in brainstem breathing centers were measured during seizures and death using chronically implanted fiber-optic oxygen probes. Breathing was measured using a nasally-implanted thermocouple, and heart rate using a bipolar electrode implanted across the heart. This research provides preclinical data regarding the relationship between seizure activity, brainstem oxygen levels, breathing, heart rate, and death underlying SUDEP.

Title: Brain proton magnetic resonance spectroscopy and T2-weighted in the pilocarpine model of temporal lobe epilepsy: changes after status epilepticus in rats

Authors: *R. BARBOSA[1], A. S. VIEIRA[2], A. H. B. DE MATOS[2], B. M. DE CAMPOS[1], R. F. CASSEB[1], L. RAMALHO PIMENTEL-SILVA[1], B. CARVALHO[3], R. GILIOLI[4], I. LOPES-CENDES[2], F. CENDES[1];
[1]Dept. of Neurol., [2]Dept. of Med. Genet., [3]Inst. of Mathematics, Statistics and Computing Sci., [4]Multidisciplinary Ctr. for Biol. Investigation on Lab. Animal Sci., Univ. of Campinas, Campinas, Brazil

Abstract: Our aim was to evaluate *in vivo* changes in T2-weighted MRIs and proton magnetic resonance spectroscopy (^{1}H-MRS) in the pilocarpine (PILO) model of hippocampal sclerosis. We studied 31 Wistar rats with ^{1}H-MRS and T2-weighted images acquired in a 3-T Philips scanner with an 8 integrated channels volumetric coil (Rapid Biomedical GmbH, Wurzburg, Germany). Spectra were obtained in the hippocampus using a single voxel with point-resolved spectroscopy (PRESS) at TE/TR: 135/2000ms. We acquired MRI prior to any intervention and then 48 hours, 15 and 30 days after pilocarpine induced status epilepticus (SE). After the first MRI, we induced seizures with intraperitoneal injections of PILO hydrochloride (320mg/kg). Thirty minutes prior to pilocarpine the animals received scopolamine (1mg/kg) to reduce systemic cholinergic side effects. After four hours of the onset of SE, we administrated diazepam (4mg/kg) to interrupt seizures. The sham-treated were injected with saline after scopolamine

injection. The metabolite quantification was analyzed by LCModel software. Only good quality spectra (with <15% of error using Cramér-Rao lower bounds) were included. Metabolites were expressed in terms of their ratio to Creatine+Phosphocreatine. Statistical analysis was performed using SPSS software. PILO group had significant lower values of the following compounds when compared to the sham-treated group: in MRI2 (cholines [GPC+PCh], t=-4.48, p<0.001; N-acetylaspartate [NAA+NAAG], t=-8.17, p<0.001; glutamate+glutamine [Glu+Gln], t=-6.58, p<0.001), MRI3 (GPC+PCh, t=-6.14, p<0.001; NAA+NAAG, t=-7.64, p<0.001; Glu+Gln, t=-7.44, p<0.001) and MRI4 (GPC+PCh, t=-5.97, p<0.001; NAA+NAAG, t=-7.94, p<0.001; Glu+Gln, t=-8.16 p<0.001). The visual assessment of repeated MRIs showed a progressive increase of T2 hippocampal signal. We showed progressive decrease of the neuronal marker NAA, as well as cholines and Glu+Gln, in addition to increased T2 signal intensity in the hippocampi 48 hours, 15 and 30 days after pilocarpine induced SE. Further correlations of these changes with EEG and histology will help to understand better the epileptogenic damage in this model of hippocampal sclerosis.

Title: Functional role of neuronal hyaluronic acid in the naked mole-rat

Authors: *D. THEVALINGAM[1,2], D. MCCLOSKEY[1,2];
[1]Col. of Staten Island, Staten Island, NY; [2]City Univ. of New York Grad. Ctr., New York City, NY

Abstract: Molecules that compose the extra cellular matrix regulate synaptic plasticity and may mediate the ionic microenviroment at the neuron membrane. Notably, Hyaluronic Acid (HA) is involved in a number of cellular processes that modulate neuronal excitability as well as CNS development. Previous work has shown that tissues in the African Naked Mole-Rat, including brain, accumulate an exceptionally high amount of HA, likely due to decreased activity of digestion enzymes, which confers early contact inhibition and cancer resistance in this species

[Tian et al. (2013) Nature. 499(7458): 346-349]. The purpose of the present study was to explore the functional outcome of HA accumulation in the naked mole-rat brain. Anatomical measures of the extracellular matrix (through Wisteria floribunda agglutinin staining) and HA (through immunohistochemical labeling of Hyaluronic Acid Binding Protein) demonstrate robust labeling of multiple cell types throughout the naked mole-rat brain, including hippocampus. In the naked mole-rat hippocampal slice, which demonstrates epileptiform hyperexcitability under routine recording conditions, application of the HA digestion enzyme, hyaluronidase, increased the frequency of epileptiform burst discharges. Thus, as in other species, HA digestion increases epileptiform activity in the naked mole-rat. The role of HA in buffering the naked mole-rat intracellular pH, an important factor in naked mole rat neuron excitability, and the sensitivity to HA digestion across the long lifespan of the naked mole-rat, are currently under investigation.

Abstract: Aging is accompanied by a decline in the expression of social behavior, with females showing a more pronounced aging-related decline than males. Although the mechanisms underlying these changes are not clear, prior studies have noted a general hyporeactivity to stimuli among aged rats. Thus, in the present study, we used *c-Fos* induction as a marker of neuronal activation to identify key sites relevant to the processing of sensory stimuli (generally) or social stimuli (specifically) after brief exposure to a social partner. To do this, 3- and 18-month-old female F344 rats (N = 60; n = 10/group) were left undisturbed in their home cage as controls (HCC), exposed to a testing context alone for 30 min (CXT), or were exposed to the context for 20 min, followed by a 10 min social interaction (SI) test with a young conspecific. CXT and SI animals were pre-exposed to the context prior to test day to allow habituation to a

novel environment. This design allowed us to separate neuronal activation to a testing environment (CXT) from activation specific to social stimuli (SI). Tissue was collected 30 min after the end of testing to assess *c-Fos* induction with *in situ* hybridization. Both the context and social interaction led to a significant increase in *c-Fos* expression in the barrel field cortex (BF), hippocampus (HPC), and medial amygdala (MeA), brain regions that play a role in sensory processing and social behavior regulation. In contrast to our previous findings in aged males, aged females exhibited blunted *c-Fos* induction in response to a social interaction compared to 3-month-old females in BF, HPC, and MeA. These data indicate that although young females exhibit substantial neuronal activation specifically in response to social stimuli, the same is not true for aged females. In fact, aged females exhibit similar levels of *c-Fos* induction, regardless of testing condition, although this response is blunted compared to young females. This pattern was observed across all structures examined, supporting the idea that aged animals exhibit hyporesponsivity to stimuli, although this appears to be sexually dimorphic. Future studies will focus on females to examine whether age-related neuroinflammation may suppress neuronal activation in these brain regions.

Title: Stereological assessment of microglia number and morphology reveals sex differences in aged male and female F344 rats in socially relevant brain structures.

Authors: *A. E. PERKINS[1,2], T. A. MCNAMARA[2], T. DEAK[2];
[2]Dept. of Psychology, [1]Binghamton Univ., Binghamton, NY

Abstract: Aging is associated with a substantial decline in social behavior regulation, as well as increased neuroinflammation indicated by enhanced expression of cytokines and chemokines and an exaggerated response to peripheral immune challenges. Furthermore, there are sex differences in microglia number across the lifespan, with males exhibiting greater number of microglia during the neonatal period, whereas females show greater numbers of microglia in young adulthood. However, most studies examining microglia number or morphology in aging have

focused on the hippocampus or cortical structures, in part due to their role in age-related cognitive decline. Thus, we examined age and sex differences in microglia within brain regions critical to social behavior regulation (PVN, BNST, and MeA). Adult (3-month) and aged (18-month) male and female F344 (N = 40, n = 4-8/group) rats were perfused directly from their home cage and a subset of 18-month-old animals were injected with lipopolysaccharide (250 μg/mL) and perfused 24 h later to assess both the number and activational state of microglia as a positive control. Iba-1 immunopositive microglia were counted stereologically and classified according to the following criteria: (i) thin ramified processes, (ii) thick long processes, (iii) stout processes, or (iv) round/ameboid shape. Females, regardless of age or LPS treatment, had fewer microglia in the MeA, a brain structure that plays a significant role in social behavior regulation. Although we did not observe any differences in microglia number as a result of aging in the MeA, there appeared to be an increase in the number of round/ameboid microglia in the MeA of aged animals, suggesting increased inflammation in late aging. Thus, we hypothesize that aging may result in enhanced cytokine release, perhaps by affecting the release of socially-relevant neuropeptides. Future studies will focus on understanding the relationship between neuroinflammation and social behavior regulation, particularly within social behavior circuits.

Title: The impact of housing conditions in aged Fischer 344 rats on social behavior and cytokine expression within socially-relevant circuits

Authors: ***J. E. MONDELLO**, A. E. PERKINS, E. I. VARLINSKAYA, T. DEAK;
Dept. of Psychology, Binghamton Univ., Binghamton, NY

Abstract: Housing conditions play a role in the expression of social behavior. Single-housing is often considered a form of social deprivation, whereas long-term housing with several cage mates constitutes a form of social enrichment. However, nearly all studies in rodents have tested the influence of housing conditions in early development, leaving a gap in our knowledge of how housing conditions impact social processes in late aging. Here, we assessed the influence of housing on social behavior and inflammation within brain structures implicated in the

modulation of social behavior in male and female 18-month-old Fischer 344 rats (N = 54; n = 8-10/group). We varied the number of housing partners to include 3 conditions: single, pair, and triple-housing with sex-matched 3-month-old animals. Conditions were maintained for 5-6 weeks, after which social behavior toward a novel 4-month-old conspecific was assessed. Animals were re-housed for 7 days before tissue collection under ambient conditions. Aged males pair- or triple-housed with young animals exhibited social avoidance and reduced frequency of social behavior, whereas housing condition did not impact social behavior in females. Cytokine gene expression was examined in three socially relevant brain regions: PVN, BNST, and MeA. IL-1β and IL-6 expression were significantly increased in the MeA of triple-housed females, indicative of heightened inflammatory signaling. No such increase was observed in the PVN or BNST, arguing against widespread inflammation that would suppress social behavior, as is the case with sickness. Although males exhibited significant changes in social behavior as a result of housing condition, there were no changes in cytokine expression. We hypothesize that increased cytokine activity within the MeA may alter socially-relevant neuropeptide systems, as prior research demonstrated that IL-1β administration can enhance release of oxytocin and vasopressin. This, in turn, may attenuate the suppression of social behavior that occurs as a result of housing with younger cage mates. Future studies will examine the interaction between neuropeptides and inflammation in order to better understand the mechanisms driving social behavior during senescence.

Title: Towards multivariate genetic models predicting Alzheimer's disease risk

Authors: *B. C. RIEDEL[1], R. D. BRINTON[3,2], P. M. THOMPSON[2];
[1]Neurosci., [2]USC, Los Angeles, CA; [3]3Center for Innovation in Brain Sci. and Dept. of Pharmacology, Sch. of Med., Univ. of Arizona, Tucson, AZ

Abstract: Alzheimer's disease (AD) is a complex and multifactorial disease that ultimately leads to severe memory impairment and neuronal death. The clinical phenotype of AD is highly variable, which is indicative of multiple etiologies and progression trajectories. Consequently, up to 40% of patients living with AD in the U.S. are undiagnosed until the late stages of the disease. Identifying individuals early in the disease process is critical for reducing the substantial health burden that AD causes at the individual, familial, and societal levels. Until recently, apolipoprotein E (APOE) was the only well-established high penetrance susceptibility gene for AD. Although the heritability of AD based on twin studies is as high as 80%, APOE accounts for less than 1/3 of this estimate. Furthermore, APOE-*ε4* is neither necessary nor sufficient to cause AD, and most genetic factors influencing Alzheimer's risk are unknown. Genome-wide association studies (GWAS) have identified over 30 different AD susceptibility genes. Using the curated GWAS Catalog and the ENDEAVOR gene prioritization tool trained on the top 10 consistently replicated Alzheimer's risk genes, we identified 37 Alzheimer's risk genes that show evidence of systems biology interactions in mediating risk for the disease. Our preliminary analyses with participants from the Alzheimer's Disease Neuroimaging Initiative (ADNI) (N=1,477, mean age: 74 ± 7; 634 women, 843 men) followed for an average of 3.4 years found 9,752 variants among these 37 genes, with a minor allele frequency of .05 or greater. Individually, no risk variant was a better predictor of CSF Aβ-142, CSF phosphorylated tau levels, right or left hippocampal volume, or longitudinal clinical diagnosis of Alzheimer's, than positive carrier status of the APOE-ε4 allele. Notably, of the APOE deterministic variants, rs429358 was a better predictor of each disease-related variable than rs7412. Ongoing analyses are creating multivariate genetic models combining these risk variants in order to understand the systems biology of the disease and improve overall genetic detection and understanding of Alzheimer's.

Title: Mechanistic role of brain hypometabolism and mitochondrial uncoupling in perimenopausal hot flash

Authors: *R. D. BRINTON[1,2], F. YIN[1], J. YAO[1], A. MISHRA[1], Q. DENG[1], Z. MAO[1], E. CADENAS[1];

Abstract: The goal of the current study is to determine the mechanism of the signature symptom of the menopausal transition, the perimenopausal hot flash. We hypothesized that loss of ovarian hormone regulation of bioenergetics in brain induces a series of adaptive responses in the brain, which are initiated by decline in glucose metabolism, followed by activation of alternative fuel sources, ketone bodies and free fatty acids, which lead to mitochondrial uncoupling and temperature dysregulation. We used the ovariectomy (OVX) rat model as a reliable and predictive inducer of temperature dysregulation. Loss of ovarian hormones in the OVX rats led to decreased uterine weight, increased body weight and a significant increase in peripheral (tail skin) temperature. Further, our analyses in the OVX rat model indicated that peripheral temperature dysregulation coincided with systemic glucose intolerance and decreased cerebral glucose metabolism (FDG-PET). We further tested our hypothesis that loss of ovarian hormones leads to disruption and uncoupling of the proton motive force-dependent energy conservation systems and the consequent dissipation of energy as heat. Results of these analyses indicated that mitochondrial respiratory control ratio (RCR) was decreased in OVX rats accompanied by increased mitochondrial uncoupling, the upregulation of mitochondrial uncoupling proteins (UCPs), and enhancement of mitochondrial fragmentation in multiple brain regions. OVX-induced changes were completely or partially prevented by 17beta-estradiol treatment, suggesting an obligatory role of estrogen signaling in these events. Finally, to investigate the relationship between mitochondrial uncoupling in the brain and the increase in peripheral temperature, mitochondrial uncoupling was induced by 2,4-dinitrophenol (2-DNP), a mitochondrial uncoupler. Our analyses indicate that intracerebroventricular injection of 2-DNP induced sequential fluctuations in brain temperature, core temperature and tail skin temperature. Collectively, we established the physiological and bioenergetic phenotype of a rat model of hot flash, and our findings provide new mechanistic details of hot flash by connecting loss of ovarian hormones, brain hypometabolism, mitochondrial uncoupling and dysfunction, and peripheral temperature dysregulation. Title: Transcriptional and epigenomic changes across the perimenopause transition

Authors: *E. BACON[1], M. K. DESAI[1], A. MISHRA[1], Y. WANG[1], F. YIN[1], R. D. BRINTON[2]; [1]USC, Los Angeles, CA; [2]Univ. of Arizon, Tucson, AZ

Abstract: Transition states represent critical periods during development when systems under go dramatic and widespread changes. In women, the perimenopause transition spans several years and the resulting loss of estrogen has profound effects in nearly all tissues, including breast, bone, cardiovascular, and brain. Menopause in humans is also marked by an increased risk for stroke, coronary heart disease, and neurological disorders. Although a majority of women have no serious long-term health consequences, many women suffer neurological symptoms during and after the perimenopause transition. Heritability of menopause timing is 44-66% and variability is present in monozygotic twins and inbred rat strains, suggesting that epigenetics and environmental factors could play a large role in orchestrating timing of events involved in reproductive aging. Individual differences in epigenetic regulation, in addition to individual differences of sex hormone levels may help explain some of the differences seen in menopausal age, risk for cognitive impairment, and response to hormone therapy. To better understand the potential underlying mechanisms of neurological symptoms associated with perimenopause, as well as the control of age of onset, the current study aims to characterize the transcriptional and epigenomic changes that occur during this transition using a rat model recapitulating fundamental characteristics of the human perimenopause. Duration of the perimenopause transition in Sprague Dawley rats (time spent cycling irregularly before loss of cyclicity) can be separated into three groups: short, average, long. All animals begin to cycle irregularly around the same time (9-10mo), however animals complete the perimenopause transition at different ages. Older ages are correlated with longer overall durations of transition. Transcriptional changes of genes related to epigenetic regulation were observed across all perimenopause groups (RC, IR, AC). Our analysis suggests that hypothalamic aging and changes in epigenetic regulation begin before the onset of irregular cycling, between 6 and 9 months. Changes in DNA methylation across the perimenopause transition were investigated via global 5mC ELISA and genome-wide bisulfite sequencing (RRBS). Furthermore, IPA upstream analysis of transcriptional data identifies key players of one-carbon metabolism (involved in epigenome

maintenance) as likely regulators of endocrine aging. Impaired one-carbon metabolism during perimenopause may contribute to increased risk for neurodegenerative diseases after menopause.

Title: Evidence for immune cell infiltration into the brain during perimenopausal transition: Implications for autoimmunity and neurodegenerative diseases.

Authors: *M. DESAI[1], Y. CHEN[2], F. YIN[3], Z. MAO[3], R. BRINTON[3,4];
[1]Clin. Pharm. and Pharmaceut. Econ. & Policy, [2]Norris Med. Library, [3]Pharmacol. and Pharmaceut. Sci., USC, Los Angeles, CA; [4]Ctr. for Innovation in Brain Sci. and Dept. of Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: The onset of reproductive senescence occurs at the perimenopause, which is characterized by major physiological changes in the endocrinological and reproductive systems which can be associated with altered energy metabolism, cognition, bone-mineral density, cardiovascular function and immune system responses. Our rat model of the perimenopause to menopause to post menopause transitions captures both chronological and endocrinological conversions. In the current study, we investigated the differential regulation of genes in the hippocampi of the endocrine characterized female rats by sequencing hippocampal total RNA. We conducted paired end sequencing of hippocampal total RNA from 36 Sprague Dawley female rat hippocampi with read length of 50 base pairs and a read depth of ~50 million reads per sample using Illumina HiSeq 2500. Raw data files in the FASTQ format underwent QA/QC and trimming procedure in the cloud-based Partek Flow environment (http://www.partek.com/). The paired end reads for each sample were then aligned using TopHat to the rat reference genome rn6 (Ensembl 80). Transcript assembly and quantification of aligned reads were carried out using Cufflinks. The Cufflinks output consisted of a list of differentially expressed genes (DEG) for each comparison. Differentially expressed genes were analyzed using Ingenuity

Pathway Analysis to identify gene pathways altered during the perimenopause. Results of this curated literature based bioinformatic analysis indicated activation of pathways related to lymphocytic proliferation and differentiation during the transition from regular to irregular cycling and inactivation of pathways responsible for T cell apoptosis. RNAseq also detected a decrease in platelet-derived growth factor (PDGF) activity, associated with decreased brain estrogen, indicating potential for increased blood brain barrier permeability during the perimenopausal hippocampus. Analyses of significantly differentially expressed genes (DEG) using PANTHER (http://pantherdb.org/index.jsp) revealed enrichment of B and T lymphocyte genes. Interestingly, Interleukin-27, a pan-T lymphocyte regulator was down-regulated during the perimenopausal transition, reinforcing the hypothesis that T lymphocyte dysregulation is associated with the perimenopausal transition. These RNAseq and bioinformatic analyses extend our findings to the immune system as a potential key regulator of the perimenopause transition state. Ongoing analyses are pursuing functional evidence for increased blood brain barrier permeability, increased T cell infiltration into brain and immune dysregulation in periphery and brain.

Title: Effects of APOE genotype on obesity-induced acceleration of Alzheimer-related pathology in female EFAD mice

Authors: ***A. CHRISTENSEN**[1], E. BACON[2], F. YIN[2], R. BRINTON[2,3], C. PIKE[1]; [1]Dept. of Gerontology, [2]Sch. of Pharm., USC, Los Angeles, CA; [3]Ctr. for Innovation in Brain Sci., Univ. of Arizona, Tucson, AZ

Abstract: Alzheimer's disease (AD) risk is significantly influenced by genetic and environmental risk factors. The greatest genetic risk factor for late onset AD is APOE genotype, with E4 carriers being at a greater risk than E2 or E3 carriers. This increased risk in APOE4 carriers is exacerbated in females. Further, obesity has been shown to play an important role in both male and female AD risk. The potential gene-environment interactions between APOE and

obesity in regulation of AD pathogenesis are not well understood. To investigate this issue, we used the EFAD mouse model, which has humanized APOE3 (E3FAD) or APOE4 (E4FAD) in the presence of 5xFAD genes. Female transgenic mice were maintained on either Western diet (WD; 45% fat, 21% sugar) or a control diet (10% fat, 7% sugar) for 12 weeks. E3FAD mice on WD were impaired on cognitive tasks including spontaneous alternation behavior and novel object recognition. E4FAD mice were more impaired on these tasks in comparison to E3FAD mice, but showed no further impairment by WD. Plaque load in the hippocampus showed a similar pattern with WD significantly increasing beta-amyloid deposition in E3FAD females. Amyloid load was relatively higher in E4FAD versus E3FAD mice, but was not significantly increased by WD. To begin identifying factors that underlie the observed interactions between APOE and diet-induced obesity, we performed hippocampal gene microarrays in transgenic APOE3 and APOE4 mice that lack AD transgenes but were maintained on the same diet interventions. The microarray data indicate numerous changes in expression of inflammation- and metabolism-related genes across diet and APOE groups that are consistent with roles in regulation of pathology. Overall, these findings demonstrate significant gene-environment interactions between APOE and obesity in female EFAD mice. Continued investigation of how AD is affected by the interactive effects of risk factors such as obesity and APOE is essential to the identification of at-risk populations and the development of preventive strategies. (EFAD transgenic mice were generously provided by Mary Jo LaDu at University of Illinois at Chicago.)

Title: Ovariectomy and hormone treatment modulates female brain bioenergetic function in an endocrine aging dependent manner

Authors: ***Z. MAO**[1], F. YIN[1], J. YAO[1], E. CADENAS[1], R. BRINTON[1,2];
[1]Sch. of Pharm., USC, Los Angeles, CA; [2]Ctr. for Innovation in Brain Sci., Univ. of Arizona, Tucson, AZ

Abstract: The perimenopause is an aging transition unique to the female that is associated with multiple neurological symptoms. Our recent study in a rodent model of human perimenopause revealed the perimenopausal transition from regular- to irregular cycling as a critical period for brain metabolic function, characterized by a significant decline in bioenergetic and synaptic functions. Combinations of estrogens and progestogens in varying regimens are widely used as hormone therapy for menopause-related climacteric symptoms. We previously reported that a two-month treatment of continuous 17β-estradiol (E2) in combination with cyclic progesterone (P4) (E2+CyP4) on ovariectomized (OVX) young rats induced a bioenergetic gene-expression profile comparable to the ovary intact females. The present study was aimed to determine the efficacy and optimal intervention window of the E2+CyP4 therapy on female rat brain at different stages of the perimenopausal transition. Placebo or E2+CyP4 therapy was initiated on female rats at 9-10 months old with either regular cycling or irregular cycling, and for each cycling status, Sham OVX or OVX surgery was performed before the intervention. Hormone therapy consisted of two 30-day cycles of continuous E2 and cyclic P4 (10 days/cycle) delivered by silastic capsules. Upon completion of the regime, brain derived samples were analyzed for genomic, biochemical and brain metabolic responses. Our data indicate that the efficacy of E2+CyP4 therapy on brain bioenergetic functions in terms of glucose metabolism and mitochondrial respiratory capacity was differentially affected by the endocrine aging state of the rats when the intervention was initiated. Interestingly, our data also suggested that OVX initiated in regular or irregular cyclers elicited opposite effects on bioenergetic- and inflammatory gene expression. Outcomes of this study in the model of natural perimenopause will determine the window of opportunity for preventing the at-AD-risk bioenergetic phenotype by hormone intervention and will provide mechanistic details for developing novel strategies to maintain neurological health and function throughout female brain chronological and endocrine aging.

Title: Impact of APOE genotype on the bioenergetic system in perimenopausal mouse brains

Authors: *F. YIN[1], Y. WANG[1], A. MISHRA[1], Z. MAO[1], E. CADENAS[1], R. D. BRINTON[2,1]; [1]Sch. of Pharm., USC, Los Angeles, CA; [2]Ctr. for Innovation in Brain Sci., Univ. of Arizona, Tucson, AZ

Abstract: Our previous studies in a rodent model of human perimenopause demonstrated that the perimenopause is a neurological bioenergetic transition state that is reminiscent of early stage of Alzheimer's disease (AD) and suggested that bioenergetic shifts that occur in the female aging brain contributes to an increased risk for AD in women. As one of the greatest genetic risk factors for AD, APOE4 genotype manifests stronger impact of pathology and risk of AD in females. The aim of the current study is to provide a mechanistic rationale for the adverse impact of the APOE4 gene on the female bioenergetic system shifted during normal perimenopausal transition. Preliminary gene expression analyses of humanized ApoE4 and ApoE3 targeted replacement (TR) female mice revealed that ApoE4-TR mice at pre-menopause age (6-month old) exhibited a significantly different bioenergetic gene expression profile in the hippocampus relative to the age-matched ApoE3-TR controls. Surprisingly, pre-perimenopausal ApoE4 mice exhibited a significant increase in the RNA expression of genes encoding subunits of mitochondrial complexes for oxidative phosphorylation, multiple mitochondrial inner- and outer-membrane transporters, as well as a gene that controls mitochondrial fusion, Opa1. In parallel, the ATP citrate lyase gene was downregulated, which could be interpreted as a decrease of citrate-transported acetyl-CoA units for fatty acid and cholesterol biosynthesis. It remains to be determined whether increased expression of bioenergetic genes in pre-menopause ApoE4 mice is an indicator of hypermetabolism, or it represents an adaptive response to deficits in other components of the metabolic system such as substrate uptake and utilization, or it is due to a shift in brain energy fuels from glucose to ketone bodies and fatty acids. The last hypothesis is supported by peripheral data we obtained, where ApoE4 mice have higher levels of plasma ketone bodies and triglycerides compared to the age-matched ApoE3 female controls and to the ApoE4 male mice. Outcomes of our ongoing systems biology analyses of the ApoE-perimenopause phenotypes will determine how the bioenergetic profile observed in the pre-menopause stage changes upon peri- and post-menopause, which will provide mechanistic details of the ApoE4 genetic burden on the bioenergetic fluctuation of the perimenopausal transition and its contribution to AD risks in women. This work was supported by NIA 5P01AG026572 to RDB; Project 1 to RDB & EC.

Title: Transitions in the inflammatory phenotype during the perimenopausal transition: Implications in Alzheimer's disease

Authors: *A. MISHRA[1], M. K. DESAI[1], E. BACON[2], Y. WANG[1], F. YIN[3], E. CADENAS[3], R. D. BRINTON[4,3];
[1]Clin. therapeutics, [2]Neurosci. Grad. Program, [3]Dept. of Pharmacol. and Pharmaceut. Sci., USC, Los Angeles, CA; [4]Ctr. for Innovation in Brain Sci. and Dept. of Pharmacol., Univ. of Arizona, Tucson, AZ, CA

Abstract: Alzheimer's disease (AD) is characterized by a long latent prodromal stage, and the perimenopausal transition in women is considered a "tipping point" in the development of the AD phenotype. Characterization of the inflammatory phenotype during the prodromal phase is crucial for development of inflammation based therapeutics and biomarkers. The disparate results from the ADAPT trial showed the beneficial effects of NSAIDs treatment at an early stage but the worsening of pathology and symptoms in older adults, highlighting the changing course and function of inflammation with the disease. Both age and menopause are causative factors that affect inflammation. This study is an effort towards studying the effects of the perimenopasual transition on the emerging inflammatory phenotype and understanding its possible implications on the development of Alzheimer's disease.
In our preliminary study using the perimenopausal rat model, which isolates endocrine aging from chronological aging, we observed an increase in inflammation during pre-menopausal chronological aging in the hippocampus. We observed a significant increase in expression of MHC-II (Major histocompatibility complex-II) molecules, involved in antigen presentation: HLA-DQA1, HLA-DQB1, HLA-DRA, HLA-E, HLA-G, HLA-DRB5 during pre-menopausal chronological aging, identified by RNA-Seq analysis. Upregulation of the complement pathway is also observed during this phase. During endocrine aging, the female rats transition from regular cycling to irregular cycling followed by acyclicity, we observed a decline in the expression of MHC-II molecules, HLA-DQA1 and HLA-DQB1. In post-menopausal chronological aging, the MHC-II signaling molecules: HLA-DQA1, HLA-DQB1, HLA-DRA increased significantly. The differences in the expression of MHC-II in the hippocampus, during the course of chronological aging and the perimenopausal transition, implies that there are changes in the reactivity of key immune players: microglia, perivascular macrophages and

astrocytes. Peripherally, serum cytokine levels of IL-1α and IL-12, measured by multiplex assay, were significantly increased in acyclic 9 month old rats and acyclic 16 month old female rats, in comparison to regular cycling 9 month old rats. These data are indicative of dynamic and distinct immune signaling during both endocrine and chronological aging. Further, the distinctive inflammatory phenotype in the perimenopausal transition and chronological aging provide insights key to the development of therapeutics and biomarkers targeting risk of AD.

Title: Mitochondrial and nuclear gene expression required for mitochondrial respiration are differentially affected by endocrine and chronological aging.

Authors: ***Y. WANG**[1], M. DESAI[1], R. BRINTON[2];
[1]Clin. and Exptl. Therapeutics, Sch. of Pharm., USC, Los Angeles, CA; [2]Ctr. for Innovation in Brain Sci. and Dept. of Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Human mitochondrial oxidative phosphorylation system comprises five electron transport chain complexes. The system is made up of roughly 130 subunits, of which 13 core subunits are encoded by the mitochondrial genome. Alterations in gene expression can lead to changes in cellular respiration and bioenergetics, which are implicated in multiple neurodegenerative diseases including Alzheimer's disease. To study the initiation of the prodromal phase of AD, we investigated the endocrine perimenopausal transition and chronological aging. Our analyses focused on mitochondrial respiration and electron transport chain gene expression in female brain using a rat model recapitulating fundamental characteristics of the human perimenopause and aging. Specifically, female Sprague-Dawley rats between 9-10 months old were classified as either regular cycling, irregular cycling, or acyclic based on their estrus status. 6-month-old regular cycling and 16-month-old acyclic rats were included to distinguish the effects of chronological aging from endocrine aging. We used rtPCR to determine gene expression profile of mitochondrial-encoded genes and RNAseq for that of

nuclear encoded genes. Results of these analyses indicated that in the hippocampus, during perimenopause, MT-ND3 , MT-CYB , and MT-ATP6 had significantly lower expression in both irregular and acyclic 9-month-old animals compared to regular cyclic 9-month animals. MT-CO1, MT-CO2, and MT-CO3 had significantly lower expression in acyclic 9-month old animals compared to regular cyclers. Although expression level of other mitochondrial protein coding genes was not statistically different, they did share a trend of decreased gene expression. In terms of chronological aging, relative to 6-month-old female rats, mitochondrial genes in 9-month-old animals were generally up-regulated in hippocampus. However, following menopause, chronological aging did not affect mitochondrial gene expression. While the nuclear encoded genes exhibited a similar pattern of decline during perimenopause, a different pattern of expression was observed during chronological aging. Most of the nuclear encoded mitochondrial genes were up-regulated during chronological aging, especially after menopause when aging from 9 to 16 months. We also observed changes in key metabolic pathways. Our data suggest that in the hippocampus of aging female brain, mitochondrial and nuclear encoded electron transport chain subunits are under differential transcription regulation, and that the difference may be fuel source dependent.This work was supported by NIA 5P01AG026572 to RDB; Project 1 to RDB & EC.

Title: Physical and cognitive activity drive transcriptional signatures in the aged human hippocampus

Authors: *N. C. BERCHTOLD[1], A. PRIETO[2], M. PHELAN[3], D. GILLEN[3], D. A. BENNETT[4], A. S. BUCHMAN[4], C. W. COTMAN[2];
[2]Memory Impairments and Neurolog. disorders, [3]Dept. of Statistics, [1]Univ. California Irvine, Irvine, CA; [4]Dept. of Neurolog. Sci., Rush Univ. Med. Ctr., Chicago, IL

Abstract: A growing literature suggests that declines in cognitive performance associated with normal aging and even Alzheimer's disease (AD) can be buffered by physical and cognitive activity, with some evidence also supporting benefits of social participation. The underlying mechanisms by which lifestyle factors support brain function and health in the human brain are poorly understood.
We used a microarray-based genome-wide approach in combination with multiple linear regression analysis and high throughput data-mining tools to evaluate the relationship between hippocampal gene expression and late-life physical activity, cognitive frequency or social activity in the aged human brain. Hippocampal tissue was obtained from clinically well-defined cases that had been followed longitudinally for up to 18 years until death with detailed annual assessments of cognitive function and multiple lifestyle variables (physical activity, cognitive activity, social participation) as part of the Memory and Aging Project at Rush University Medical Center.
We found that physical and cognitive activity, but not social activity, have major programming effects on hippocampal gene expression patterns in the aged human brain and counteract specific age- and AD-related transcriptional patterns that contribute to cognitive decline. Core functions that are essential to build brain health are globally regulated at the transcriptional level, with physical and cognitive activity characterized by broadly increased expression of genes regulating mitochondrial function and energy production, protein trafficking and turnover, ubiquitin-proteasome function, RNA processing, DNA repair, and synaptic function. A central prediction of the study was that lifestyle modalities would counteract molecular changes specifically associated with aging and AD. Consistent with this hypothesis, our data revealed that 40% of the transcriptional changes associated with physical activity, and nearly 30% of those associated with cognitive activity, specifically counteracted Age- and AD-associated gene expression patterns in the human hippocampus. Our data are the first in the human brain to suggest that physical and cognitive activity promote at the transcriptional level a global shift toward preserved function of multiple core processes fundamental for maintaining a healthy brain state and high-level function with age.

Title: Aging and exercise induced epigenetic modifications in prefrontal cortex of Wistar rats

Authors: *I. R. SIQUEIRA, C. G. BASSO, K. BERTOLDI, B. SCHALLENBERGER, L. C. MEIRELES, L. R. CECHINEL;
Univ. Federal Do Rio Grande Do Sul, Porto Alegre, Brazil

Abstract: Beneficial effects of exercise have been recently linked to epigenetic mechanisms. Age and protocol- dependent epigenetic effects of exercise have been described in hippocampus of rats. However, the impact of treadmill exercise on epigenetic marks in aged cortices yet remains poorly understood. We investigated the effects of different exercise protocols, single session and daily exercise, on epigenetic marks, specifically H4 acetylation, DNA methytransferase (DNMT1 and DNMT3b), and histone methyltransferase H3K27 (HMT H3K27) activity, in prefrontal cortices from 3 and 21-months aged Wistar rats. The animals were submitted to two treadmill exercise protocols, single session or daily moderate. The daily exercise protocol induced an increased in histone H4 acetylation levels in prefrontal cortices of 21-months-old rats, without any effect in young adult group. DNMT3b levels were increased in aged cortices of animals submitted to single session of exercise. Our results indicate that prefrontal cortex is susceptible to epigenetic changes in a protocol and age dependent-manner and that H4 acetylation and DNMT3b changes might be linked at least in part to exercise-induced effects on brain functions in aging process.

Title: Behavior, adult hippocampal neurogenesis & brain dopaminergic system in rat model with innate difference in running capacity & metabolism

Authors: *S. T. LENSU[1], M. S. NOKIA[2], E. MÄKINEN[1], H. VALLI[2], J. JOLKKONEN[3], L. G. KOCH[4], S. L. BRITTON[4,5], J. WIKGREN[2], H. S. O. KAINULAINEN[1];

Abstract: Numerous studies have shown positive correlation between physical activity and brain health. Physical activity improves and maintains metabolic health, and seems to support learning and memory, and increase neurogenesis. However, it is difficult to make causal inferences between aerobic fitness and cognition, because exercise and a physically active lifestyle involve factors (e.g. social interaction and enriched living environment) known to support cognition. To study the neurobiological factors through which aerobic fitness influences cognition, we utilize a heterogenic rat model that is genetically determined for the intrinsic aerobic fitness: High and Low running Capacity Rats (HCR and LCR). Our group has shown that in this model, intrinsic aerobic fitness is related to improved learning that requires flexible cognition. All the experimental procedures were implemented in accordance with the directive 2010/63/EU of the European Parliament and approved by the National Animal Experiment Board, Finland. We determined baseline differences between the rat lines in spatial learning (T-maze test), brain dopaminergic system, and adult hippocampal neurogenesis (AHN). Both juvenile (at necropsy 8 weeks old) and adult rats (at necropsy 10 months old) were studied. AHN was studied by immunohistochemistry for doublecortin (protein expressed in newly divided cells maturing into neurons); brain dopaminergic system was investigated by immunohistochemistry for tyrosine hydroxylase (TH) and dopamine transporter. In behavior, no ratline differences were found in T-maze test at young ($p = 0.232$, mixed model ANOVA, LCR: $n = 19$, HCR: $n = 20$), while as an adult LCRs learned and remembered more efficiently this food motivated task compared with HCRs ($p < 0.001$, mixed model ANOVA, LCR: $n = 13$, HCR: $n = 12$). Young HCR rats ($n = 18$) had more new hippocampal neurons ($p < 0.05$, T-test) and more TH positive fibers ($p = 0.005$, t-test) in caudate putamen than LCRs ($n = 19$), while the analyses of adult animals are ongoing.

Our results indicate that a genetic predisposition for a high or a low aerobic capacity results differences within brain already as a young between LCR and HCR rats. The effect of aging remains to be shown. Furthermore, the studies for the effect of exercise on brain function and morphology would be needed, to see if we can diminish by exercise the early differences between the rat lines.

Title: Neural network decorrelation for healthy brain aging: A cross-sectional and longitudinal MEG study

Authors: ***L. JAMES**[1], A. LEUTHOLD[1], A. GEORGOPOULOS[1], C. CHORN[1], J. HEATH-MATHISON[2], A. GEORGOPOULOS[1];
[1]Brain Scienes Ctr., Univ. of Minnesota, Minneapolis, MN; [2]Minneapolis VA Med. Ctr., Minneapolis, MN

Abstract: Neural network decorrelation is regarded as fundamental to information processing. We have previously demonstrated that neural decorrelation, primarily involving temporal regions, distinguishes healthy veterans from those with psychiatric disorders, and have hypothesized that network decorrelation underlies healthy brain functioning by permitting neural flexibility (James et al., 2012 JAMA Psychiatry 70: 410-418). In the present study (http://brain.umn.edu/brp/womenshealthybrain.shtml), we evaluated neural network functioning derived from 1-min resting-state magnetoencephalographic (MEG; 248 sensors, sampled at 1.017 kHz) data in 185 cognitively healthy women, 30-100+ years old, who have participated in a longitudinal study aimed at defining factors underlying healthy brain function across the lifespan. We expected that within and among cognitively healthy individuals, decorrelation would increase with age, serving as a mechanism that promotes neural flexibility and maintains

healthy brain functioning across the lifespan. To test that hypothesis, we determined the strength of network functional connectivity by computing all pairwise crosscorrelations (-50 to +50 lags, 0.974 ms/lag) between prewhitened MEG sensor time-series and regressing them against age (in months) to evaluate neural network properties cross-sectionally and longitudinally. As expected, results suggested that among cognitively healthy women, decorrelation increased with age both cross-sectionally and longitudinally, and involved primarily the temporal lobes, within and across hemispheres. Furthermore, the amount and location of decorrelation varied across lags, providing robust real-time evidence of the active neural processes involved in decorrelation. These findings support our hypothesis above that neural network decorrelation underlies healthy brain functioning by maintaining adequate capacity of the networks for information processing.

Title: A clinically relevant frailty index for aging rats

Authors: *M. G. MILLER[1], N. THANGTHAENG[2], T. M. SCOTT[2], B. SHUKITT-HALE[2]; [1]Neurosci. and Aging Lab., [2]USDA-HNRCA, Boston, MA

Abstract: Frailty is a clinical syndrome that is increasingly prevalent during aging. Frailty involves the confluence of reduced strength, speed, physical activity, and endurance, and it is associated with adverse health outcomes. Frailty indices have been developed to diagnose frailty in older adult populations, and a pre-clinical frailty index has been developed for the C57BL/6 mouse. The present study adapts these existing clinical and pre-clinical indices of frailty to the Fischer (F344) rat, which is commonly used in aging research. One hundred and thirty-three male F344 rats (17mo) completed a battery of commonly administered behavioral tasks, including: forelimb wire-hang (strength), rotarod (speed), open field (physical activity), and inclined screen (endurance). This age was selected because it provides adequate remaining lifespan in which to conduct an intervention study without undo mortality and at which age-

related risk factors may still be modifiable. Within this cohort, rats whose performance put them in the lowest quintile were identified for each task, and the number of tasks on which a rat performed poorly determined their frailty index. Rats that performed poorly on two tasks were considered mildly frail (17.29%, n = 23), and rats that performed poorly on 3-4 tasks were considered frail (2.26%, n = 3). Logistic regression of 100-day survival revealed that mildly frail rats were 3.8 times and frail rats were 27.5 times more likely to die during that period than non-frail rats (p = 0.038; 95% CI: 2.030, 372.564). The selected criterion tests, cutoff points, and index provide a potential standardized definition for frailty in aged F344 rats that is consistent with existing frailty indices for humans and mice, and present a potentially useful tool for excluding frail animals which may not survive a chronic intervention study.

Title: Raspberry supplementation alleviates age-related motor dysfunction in select populations

Authors: ***N. THANGTHAENG**, M. G. MILLER, M. E. KELLY, D. E. SMITH, B. SHUKITT-HALE;
Neurosci. and Aging, USDA-HNRCA, Boston, MA

Abstract: Age-related declines in balance, muscle strength and coordination often lead to a higher incidence of falling. Among older adults, falls are the leading cause of distress, pain, injury, loss of confidence, and ultimately, loss of independence and death. Previous studies in our laboratory have demonstrated that berry supplementation improves age-related declines in motor function even when fed to aged animals. However, it is still unclear whether the requisite daily intake for efficacy differs based on motor capability. The purpose of this study was to explore the interaction between baseline motor performance and daily raspberry intake required to achieve improvement and/or preservation in motor function. Aged male F344 (17 mos old) rats were tested for baseline (pre-test) balance, muscle strength and coordination and divided into

good, average and poor performers based on their motor composite score (MCS), which was comprised of tests for strength (grip strength, wire suspension, and inclined screen), balance (plank and rod walking) and endurance (accelerating rotarod). Rats in each category were fed with either a 0%, 1%, or 2% raspberry-supplemented diet (RB). After 8-weeks on their respective diets, the rats were retested (post-test). Overall, the good performers performed worse in all of the post-tests compared to the pre-tests regardless of their diet. Interestingly, 1% and 2% RB appeared to preserve the performance of the good performers and improve the performance of poor performers on plank walking ($p< 0.05$). Two-percent RB improved post-test grip strength of the poor performers ($p<0.05$). Poor performers fed with 1% or 2% RB had higher post-test MCS ($p< 0.05$), while 2% RB lowered post-test MCS in the good performers ($p< 0.05$). The findings from this study identified poor performers as being most likely to benefit from daily consumption of ½-1 cup of raspberry to improve/preserve motor function. When extended to humans, raspberry may reduce fall risk, extend independence, and improve quality of life in the aging population.

Title: The effects of blueberry and strawberry serum metabolites on age-related oxidative and inflammatory stress signaling *In vitro*

Authors: D. R. FISHER[1], M. G. MILLER[1], N. THANGTHAENG[1], M. E. KELLY[1], D. F. BIELINSKI[1], *B. SHUKITT-HALE[2];
[2]USDA, ARS, [1]USDA-ARS Human Nutr. Res. Ctr. on Aging, Boston, MA

Abstract: Age-related decrements in cognition are thought to result from the increased susceptibility to and accumulating effects of oxidative stress and inflammation. Berry fruits contain a variety of bioactive polyphenolic compounds, such as anthocyanins, that exhibit potent

antioxidant and anti-inflammatory activities. In previous studies, we have shown that consumption of freeze-dried whole berry powder, equivalent to 1 cup/day of blueberry (BB) or 2 cups/day of strawberry (SB), can differentially improve some aspects of cognition in healthy, older adults, compared to placebo-supplemented controls. Cell models provide valuable tools for the development of novel strategies and assessment of the mechanisms behind the protective effects of various foods against the oxidative stress and inflammation seen in aging. Because the bioactive compounds in foods are different than those found in circulation following consumption, pre-treatment of cells with serum from people fed these foods may be a more valid model system than treating with extracts of the foods themselves. In this study, we investigated whether fasting and postprandial serum from BB- or SB-supplemented older adults (60-75yo) taken at baseline or after 45 or 90 days of supplementation would reduce the production of inflammatory and oxidative stress signals, compared to a placebo group, in stressed HAPI rat microglial cells, *in vitro*. Serum from both blueberry and strawberry were able to reduce inflammatory stress signals, e.g. nitric oxide ($p < 0.05$), relative to serum from placebo controls. Measurements of oxidative stress signaling are currently ongoing. These results suggest that berry metabolites, present in the circulating blood, may be mediating the anti-inflammatory effects of dietary berry fruit. It is likely that this attenuation of inflammation is responsible for the beneficial effects on age-related declines in cognition.

Title: Tau PET imaging in the Lewy body diseases

Authors: *S. N. GOMPERTS[1], J. J. LOCASCIO[2], S. MAKARETZ, 02129[1], A. SCHULTZ[1], C. CASO[1], N. VASDEV[1], R. A. SPERLING[1], B. C. DICKERSON[1], J. H. GROWDON[2], K. A. JOHNSON[2];
[1]Massachusetts Gen. Hosp., Charlestown, MA; [2]Massachusetts Gen. Hosp., Boston, MA

Abstract: Background The causes of cognitive impairment in dementia with Lewy bodies (DLB) and Parkinson disease (PD) are multifactorial. Tau pathology is commonly observed at autopsy in DLB and PD dementia, but its contribution during life to these diseases is unknown. In this study, we sought to contrast tau aggregation in DLB, cognitively impaired PD (PD-impaired), cognitively normal PD (PD-normal), and normal control (NC) subjects and to evaluate the relationship between tau aggregation, amyloid deposition, and cognitive function. **Methods** This cross-sectional study was conducted from 2014 to 2016. Subjects were recruited from the MGH Memory and Movement Disorders Units. 24 patients with Lewy body disease (7 DLB, 8 PD-impaired, and 9 PD-normal) underwent multimodal brain imaging, cognitive testing, and neurological evaluation, and imaging measures were compared to those of an independently acquired group of 29 NC subjects with minimal brain amyloid burden, as measured with [^{11}C]PiB PET. Subjects underwent tau PET imaging with [^{18}F]AV-1451, MRI, detailed cognitive testing, and neurological examination. All but 3 subjects also underwent amyloid imaging with [^{11}C]PiB PET. **Results** In DLB, cortical [^{18}F]AV-1451 uptake was highly variable and greater than in NC, particularly in the inferior temporal gyrus (ITG) and precuneus. Foci of increased [^{18}F]AV-1451 binding in the ITG and precuneus were also evident in PD-impaired subjects. Elevated cortical [^{18}F]AV-1451 binding was observed in 4/17 Lewy body disease cases with low cortical [^{11}C]PiB retention. For DLB and PD-impaired subjects, greater [^{18}F]AV-1451 uptake in the ITG and precuneus was associated with increased cognitive impairment, as measured with the MMSE and the CDR sum-of-boxes score. **Conclusions** Patients with Lewy body disease manifest a spectrum of tau pathology. Cortical aggregates of tau are common in DLB and PD-impaired patients, even in patients without elevated amyloid. When present, tau deposition is associated with cognitive impairment. These findings support a role for tau co-pathology in the Lewy body diseases.

Title: Elucidating the relationship between mitochondrial respiratory supercomplex plasticity and reactive oxygen species production

Authors: *C. A.-M. PORRAS[1], Y. BAI[2];
[1]Neurosci., Brown Univ., Providence, RI; [2]Cell and Structural Biol., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: The textbook model of the mitochondrial respiratory chain describes the system as a liquid arrangement of respiratory complexes acting as independent entities. Inversely the solid model envisions these complexes coming together to form stable, functional, supra-molecular supercomplexes. New evidence however points to a more dynamic environment between these two extremes. The plasticity model describes a cell that is able to manipulate the composition of its respiratory chain to favor certain confirmations of complexes in response to changes in its environment. In this model the more efficient supercomplexes are especially important for cell types with a high ATP demand as a method for preventing reactive oxygen species (ROS) production. In contrast cells with a low ATP demand may prefer to use free complexes to avoid the extra energy demand to build and maintain supercomplexes.
In this study we have attempted to observe supercomplex plasticity by using serum-starvation to induce a shift in the balance between supercomplexes and free complexes. In this situation growth factors are removed, and the cells become quiescent and thus lower their ATP demand, so according to the plasticity model there should be a shift away from supercomplexes towards free complexes. Using Blue Native Gel Electrophoresis, we have shown that this shift does occur during chronic serum-starvation. Additionally during this shift in supercomplex assembly, there is a decrease in ATP production and a robust increase in ROS production. This increase may hint at the role of supercomplexes in maintaining a low level of ROS by an efficient mitochondrial respiratory chain.
This role has far reaching applications in diseases characterized by oxidative stress. In particular supercomplexes may play a relevant role in neurodegenerative disease and the aging process where the ability to build supercomplexes may be lost in neurons that are sensitive to mitochondrial dysfunction. In these cell types, the demand for ATP and the loss of supercomplexes may lead to rampant ROS production causing extensive damage to proteins, lipids, and DNA. In aging this may cause a vicious cycle where oxidative damage causes the

respiratory complexes to become even more inefficient leading to further production of ROS. This research helps to establish a system whereby supercomplex plasticity and the mechanisms that regulate it can be studied in an effort to discover therapeutic targets that can rescue the loss of supercomplexes and potentially reduce the production of ROS.

Title: CCL5/RANTEs contributes to the hypothalamic insulin sensitivity to systemic insulin sensitivity through CCR5

Authors: ***S.-Y. CHOU**, Y.-T. HSIEH, R. AJOY;
Grad. Inst. of Neural Regenerative Med., Taipei Med. Univ., Taipei, Taiwan

Abstract: Many neurodegenerative diseases are accompanied by impaired energy metabolism as also seen with as diabetes mellitus (DM). CCL5/RANTES and its receptor CCR5 are known to contribute to neuronal activity a as well as type 2 DM but their mechanisms are unclear. Herein, we found that the lack of CCR5 or CCL5 in mice impaired the regulation of energy metabolism in hypothalamus. Immunostaining and co-immunoprecipitation revealed the specific expression of CCR5, associated with insulin receptors, in hypothalamic arcuate nucleus (ARC). Both ex vivo stimulation and in vitro culture studies demonstrated that the activation of insulin, and PI3K-Akt pathway were impaired in CCR5 and CCL5 deficient hypothalamus. The inhibitory phosphorylation of insulin response substrate-1 (IRS-1) at Ser302 (IRS-1S302) by insulin was markedly increased in CCR5 and CCL5 deficient animals but not IRS-2. Elevating CCR5 by CCL5 induced GLUT4 membrane translocation and reduced phospho-IRS-1S302 through AMPKα - S6 Kinase. Blocking CCR5 using the antagonist, MetCCL5, abolished the de-phosphorylation of IRS-1S302 and insulin signal activation. In addition, intracerebroventricular delivery of MetCCL5 interrupted hypothalamic insulin signaling and elicited peripheral insulin responsiveness and glucose intolerance. Taken together, our data suggest that CCR5 regulates

insulin signaling in hypothalamus which contributes to systemic insulin sensitivity and glucose metabolism.

Title: *In vivo* evaluation of cerebral glucose utilization in aged rats and non-human primates assessed by [^{18}f]-fluorodeoxyglucose positron emission tomography

Authors: ***A. M. BASSO**, R. RAJAGOVINDAN, D. R. REUTER, A. E. TOVCIMAK, S. J. BAKER, B. A. HOOKER, M. J. VOORBACH, J. D. BEAVER;
Translational Sciences-Imaging, AbbVie, North Chicago, IL

Abstract: Alzheimer's disease (AD) is associated with reduction in glucose utilization in temporal, posterior cingulate, frontal cortex and hippocampal brain areas during early asymptomatic stages of the disease, in patients with mild cognitive impairment and in individuals at risk for AD. The progressive decrease of cerebral metabolic rate of glucose is related to the severity of cognitive and functional decline in AD. Reduction in cerebral glucose uptake assessed by [^{18}F]-fluorodeoxyglucose positron emission tomography (FDG PET) has been proposed as a sensitive pharmacodynamic marker to quantify physiologic /metabolic processes in the brain *in vivo*, associated with neurodegenerative pathologies and potential modulation by novel therapies. The aim of the current study was to test the hypothesis that cerebral glucose uptake *in vivo* in aged animals (rats and non-human primates, NHP) is reduced compared to young control subjects and can serve as a suitable preclinical model of impaired cerebral metabolic function. Male Sprague Dawley rats (5-7 month-old, n=23 and 20 month-old, n=19) and female cynomolgus macaques (5-7 year-old, n= 7 and 20-21 year-old, n=7) were evaluated for brain glucose utilization using the Inveon PET/CT scanner (Siemens) and MicroPET Focus 220 (Siemens). Animals were fasted overnight (16-18 h) and plasma glucose levels were measured prior to each scan to ensure eligibility of the animal for the study. In all cases, [^{18}F]-FDG was injected i.v. into awake animals and after approximately 45-50 min, they were anesthetized (1.75-2.5% isoflurane) for CT followed by a static PET scan for 10 or 30 min duration (rats and NHP respectively). The average interval between [^{18}F]-FDG administration

and PET scan was 73+/-8 min in NHP. Throughout the study, body temperature of the animals was maintained stable. Standardized uptake values (SUV) in brain regions of interest were derived followed by statistical analysis employing linear mixed effect model with Group (young, aged) as a fixed factor and plasma glucose level as a continuous covariate. [^{18}F]-FDG whole brain SUV glucose uptake in aged rats was significantly decreased (approximately 35% reduction) compared to young adults ($p<0.01$). In the NHP study, there was also an effect of age, with older animals demonstrating 20-25% reduction in FDG brain uptake (SUV) relative to the young animals in the hippocampus, posterior cingulate, temporal cortex, occipital cortex , frontal cortex and cerebellum ($p<0.05$). Results confirm our hypothesis and highlight the potential value of using aged animals to study brain metabolic changes as a preclinical model relevant for aging, AD and neurodegenerative diseases.

Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA; [10]Dept. of Nuclear Med., Univ. of Aachen, Aachen, Germany

Abstract: Background: Pseudo-continuous arterial spin labeling (pCASL) is a magnetic resonance imaging (MRI) technique for contrast agent-free perfusion measurement. Previous studies found associations between pCASL with fluorodeoxyglucose positron emission tomography (FDG-PET).
Goals: We aimed at comparing perfusion (pCASL) to the two traditional imaging methods of voxel based morphometry for measurement of gray matter probability (GM) and quantification of glucose metabolism (FDG-PET). We examined patients with subjective cognitive decline (SCD) and manifest Alzheimer's disease (AD).
Methods: 19 SCD (aged 65.3 ± 8.3, MMSE 28.6 ± 2.0) and 25 AD patients (aged 70.4 ± 6.0, MMSE 24.3 ± 2.7) were scanned with pCASL, T1 mprage and FDG-PET (N: 11 SCD & 17 AD). All statistical tests were age- and atrophy-corrected, if applicable, and restricted to a region of interest encompassing the parietal cortex and (para-)hippocampus. Analyses of co-variance (ANCOVA) tested for between-group differences of mean GM, mean glucose metabolism and mean perfusion with eta squared (η^2) as the corresponding effect size. Furthermore, a voxel-wise regression evaluated regional distribution of group differences of perfusion. Mean GM, mean glucose metabolism and mean perfusion in AD were correlated with each other in a pairwise manner.
Results: Mean GM, glucose metabolism and perfusion were reduced in AD compared to SCD ($p<.0000005$, $\eta^2 =.35$, $p<.00001$, $\eta^2 =.15$; $p<.05$, $\eta^2 =.01$, respectively). The voxel-wise regression revealed lower perfusion in the posterior cingulate cortex (PCC) in AD compared to SCD ($p<.05$, family wise error-corrected). Glucose metabolism correlated with perfusion in AD ($p<.05$, $r=.51$).
Discussion: All measures were significantly reduced in AD. GM was reduced with a large effect, and after age and atrophy correction, glucose metabolism with a medium and perfusion only with a small effect. Perfusion was especially lower in the bilateral PCC in AD compared to SCD. Functional measures (perfusion and glucose metabolism) were associated with each other in AD, while neither was with structural measures (GM). FDG-PET and perfusion shared similar informative values, while FDG-PET and GM were much more robust in discriminating AD and SCD. Further research is warranted to aid in establishing pCASL as both, an addition and, in some cases, as an alternative to PET imaging.

Title: Comparison of hypometabolism and cortical atrophy in Primary Progressive Aphasia

Authors: *K. ADAMCZUK[1,2,3,4], M. STEPANOVIC[1,3], S. MAKARETZ[1,5], M. BRICKHOUSE[5,3], C. CASO[5,6], M. QUIMBY[5], R. VANDENBERGHE[2,7], B. DICKERSON[5,1,3,4]; [1]MGH Dept. of Neurol., Boston, MA; [2]KU Leuven, Leuven, Belgium; [3]Martinos Ctr. for Biomed. Imaging, Boston, MA; [4]Harvard Med. Sch., Boston, MA; [5]MGH Frontotemporal Disorders Unit, Boston, MA; [6]MGH Dept. of Psychiatry, Boston, MA; [7]UZ Leuven Dept. of Neurol., Leuven, Belgium

Abstract: BACKGROUND: Recent diagnostic criteria for Primary Progressive Aphasia (PPA) include neuroimaging as a supportive feature [Gorno-Tempini et al., 2011]. The regional overlap between atrophy (measured by structural MRI) and hypometabolism (measured by FDG-PET) may vary throughout the PPA spectrum. Comparison of territories affected by atrophy and hypometabolism will shed light on the sequence of pathophysiological changes in the disease.
HYPOTHESIS: Subtle hypometabolism is detectable in the PPA affected language regions which do not yet show cortical atrophy.
METHODS: 30 right-handed PPA patients (10 logopenic, 11 non-fluent agrammatic, 9 semantic) underwent FDG-PET scan within 12 months from structural MRI scan. PET was co-registered to MRI and glucose uptake was quantified by standardized uptake value ratios (SUVR) with pons as reference region. MRI scans were analyzed according to FreeSurfer pipeline. SUVR and cortical thickness values were projected to surfaces in fsaverage space. Hypometabolism and atrophy Z-maps were calculated based on a set of 30 age and sex matched controls from Harvard Aging Brain Study [Dagley et al., 2015].
RESULTS: Hypometabolism and cortical atrophy were localized to regions involved in language dysfunction in PPA, which were mainly left hemispheric. Regions with cortical atrophy were smaller and contained within regions displaying hypometabolism.
CONCLUSION: Our data suggest that hypometabolism is present without co-occurring atrophy in parts of the PPA affected language regions, which likely indicate future disease spread. Hypometabolism reflects synaptic and neuronal dysfunction, therefore, may occur earlier than cortical atrophy which represents neuronal death.

Title: Evaluating a lack of creatine in the dopaminergic neurotransmitter system

Authors: *Z. I. ABDULLA[1,2], B. PAHLEVANI[1], M. SKELTON[1,2];
[1]Neurol., Cincinnati Children's Res. Fndn., Cincinnati, OH; [2]Pediatrics, Univ. of Cincinnati, Cincinnati, OH

Abstract: Creatine's (Cr) primary function is as an intracellular buffer that maintains high levels of ATP through the Cr/Phosphocreatine (PCr) shuttle. In this reversible reaction PCr donates its phosphate group to ADP, yielding ATP. This is relevant to the pathology associated with Parkinson's disease (PD) as reductions in both ATP and PCr are observed in the dopamine (DA) rich midbrain, caudate, and putamen of those with PD. Cr also exhibits mitochondria-protective properties and dysfunctional mitochondria have been observed in the substantia nigra of those with PD. Importantly, Cr relies upon the Na^+, Cl^--dependent Cr transporter (CrT) to enter cells. The CrT is encoded by the X-linked SLC6A8 gene, mutations of which result in CrT Deficiency (CTD), a developmental disorder characterized by a lack of cellular creatine, intellectual disability, epilepsy, and autistic-like symptoms. A high comorbidity of attention-deficit hyperactivity disorder (ADHD) - itself often attributed to dysfunctions in DA modulation - is also reported. With this in mind, we evaluated adult mice lacking Cr in the DA neurotransmitter system for PD-like symptoms and hyperactivity. Dopamine-specific *Crt* knockout (DAT-CrT) mice were generated by crossing $Crt^{flox/+}$ mice with mice that express Cre recombinase driven by the DA transporter (DAT) promoter. Brain specific *Crt* knockout (BKO) and $Crt^{flox/y}$ mice were included as controls. Motoric function was evaluated every 30 days from P90 until P360. Locomotor activity was evaluated in both light and dark phases. In the challenging beam (CB) task, mice traverse a beam consisting of four 25 cm segments, each segment being 1 cm narrower than the previous. Errors, latency to transverse the beam and steps taken are recorded. Spontaneous activity (SA) was assessed by placing mice in a glass beaker on a transparent table and recording number of fore and hind limb steps, total rears and grooming events, and time spent grooming. Gait was analyzed using the DigiGait system. No differences were observed in measures indicative of a parkinsonian phenotype, i.e. increased errors in CB or decreased activity in SA. Both DAT-CrT and BKO mice display hyperactivity, evidenced by their quickness to cross the beam in CB as well as increased locomotion during both light and dark phases. The hyperactivity in DAT-CrT mice suggests that depleting Cr in DA neurons results in

hyperactivity. Furthermore, this could point to energetic impairments in the DA system as a mechanistic factor of ADHD in CTD.

Title: Sleep disordered breathing severity is related to GABA in the Dorsolateral Prefrontal Cortex

Authors: *A. C. PEREIRA[1], R. DAVIDSON[2], A. KRIEGER[4], D. SHUNGU[4], B. MCEWEN[3]; [1]Neuroscience/ McEwen laboratory, [2]Rockefeller Univ., New York, NY; [3]Rockefeller Univ., Rockefeller University, NY; [4]Weill Cornell Med. Col., Weill Cornell Medical College, NY

Abstract: Sleep-disordered breathing (SDB), a condition with repeated episodes of hypopnea and apnea during sleep, is more prevalent in the elderly than younger populations, and can contribute to cognitive decline. SDB is characterized by sleep fragmentation and intermittent hypoxia. Hypoxia in animal models have resulted in dysregulation in gamma-aminobutyric acid (GABA) and glutamate, the major inhibitory and excitatory neurotransmitters in the brain, respectively, leading to excitotoxicity, neuronal damage and/or loss. However, excitatory and inhibitory neurotransmitter dysregulations in the human elderly brain with SDB remain poorly understood, and in particular in the dorsolateral prefrontal cortex (dlPFC). The dlPFC is critical for executive functions and it is highly vulnerable to synaptic and functional changes in aging. SDB can exarcebate executive dysfunction and other cognitive impairment in the elderly, decreasing quality of life. Investigation of the neurometabolic changes in elderly SDB patients can advance our understanding of the neuropathophysiology of SDB and point to potential novel biomarkers and treatment targets. We used proton magnetic resonance spectroscopy (H MRS) which allows *in vivo* non-invasive measures of neurometabolites such as GABA and Glx (combines resonances of glutamate and glutamine) in the dlPFC and in the hippocampus of elderly individuals with moderate-severe SDB (AHI>15) and without SDB (AHI<5), who have

undergone polysomnography, to examine the hypothesis that alterations in one or both of these neurotransmitters occur in SDB and correlates with oxygenation measures, potentially contributing to increased neural excitability in SDB. GABA levels were significantly reduced in the dlPFC in elderly with SDB compared with elderly subjects without SDB. Moreover, we observed a relationship between GABA levels in dlPFC and severity of sleep apnea, measured through apnea-hypoxia index (AIH) and minimal saturation levels. Our findings implicating GABA in the pathophysiogical mechanisms of SDB may contribute to future studies that can ultimately help prevent neural damage and cognitive decline in the elderly population and identify novel treatment targets.

Title: 4-CIN, a neuronal lactate inhibitor affects ion homeostasis and energy metabolism

Authors: ***U. HEINEMANN**[1], R. KOVACS[1], E. A. ANGAMO[2];
[1]Neurosci. Res. Ctr., Charité Universitätsmedizin Berlin, Berlin, Germany; [2]Neurosci. Res. Ctr., Charite Universitätsmedizin Berlin, Berlin, Germany

Abstract: Here, we determined the contribution of astrocytic neuronal lactate shuttle to maintenance of ion homeostasis and energy metabolism. We tested for the effects of α-cyano-4-hydroxycinnamic acid (4-CIN, less tan 200 μM), which could interfere with energy metabolism by blocking monocarboxylate-transporter 2 (MCT2) mediated neuronal lactate uptake, on evoked potentials, stimulus induced changes in K^+, Na^+, Ca^{2+}, pH and oxygen concentrations as well as on changes in flavine-adenine dinucleotide (FAD) autofluorescence in hippocampal area CA3. MCT blockade by 4-CIN reduced synaptically evoked but not antidromic population spikes. This effect was dependent on the activation of K_{ATP} channels indicating reduced neuronal ATP synthesis. By contrast, lactate receptor activation by 3,5-dihydroxybenzoic acid (3,5-DHBA) resulted in increased antidromic and orthodromic population spikes suggesting that 4-

CIN effects are not mediated by lactate accumulation and subsequent activation of lactate receptors. Recovery kinetics of all ion transients were prolonged and baseline K^+ concentration and proton concentration became elevated by blockade of lactate uptake. Lactate contributed to oxidative metabolism as both baseline respiration and stimulus induced changes in pO_2 were decreased, while FAD fluorescence increased likely due to a reduced conversion of FAD into $FADH_2$. These data suggest that lactate shuttle contributes to regulation of ion homeostatsis and synaptic signaling even in the presence of ample glucose.

Title: Nrf1 knockdown as a modulator of mitochondrial electron transport chain and biogenesis

Authors: ***P. SADEGHI**[1,2], S. KHALIFEH[3,4], F. KHODAGHOLI[2,1], M.-R. ZARRINDAST[3,4]; [1]Neurosci. Res. Ctr., Tehran, Iran, Islamic Republic of; [2]NeuroBiology Res. Ctr. and Sch. of Advanced Sci. in Med., [4]Cognition and neuroscience research center, Islamic Azad University, Tehran Med. Sci. Br., Tehran, Iran, Islamic Republic of

Abstract: ***Introduction***
The nuclear factor, erythroid-derived 2,-like 1(Nrf1) is a member of the cap "n" collar subfamily of basic region leucine zipper transcription factors and plays major role in regulating the adaptive response to oxidants and electrophiles within the cell. Interestingly, mitochondrial electron transport chain (ETC) is the most energy producer in the cell which consists of multi-subunit enzyme complexes. Mitochondrial biogenesis results from organized and precise activity of nuclear and mitochondrial genomes. In the present study, the level of peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1α), an important factor involved in mitochondrial biogenesis has been evaluated after Nrf1-siRNA injection.
Methods
Here, we injected small interfering RNA (siRNA) targeting Nrf1 in dorsal third ventricle (D3V) of adult male albino Wistar rats (weighting 200-250 g) and subsequently examined the effect of this silencing on mitochondrial biogenesis factors, along with ETC activity in three brain regions: hippocampus, amygdala, and prefrontal cortex. Three groups were designed for this study: control group 1 received intra-D3V injection of 5 µl scrambled siRNA; control group 2

received 5 µl RNase-free water in their D3V, and the third group received intra-D3V injection of 5 µl Nrf1-siRNA. Stereotaxic surgery and siRNA administration in rat brain was conducted due to standard protocol. To be noticed, western blotting using Anti-Nrf1 and PGC-1α antibodies and spectrophotometric analysis of ETC complexes activities were applied for evaluation.

Results

We evaluated the level of Nrf1 by Western blotting, 4 and 8 h after Nrf1-siRNA injection. Protein level of Nrf1 reduced in consequence of Nrf1-siRNA injection. The most reduction of Nrf1 level was detected in prefrontal cortex, 8 h after siRNA injection (35.5 % compared to the control group). Also, having ETC as the most energy producer in the cells, complex I activity did not show any significant changes in all studied regions. Complexes II-III activity did not change significantly in prefrontal cortex and amygdala, but accumulated activity of complexes II-III in hippocampus increased to 32.13 and 33.76 nmol/min/mg protein, 4 and 8 h after Nrf1-siRNA knockdown, respectively. Otherwise, activity of complex IV in all three regions increased significantly. In addition, Nrf1-siRNA injection increased PGC-1α and cytochrome-c level compared to the control group. The most increase in PGC-1α level (2.3-fold compared to the control group) was in amygdala, 8 h after Nrf1-siRNA injection.

Abstract: The fetal and neonatal pancreas shows developmental plasticity and responsiveness to its metabolic environment, including poor maternal nutrition. Low-protein (LP) maternal diets

decrease fetal b-cell mass and isolated islet insulin secretion at term. Life-time consequences of poor fetal pancreatic development can impair offspring carbohydrate metabolism predisposing to diabetes even when the diet is normalized at weaning. Also this can leads to damage in the brain since the developmental stage in which nutrition was altered. The effect can alter in short term some neural process such learning and memory, anxiety, satiety, oxidative stress causing in an long term a development of neurodegenerative disease like Alzheimer. The aim for this work was to study the effect of the low protein diets in pregnancy and/or lactation rats on the hippocampus, a special area for memory and learning. We studied female rat offspring exposed to low-protein maternal diet (50% control protein diet) in pregnancy and/or lactation at postnatal day 36. Rats were fed either control 20% casein diet (C) or restricted diet (R - 10% casein) during pregnancy. After delivery, mothers received either C or R diet until weaning to provide four offspring groups: CC, RR, CR and RC (first letter denoting maternal pregnancy diet and the second lactation diet). Pups were euthanized at 36 days old and the hippocampus was dissected and western blot was performed to evaluate the context of GFAP and MAP-2. For GFAP was observed an increase in the RR and RC diets, on the other hand for MAP-2 a decrease in the diets RR and RC. This result suggest that a restriction diet and a diet that after is normalized affect some molecular process in the brain and this can leads to an behavioral impairment at long term.

Title: Acetyl l-carnitine targets ATP synthase in protecting zebrafish embryos from ketamine-induced toxicities

Authors: ***J. KANUNGO**, B. ROBINSON, Q. GU, S. ALI, M. PAULE, X. GUO; Neurotoxicology, Natl. Ctr. For Toxicological Research/Food and Drug Admin., Jefferson, AR

Abstract: Ketamine, an antagonist of the Ca^{2+}-permeable N-methyl-d-aspartate (NMDA)-type glutamate receptors, is a pediatric anesthetic. We show that acetyl L-carnitine (ALCAR) reverses ketamine-induced attenuation of heart rate and neurotoxicity (motor neurons, sensory neurons, serotonin and dopamine systems) in zebrafish embryos. However, it's not clear how ALCAR reverses ketamine-induced toxicities. In order to delineate the mechanism, we used 48 hours post fertilization (hpf) zebrafish embryos that were exposed to the drugs for 2 or 4h. In the 48 hpf embryos, 2 mM ketamine reduced heart rate in a 2- or 4-h exposure and 0.5 mM ALCAR neutralized this effect. ALCAR could reverse ketamine's effect, possibly through a compensatory mechanism involving extracellular Ca^{2+} entry through L-type Ca^{2+} channels that ALCAR is known to activate. Hence, we used verapamil to block the L-type Ca^{2+} channels. Verapamil was more potent in attenuating heart rate and inducing morphological defects in the embryos compared to ketamine at specific times of exposure. ALCAR reversed cardiotoxicity and developmental toxicity in the embryos exposed to verapamil or verapamil plus ketamine, even in the presence of 3,4,5-trimethoxybenzoic acid 8-(diethylamino)octyl ester (TMB-8), an inhibitor of intracellular Ca^{2+} release, suggesting that ALCAR acts via effectors downstream of Ca^{2+}. In fact, ALCAR's protective effect was blunted by oligomycin A, an inhibitor of ATP synthase that acts downstream of Ca^{2+} during ATP generation. We have identified, for the first time, a downstream effector of ALCAR that's critical in abrogating ketamine- induced developmental toxicities.

Title: Identification of putative neurogenesis-associated transcriptional biomarkers

Authors: *N. M. WALTON[1], S. MIYAKE[2], M. MATSUMOTO[2], H. ITO[1], K. TAJINDA[1]; [1]Neurosci., Astellas Res. Inst. of America LLC, Skokie, IL; [2]Neurosci. Res. Unit, Drug Discovery Res., Astellas Pharma Inc, Tsukuba, Japan

Abstract: Hippocampal neurogenesis is a fundamental constituent of learning and memory; alterations in this process have been implicated in a number of CNS diseases. However, despite the obvious contribution of this process to CNS function, dynamic descriptions of postnatal neurogenesis remain hampered by technical limitations. Current studies are largely constrained

to postmortem evaluation, preventing real-time evaluation of live populations. This is particularly true in human subjects, for whom consensus defined biomarkers do not exist.
In an effort to identify peripheral transcriptional biomarkers that mirror neurogenesis-specific transcriptional expression changes associated with hippocampal neurogenesis, we compared a number of microarray datasets from brain and peripheral blood mononuclear cells (PBMCs). Using reductive comparison, we identified transcripts that exhibited robust, conserved expression in both blood and brain. We then compared this dataset to hippocampal- and/or PBMC-derived samples isolated from rodent models of perturbed neurogenesis. These included voluntary exercise and chronic fluoxetine administration, as well as animal models that display alterations in early- and late stages of neurogenesis and/or neuronal maturation. To further refine gene expression changes to neural stem/progenitor cell-specific genes and/or populations, we compared hits identified in vivo to an in vitro neurogenesis assay containing an enriched population of primordial neuropoietic cells.
Using this approach, we were able to identify numerous examples of genes exhibiting concomitant transcriptional alteration in both hippocampal and PBMC samples. From this dataset, it may be possible to identify responsive elements in nucleated blood cells that retain a conserved transcriptional response to those of hippocampal stem/progenitor cells.

Title: Identification of withania somnifera active constituents on $GABA_{rho}$ receptors

Authors: ***H. AHMED**[1], A. LI[1], N. DARABEDIAN[2], F. ZHOU[1], A. RUSSO-NEUSTADT[1], A. LIMON[3];
[1]California State University, LA, Los Angeles, CA; [2]Univ. of Southern California, Los Angels, Los Angeles, CA; [3]Univ. of California, Irvine, Irvine, CA

Abstract: Recent scientific evidence suggests that hyperexcitability in neural circuits may be responsible for neurodegeneration and cognitive impairment during aging. This may, in turn, be due to an imbalance between excitation and inhibition neurotransmission or a reduction in GABAergic signaling. Thus, developing a way to prevent hyperexcitability in the brain can be an excellent strategy for preventing neuronal death and cognitive decline. *Withania somnifera* (WS), also known as ashwagandha, is herbal medicine that is been used for centuries in Ayurvedic medicine and is known as an adaptogenic plant because of its stress reducing capability. We have chosen to study this plant because evidence indicates that it has calming and GABA-enhancing capabilities. Our preliminary studies show that whole root WS modulates hippocampal activity and survival via a GABA-mimetic mechanism. In addition, the most widely studied active components of WS root extract, withaferin A and withanolide A, were not responsible for the observed GABA receptor activation. Thus, we hypothesize that other key WS constituents promote optimal hippocampal function and neuronal survival via GABAergic mechanism. To test this hypothesis, whole WS extracts have been separated into eight fractions using liquid-liquid extraction. To identify bioactive fractions with GABA activity, the *Xenopus laevis* oocyte model was utilized to study $GABA_{rho}$ ($GABA_A$ subtype) receptor function. Cloned $GABA_{rho}$ cDNA from rat brain was injected into *Xenopus* oocytes. Two days after injections, GABA currents were recorded from voltage clamped oocytes using microelectrodes filled with 3M KCl and membrane potential held constant at -80 mV. The oocytes were continuously perfused with ringer solution at room temperature, followed by perfusion of the eight extracted WS fractions at 1: 100 dilution to test their physiological activity. Results showed that two out of eight fractions (water and butanol) exhibit significant maximal GABA response as compared to 10 uM GABA as a control (One Way ANOVA, $p < 0.0001$). This finding supports our hypothesis that major WS constituents may be responsible for the GABA-mimetic activity and have specificity for $GABA_{rho}$ receptors as shown by significant GABA response in the two identified WS fractions and minimal response in the remaining six WS fractions. These results suggest that these constituents may be polar substances such as withanosides IV and VI, or small molecules such as amino acids. Understanding the mechanism of WS may be valuable for the development of pharmacological treatments for neurological disorders associated with GABAergic signaling dysfunction.

Title: Altered parvalbumin cell populations in dorsolateral prefrontal cortex after neonatal hippocampal damage in macaques.

Authors: *T. J. LIBECAP[1], A. J. HOWLEY[1], M. C. ALVARADO[3], J. BACHEVALIER[2,3], H. R. RODMAN[2];
[1]Neurosci. and Behavioral Biol., [2]Psychology, Emory Univ., Atlanta, GA; [3]Yerkes Natl. Primate Ctr., Atlanta, GA

Abstract: GABA, the primary inhibitory neurotransmitter in the mammalian brain, plays a fundamental role in the dorsolateral prefrontal cortex (dlPFC) under normal working conditions. In particular, the parvalbumin (PV) class of GABA interneurons is involved in sustaining the normal neuronal signaling that supports proper functionality of the dlPFC executive system. Because the dlPFC undergoes a protracted development, early disruption may play a role in working memory impairment and other cognitive deficits associated with neurodevelopmental disorders including schizophrenia (SCZ). Further, the hippocampus, a structure in the medial temporal lobe, matures relatively early in life and has been implicated in dlPFC development. Thus, we predicted that a neonatal hippocampal lesion would disrupt the normal PV-positive cell maturation within the dlPFC, consistent with an early limbic-prefrontal disconnection model of SCZ. In this study, we used tissue harvested from adult rhesus monkeys (*Macaca mulatta*) that had sustained either bilateral ibotenic acid lesions of the hippocampus (Neo-H, n = 4) or sham operations (Neo-C, n= 4) as neonates to analyze the relative density of PV-positive GABAergic interneurons in cortical layers IIIA and IIIB of Brodmann Area 46d.We used immunohistochemistry, Giemsa counterstaining, systematic random sampling, and the optical disector and optical fractionator stereological principles to visualize and quantify PV-immunoreactive neurons. We found a significantly higher density of PV-positive cells specifically within layer IIIA of the dlPFC of Neo-H monkeys relative to the Neo-C monkeys, both between the left hemispheres of the two groups and across the groups when both hemispheres were considered together. These results were confirmed by estimations of total PV-positive cell populations in layer IIIA of area 46d. Moreover, layer IIIA PV densities of the Neo-H group were significantly positively correlated with the extent of hippocampal damage. The finding of PV density changes in IIIA but not IIIB suggests that the alterations are related to specific components of GABAergic circuits rather than general disruption of PV expression. Furthermore, these results are consistent with functional connectivity changes and behavioral deficits observed in the same Neo-H cases. Ultimately, these findings have implications for how neonatal lesions of the hippocampus may affect vulnerable structures and disrupt cognitive processing, eventually leading to deficits characteristic of neurodevelopmental disorders including schizophrenia.

Title: Mitochondrial dynamics in parvalbumin interneurons

Authors: *G. KONTOU, N. F. HIGGS, G. LÓPEZ-DOMÉNECH, J. T. KITTLER; Neurosci. Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Parvalbumin interneurons (PV+INs) require very high amounts of energy to sustain their firing rates that are implicated in the generation of high frequency oscillatory behavior. It has been observed that these interneurons contain high levels of mitochondria which reflect the large energy utilization that takes place. Hence, they are susceptible to incidents of mitochondrial impairment as mitochondria provide the predominant source of energy. A shortage in energy provision, due to deficits in the ability of mitochondria to generate ATP and buffer calcium, may result in a dysfunction in PV+INs metabolic activity and signaling. These dysfunctions can cause aberrant rhythmic activities and cognitive decline which are observed in neurological and neuropsychiatric disorders. Neurons are characterized by an exaggerated polar morphology and therefore, specialized mechanisms have evolved to distribute mitochondria to sites of high energy demand in order to meet the metabolic needs of the cell. We have generated a conditional transgenic mouse line using the PV-Cre and the PhAM^{floxed} lines where mitochondria are fluorescently labeled with MitoDendra only in PV+INs. By employing organotypic brain culture preparations from young animals, we are able to investigate mitochondrial dynamics such as trafficking, fission and fusion using live two-photon and confocal microscopy. We show that the expression of MitoDendra under the parvalbumin promoter begins around P10 and is stabilized around P28 and that more than 90% of the Mitodendra-expressing cells are immunopositive for parvalbumin. This suggests that the PV-Cre MitoDendra mouse is a suitable model for the cell-type specific investigation of mitochondrial dynamics in PV+INs. Using live-imaging of *ex vivo* organotypic brain cultures, we have characterized the trafficking properties of mitochondria in PV+INs in the hippocampus under basal conditions. Additionally, MitoDendra can be successfully photoconverted for implementing single mitochondrion tracking experiments and for investigating fusion and fission. Here, we introduce for the first time a strategy to investigate mitochondrial dynamics in PV+INs in intact brain tissue. By taking advantage of this approach, we can now specifically manipulate mitochondrial trafficking and investigate how changes in

energy provision and calcium homeostasis could be implicated in the PV+INs physiological behavior and network activity.

Title: Aging-related increase in the Ca^{2+}-dependent slow afterhyperpolarization (sAHP) of neurons in layer III of the entorhinal cortex

Authors: *J. C. GANT, P. W. LANDFIELD;
Molec. and Biomed. Pharm, Univ. of Kentucky, Lexington, KY

Abstract: Normal aging results in a decline of cognitive function that has been associated with Ca^{2+} dysregulation in hippocampal CA1 pyramidal neurons of several species. Among the most consistent and well-studied electrophysiological markers of neuronal Ca^{2+} dysregulation is the age-related enlargement of the Ca^{2+}-dependent sAHP. This enlargement is generated by an increase in Ca^{2+} influx via L-type Ca^{2+} channels and enhanced Ca^{2+} release from ryanodine receptors. Most studies to date showing an aging-related increase in the sAHP have been conducted in hippocampal pyramidal neurons. Therefore, it is not clear whether this form of Ca^{2+} dysregulation is widespread across brain regions and cell types or is instead restricted primarily to the hippocampus. Resolving this question may substantially facilitate identification of the neuronal circuits involved in aging changes in memory processing. In particular, the extensive reciprocal connectivity between the Entorhinal cortex (EC) and hippocampus is well recognized to play an important role in memory formation but it is not known whether Ca^{2+} dysregulation extends to the EC. We obtained intracellular current clamp recordings from layer III neurons in entorhinal slices from young (3-5 months-old) and aged (20-22 months-old) male rats. Layer III of the EC contains a high proportion of pyramidal cells and essentially all neurons we recorded exhibited a sAHP. Results revealed a highly significant increase in the magnitude of the sAHP and sAHP duration in aged rat EC neurons compared to young rat EC neurons ($p<0.002$ and

p<0.0004 respectively). This aging-related increase was larger than is typically seen in CA1 neurons. Thus, at least one component of the EC projection to hippocampus exhibits strong evidence of Ca^{2+} dysregulation with aging that appears similar to the form found in CA1 pyramidal neurons.

Title: Effects of aging on the food intake and the function of the related synapse in the feeding behavior of *Aplysia* kurodai

Authors: *T. NAGAHAMA, R. ABE, M. MURAMATSU, A. KASHIMA;
Toho Univ. Fac Phar, Funabashi 274-8510, Japan

Abstract: In the wild animals of *Aplysia kurodai*, the birthdate of each individual cannot be determined. Therefore, we initially sought a reliable index of old age by taking the distinguished Japanese seasons into consideration. During and after the second half of May, we commonly find large amounts of animal eggs on the surface of rocks along the coast. And dead bodies of animals begin to appear, which increase in number with the passage of time. The body weights of the collected animals were found to decrease after May. We roughly classified animals collected before and after the second half of May as mature-CP and old-CP. Plots of internalized shell length (*S*) against body weights (*W*) gave distinct best-fit curves for mature-CP and old-CP. The *W/S* significantly decreased in the second half of June, suggesting that body weight decreases with age but the shell length is maintained in each animal. Therefore, collected animals were classified into mature and old animals by using the best-fit curves for mature-CP and old-CP. Whether the plots of the shell length against the body weight were located above the *W-S* curve for old-CP or below the *W-S* curve for mature-CP was used for our judgment on the old or mature animals, respectively. In the present experiments the effect of aging on the food intake was examined. When we measured amount of food intake every 2 hrs up to 8 hrs after providing food, the amount increased linearly in all animals but the rate was significantly lower in old animals than in mature animals. The amount of one-day food intake was also significantly lower in old animals. These results suggest that food intake may decline with age and this may cause weight loss in old animals. We next examined the effect of aging on the function of the related synapse in the feeding neural circuit. Then it was focused on the monosynaptic cholinergic

response in the jaw-closing (JC) motor neurons induced by the buccal multiaction (MA) neurons. We found that the inhibitory postsynaptic currents (IPSCs) significantly decreased with age. We previously showed that reduction of this synaptic response by the modulatory dopaminergic neuron (CBM1) may contribute to generation of the patterned jaw movements for rejection of food. Therefore, an injury of the cholinergic synaptic function with aging may partly contribute to the decline of the food intake.

Title: Dysregulation of mitochondrial morphology during aging in the monkey dorsolateral prefrontal cortex

Authors: *D. DATTA, Y. M. MOROZOV, C. D. PASPALAS, A. F. T. ARNSTEN;
Yale Univ., New Haven, CT

Abstract: The dorsolateral prefrontal cortex (DLPFC) is one of the most newly evolved regions in the primate brain and mediates highest-order cognitive functions. A prototypic cognitive function executed by the DLPFC involves working memory (WM), the ability to use representational knowledge to regulate behavior, thought and emotion. Within DLPFC, modules of pyramidal cells in layer 3 microcircuits engage in recurrent excitation to sustain persistent neural firing required to maintain WM, so-called “Delay cells”. These DLPFC layer 3 microcircuits are highly vulnerable to age-related cognitive decline and to genetic insults in psychiatric diseases such as schizophrenia. For example, the firing of “Delay cells” and dendritic spine density within DLPFC layer 3 microcircuits decrease with advancing age. Since the recurrent excitation required to sustain WM is highly energy demanding, the PFC contains a higher density of mitochondria compared to other cortical regions. However, whether dysregulation of mitochondria contribute to the neurobiological underpinnings of age-related cognitive decline is unknown. Here, we tested the hypothesis that mitochondrial morphology in DLPFC is altered with aging and that impairments in mitochondrial dynamics would be most pronounced in DLPFC layer 3. Using stereological electron microscopy with ultrathin serial sections, we performed 3D reconstructions and volume measurements of mitochondria from

young adult rhesus macaques (7-11 y) and aged rhesus macaques (26, 27, 31 and 33 y). Qualitatively, aged mitochondria exhibited frequent swellings next to highly constricted areas, consistent with "incomplete" mitochondrial fission. Quantitatively, the percentage of mitochondrial profiles (n=365) with "incomplete" fission was ~0% in young adults; however, the frequency of "incomplete" fission profiles (n=774) increased in a dramatic fashion across all laminar locations during aging (43%, 26y; 10%, 27y; 40%, 31y; 18%, 33y). Although individual variability in monkeys was present, layer 3 showed a progressive, linear increase in dysregulated mitochondrial dynamics. These "incomplete" fission mitochondria in aged DLPFC are also associated with cisterns of ER tubules suggesting that aberrant ER-mitochondria processes might induce impairments in mitochondrial dynamics. These findings reveal a robust pathological abnormality that may contribute significantly to age-related cognitive decline in the DLPFC. Future studies will address how intracellular signaling pathways that modulate the physiological strength of recurrent DLPFC network connections can synergistically produce these pathological hallmarks.

Title: Hyperpolarized resting membrane potential of fast spiking neurons: a putative cause of decreased activity-dependent IPSCs in pyramidal neurons of the barrel cortex of aged mice

Authors: *I. R. POPESCU[1], K. Q. LE[2], R. MOSTANY[1];
[1]Pharmacol., [2]Neurosci. Program, Tulane Univ., New Orleans, LA

Abstract: Previous studies using long-term *in vivo* two-photon imaging of the dendritic spines of layer 5 pyramidal neurons in the primary somatosensory cortex have shown that advanced age brings about an increase in the spine turnover rate, potentially interfering with memory storage. Excitatory and inhibitory synaptic inputs to pyramidal neurons may modulate dendritic spine

dynamics either directly by controlling the resting membrane potential and Ca^{2+} influx or by affecting the expression of proteins which play a role in the structure of dendritic spines. Identifying which synaptic inputs are altered by age and what underlies these changes will provide specific targets for interventions aimed at redressing the acceleration of spine turnover. The pyramidal (excitatory) neurons in the somatosensory barrel cortex receive GABAergic inputs from several types of interneurons, including parvalbumin-expressing fast spiking (FS) neurons, somatostatin-expressing neurons and vasoactive intestinal peptide-expressing neurons. Using whole-cell patch clamp recordings in brain slices, we are pinpointing age-related changes in this circuit. Our recordings from pyramidal neurons indicate a decrease in sIPSC frequency and amplitude, as well as a lack of TTX suppression of IPSCs in layer 5 pyramidal neurons from aged mice (> 18 mo), compared to pyramidal neurons from young adult mice (3-6 mo). We hypothesized that a likely cause of this age-related decrease in IPSCs in pyramidal neurons is a decline in the activity of FS neurons, since they provide the majority of perisomatic inputs to pyramidal neurons. To ascertain this, we recorded from FS neurons classified as putative basket or chandelier cells based on their electrophysiological properties, and found an increase in the resting potential of basket cells in aged mice. The age-related hyperpolarization of the resting potential of basket cells is expected to decrease action potential frequency and may also decrease the probability of release of GABA, thereby contributing to the observed deficit of inhibition in pyramidal neurons. Our results suggest that deficits in inhibitory synaptic inputs to pyramidal neurons could be playing a role in the synaptic instability observed in the cortical circuits of aged mice, thus making fast spiking basket cells a potential target for the development of therapeutic interventions designed to delay the onset of aging-related brain decline and hence prolong the quality of life and welfare of the elderly.

Title: Proteomic analysis of human plasma as a source for diagnostic and therapeutic targets for aging-related disorders

Authors: B. SZOKE[1], W. KIM[1], T. WILLIS[2], *S. P. BRAITHWAITE[1];
[1]Alkahest, San Carlos, CA; [2]Grifols, Clayton, NC

Abstract: Blood forms a systemic milieu that connects all tissues in higher order animals. As such, it reflects the state of the cells, organs, and the entire organism, and has extensively been used as a source of diagnostic biomarkers. Accumulating evidence from parabiosis experiments suggests that it can also influence function, with young blood being beneficial and old blood detrimental, particularly for cognitive performance. Similar effects have been observed for plasma suggesting that these functional effects are mediated by soluble factors rather than cells. To identify factors that can potentially serve as targets of novel diagnostics and therapeutics for age-associated pathologies, we set out to understand aging-related changes in the human plasma proteome.

Proteomic analysis of plasma is highly challenging due to the very large number of proteins and proteoforms present in plasma (10^4 - 10^5) combined with their wide dynamic range in abundance (up to 10^{10}-fold). We employed complementary approaches, both affinity based targeted and mass spectrometry based discovery proteomics analyses. Using high quality human plasma samples from Grifols at 18, 30, 45, 55, and 66 years of age, we analyzed >1000 proteins and detected significant age-dependent changes in over 100 proteins. Approximately half of the changing proteins increased and half decreased from 18 to 66 years of age. Analysis over the multiple age groups provided high resolution and revealed differential time courses of changes of individual proteins. The dynamics of protein levels over aging adds a valuable new dimension to understanding the role of age-dependent plasma proteins. These results provide a comprehensive basis for identifying biomarkers of biological age and suggest the existence of both pro-youth and pro-aging factors in human plasma. The understanding of the changes in the plasma proteome can also inform selection of potential targets for therapies for age-associated diseases like Alzheimer's disease.

Title: Environmental isolation impairs measures of brain health

Authors: *S. CASTRO-SCHEIRER[1], J. D. JAUMOTTE[1], R. J. SMEYNE[2], M. J. ZIGMOND[1];
[1]Neurol., Univ. of Pittsburgh, Pittsburgh, PA; [2]Developmental Neurobio., St. Jude Children's Res. Hosp., Memphis, TN

Abstract: Many individuals experience an impoverished lifestyle often associated with cognitive, emotional, and motor decline and can lead to a reduced life span. Such individuals include elderly living with little social contact, the homeless, and those living in jails and prisons, particularly those in solitary confinement. We are assessing the impact of housing under isolation conditions using a behavioral test battery and biochemical, molecular biological, and anatomical methods. F344/BN male rats 18 month old at the outset of our study were housed either individually in a standard shoebox cage (18 cm W x 38 cm D x 27 cm H; SE) or in groups of 6 in a relatively enriched environment (1 m W x 1m D x 0.6m H; EE) containing running wheels, tunnels, platforms, and toys. Body weights remained relatively stable in the SE rats but increased by an average of 10% for the EE rats over a 4-month period. The SE animals showed relatively little behavioral activity, which was consistent with the small space in which they were housed. In contrast, the EE rats showed a good deal of exploration, climbing, playing, and social interaction. After 4 months, all rats were euthanized, brain, peripheral tissues, and blood collected, and the brain dissected into several regions. Assays are being performed and and comparison made between SE and EE groups. Although not all the differences were statistically significant, a number of promising trends have already been observed. For example, we found that the SE rats housed in isolated, impoverished conditions had a 72% decrease in BDNF. These rats also had a 37% decrease in the ratio of dopamine (DA) metabolites to DA and a 30% decrease in the level of phosphorylated tyrosine hydroxylase in the striatum; both of which suggested a decrease in DA synthesis and release in that structure. There was a five-fold increase in mitochondrial DNA damage levels in hippocampus in the SE rats. In addition, substantia nigra from rats in the SE showed a number of significant differences in mRNA expression, including changes in Azin1, Tssc4, Ddit4, Nfkb1a, Pdk4, and Sgk1 (downregulated) and Cxcl13 and

slc47a1 (upregulated). Additional assays are ongoing. Thus far our results indicate that isolated housing produces significant changes consistent with decreased neuroplasticity. In a parallel study, a marked change in cytokine levels in response to an LPS challenge was observed as a result of isolated housing (see Jaumotte et al., at this meeting). These results suggest that isolated, impoverished living conditions can produce profound changes in the brain that may be at least partially responsible for the behavioral impairments observed in people experiencing such conditions.

Title: Isolated housing decreases the immune response in sera and brain following exposure to a bacterial toxin in older rats

Authors: *J. D. JAUMOTTE[1], S. L. CASTRO[1], M. J. ZIGMOND[1], R. J. SMEYNE[2]; [1]Neurol., Univ. of Pittsburgh, Pittsburgh, PA; [2]Developmental Neurobio., St. Jude Children's Res. Hosp., Mephis, TN

Abstract: As people age they often are more likely to become ill. Among the many factors that could explain their reduced health span is the increasing isolation commonly experienced by the elderly, as well as other segments of our society. This, in turn, can be associated with an impaired immune system, including a decline in B- and T-cell production, which is reflected by changes in the expression of cytokines produced in response to exposure of viral or bacterial agents. In this experiment, we examined the immune response elicited by exposure to lipopolysaccharide (LPS), an endotoxin produced by bacteria. We first examined a small dose-response curve for LPS (0-2 mg/kg, i.p.) in 28-month-old male Fisher 344/Brown Norway hybrid rats (F344/BN) to determine the highest tolerable dose of a single intraperitoneal injection of

LPS. We then used an intermediate dose from that analysis (empirically determined to be 1 mg/kg) and delivered it to male F344/BN rats housed housed in our facility for 8 months beginning at 19 months of age. The two groups studied were either singly housed in a standard shoebox cage (18 cm W x 38 cm D x 27 cm H; SE) or a relatively enriched environment consisting of a large cage (1 m W x 1m D x 0.6m H) containing 6 rats, running wheels, tunnels, platforms, and toys (EE). Seven days after the LPS injection all animals were euthanized and brain and serum collected. Using a Luminex multiplex assay kit, we observed that several cytokines and chemokines were significantly altered in both sera and brain from isolated animals in comparison to those in enriched housing. The pattern of change indicated that in isolation led to a reduction in the immune response. Cytokines and chemokines that changed in response to isolation included G-CSF (sera), IL-1 alpha (sera and brain), IL-1-beta (sera and brain), IL-4 (sera and brain), IL-6 (sera), IL-10 (sera), IP-10 (sera), INF-gamma (sera and brain). These data suggest that older, isolated animals have a less reactive immune response than their more enriched counterparts, which could indicate a lowered ability to fight off infections or stave off neurological disease that have an immunological component, including Alzheimer's and Parkinson's disease.

Title: Age-related changes of PGRN expression in the gerbil hippocampus

Authors: K. LEE[1], D. YOO[3], J. CHUNG[2], I. HWANG[3], *J. CHOI[4];
[1]Dept. of Anat., [2]Dept. of Intrnl. Med., Col. of Vet. Medicine, Kangwon Natl. Univ., Chuncheon, Korea, Republic of; [3]Dept. of Anat. and Cell biology, Col. of Vet. Medicine, Seoul Natl. Univ., Seoul, Korea, Republic of; [4]Kangwon Natl. Univ., Chuncheon, Korea, Republic of

Abstract: Progranulin (PGRN) is a growth modulating factor which is known to be related with normal brain development and neurodegenerative disorders. In the present study, we compared immunoreactivity and distribution of PGRN between the adult and aged gerbil hippocampus.Immunoreactivity of PGRN was detected in the all hippocampal sub-regions and

pyramidal cells in the CA 2/3 region were more darkly stained than those in the CA1 in the both groups. However, PGRN immunoreactivity in the aged hippocampus was significantly decreased compared to that in the adult group. Double immunofluorescence showed that PGRN-immunoreactive structures were detected in cytoplasm of NeuN-positive neurons and Iba-1-positive microglia in the hippocampus of the both groups, but, in the GFAP-positive astrocytes, PGRN-positive structures were observed around and in their processes.In conclusion, PGRN immunoreaction was detected throughout the all hippocampal sub-regions in both adult and aged gerbil. However, marked decrease of PGRN immunoreactivity in the hippocampus was observed in the aged gerbil. Therefore, the decrease of PGRN immunoreactivity in the hippocampal neurons in aged hippocampus may be associated with age-related changes of hippocampal function.

Title: Peripheral and spinal postoperative anti-hypersensitivity by mu-opioids DAMGO and buprenorphine in aged versus adult mice

Authors: *J. M. MECKLENBURG[1], M. J. PATIL[1], W. KOEK[2], A. N. AKOPIAN[1];
[1]Endodontics, [2]Psychiatry, Sch. of Med., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Background: Postoperative pain management in the elderly is challenging. This challenge arises due to the changes in their anatomy, physiology, biochemistry and especially wound healing dynamics, which are negatively affected by aging (Benyamin et al., 2008; Portenoy et al., 2004). In addition, old age could affect plasticity in the nociceptive pathway. These changes in the elderly may alter opioid effects, the main medicine for pain management. Therefore, we have investigated whether old age alters opioid-induced postoperative anti-hypersensitivity. **Methods:** Postoperative conditions were modeled by plantar incision in mice (Pogatzki and Raja, 2003). To evaluate the effects of a mu-opioid (DAMGO) and a partial opioid

antagonists/agonist (buprenorphine) on postoperative anti-hypersensitivity in adult and aged mice, thermal and mechanical nociception was measured using Hargreaves apparatus and Dynamic Plantar Aesthesiometer, respectively. Various doses of each drug were administered via local (surgical site) or intrathecal (spinal) injections and pain measurements were recorded 30 minutes and 120 minutes post opioid injection. **Results:** Locally injected DAMGO and buprenorphine had a mild effect on postoperative anti-hypersensitivity in adults and aged mice. However, this effect was not peripherally mediated. In contrast, spinal injection of DAMGO and buprenorphine showed very robust anti-hypersensitivity in adults and to lesser extend in aged mice. Importantly, peripheral and especially spinal DAMGO and buprenorphine-induced postoperative anti-hypersensitivity was substantially more effective in adult compared to aged mice. Thus, dose-response curves were leftward shifted in adults compared to aged mice. The dose-response curve for analgesic effects of buprenorphine was bell-shaped. Finally, buprenorphine had a stimulatory side effect in adults, but not in aged mice, that significantly affected the locomotor activity of adult mice. **Conclusion:** Our data indicates that mu-opioids are less effective for postoperative anti-hypersensitivity in aged as it is in adult mice. Nevertheless, the bell-shaped dose-response curve for buprenorphine analgesic effects and absence of stimulatory side effects at analgesic dosages in aged mice could make buprenorphine a better candidate for postoperative pain management in the elderly.

Title: Genetics of co-regulation of iron, copper, and zinc in mouse brain

Authors: P. JIMENEZ[1], W. ZHAO[2], L. LU[2], *B. C. JONES[2];
[1]Univ. of Memphis, Memphis, TN; [2]Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Iron, copper and zinc are important trace nutrients for development and functioning of the brain. All three require tight homeostatic regulation and there is evidence for co-regulation in various brain regions. Deficiency in each of the metals may have developmental or other functional consequences and excess iron and copper, especially, is implicated in neurodegeneration. In our work, we are interested in the co-regulation among these metals both within and across brain regions.
Twenty strains of the BXD panel of recombinant inbred mice and their parental strains (C57BL/6J and DBA/2J) were analyzed for hippocampal, ventral midbrain and cortex Fe, Cu and Zn content. The age of the mice was 60-120 days of age.
The analysis of Fe, Cu, Zn was performed by X-ray fluorescence spectroscopy (TXRF) using a S2 PICOFOX Spectrometer for Trace Analysis (Bruker, AXS Inc., Madison, WI). This gave us the Fe, Cu and Zn values which were then normalized to tissue weights (µg/g). Correlational analyses including genome mapping were performed using Genenetwork, a public database (http://www.genenetwork.org). The results showed that in the ventral midbrain, iron and copper and copper and zinc were significantly correlated. In the hippocampus, copper and zinc were significantly correlated and in the cortex, none of the metals showed significant associations; however latent associations were revealed by principal components analysis of the strain means. The data thus show that co-regulation of these trace metals are highly tissue-specific. Moreover, we were able to map one quantitative trait locus for the three metals in the ventral midbrain as a principal component, on chromosome 12, near the *Ighg* gene. This gene codes for immunoglobulin heavy chain (gamma polypeptide). It is *cis*-regulated and its expression correlates 0.83 with the principal component for the three metals in the ventral midbrain, thus making it a candidate gene. We performed similar analyses for hippocampus and cortex and while we found suggestive QTL for each, we have yet to identify candidate genes. This will require the analysis of more of the BXD strains.
This work is the first of its kind to reveal interrelationships among Fe, Cu and Zn in brain, using a systems genetics/systems biology approach.

Title: Gaboxadol as a drug intervention for psychosocial stress in young and aged male F344 rats

Authors: *E. M. BLALOCK[1], S. QUTUBUDDIN[2], K. STAGGS[2];
[1]Dept Pharmacol, [2]Pharmacol. and Nutritional Sci., Univ. Kentucky Coll Med., Lexington, KY

Abstract: Psychosocial stress (PS) occurs when a non-noxious stimulus (e.g., loss of a loved one, solitary confinement) provokes a physiological stress response. PS can have negative systemic effects (e.g., elevated immune signaling, sleep loss, cognitive deficits) that are similar to those observed in aging. Further, new onset PS becomes more prevalent with aging. Despite this, relatively few studies have investigated the relationship between aging and PS. In prior work, we demonstrated that aged animals were hyporesponsive to PS, and that both young stressed animals and aged animals in general had reduced deep sleep. Because deep sleep loss exacerbates immune signaling, worsens cognition, and is lost with age, here we tested a pharmacologic deep-sleep promoting intervention on PS in young and aged animals. We hypothesized that the deep sleep promoting drug, gaboxadol (GBX), would improve PS outcomes in young animals and would generally improve age-related cognitive and sleep activity measures. To test this, young (3 mos) and aged (19 mos) male Fischer 344 rats were divided into four groups: control vehicle, control GBX, stress vehicle, stress GBX. Restraint (3h/ day, 4 days) was used as a model of PS. All animals were trained in the Morris water maze during these four days and movement activity was measured in the animals' home cages throughout. In line with previous work, young animals suffered cognitive deficits. Consistent with our hypothesis, PS-induced deficits in young animal probe trial performance were rescued by GBX, and GBX reduced home cage activity in stressed but not control young subjects. Further, as in prior studies, aged animals were hyporesponsive to PS, and did not respond to GBX. This work suggests that deep-sleep promoting therapies can be effective for combating PS-induced cognitive deficits in young, but not aged animals, and further highlight the need to evaluate interventions in age-appropriate models.

Title: African green monkeys as a model for Alzheimer Disease: RNA transcriptomics and CSF biomarker evaluation

Authors: *P. E. CRAMER, K. TANIS, Y. WANG, K. LODGE, I. HAYASHI, C. ZERBINATTI, J. RENGER;
Merck Sharpe & Dohme, West Point, PA

Abstract: While many preclinical models of Alzheimer disease (AD) are reported, none fully recapitulates the features of human disease. We sought to determine whether higher order species, specifically non-human primates, the vervet African Green Monkey (AGM) or the rhesus macacque, could prove to be a more valid and translational model of AD. We analyzed the gene expression profiles of the dorsolateral prefrontal cortex and the visual cortex from a cohort of AGMs ranging in age from 6-33 years and a cohort of rhesus ranging from 3-33 years. We report gene expression changes in aged AGM cortex that were previously published to occur selectively in affected brain areas of human AD. These AD-specific changes were not observed in the aged rhesus. Additionally, we found changes in inflammatory cytokines and microglial genes in both AGM and Rhesus cortex that are consistent with the changes in the aging human brain that are accentuated in AD (Podtelezhinikov, A. et al, PLOS One 2011). We further evaluated cerebrospinal fluid (CSF) from the AGMs and found increases in total tau, phospho-tau, and decreases in A-beta42 levels in aged compared to young AGMs, also consistent with human AD biomarker changes. These data along with our additional characterization of cholinergic-related behavioral deficits in aged AGMs and AD-specific histopathology shown in Vardigan et al. and Gentzel et al., respectively, further suggest that the AGMs represent a novel and potentially useful translational model of AD.

Title: African green monkeys as a model for Alzheimer's Disease: evidence from cognitive measures and response to pharmacology.

Authors: *J. M. USLANER, J. VARDIGAN, V. GAKHAR;
Merck & Co. Inc, West Point, PA

Abstract: There are several key characteristics of Alzheimer's Disease (AD), perhaps most notably loss of cholinergic neurons, A-Beta aggregates (plaques), tau aggregates (tangles), cognitive dysfunction, and old age. Of particular value would be a preclinical model that exhibits all of these characteristics. Whereas rodent models exist in which many of these features are present, the uncertainty of translating pharmacology from rodent to human limits the value of these rodent models. Developing a non-human primate model of AD with validity to the human disease could dramatically improve the ability to discover novel therapeutics. The African Green monkey (AGM) may offer a special opportunity toward this goal. AGM have been shown to develop age-dependent A-Beta pathology, and we have recently shown that other biomarkers associated with AD are present in these animals (see posters from Cramer et al. and Gentzel et al). We therefore hypothesized that AGMs would show an age-dependent deficit on cognition tasks and that symptomatic treatments which improve cognition might be efficacious in improving cognitive performance in this animal model. To address this hypothesis, we trained young and aged AGMs in the Object Retrieval Detour (ORD) task, which is believed to be dependent on prefrontal cortex function and is sensitive to cholinergic disruption. We report that under vehicle conditions, aged AGM perform significantly poorer than younger monkeys on ORD. We also report that drugs which enhance cholinergic function were able to improve this deficit in aged AGM. Specifically, the acetylcholinesterase inhibitor donepezil (0.25 and 0.5mg/kg, IM) and the M1 muscarinic positive allosteric modulator PQCA (1mg/kg IM) produced a significant improvement in performance in aged AGM. These results, along with our additional characterization of CSF biomarkers, RNA sequencing, and histology shown in Cramer et al and Gentzel et al. suggest that the AGMs represent a novel and potentially very important model of mild/moderate AD.

Title: African Green Monkeys as a Model for Alzheimer's Disease: Effects of aging on brain histopathology

Authors: *R. C. GENTZEL, B. CONNOLLY, P. MANFRE, J. J. RENGER, P. CRAMER, J. USLANER;
Merck & Co., West Point, PA

Abstract: Pathological hallmarks of Alzheimer's disease (AD) include amyloid beta (A-Beta) and tau deposits in the brain, known respectively as plaques and tangles. Identification of animal models which recapitulate this pathology and the temporal pattern in which it occurs would improve the likelihood of identifying a treatment for AD. Non-human primates are attractive candidates for such a model due to the ease of translating research findings from higher-order species to humans. Given that the African Green Monkey (AGM) has been reported to have an age-related increase in A-Beta pathology, here we further characterized the histopathology these animals develop with age and compare it to the documented pathology of AD. We acquired a cohort of AGM brains, ranging from young to elderly adult, and performed immunohistochemistry on coronal sections through the frontal cortex, hippocampus, and occipital cortex. We confirmed that plaques increase in the cortex as a function of age. Tangles, which typically occur after the formation of plaques in humans with AD, were noted in the hippocampus from two old monkeys. Markers of inflammation and gliosis were associated with the presence of plaques, and further reflective of AD pathology. Additional work by Cramer et al. (see poster) has demonstrated that changes in AGM CSF biomarkers and gene expression are similar to that observed in AD patients. Furthermore, Vardigan et al. (see poster) has demonstrated that AGMs suffer cognitive decline with age, which can be alleviated with AD therapeutics. In totality, these data suggest that AGMs may serve as a novel model of mild-to-moderate AD.

Title: Pathological characterization of a novel transgenic rat model of cerebral amyloid angiopathy with microhemorrhage

Authors: *F. XU;
Neurolog. Surgery, Stony Brook Univ., Stony Brook, NY

Abstract: Cerebral amyloid angiopathy (CAA) is a prevalent cerebral small vessel disease in the elderly that causes cerebral hemorrhage, is a common co-morbidity of Alzheimer's disease (AD) and contributes to vascular cognitive impairment and dementia (VCID). Additionally, familial forms of CAA occur due to specific mutations within the amyloid β-protein (Aβ) including Dutch E22Q and Iowa D23N. Although much work has been performed previously to study CAA using various human AβPP transgenic mice these investigations have been somewhat limited with this species. On the other hand, rats provide a more advantageous species to model human cerebral disease due to their closer link to humans, larger brain size, higher white matter volume and more sophisticated cognitive testing. Here, we present the generation and pathological characterization of a novel transgenic rat to model human CAA. The rats, designated rTg-SwDI, were designed to express human AβPP and produce familial Dutch/Iowa CAA mutant Aβ in brain. rTg-SwDI rats develop progressive and extensive small vessel CAA starting at about 3 months of age in the cortex, thalamus and hippocampus. As rTg-SwDI rats age to 12 months they develop many of the pathological features of human CAA including dilated perivascular spaces, microinfarcts and numerous microbleeds that can be detected by both histological staining and MR imaging. Progressive small vessel disease in rTg-SwDI rats is accompanied by deteriorated cognitive performance. Our findings indicate that the novel rTg-SwDI rats provide an exciting and improved model for studying CAA and its contribution to VCID.

Title: Assessing cognitive dysfunction, neuroinflammation and degeneration following an endothelin-1 induced stroke injury in an APP transgenic rat

Authors: *A. M. REGIS[1], L. WANG[1], B. ALLMAN[1], V. HACHINSKI[2], S. N. WHITEHEAD[1]; [1]Anat. & Cell Biol., [2]Clin. Neurolog. Sci., Western Univ., London, ON, Canada

Abstract: It is estimated that by age 60, one in three individuals will develop Alzheimer's disease (AD), suffer a stroke, or experience both. While traditionally regarded and treated as distinct conditions, the roles of Alzheimer's disease (AD) and stroke as interacting ailments has attracted interest, though a conclusive pathophysiological link has yet to be determined.
Using an *in vivo* rat model, it is hypothesized that following ischemic stroke, a transgenic rat model carrying human amyloid precursor protein (APP) mutations will display enhanced stroke-related pathology, heightened neuroinflammation, and more severe cognitive decline.
To model AD pathology, our study uses a genetically engineered rat model exhibiting mutations in APP; this model overproduces the human pathogenic protein attributable in AD called amyloid-β. To model an ischemic stroke injury, a unilateral striatal injection of endothelin-1, a potent vasoconstrictor, is utilized.
The proposed models are studied both in combination as well as singularly over a period of four months post-Endothelin-1 injury. A variety of behavioural tests will be used to determine any apparent cognitive and motor deficits, including Attentional Set-Shifting, Novel Object Recognition, Exploratory behavior analyses, as well as analyses of gait and limb co-ordination. Histological analytical methods will be used to determine any mechanistic changes at the cellular level in our injured animals. These strategies will help us better understand how stroke and AD manifest themselves in combination throughout the disease processes.
Preliminary results from our laboratory using rat models suggest that in the presence of amyloid deposition, facets of stroke including infarct size and the degree of neuroinflammation are heightened. These pathological effects are shown to be translated into behavioural deterioration in rodent models of AD and stroke. However, further studies are required to truly understand the interactions between amyloid toxicity, ischemic stroke damage, and neuroinflammation.
Upon defining the specific pathological mechanisms, use of therapeutic intervention may be employed. Overall, with a better understanding of the mechanistic roles of stoke and AD pathology on resultant cognitive impairment, it may be possible to employ strategies in rodents to minimize post-stroke cognitive burden; interventions that may become a translational strategy in humans who are susceptible to stroke and Alzheimer's disease related cognitive impairment.

Title: Impairments of working memory in 5XFAD mice

Authors: *J.-S. HAN[1], H.-A. KIM[1], W. JEON[2,3];
[1]Konkuk Univ., Seoul, Korea, Republic of; [2]Korea Inst. of Oriental Med., Daejeon, Korea, Republic of; [3]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Alzheimer's disease (AD) is the most prevalent neurodegenerative disorder. Early diagnosis and treatment of AD is critical for delaying its progression, but early detection of AD has not been successful. In order to provide a research platform of animal model for early detection of AD, the present study was conducted to examine cognitive impairments and neuropathological characteristics of 4 months old 5X familial AD (5XFAD) transgenic mice, because, at 6 months of age, cognitive impairments and neuropathological characteristics are clearly observed in 5XFAD mice. Capacity of working memory was measured in 5XFAD transgenic mice, using novel object recognition task. Novel object recognition task was performed at various intervals (10 min, 1 h, 4 h, and 24 h) to measure retention of recognition memory. Because early or mild AD patients show impairments in delayed recall, it is expected that 5XFAD mice would show worse performances at the intermediate retention intervals than non-Tg control mice. Consistent with our expectation, the investigation ratio of 5XFAD mice was significantly lower than those of non-Tg control mice at 4 h interval (Mann-Whitney U test, $p < 0.05$). The results indicate that the capacity of working memory was impaired in 5XFAD mice. In addition, accumulation of amyloid β 42 was measured in the brain structures responsible for working memory, using the immunohistochemistry. These findings indicate that cognitive impairments and neuropathological characteristics of 4 months old 5XFAD mice would provide a research platform for studying early diagnosis and treatment of AD. Supported by the National Research Council of Science & Technology (NST) grant by the Korean government (MSIP) (No. G15120 and CRC-15-04-KIST).

Title: Retinal function and structure analyses in transgenic APP_{swe}/PS1ΔE9 mice, a model for Alzheimer's disease

Authors: *S. M. JOLY, S. LAMOUREUX, V. PERNET;
Ophthalmology, Ctr. De Recherche Chuq/Université Laval, Quebec, QC, Canada

Abstract: In this study, the structure and function of the retina were studied in APP_{swe}/PS1ΔE9 transgenic mice, a well-accepted experimental model for Alzheimer's disease (AD). Ocular manifestations of the disease in this model are controversial. Previous studies reported amyloid beta (Aβ) plaque formation in the retina and visual function deterioration by electroretinogram (ERG) recordings in APP_{swe}/PS1ΔE9 mice. However, other laboratories failed to detect AD-associated defects. We thus sought to determine if 5.5-6-month old APP_{swe}/PS1ΔE9 mice (C57BL/6 background) presented signs of cellular degeneration and visual alterations. The expression of amyloid-derived peptides/Aβ was monitored by immunofluorescence in cryosections and by Western blotting in retinal lysates. To follow RGC survival by immunofluorescence, retinae were stained for RNA-binding protein with multiple splicing (RBPMS), osteopontin and melanopsin. Cones and rod bipolar cells were respectively labelled with peanut agglutinin (PNA), and antibodies recognizing opsins and PKCα. To study the retinal function, ERG recordings were carried out in photopic and scotopic conditions. Our results showed that amyloid/Aβ was elevated in retinal ganglion cells and in the inner nuclear layer of APP_{swe}/PS1ΔE9 compared with wild-type animals (WT). Interestingly, amyloid/Aβ immunoreactivity was especially high in OPN-positive RGCs. At this age, no amyloid plaque could be observed (n=4 mice/group). Western blot analysis revealed a higher amount of the alpha C-term fragment than that of beta C-term fragment in APP_{swe}/PS1ΔE9 samples. The number of RBPMS-labelled RGCs/section did not significantly differ between WT (278.6±7.4 RGCs, mean±SEM, n=4) and APP_{swe}/PS1ΔE9 (287.3±8.0 RGCs, n=4) mice. The number of OPN-expressing RGCs was also similar between WT (17.8±1.8, RGCs, n=4) and APP_{swe}/PS1ΔE9 (17.7±1.3 RGCs, n=4) mice. The number of M-cones was not changed in APP_{swe}/PS1ΔE9 (648.2±26.1 cells, n=4) relative to WT (614.0±17.0 cells, n=4) eyes. PNA and PKCα staining did not show obvious change in APP_{swe}/PS1ΔE9 outer retinae. The analysis of scotopic and photopic ERGs show no significant variation in a- and b-wave amplitudes in WT

(n=6) compared with APP_{swe}/PS1ΔE9 (n=5) littermates. In summary, the expression of human amyloid peptides in RGC and inner nuclear layers of APP_{swe}/PS1ΔE9 retinae do not cause cellular or functional alteration at 5.5-6 months of age. Additional experiments in older APP_{swe}/PS1ΔE9 mice will be required to determine if retinal physiology impairments arise during aging.

Title: Longitudinal cognitive testing in a mouse model of Aβ toxicity using an automated CognitionWall task

Authors: *M. LOOS[1], B. KOOPMANS[1], E. REMMELINK[1], B. R. LUBBERS[1], R. E. VAN KESTEREN[2], M. VERHAGE[2], A. B. SMIT[2];
[1]Sylics, Amsterdam, Netherlands; [2]Mol. and Cell. Neurobio., VU university, Amsterdam, Netherlands

Abstract: Alzheimer's disease (AD) is characterized by progressive neuropathological changes and decline in cognitive function. To study the consequences of Aβ oligomer-induced synaptotoxicity on cognitive function, and the efficacy of novel treatments to revert these effects, it is key to develop robust cognitive tests in mice. Here we describe the novel 1-night CognitionWall discrimination learning task, which measures cognitive function in mice in an automated home-cage. In this task, which executes without any human intervention, mice obtain their food by passing through one of three entrances in a wall placed in front of a reward dispenser. Transgenic APP/PS1 mice overproducing Aβ oligomers were significantly slower at reaching the learning criterion, not only around the age at which amyloid plaques start to be visible (26 - 30 weeks of age), but also long before plaque formation at 16 weeks of age. Moreover, the same behavioral deficit could repeatedly be observed in the same cohort tested at 17, 18 and 19 weeks of age. Several proof-of-concept interventions, including BACE1 inhibition (LY2886721), Memantine and Donepezil were used with the aim to pharmacologically validate this task. Thus, in contrast to tests such as the Morris Water Maze, which are performed once at the endpoint of an experiment (cross-sectional between-subject design), we can now longitudinally (within-subject) measure cognitive function in a single cohort of mice. Thus, the CognitionWall discrimination learning task enables longitudinal within-subject testing of AD

mouse models, it strongly reduces the number of mice required for cognitive testing in comparison to current cross-sectional studies, it is fast, and most importantly, it provides a more accurate and sensitive assessment of treatment effects in these models.

Title: Effects of extended isolation stress on amyloid beta production and cognition in 5xFAD transgenic mice

Authors: ***J. L. PETERMAN**, J. D. WHITE, M. J. EIMERBRINK, K. C. PAULHUS, M. A. THOMPSON, H. B. HAYES, G. W. BOEHM, M. J. CHUMLEY;
Texas Christian Univ., Fort Worth, TX

Abstract: The prevalence of Alzheimer’s Disease, a neurodegenerative disease characterized by the pathological hallmarks of amyloid beta (Aβ) plaques and neurofibrillary tangles, is increasing while its causes are unknown (2013 Alzheimer's Disease Facts and Figures, 2013; Hochstrasser et al., 2013). Interestingly, stress has been found to exacerbate Aβ production in transgenic mouse models of the Alzheimer’s (Devi et al., 2010; Lee et al., 2009). We hypothesized that a social stressor, isolation stress, would exacerbate amyloid beta production in 5xFAD+ transgenic mice in comparison to group-housed control animals and 5xFAD- mice. Further, it was hypothesized that isolated, 5xFAD+ animals would perform worse in contextual fear conditioning, a hippocampus-dependent memory task, than group housed, 5xFAD+ or isolated 5xFAD- animals. After extended isolation or group housing, animals underwent contextual fear conditioning, following which freezing behavior was monitored during testing 24 hours later. Twenty four hours after testing, animals were perfused and a hemisphere was collected for sectioning and staining for plaques, while the hippocampus was removed from the other hemisphere and Aβ was quantified by an Aβx-42 ELISA. The hypothesized results include significant elevations in Aβ and plaques for the isolated, 5xFAD+ animals over the group

housed, 5xFAD+ animals, both of which are significantly elevated from the isolated and group housed 5xFAD- animals. This study may help provide insight into factors that contribute to Alzheimer's, critical research when the prevalence of the disease is increasing and its causes are not yet known. Future research will explore ways to rescue these deficits.

Title: Characterization of vascular alterations in transgenic 5xFAD mice

Authors: *E. AUER[1], K. LANEGGER[2], M. TEMMEL[1], J. NEDDENS[1], B. HUTTER-PAIER[1]; [1]Neuropharm., QPS Austria GmbH, Grambach, Austria; [2]FH Joanneum, Graz, Austria

Abstract: Accumulating evidence emphasizes the importance of neurovascular dysfunction in Alzheimer´s Disease (AD). Alterations in brain vasculature morphology and function have been reported to correlate with the progression of AD. Among these changes are microvascular atrophy, changes in blood vessel density and decreased clearance of beta-amyloid resulting in cerebral amyloid angiopathy (CAA). The astrocytic water channel aquaporin-4 has been shown to be vitally involved in the latter process.
Transgenic mouse models are frequently used to analyze the efficiency of new test compounds against AD und should thus mimic the disease as closely as possible. The present study aimed at investigating progressive vascular changes in the transgenic 5xFAD mouse model of AD by labeling 5xFAD brain tissue using antibodies directed against beta-amyloid, collagen IV as a marker for blood vessels, and aquaporin-4. The quantification of beta-amyloid over age showed increased levels in the hippocampus and cortex of transgenic 5xFAD mice compared to control littermates. This effect was first detected in 3 month old animals and became more pronounced with age. The analysis of CAA over age showed a similar progression. Furthermore, analysis of aquaporin-4 revealed that vascular-related aquaporin-4 decreased over age while parenchymal aquaporin-4 increased over age. Together, our data indicate that 5xFAD mice represent a valuable tool for studying various aspects of blood vessel dysfunction in an established AD mouse model.

Title: Deep proteome profiling of hippocampus in 5xFAD mouse model describes alterations in biological process related to Alzheimer's disease

Authors: *D. KIM[1], J. WOO[1], D. HAN[3], J. PARK[2], Y. KIM[2], I. MOOK-JUNG[1]; [2]Biomed. Engin., [1]Seoul Natl. University, Grad. Sch., Seoul City, Chongno-Gu, Korea, Republic of; [3]Biomed. Res. Inst., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disease and characterized by the deposition of extracellular amyloid plaques and intracellular neurofibrillary tangles. Although extensive research was performed for decades, the exact mechanisms and pathological causes of the disease still remain unknown. In order to perform comprehensive and integrative characterization of AD brain, assessment of global proteomic dynamics is required. We performed hippocampal proteome analysis to compare differentially expressed proteins in wild-type and 5XFAD model mice by label-free LC-MS. To reveal the relation between proteome changes and progression of amyloid plaques deposition in hippocampus, the hippocampal proteome was identified in age-dependent manner. 9,313 total proteins and 1411 differentially expressed proteins (DEP) were identified in 5 and 10-month-old wild-type and 5XFAD mice. To explore the altered biological pathway in AD mouse model, the functional and pathway-based analyses of DEP were performed by bioinformatics analysis. Using immunohistochemistry and western blot analysis, we validated novel hippocampal proteins specifically regulated in 5 and 10-month-old 5XFAD mouse model. Therefore, quantitative proteome identification of 5XFAD model mice is able to provide meaningful data to predict real biological alterations in AD and suggest novel protein biomarkers.

Title: Spatial learning and memory performance in two APP21-overexpressing transgenic rat models of Alzheimer's disease

Authors: D. KLAKOTSKAIA[1], R. RICHARDSON[1], D. BOWIE[2], S. CROSBY[2], C. JUSZCZYK[2], L. PAK[2], S. MUDD[2], C. AGCA[3], *T. SCHACHTMAN[2], Y. AGCA[3]; [1]Psychological Sci., [3]Vet. Pathology, [2]Univ. of Missouri, Columbia, MO

Abstract: Alzheimer's disease is a progressive neurodegenerative disorder that results in synaptic and neuronal loss in regions of the brain responsible for memory and cognition. To date, transgenic animal models have played a crucial role in our understanding of the underlying mechanisms of the disease. In this study, spatial memory performance in the Barnes maze was assessed in two strains of transgenic female rats that overexpress human beta amyloid precursor protein (APP21). Female rats aged 12-14 months received nine 3-min acquisition trials over the course of three days, after which 14-day retention was evaluated, and subsequently followed by three days of reversal training trials. The number of nose-poke errors made and latency to enter the target hole were recorded. There were significant group differences in performance during all three phases of Barnes maze training. It was found that both singly transgenic APP21 rats and APP21 rats with an additional presenilin 1 transgene (APP21+PS1) made significantly more errors than control Fischer rats during acquisition and reversal training. During the retention interval test, doubly transgenic APP21+PS1 rats made significantly more errors than both the control Fischer and the singly transgenic rats. These results suggest an overall spatial memory deficit in the transgenic rats and a larger spatial memory deficit in the doubly transgenic APP21+PS1 rats than the singly transgenic APP21 rats.

Title: Heightened emotional contagion in the mouse model of alzheimer’s disease

Authors: *J. CHOI, Y. JEONG;
KAIST, Daejeon, Korea, Republic of

Abstract: Emotional symptoms, as well as cognitive symptoms, have been found commonly in patients with Mild cognitive impairment (MCI) and Alzheimer’s disease (AD). Although cognitive deficits such as memory impairments are considered as typical symptoms of AD, emotional or neuropsychiatric symptoms are often more difficult to manage, since those symptoms can be distress and burden to their caregivers. It is well known that the patients usually showed emotional alterations, for example, depression, irritability, and agitation. In addition to those symptoms, a few researches recently suggested that they also showed high level of ‘emotional contagion’, the ability to mimic another person’s emotion unconsciously. However, the causal mechanism of the heightened emotional contagion in AD patients is still unclear.

As emotional contagion is the primitive form of cognitive empathy, it presents not only in human beings but also in rodents. Here, we carried out ‘observational fear conditioning (OFC)’, a method that can measure the level of emotional contagion in mouse model of AD to see whether they have changes in emotional contagion. Local field potential (LFP) in anterior cingulate cortex (ACC), anterior insular (AI), basolateral amygdala (BLA), and retrosplenial cortex (RSC) of the mouse brain were recorded simultaneously during the behavior and the resting state. In line with the human AD patient results, the disease model mice also showed significantly higher freezing level, which is indicating the heightened emotional contagion, compared to the littermate normal mice when they reached at the age of full symptom manifestation. Moreover, ACC in AD mice displayed significantly higher theta wave synchrony with BLA and AI, when the mice observed the suffering of others.

Thus, this study demonstrated that the heighted emotional contagion, which was reported in human AD patients, was observed in AD mouse model as well. Furthermore, the behavioral alteration had a causal relationship with neuronal synchrony within ACC, BLA and AI, which are the regions included in the salience network in the case of human brain. These results suggested a possible explanation how and why the patients with AD were easily influenced by the caregiver’s emotional state in terms of the specific brain region network connectivity.

Title: Longitudinal *In vivo* tracking of neurovascular function in a mouse model of Alzheimers disease

Authors: *J. BERWICK, P. S. SHARP, L. BOORMAN, S. HARRIS, P. HEATH, S. B. WHARTON;
Univ. Sheffield, S. Yorkshire, United Kingdom

Abstract: Neural activity is closely followed by a localised change in cerebral blood flow, a process termed neurovascular coupling. Accumulating evidence indicates that impaired neurovascular coupling may be an early pathogenic factor in Alzheimer's disease (AD), which could also serve as a perfusion-based imaging biomarker of cerebral pathology. However, there are a lack of studies examining the evolution of neurovascular dysfunction in mouse models of AD. This may be due to the challenges of controlling physiological parameters in mice and profound effects of anesthetics on vascular physiology. Our previous work has established an anesthetic regime that produces hemodynamic responses comparable to those in the awake mouse. In the present study, our aim was to adapt this protocol for use as a chronic anesthetized preparation and determine the onset and evolution of neurovascular alterations in a transgenic mouse model of AD (hAPP-J20). In addition to evoked hemodynamics, we also investigated the potential emergence and/or attenuation of low frequency hemodynamic oscillations (0.1 Hz, 'vasomotion'), which have been linked to pathophysiological conditions and could act as a disease biomarker. To visualise cerebral vasculature, mice were equipped with a cranial window and a head plate for fixation. We used optical imaging spectroscopy (OIS) to produce functional maps of changes in tissue oxygenation and cerebral blood volume in response to whisker stimulation. In addition, concurrent multi-depth electrophysiology and OIS was used to examine the relationship between neural activity and a range of hemodynamic responses. Spontaneous and evoked hemodynamics were measured every month between 3 and 12 months, which precedes the impact of vascular amyloid deposition on vessel reactivity. Our findings demonstrate the reliability of our chronic anesthetized preparation showing highly reproducible responses in the same animal over 3 months, at which time acute neural/OIS experiments were conducted. Contrary to previous reports, hAPP-J20 mice did not exhibit reductions in responses compared to controls during the first 12 months. Furthermore, vascular dynamics were also largely unchanged, however, by 9 months a larger post-stimulation undershoot emerged in

hAPP-J20 mice as a result of a rapid return to baseline. Fourier frequency analysis of spontaneous hemodynamic data, also indicated impaired 'vasomotion' in hAPP-J20 mice. Our initial findings suggest that cerebrovascular dysfunction is closely linked to vascular amyloid deposition. We will present further data exploring this possibility and include analysis of neural activity in hAPP-J20 and control mice.

Title: Using synthetic extracellular matrix mimics to recapitulate key pathologies of Alzheimer's disease

Authors: *A. D. MARTIN[1], L. M. ITTNER[2], Y. D. KE[2], S. CHUA[2];
[1]Chem., [2]Sch. of Med. Sci., Univ. of New South Wales, Sydney, Australia

Abstract: Two of the key neuropathologies associated with Alzheimer's disease are the formation of amyloid beta plaques and neurofibrillary tangles. Much research has been devoted to studying the formation of these key pathologies within human and animal models, including the generation of transgenic mice which overexpress the amyloid precursor protein or the tau protein. From these animal models, it has been shown that the extracellular matrix (ECM) may play a role in the fibrillogenesis of amyloid fibres, and that plaque deposition is detrimental to physiochemical properties of the ECM.
Three dimensional cell culture systems are able to offer a bridge between traditional two dimensional cell culture and animal models. Such a 3D system offers advantages from both techniques, including the high throughput associated with monolayer cell culture whilst maintaining conditions which mimic the in vivo environment found in animal models. Currently, the most common choice for creating three dimensional cell culture models is MatriGel, however it suffers from batch-to-batch variability, the presence of xenogenic components and heterogeneity. Clearly, a more reproducible, homogenous candidate is required for future 3D cell culture studies.
In this work, a series of short peptides (2-6 amino acids) bearing bulky aromatic groups at their

N-terminus have been synthesised. Upon treatment with cell culture media such as Dulbecco's Modified Eagle Medium (DMEM) or NeuroBasal, these peptides self-assemble into hydrogel networks composed of uniform, cross-linked fibres in the same manner as the extracellular matrix. Through the selection of amino acid sequence and capping group, the physical and chemical properties of these ECM mimics can be tuned, allowing the effect of parameters such as stiffness, mesh size and fibre charge on the growth of neural networks to be investigated. As such, a series of these ECM mimics have been used as three dimensional cell cultures for primary neuronal cells. The presence of the fibronectin sequence arginine-glycine-aspartic acid (-RGD) results in increased adhesion of neuronal cells to these synthetic ECM materials, with neuronal development comparable to that observed in poly-D-lysine controls. Thus it can be shown that these homogenous, reproducible hydrogel networks comprised of short peptides are able to support neuronal development. In the future, primary neuronal cells derived from transgenic mice will be cultured within these 3D systems, with the aim of concurrently recapitulating key amyloid and tau pathologies in a tuneable extracellular matrix mimic.

Title: A longitudinal investigation into the effects of Zn and Cu on spatial learning/memory and social preference in a mouse model of LOAD

Authors: *S. N. HOWELL, K. N. BOGGS, T. P. IOBST, J. M. FLINN;
Psychology, George Mason Univ., Fairfax, VA

Abstract: This study examines the effect of dietary copper (Cu) and zinc (Zn) on spatial learning/memory and social preference in a mouse model of late onset Alzheimer's disease (AD). Previous research has indicated that excess dietary Zn may cause behavioral impairments through an induced Cu deficiency. Using a mildly Cu deficient hard diet, we initially tested this theory in an early onset model of AD, which suggested instead that 1.) the effects of Cu and Zn may differ in the brain regions controlling different behaviors, and that 2.) the effect of excess Zn may not be entirely due to an induced Cu deficiency.
To examine the effects of the dietary manipulations in a late onset model, we crossed male hAPP

transgenic (Tg) mice with homozygous ApoE4 females. We are particularly interested in the E4 allele of the APOE gene, as it constitutes a high risk factor for development of AD, with some evidence showing that it may be protective early on. Six groups are being tested for spatial learning/memory (Morris water maze (MWM)) and social preference (3-chamber apparatus) at 6 and 12 months of age (wildtype (Wt) and Tg mice on (a.) lab water + Cu control diet, (b.) lab water + Cu deficient diet, or (c.) Zn-enhanced water + Cu control diet). These time points were chosen to identify longitudinal changes in behavior, allowing for identification of the potentially protective effects of the E4 allele and dietary interactions in early and late stages of AD. Open field (OF) and odor habituation/dishabituation (OHD) are being assessed as controls for the social behavior task (locomotor activity and odor sensitivity respectively).
Data at 6 months suggests early spatial learning/memory deficits but intact social preference in AD mice. AD mice showed significantly longer latencies than Wt's in the MWM ($p<.001$), but display normal preferences for social interaction in the 3-chamber test. Twelve-month data will be collected between July-November 2016 and will also be presented.

Title: Tracking of disease progression *In vivo* in a Primate Model fo Alzheimer's Disease

Authors: *R. G. WITHER[1], S. E. BOEHNKE[1], A. LABLANS[1], B. C. COE[1], J. Y. NASHED[1], D. J. COOK[1], F. G. DE FELICE[2], D. P. MUNOZ[1];
[1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Inst. of Med. Biochem. Leopoldo de Meis, Rio De Janeiro, Brazil

Abstract: Alzheimer's disease (AD) is a devastating neurodegenerative disease and there is an urgent need to develop new therapeutics. Promising drugs developed in rodents have failed to work in AD patients in clinical trials. To bridge this translational gap, our laboratory has developed a non-human primate (NHP) model of AD via intracerebroventricular (icv) injection of neurotoxic amyloid beta oligomers (AβOs). This model recapitulates the molecular aspects of human AD pathology, such as tau hyperphosphorylation coupled with tangle formation, synaptic loss, and astrocytic activation (Forny-Germano et al., J.Neurosci, 2014). Here, we present results

from a pilot study tracking disease progression *in vivo* in male rhesus macaques given large icv injections of AβOs (100-400μg) every 4-6 weeks over 12-18 months. During a baseline period and across the months of injections we regularly tracked behavioural, neuroimaging and cerebrospinal fluid (CSF) and blood biomarkers. To track behavior we measured cage activity using a 3-d accelerometer activity tracker on the animal's collar and 24/7 video. To measure cognition we used a cage-side touch-screen device which implemented visuo-spatial tasks from the CANTAB AD battery (Monkey CANTAB, Lafayette). To track synaptic degradation we conducted functional magnetic resonance imaging and analyzed resting state functional connectivity. To track molecular biomarkers in the CSF we conducted lumbar punctures and used ELISA and Luminex platforms to quantify levels of Aβ1-40, Aβ1-42, total Tau, pTau and panels of cytokines. To track blood biomarkers, blood samples were analyzed regularly with glucose metabolism measured. Using the CANTAB apparatus, we observed spatial working memory deficits on the self-ordered spatial search task, and the inability to learn new tasks (delayed match to sample and paired associates learning) following AβO injections. In addition to learning and memory deficits, overall home-cage activity was diminished as assessed using 24/7 activity and video monitoring. Reductions in resting-state functional connectivity were observed among memory-related areas including the frontal cortex and hippocampus. Changes in Aβ with injections could be tracked in the CSF, along with an increase in pTau. The long-term goal is to relate these *in vivo* metrics to each animal's post-mortem brain pathology. Overall, we validate a viable platform by which to evaluate development of AD in primates, which could easily be translated to track disease in other primate models.

Title: Generation of progranulin inducible mouse lines to determine the timeline of therapeutic intervention

Authors: *M. TOWNSEND, L. MARTENS, G. KOENIG, H. PATZKE;
FORUM Pharmaceuticals, Waltham, MA

Abstract: Frontotemporal dementia (FTD) is the second most common neurodegenerative dementing disorder and is characterized by impairments in behavior, language, and planning.

Loss of function mutations in the progranulin gene (*GRN*) are a cause of FTD. Several mouse models of progranulin (PGRN) deficiency have been generated by knocking out the *Grn* gene. Heterozygous mice, which produce approximately half the normal levels of PGRN, have been reported to exhibit a minimal phenotype at the molecular and pathological level. By comparison, knockout mice consistently show microgliosis, accumulation of lipofuscin, and altered expression of lysosomal proteins. Whether restoration of progranulin can arrest the progression of these phenotypes has not been examined.
We have generated a conditional knockin mouse model of PGRN deficiency. A stop sequence flanked by loxP sites was inserted into exon 1 of the mouse GRN genomic locus. Untreated, these mice produce no detectable PGRN in the brain. When crossed into a mouse line expressing a constitutively active CRE, progranulin levels are equal to WT. Ongoing experiments are exploring the use of stereotaxically injecting AAV-CRE to restore PGRN in discreet brain regions. Crossing the knockin mice to a CreESR1 line, should enable tamoxifen inducible excision of the stop sequence and reactivation of PGRN expression.
A second conditional knockin mouse was also developed that contains a mKate2 fluorescent tag between the signal peptide and GRNP, at the n-terminus of PGRN. The long wavelength red may prove useful in tracking the expression and distribution of mKate2-PGRN both *in vitro* and *in vivo*. Both lines are expected to be valuable tools in understanding the potential for therapeutics designed to restore PGRN to slow or reverse disease progression.

Title: Induction of tau pathology in HEK cells recapitulates aspects of the transcriptional alternations found in human Alzheimer's disease brain

Authors: *J. N. MARCUS, K. TANIS, M. COSDEN, J. MAJERCAK, C. WINROW, J. SCHACHTER;
Merck Res. Labs, West Point, PA

Abstract: A significant hurdle in Alzheimer's disease (AD) research is the lack of translationally relevant models of disease with phenotypes similar to the pathologies found in diseased human brain. The relevance of preclinical animal models of Alzheimer's-like pathology is poorly understood and often relies on genetic mutations found in a small percentage of human AD cases. On the other hand, cellular models of AD are typically not thought to capture complex long term disease processes. We sought to determine what acute aspects of AD pathophysiology are represented in HEK293 cells overexpressing wild type or a proaggregating form of the human tau protein under control of a doxycycline inducible promoter that does not contain frontotemporal dementia mutations. In this system, tau aggregates are observed when pro-aggregating, but not wildtype, tau expression is induced. We generated genome-wide transcriptome profiles by next generation sequencing from these cells after 0, 24, or 48 hours of doxycycline induction. Significant transcriptional changes were observed in the pro-aggregating tau cell line which were distinct from those observed under conditions of overexpression of wild-type human tau. These results were compared to transcriptional modules correlating with normal aging and/or AD disease onset and progression in human brain tissue samples to determine whether any changes associated with the human disease were present in either cellular model. The presence of tau pathology in the pro-aggregating cell model recapitulated several transcriptional signatures observed in human brain tissue, whereas the wild-type tau cell line did not. These results suggest that even in the absence of the multiple cell types and chronic disease characterizing human AD, this acute cellular model of tau pathology can engage many similar cellular processes that are altered in the diseased human brain. Notably, gene expression signatures driven by changing cell type populations in AD, such as increased numbers of microglia, were not observed in the HEK model. These studies highlight the utility of transcriptional profiling in determining relevance of preclinical models and their utility for focusing on specific aspects of disease pathophysiology.

Title: Conditional ablation of Tau in the adult brain leads to anxious and depressive pathology

Authors: *J. M. SILVA[1,2], C. SOARES-CUNHA[2], A. RODRIGUES[2], N. SOUSA[2], I. SOTIROPOULOS[2];
[1]Life and Hlth. Sci. Res. Inst. (ICVS), Braga, Portugal; [2]Life and Hlth. Sci. Res. Inst. (ICVS), Sch. of Hlth. Sciences, Univ. of Minho and ICVS/3B's - PT Government Associate Lab., Braga/Guimarães, Portugal

Abstract: The microtubule associated protein Tau is suggested to be involved in many cellular processes such as microtubule stability, axonal transport while recent evidence suggests a role for Tau in synaptic signaling and plasticity. However, the *in vivo* significance of these Tau actions remains uncertain as conventional Tau knock-out Tau-KO) models don't exhibit the expected deficits. Overcoming the compensation mechanisms that are suggested to be involved in conventional Tau-KO models masking the real contribution of Tau protein in neuronal and brain function, we created a novel model based in a LoxP/Cre-recombinase system offering a conditional and inducible approach for studying Tau role in neuronal function and brain circuits. After an extensive characterization of the model, we demonstrate that induction of Tau deletion at 4 months old animals lead to an anxious and depressive phenotype without memory impairments. Further analysis correlates the above behavioral phenotype with morphological alterations in neurons of the prefrontal cortex (PFC) and amygdala (Amy) and electrophysioligcal coherence pointing towards an important involvement of Tau in amygdala-PFC circuitry. Moreover, current molecular analysis provides novel insights about the role of Tau in dendritic and synaptic signaling. Altogether, the loss of Tau and its function has a clear pathological impact on both neuronal structure and function in adult brain offering a new window of research that will add to our limited knowledge about the real function(s) of Tau in adult brain circuits.

Abstract: Decreased ability of olfaction is measured prevalently in several neurodegenerative disease including Alzheimer's disease (AD). Olfactory system has a spatially conserved map depending on axon guidance when they transduce odor information. Although various attempts to define relationship which exists between olfactory circuit and AD, it has not been still fully understood how AD pathogenesis influences on abnormal behavior in olfaction. In order to provide direct correlation between olfactory dysfunction and AD, transgenic mice, Tg6799 were applied. Using immunohistochemistry, we demonstrated that loss of dopaminergic neurons in periglomerular cell by decreasing tyrosine hydroxylase and accumulation of oligomerized-amyloid beta and beta-secretases was increased in the ventral region of the olfactory bulb, as well as in the ecto-turbinate of olfactory epithelium. The immunostaining of cleaved-caspase 3 showed increase in neuronal death in the olfactory system. Next, we tried to reveal functions of the distinct odorant pathway which regions were damaged in the progress of AD. Results from real-time PCR showed decreases in expression of odorant receptors located in damaged regions. Moreover, behavioral assay demonstrated that the Tg mice lacked the response to several odorants combining with reduced receptor expression as well as behavior responses. Our results suggest that abnormal variation in the olfactory responses during AD progression may lead alternation of odor recognition pattern, as a consequence may show distinct behaviors upon odorant stimulation. Title: The locus coeruleus neurotoxin, DSP4, and/or a high sugar diet induce behavioral and biochemical alterations in wild-type mice consistent with Alzheimer's-like neurodegeneration

Authors: *L. K. BEKAR, J. PALASCHUK, P. CHOUDHARY;
Pharmacol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Neurodegenerative diseases are a growing concern in our aging population. Alzheimer's disease (AD) is the sixth leading cause of death in the United States where it is estimated that one in three seniors dies with Alzheimer's or another dementia. Are modern lifestyle habits a contributing factor? Increased carbohydrate (sugar) consumption, stress and disruption of sleep patterns are quickly becoming the norm rather than the exception. Stress and high carbohydrate diets appear to be escalating diabetes and dementia cases (Alzheimer's disease is increasingly referred to as type-3 diabetes; diabetes of the brain). Interestingly, seven months on a very simple non-invasive high sucrose diet (20% sucrose in the drinking water) has been shown to induce behavioral, mitochondrial/metabolic and pathological changes consistent with AD in wild-type mice. As chronic stress and depression are associated with loss of locus coeruleus (LC) neurons and projections (source of anti-inflammatory and trophic factor control), we assessed the ability for a selective LC neurotoxin (DSP4) to accelerate and aggravate a high-sucrose mediated AD-like phenotype in wild-type mice. Male C57/Bl6 mice were divided into four groups consisting of mice that were 1) saline injected, 2) DSP4 injected, 3) given high sucrose drinking water (20%) or 4) DSP4 injected and given high sucrose drinking water. Behavioral studies at 3 months indicate that while a chronic high sucrose diet increases immobility in the forced swim test and DSP4 reduces thigmotaxis and freezing behavior in the open field test, a high sucrose diet or combined DSP4/high sucrose diet are sufficient to reduce memory in a modified Y-maze task; indicating cognitive deficits are already present 3 months after initiating treatments. The decrease in cognitive performance is consistent with an observed increase in hemibrain acetylcholinesterase activity. The process of developing a simple model in wild-type mice will highlight environmental and societal factors that need to be addressed to slow, prevent or even reverse the rising trend in national dementia patient numbers and costs.

Title: Selective targeting of the corticothalamic network in an Alzheimer's disease mouse model

Authors: *R. JAGIRDAR, Y. ZHENG, J. CHIN;
Memory and Brain Res. Center, Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Alzheimer's disease (AD) is associated with progressive memory impairment, cognitive dysfunction and a deficit in sleep maintenance. The incidence of unprovoked seizures is also higher in AD patients than in reference populations. These seemingly disparate symptoms of AD all have in common the fact that they are regulated by activity in the corticothalamic network. Transgenic mice that express human amyloid precursor protein (APP) carrying mutations linked to AD also exhibit all of these symptoms. We recently identified robust alterations in activity in the corticothalamic network in APP mice, suggesting that indeed, dysfunction in this network may be a common denominator underlying many aspects of AD pathophysiology. We found that much of the dysfunction in the corticothalamic network of APP mice appears to be downstream of a marked reduction of activity in the reticular thalamic nucleus (nRT). Such reduction was associated with impairments in sleep maintenance, deficits in hippocampal spatial memory, and seizures. We therefore hypothesized that restoration of activity in nRT might be a therapeutic strategy to improve cognition and behavior as well as reduce seizure incidence in APP mice. To do so, we are expressing Gq coupled hM3D (DREADD) receptors in nRT in both wild-type and APP mice, and then treating the mice with clozapine-n-oxide (CNO) to specifically activate DREADD-expressing nRT neurons. We demonstrate that an AAV-hM3Dq vector stereotaxically targeted to nRT reliably expresses throughout the extent of nRT. Moreover, administration of CNO to wildtype mice expressing DREADDs in nRT results in alterations in sleep maintenance, as predicted. Dose dependent responses will be evaluated in both wildtype and APP mice to study the effect on neuronal activity and sleep behavior, as well as seizures. These studies will determine whether selectively targeting the corticothalamic network might be an effective therapeutic strategy to reduce seizures and improve cognition and behavior in APP mice and possibly also in AD patients.

Title: Impairments in circadian wheel running behavior and motivated behaviors in a late onset mouse model

Authors: *K. BOGGS, S. N. HOWELL, J. M. FLINN;
George Mason Univ., Fairfax, VA

Abstract: Most studies concerning mouse models of Alzheimer's disease (AD) focus on early onset AD (EOAD) due the genetic nature of the disease. These early onset cases, only account for 1-5% of total AD cases, while late onset AD (LOAD) constitutes the majority. The most well established risk factor for LOAD is the E4 allele of the apolipoprotein E gene. In an effort to model LOAD in mice, APP mutant mice (J20s) have been crossed with E4 mice to generate APP/E4 LOAD mice. The primary symptom of AD is memory loss, yet secondary symptoms are often the reason for institutionalization. Such symptoms include circadian rhythm (CR) sleep disturbances, and loss of activities of daily living (ADL). To measure ADL in APP/E4 and C57 wildtype mice, nest building and burrowing behavior were analyzed at 6 months, and will be analyzed at 12 months. These species typical behaviors in mice are likened to basic ADL in humans, which would include activities such as bathing or dressing. To assess CR sleep disturbances, wheel-running behavior was measured at 6 months and will be repeated at 12 months. For the burrowing assay, animals were individually housed 3 hours before dark onset in cages equipped with a plastic burrow filled with 250 grams of pea gravel. Burrows were weighed after 2 hours and again the following morning. At 6 months, C57 animals burrowed significantly more pea gravel overnight than APP/E4 animals ($p<.05$). For the nest-building assay, animals were individually housed for a period of 24 hours in cages lined with corncob bedding and shredded paper. At the end of the testing period, pictures of the nests were scored by blind raters. Nesting scores were lower in APP/E4 animals compared to C57 mice ($p<.05$). Taken together, APP/E4 animals performed significantly worse on both measures of ADL at 6 months of age. CR wheel running-behavior was measured using cages that track wheel rotations. Animals were individually housed in these cages for 9 days. Preliminary data suggests that APP/E4 animals have significantly altered wheel-running behavior at 6 months of age compared to controls. Measures of wheel-running behavior include: hour of onset, hour of offset, bout length, counts per bout, and bouts per day. Both 6 month and 12 month data will be presented in November.

Abstract: Alterations of the Blood-Brain Barrier (BBB) are likely involved in several neurodegenerative diseases. The BBB is a dynamic interface that doesn't only react to vascular signals but also produces prostaglandins, nitric oxide, and cytokines that affect Central Nervous System (CNS) function through its detoxification and anti-inflammatory capacities. Conversely, cerebral capillaries are innervated by different noradrenergic, serotonergic, cholinergic or GABA-ergic neurons that regulate important aspects of BBB function and induce the expression of BBB-related proteins. Several studies argue that dysfunction of BBB precipitates Alzheimer Disease (AD). Faulty BBB clearance of A-beta (Aβ) may promote its accumulation in the brain. Additional features of AD such as angiogenesis and arterial dysfunction may also initiate neurovascular uncoupling leading to Aβ accumulation and neurovascular inflammation resulting in synaptic and neuronal dysfunction. Barrier alteration in neurodegenerative diseases also has significant implications for drug therapy. Numerous drugs weren't tested because preliminary studies suggest they don't cross the BBB despite the fact that they could benefit from increased brain delivery across a compromised BBB. The study of the dynamic nature of BBB, its dysfunction and the potential involvement of the peripheral compartment in neurodegenerative processes may help to better understand the pathophysiology of CNS disease. We developed an improved *in vitro* rat syngeneic BBB model that includes primary cortical neurons. First, we established in 12 well plates the best conditions of culture between astrocytes, cortical neurons and microvascular endothelial cell monolayers. We characterized each cell partners by phenotypical features and specific immune-labelling (Claudin-5, ZO-1, MAP2, GFAP…) before investigating integrity of the monolayers by quantification of endothelial permeability coefficient (Pe) for lucifer yellow (LY). Then we miniaturized the model in 96 well plates for high content screening and applied oxidative stress damage (glutamate injury) and Aβ intoxication, two processes involved in AD. We showed the responsiveness of our cell system and the implication of each cellular counterpart in the neurodegenerative events. Finally, we tested some reference compounds and demonstrated the robustness of this neuro-glio-vascular model. This new

relevant BBB cell model based on co-culture of three types of primo-cultures will allow a more predictive evaluation of therapeutic compounds.

Title: Next-generation neurological disease models - Directed differentiation of iPSCs to functionally model Alzheimer's and Parkinson's diseases

Authors: A. ARMESILLA-DIAZ[1], R. SHARMA[3], R. SANTOS[1], B. NEWMAN[3], *K. M. GAMBER[2], G. GIBBONS[3], C. L. SCHOFIELD[1], N. CARPENTER[3], C. E. LOWE[1], Y. SHI[3]; [1]Horizon Discovery, Cambridge, United Kingdom; [2]Horizon Discovery, Saint Louis, MO; [3]Axol Biosci., Cambridge, United Kingdom

Abstract: Alzheimer's and Parkinson's diseases are incurable and debilitating neurodegenerative conditions with strong links to age. Today Alzheimer's disease alone accounts for 60-70% of dementia cases and Parkinson's disease is expected to affect ~2% of individuals over 65 years. The human and economic impact of these conditions is expected to increase significantly with the increasingly aging global populations unless new therapeutic strategies can be developed. Currently, there are a lack of human cell-based models available in which to carry out such studies and further investigation is needed in order to elucidate disease mechanisms and determine the efficacy of novel drug compounds. iPSC-derived neural stem cells (NSCs) offer a virtually unlimited source of physiologically relevant isogenic lines for use in both disease modelling and drug discovery.Combining the powerful tools of iPSC genome editing using CRISPR-Cas9 and directed differentiation, we have generated patient relevant NSC disease models carrying Alzheimer's disease-associated microtubule-associated protein TAU (MAPT) mutations, R406W, P301L and V337M and Parkinson's disease-associated leucine-rich repeat kinase 2 (LRRK2) mutation, G2019S in both a heterozygous and homozygous manner. These clinically identified missense mutations in MAPT are thought to reduce the ability of TAU to promote microtubule assembly and may contribute to neuronal death in Alzheimer's disease. LRRK2 is thought to contribute to Parkinson's disease via pathological mechanisms involving TAU, oxidative stress, α-synuclein, and mitochondrial-synaptic-dysfunction. Genome-edited

iPSC lines were genotyped, karyotyped and subsequently differentiated using fully-defined, xeno-free neural induction conditions (Shi et al., 2012). Once the cells formed polarized neural tube-like rosette structures in monolayer culture, immunocytochemistry confirmed the expression of typical cerebral cortical NSC markers namely, PAX6 and FOXG1. Electrical activity was confirmed used multi-electrode array (MEA).These genetically defined, functionally validated human iPSC-derived NSCs provide a renewable resource of disease- and biologically-relevant cells. These cells, carrying relevant mutations, offer a stable platform on which novel therapeutic agents can be screened and validated. Furthermore, these cells enable a direct comparison of the variant effect on cellular phenotype between isogenic lines cells and may therefore provide further insight into the pathology of these diseases.

Title: Ultrastructural neuropathology at pre-plaque ages in triple transgenic mouse model of Alzheimer’s disease

Authors: S. CHAWLA, L. HANLEY, E. E. MAHER, *A. ERISIR;
Psychology, Univ. of Virginia, Charlottesville, VA

Abstract: Amyloid plaques, the major anatomical diagnostic criteria for Alzheimer’s Disease (AD), manifest decades before clinically diagnosed dementia, which correlates more directly

with neurofibrillary tangles and neuron degeneration. A similar symptom mismatch is observed in transgenic mouse models of the disease: behavioral deficits become evident months before any extracellular amyloid accumulation or cell death occurs. In contrast, myelin deficits are the earliest neuropathological findings detected both in human familial AD patients and in transgenic mouse models. In the triple transgenic mouse model (3xTg), behavioral defects, white matter disruptions, and changes in myelin marker expression are all evident as early as 3–4 months of age. We used electron microscopy to document early neuropathological alterations in 3xTg mice at postnatal months (PM) 3, 5, 8, and 12. While non-toxic A11 fragments were detected intracellularly in hippocampal neurons of young animals, the organelle and fibril morphology in labeled neurons were not notably altered. Similarly, extracellular $A\beta_{42}$ labeling, nor plaques, were not robust before PM12. Early signs of neuronal aging are evident at PM8, in form of vacuoles, lipofuscin accumulations and tight fibril bundles in karyoplasm, protoplasm and dendrites. While synapse density was minimally altered in the hippocampus, small dendrites and terminals in the basal forebrain were notably damaged by PM5, despite unaltered cell bodies and large dendrites. The earliest neuropathological manifestations were found in myelinated axon tracts. Several abnormal myelin structural formations were encountered, including vacuolization and uncompacting of myelin stacks, ruffling of oligodendrocyte membranes, herniation, double myelin, extensive myelin outfolding and myelin bulbs. While pathological morphologies associated with oligodenrocytes progressed in severity and frequency by age, most axons surrounded by altered myelin formations, including myelin bulbs, displayed relatively intact axon morphology, indicating that oligodendrocyte pathology preceded axonal degeneration. Subtle myelin outfolding encountered at PM3 progressed to extensive hypermyelination of non-axonal neuropil and myelin bulbs, leading degeneration of sequestered neuronal elements. Our results highlight the importance of alterations in oligodendrocyte function as the earliest neuropathology in the 3xTg mouse model, indicating that oligodendrocyte pathology may be responsible for deficits in neuronal function and behavior that occur in transgenic animals prior to amyloid and tau-associated pathologies.

Title: Increase in beta-sheet secondary structures of peptides associated to amyloid beta 1-42 expression in hippocampal rats exposed to ozone

Authors: *S. L. RIVAS-ARANCIBIA[1], E. RODRIGUEZ-MARTÌNEZ[2], U. LÓPEZ-GONZÁLEZ[3], I. BADILLO-RAMÍREZ[4], J. M. SANIGER[5];
[1]Facultad De Medicina, UNAM, 04510 Mexico DF, Mexico; [2]Facultad De Medicina, UNAM, Ciudad de México, Mexico; [3]Ctr. de Ciencias Aplicadas y Desarrollo Tecnológico, Ctr. de Ciencias Aplicadas y Desarrollo Tecnológico, Ciudad de México, Mexico; [5]Ctr. de Ciencias Aplicadas y Desarrollo Tecnológico, [4]Ctr. de Ciencias Aplicadas y Desarrollo Tecnológico. UNAM, Ciudad de México, Mexico

Abstract: The aim of this work was to study the effect of oxidative stress on the changes of the secondary structure (alpha-helix or beta-sheet) of peptides. These changes could be associated to amyloid beta 1-42 peptide (AB 1-42) expression in dentate gyrus of rats exposed to low ozone doses, during different periods of time. Thirty-six animals were divided in 6 groups (n=6) exposed to ozone-free air stream (control group) and to ozone (0.25 ppm) during 7, 15, 30, 60, and 90 days respectively. After the rats were deeply anesthetized and processed by the following technics: Raman spectroscopy and immunohistochemistry against AB 1-42. Raman spectroscopy was performed on the hippocampal dentate gyrus of one rat per group and 20 single spectra per group were acquired. Results of the deconvolution of Amide I in the Raman spectra showed that exposure to ozone decreased the percentage of alpha helix secondary structure of peptides as it follows: control group (60%), 7 days (47%), 15 days (46%), 30 days (41%), 60 days (22%) and 90 days (20%). On the other hand the percentage of beta folded sheets increased compared with the control groups as it follows: control group (0%), 15 days (16%) 30 days (23%), 60 days (52%) and 90 days (48%). Immunohistochemistry results showed an increase of intracellular immunoreactivity to amyloid beta 1-42 at 60 and 90 days of exposure to ozone compared with the control group. In conclusion, we found that oxidative stress caused by low doses of ozone induced an increase of beta-sheet secondary structure of peptides, which is associated with an increase in intraneuronal formation and deposition of beta-amyloid 1-42 in hippocampal dentate gyrus of rats exposed to this gas. This could be similar to what happens in patients with Alzheimer's Disease. This work was supported by the CONACYT [Grant N^{o}: 219703 to S.R.-A.].

Abstract: Alzheimer's disease (AD) is the major type of senile dementia, but there is no successful treatment until now due to its complexity. To better understand the molecular mechanisms underlying AD pathology, several mouse models have been developed to mimic the main neuropathological hallmarks. In the present study, we performed a comparative gene expression profiling of two different AD model mice: the classical triple-transgenic model mice 3xTg-AD which carry two mutated human transgenes, *APP* (Swedish KM670/671NL) and *MAPT* (P301L) driven by exogenous *Thy*1.2 promoter with a knock-in mutation of *Psen1* (M146V) that promotes formation of plaques and tangles; and the recently established AD model mice APP NL-G-F with three pathogenic *App*-knock-in mutations (Swedish KM670/671NL, Arctic E693G and Iberian I716F) that promote aggressive amyloidosis under the control of endogenous *App* promoter. We prepared total RNA from cortex of 12-month-old male mice of each AD model and control, obtained their gene expression profiles using microarray technology and performed a comparative analysis. In both AD models, we observed no significant reduction in expression levels of neuronal markers, but genes involved in neuroprotection (*Fos, Nr4a1, Nr4a2, Nr4a3, Egr2*) were commonly downregulated. Among 306 significantly altered genes in the 3xTg-AD cortex (fold change < -1.2 or > 1.2, ANOVA $p < 0.05$), we found genes related to neurological diseases (21), metabolic disorders (21) and immune response (17). In contrast, among 257 altered genes in the APP NL-G-F cortex, the most significantly upregulated genes encode proteins involved in the inflammatory (18) and immune (18) responses (top 5: *Cst7, Clec7a, Ccl3l3, Lilrb4*), accompanied by a significant upregulation of astrocyte markers (*Aqp4*, *Gfap*, *S100b*) and genes encoding complement components (*C1qa, C1qb, C1qc, Tyrobp*), as well as alterations in genes related to neurological disease (18) and lipid metabolism (13). The results

observed in APP NL-G-F mice suggest that amyloidosis induced by endogenous expression of pathogenic APP protein may cause strong inflammatory/immune responses that would play important roles in AD pathogenesis. Recent reports highlight the contribution of astrocytic activation to neuroinflamation in AD, however, the mechanism involved is still unclear. To delineate the astrocytic activation by endogenous β-amyloid, we are now examining the gene expression profiles, biochemical and physiological properties of cultured astrocytes isolated from adult APP NL-G-F.

Title: Morphological characterization of glia reveals spatiotemporal changes in Alzheimer's disease pathology

Authors: *F. ABDURROB, R. CANTER, K. CHUNG, L.-H. TSAI;
Picower Inst. for Learning and Memory, Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Glia play a crucial role in maintaining homeostasis in the brain and supporting the functioning of neurons. A complex network of inflammatory and neurodegenerative responses, coupled with amyloid beta deposits, tau tangles, and oxidative stress characterize Alzheimer’s disease. Activation and proliferation of microglia and astrocytes are important in the inflammatory response, which ultimately affects disease progression. Consequently, the synergistic changes that occur during gliosis have become an intense topic of investigation, but remain poorly defined. This study utilizes 5xFAD mice, as well as healthy age-matched control animals, to spatiotemporally characterize glial cells in the brain as aging occurs. Cutting-edge CLARITY and SWITCH labeling techniques are used to visualize the cellular landscape of the diseased brain. Morphological and proliferative changes in microglia and astrocytes are observed across brain regions as Alzheimer’s disease progresses and amyloid plaque load increases. The

interaction of these immune cells with the vasculature is also examined to explore potential impacts on amyloid clearance. Ultimately, a clearer picture of the glial changes during disease progression will allow for a better understanding of the dynamic pathophysiology that underpins neurodegeneration. Abstract: Introductions
Stem cell therapy for neurodegenerative diseases has been reported with promising results through neuronal differentiation or control of microenvironment. However, the surgical transplant methods such as parenchymal or intravenous injection has limitations of secondary injury, infection and low survival rate of stem cell in the target site. Therefore, this study investigates a possibility of focused ultrasound (FUS) for targeted non-invasive stem cell transplantation into the brain.
Materials and Methods
In this study, Male Sparague-Dawley rats (300-350g) and bone marrow-derived mesenchymal

stem cell (BM-MSC; 5p) were used. Experimental groups consist of low intensity FUS+MSC, MSC-only and FUS+dye (Evans blue or Light green). All rats were anesthetized with ketamine cocktail, and FUS was applied with parameters of 1Mpa, 300s (AP+0.7, ML+2, DV-5.5). Three hours after sonication, BM-MSC was injected into the tail vein.

Results

First, the position of BBB opening was confirmed by the FUS+dye group. Comparing FUS+MSC and MSC-only group, it was confirmed that FUS increase BM-MSC homing to the sonicated brain tissue. Also, we found that location stained with Evans blue, a dye with large molecular weight, had a higher efficacy of stem cell homing compared to the location stained with Light green, a dye with smaller molecular weight. On the other hand, BM-MSC was not shown in group of MSC-only.

Conclusions

As a result, we confirmed MSC can be delivered into the brain by FUS. And the efficiency of stem cell delivery may be positively correlated to the ultrasonic energy. This study can contribute to determination of optimal energy for repetitive FUS to cell transplantation without tissue damage in neurodegenerative diseases. Further study about function of stem cell transplanted in brain and mechanisms of stem cell homing by low intensity FUS is needed.

Title: A novel $GABA_A$ alpha5 subunit inverse agonist as a potential memory enhancer

Authors: *A. B. ALI, A. KHAN, A. MONACO, M. KUTA, M. NICHOLSON, S. HAIDER, J. JOVANOVIC, S. HILTON;
Sch. of Pharm., Univ. Col. London, London, United Kingdom

Abstract: Short-term memory deficits are the first symptom of the late-onset Alzheimer's disease. This progressive disease constitutes one of the most significant health problems confronting mankind in societies with an aging population. Current medication for neurodegenerative disorders has only modest therapeutic efficacy. To tackle these problems with committed focus, we developed a novel molecule with enhanced bio-availability and target specificity with the potential to restore/halt memory deficits.
Using medicinal chemistry and computational modelling combined with site-directed mutagenesis we have developed hybrids of 6,6-dimethyl-3-(2-hydroxyethyl)thio-1-(thiazol-2-yl)-6,7-dihydro-2-benzothiophen-4(5H)-one, that demonstrated selective binding and high inverse agonism for the alpha5 $GABA_A$ receptor subtype. We have designed analogues of this compound with an array of biological activity ranging from inactive controls to highly potent derivatives. Whole-cell electrophysiological recordings performed provide evidence to suggest that one of the hybrids developed, a5AM21 shows better potency compared to other published analogues of this compound at specific interneurons that mediate inhibition via postsynaptic alpha 5 containing $GABA_A$ receptors. Behavioural studies performed using healthy rodents suggest that a5AM21 improved memory recall in vivo. Furthermore, this observation was consistent with in vitro electrophysiology experiments that demonstrated an enhanced hippocampal long-term plasticity at unitary synaptic recordings performed between specific dendrite-targeting interneurons.
In summary, using a multi-disciplinary approach we have developed a selective and potent potential cognitive-enhancer, a5AM21. This compound showed properties of selective inverse agonist for the alpha5 $GABA_A$ receptor subtype, which is important for inhibitory neurotransmission and memory formation.

Title: *In vivo* function of a novel and highly selective 5HT2b receptor antagonist devoid of agonist activity

Authors: *O. ARANCIO[1], J. P. SCHAVOCKY[3], S. M. ROY[3], L. CHICO[3], A. STANISZEWSKI[2], D. M. WATTERSON[3];
[1]Dept of Pathol, Columbia Univ., NEW YORK, NY; [2]Columbia Univ., New York, NY; [3]Northwestern Univ., Chicago, IL

Abstract: G protein-coupled receptors (GPCRs) are a well-established therapeutic target class that continues to be an area of commercial drug development and active basic science research in neurosciences. A major challenge has been the need for more selective antagonists devoid of agonist activity for a given GPCR. The goal is to avoid adverse clinical events while providing a more rational basis to therapeutic intervention. The challenge has been especially true for the 5HT2b receptor with mixed agonist/antagonist drugs being withdrawn from the market due to adverse events yet mixed GPCR antagonists low in agonist function having attractive pharmacological actions.
We report here the discovery of a novel, highly selective 5HT2b receptor antagonist, MW01-8-071HAB (MW071) that is devoid of agonist activity and rescues associative memory defect in an Alzheimer's disease (AD) relevant animal model. MW071 was synthesized as part of the experimental validation of an expert systems approach to risk reduction in drug metabolism focused on CYP2D6 substrate status, a significant contributor to individual variance in drug efficacy or toxicity (Chico et al., Drug Metab Dispos. 37:2204-2211, 2009). Remarkably, a single atom change resulted in a CYP2D6 substrate to non-substrate status. However, a recurrent theme in the discovery and development of new GPCR drug candidates is the finding that small changes in a GPCR ligand can result in significant changes in receptor modulation and in vivo function. Therefore, we took MW071 through large-scale functional screens for GPCR antagonist and agonist activities, which revealed that MW071 is a selective 5HT2b receptor antagonist that lacks detectable 5HT2b receptor agonist activity. We also subjected MW071 to large-scale hierarchical kinase inhibitor screens for potential non-GPCR ligand activity that could potentially influence GPCR mediated cellular function. Taken in its entirety, the data are consistent with MW071 being a new highly selective 5HT2b receptor antagonist that lacks both CYP2D6 substrate and 5HT2b receptor agonist liabilities capable of providing new insights into modulation of AD related cognitive dysfunction. Overall, the results add to the growing database of novel GPCR receptor modulators with new in vivo functions through the use of dual agonist/antagonist functional screens as a primary screen in drug discovery.

Title: Using high throughput screening method to identify new drugs for Alzheimer’s disease

Authors: *B. ZHU, K. HERRUP;
Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong

Abstract: Aging is the major and primary risk factor of Alzheimer’s disease (AD). In the aged brain, oxidative stress, DNA damage, chronic inflammation and other stressors increase, making neurons more susceptible to abnormal cell cycle re-entry, and further leading to neuronal loss. Thus, while each of these stressors could be studied individually, blunting the effects of aging may be the most economical strategy to fight Alzheimer’s disease. To screen for drugs that have anti-aging effects, we turned to the deep ocean, which has high bacterial biodiversity and an even broader spectrum of natural bioactive compounds. We report here our successful first use of this rich source of potential drugs. To create an *in vitro* model of aging, we use mouse primary cortical neuronal cultures on both day *in vitro* (DIV) 14 and DIV 21, which we consider to mimic mature and old states respectively. The level of the G1 phase cell cycle marker, cyclin D1, increased significantly from DIV 14 to DIV 21, indicating that with age primary neurons undergo cell cycle stress. We found further that fibrillarized amyloid-beta ($A\beta_{1\text{-}42}$), increased the cyclin D1 level at both time points, suggesting that Aβ exacerbates the cell cycle stress and does so at all ages. We used fibrillar Aβ as the stimulant and cell cycle markers as outcome measures to determine whether any marine bacterial extract might prove neuroprotective. For comparison we also used previously characterized compounds from single bacterial species as well as other marine sources such as fish oil and PCSO-524®, an extract of mussel. We used in cell western methods to measure the total level of cell cycle, synaptic density, senescence marker and other response proteins to evaluate the response to fibrillar Aβ. To make the anti-aging screening assay more efficiently, we applied the screening in a 96-well format. Using this method, we discovered significant neuroprotective activity in several of the 280 compounds we have screened. As reported previously, fish oil and PCSO-524® both significantly lowered the levels of cyclin D1 and other stress-related proteins. We will also report the results of chronic incubation of these agents. Our hypothesis is that any agent that lowers stress markers compared to control has potential to blunt the effects of aging in our system. We believe that both the novel source of natural products and the effective and efficient new screening method will be of significant value in the search for new compounds to fight aging and Alzheimer's Disease.

Title: MSCs inhibit transmission of amyloid beta through lipid raft-mediated endocytosis.

Authors: *Y. JUNG[1,2], S. OH[1,2], P. LEE[1,2,3];
[1]Dept. of Neurol., Col. of Medicine, Yonsei Univ., Seoul, Korea, Republic of; [2]Brain Korea 21 PLUS Project for Med. Science, Yonsei Univ., Seoul, Korea, Republic of; [3]Severance Biomed. Sci. Institute, Yonsei Univ., Seoul, Korea, Republic of

Abstract: A hallmark pathological feature of Alzheimer's disease (AD) is the accumulation of extracellular plaques composed of the amyloid-beta (Aβ) peptide. Aβ is propagated by cell-to-cell transmission and they affect the onset and progression of AD. To block Aβ transfer is important therapeutic strategies against AD. Using Aβ enriched models, we found that mesenchymal stem cells (MSCs) contribute to the reduction of Aβ endocytosis. And we found that MSCs inhibit Aβ transmission by blocking the lipid raft-mediated endocytosis of extracellular Aβ via modulation of the interaction with lipid raft associated proteins, which led to a prosurvival effect on neurons with functional improvement of synaptic damage and cognitive decline in Aβ-enriched models. The present data indicated that MSCs exert neuroprotective properties through inhibition of extracellular Aβ transmission, suggesting that the property of MSCs may act as a disease-modifying therapy in AD. Title: The mixed-lineage kinase 3 inhibitor URMC-099 facilitates microglial amyloid-β phagolysosomal degradation

Authors: *T. KIYOTA[1], W. DONG[1,3], C. M. EMBURY[1], Y. LU[1], W. M. WHITMIRE[1], B. DYAVARSHETTY[1], H. A. GELBARD[4], H. E. GENDELMAN[1,2];

Abstract: Amyloid-β (Aβ)-stimulated microglial inflammatory responses directly affect Alzheimer's disease (AD) progression. Such responses, in a measure, are orchestrated through mitogen-activated protein kinase (MAPK) signaling pathways. The mixed-lineage kinases (MLKs) are known to regulate MAPK pathways including c-Jun amino-terminal kinase (JNK) and p38 MAPK. However, whether MLK-MAPK participates in Aβ-mediated neuroinflammation is poorly understood. To this end, we used URMC-099, a brain penetrant small-molecule MLK type 3 (MLK3) inhibitor, to study its effect on Aβ-mediated microglial inflammatory responses. Murine microglia were stimulated with Aβ1-42 (Aβ42), and the phosphorylation of p38 (p-p38) and JNK (p-JNK) and the expression of pro-inflammatory cytokines interleukin (IL)-1β, IL-6 and tumor necrosis factor (TNF)-α were investigated. While Aβ42 stimulation enhanced p38, JNK phosphorylation and the expression of IL-1β, IL-6 and TNF-α, URMC-099 treatment reduced their phosphorylation and expression levels. URMC-099 induced gene expression of anti-inflammatory cytokines *IL-4* and *IL-13*. Furthermore, URMC-099 modulated scavenger receptor expression and facilitated Aβ uptake and degradation through endolysosomal Aβ trafficking. These data suggest a new immunomodulatory role for URMC-099 modulating microglial activation through MLK-MAPK with concomitant M2 microglial polarization. Thus, the MLK3 inhibitor may be considered as a novel disease-modifying AD therapy.

Title: Engineering novel General Amyloid Interaction Motif (GAIM)-immunoglobulin fusions for targeting misfolded protein aggregates in neurodegenerative diseases.

Authors: *M. PROSCHITSKY, E. ASP, C. CHUNG, J. LEVENSON, H. TSUBERY, M. LULU, S. GILEAD, M. GARTNER, S. SCHROETER, J. WRIGHT, R. FISHER, R. KRISHNAN;
Neurophage Pharmaceuticals, Cambridge, MA

Abstract: We have previously identified a General Amyloid Interaction Motif (GAIM) that binds and remodels a variety of fibrillar aggregates in a conformation-dependent manner (Krishnan et.al, 2014). This unique protein scaffold was derived from the tip protein g3p of the filamentous bacteriophage M13. To make an acceptable drug candidate, we genetically fused GAIM with a human immunoglobulin (hIgG1Fc). The fusion protein, NPT088, displays bivalent GAIM from human Fc, and when injected intraperitoneally, significantly reduces Aβ plaques in the brains of Tg2576 mice, hyper phosphorylated and fibrillary tau in rTg4510 mice and ameliorates cognitive deficits associated with both the animal models (Levenson et.al, under review). To understand the molecular mechanism facilitating aggregate binding and clearance, we performed extensive mutagenesis of GAIM. The binding properties of GAIM-variants to different amyloid fibers were studied using SPR, ELISA and fiber remodeling assays. Specific binding and remodeling are strongly influenced by GAIM valence, appropriate exposure of non-polar and aromatic residues in the binding sites, and the solvated stability of the molecule as a whole. We used these data and molecular modeling tools to engineer new GAIM-fusions. Here we present data on one such fusions, NPT289, that binds multiple amyloid fibers with 5-100 fold greater potency than NPT088, remodels Aβ aggregates, and blocks cell-to-cell transmission of α-synuclein and tau aggregates in primary neuronal cells more efficiently than NPT088. Characterization of NPT289 and other GAIM variants has begun to elucidate the complex

structure activity relationship of GAIM and as a result, has created a platform for discovery of new drug candidates for protein misfolding diseases.

Title: Lithium treatment suppresses IP_3-gated calcium signaling and synaptic plasticity in the hippocampus of 3xTg-AD mice

Authors: *S. S. SHIM[1], N. KAPECKI[2], C. BRIGGS[3], G. E. STUTZMANN[3];
[1]Atlanta VAMC, Decatur, GA; [2]Dept. of Neuroscience,, [3]Dept. of Neurosci., Rosalind Franklin University/The Chicago Med. Sch., North Chicago, IL

Abstract: Although lines of evidence suggest that lithium, a CNS-acting element using for mood stabilization, may be beneficial for treating Alzheimer's disease (AD), the mechanisms underlying its therapeutic potential are not well understood. To examine the effects of lithium on AD-related pathophysiology (intracellular Ca^{2+} responses, neurophysiology and synaptic plasticity), whole-cell patch clamp recording, UV photolysis of caged-IP_3, and 2-photon Ca^{2+} imaging were conducted in CA1 hippocampal pyramidal neurons from control (NonTg) and 3xTg-AD mouse models (~3 months of age). In control mice, IP_3-evoked Ca^{2+} responses were elevated in 3xTg-AD neurons (100 ± 18% over baseline, n=18) compared to NonTg neurons (68 ± 16% over baseline, n=16). Feeding with a lithium chow diet (0.2%, Harlan Lab.) for one month had no effect on NonTg IP_3-Ca^{2+} responses (68 ± 24% over baseline, n=14) but significantly reduced the IP3-Ca^{2+} response in 3xTg neurons by almost 50% (n=15, $p < 0.05$). Despite VGCC responses not being elevated in 3xTg-AD neurons, lithium treatment also suppressed action potential-evoked Ca^{2+} responses, with no effect on NonTg VGCC responses. We also measured synaptic transmission and plasticity at the CA3-CA1 Schaffer collateral synapse using field potential recordings in hippocampal slices from the same population of 3xTg-AD and NonTg mice. Lithium treatment had no significant effects on long-term potentiation (LTP) in either mouse strain, nor did it affect passive membrane properties such as resting membrane potential or input resistance. However, post-tetanic potentiation (PTP), a form of short-term plasticity reliant on calcium signaling, was significantly increased in lithium-treated NonTg mice by almost 70% ($p<0.05$); notably, lithium had no effect on PTP in 3xTg-AD mice indicating an alternative calcium signaling mechanism is recruited in the AD model. Thus, lithium treatment suppresses activity-dependent Ca^{2+} signaling and fails to potentiate PTP in 3xTg-AD mice, which may reflect its diverse actions on IP_3 receptor stabilization, kinase activity, and Na^+/Ca^{2+} exchanger properties. Based on these early findings, the extent of neuroprotection offered by lithium in AD models warrants further study.

Title: Neuroprotective effects of polydatin on amyloid beta$_{25-35}$-induced neuronal and cognitive dysfunction through inhibition of apoptosis signaling pathway

Authors: ***Y.-H. KO**[1], S.-Y. LEE[2], C.-G. JANG[2];
[1]Sch. of Pharmacol., Sungkyunkwan Univ., Suwon, Korea, Republic of; [2]Sch. of Pharm., Sungkyunkwan Univ., Suwon city, Korea, Republic of

Abstract: Polydatin, a natural precursor of resveratrol, has been shown to possess strong antioxidative bioactivity. Recent evidence has suggested that polydatin protects against chronic alcohol exposure and acute hemorrhagic shock in a rodent model of several neurodegenerative disorders, but the mechanisms underlying this protection are largely uncharacterized in Alzheimer's disease (AD). In this study, we determined the neuroprotective effects of polydatin against amyloid beta$_{25-35}$ (Aβ_{25-35})-induced apoptotic cell death in neuronal cells and cognition impairment, and investigated the possible mechanisms involved therein. Polydatin significantly prevented the loss of cell viability, release of lactate dehydrogenase (LDH), accumulation of reactive oxygen species (ROS), and dysfunction of mitochondria membrane potential (MMP) associated with Aβ_{25-35}-induced neurotoxicity in neuronal cells. Polydatin also strikingly inhibited Aβ_{25-35}-induced mitochondrial dysfunction in mice. Moreover, polydatin significantly attenuated Aβ_{25-35}-induced phosphorylation of the c-Jun N-terminal kinase (JNK), p38, and extracellular signal-regulated kinase 1/2 (ERK 1/2) MAPKs, Akt, and glycogen synthase kinase-3 beta (GSK-3β). Furthermore, polydatin significantly inhibited cognition deficits induced by Aβ_{25-35} in mice. Taken together, our results demonstrated that polydatin could protect against neuronal cell death and cognition deficits mediated by Aβ_{25-35}-induced apoptosis via inhibition of the oxidative stress signaling pathway, providing a potential therapeutic agent for the treatment of AD.

Title: High-throughput screening (HTS) of an FDA drug library for phosphodiesterase 3 inhibition: effects of selected drugs on lysosomal pH and arrested autophagy

Authors: *H. KIM[1], J.-Y. KOH[1,2];
[1]Asan Inst. For Life Sci., Seoul, Korea, Republic of; [2]Neurol., Asan medical center, Col. of Medicine, Univ. of Ulsan, Seoul, Korea, Republic of

Abstract: It has been demonstrated that cAMP acidifies lysosomes via the upregulation of lysosomal vATPase. Such changes may help normalize “arrested autophagy” caused by presenilin-1 mutation (Coffey EE et al. 2014. Neurosci). Currently, several phosphodiesterase inhibitors, which increase cAMP levels, are in clinical use. Previously, we have shown that cilostazol, a PDE3 inhibitor used for its antiplatelet effects, reduces Aβ accumulation in cultured pericytes. Hence, in the present study, we screened about 800 FDA-approved drugs (SCREEN-WELL® FDA v. 2.0 Approved Drug Library, purchased from ENZO) to see if we can find PDE3 inhibitor activities among these drugs. Drug effects on PDE3 activity were measured using PDELight™ HTS cAMP Phosphodiesterase Assay (LONZA). In the presence of PDE3, cAMP turns into AMP and then to ATP, which along with luciferase produces photons. Hence the luminescence reflects the PDE3 activity. Addition of a PDE3 inhibitor would result in the reduction of the luminescence. Add 10 µl of 40 µM inhibitor to each well in compound solvent i.e. 10%(v/v) DMSO. For control wells use compound solvent only. To all wells add 10 µl of PDE3 diluted in reaction buffer at 4x optimal concentration. To all wells add 20 µl of cAMP at 2x optimal concentration. Incubate for 60 minutes at room temperature. Add 10 µl of Stop solution and 20 µl of AMP Detection reagent. Incubate for at least 10 minutes at room temperature. Measure luminescence using a 0.1 second integration time. Using this method, 800 drugs were screened. After two runs (Z’ factors: 0.91 and 0.93 respectively), 16 drugs were found as possible PDE3 inhibitors. Of these, we selected 6, and with individual assays, confirmed that they inhibited PDE3. Like cilostazol, a standard PDE3 inhibitor, these drugs re-acidified lysosomes to variable extents, and increased autophagy flux in a chloroquine model of arrested autophagy in RPE cells. Further experiments in APP/PS-1 expressing CHO cells are under way. Designing new chemicals and developing them into new drugs are a very time-, money- and labor-consuming process. In contrast, finding new indications for pre-existing drug

(drug repositioning) may have much higher chance of success. Since PDE3 inhibitors may help boost lysosomal functions that are often impaired in diverse neurodegenerative conditions, these new indications may prove useful for the treatment of these conditions.

Abstract: Introducction: Alzheimer`s disease (AD) is characterized by beta-amyloid (Aβ) accumulation and neurofibrillary tangles that are associated to synaptic deficit and dementia. Liver X receptor (LXR) agonist have demonstrated to have beneficial effect in murine models of AD through regulation of Apolipoprotein E, ABCD1, neuroinflamation and Aβ levels. However, the role of LXR in the regulation of synaptic function remains unknown. Aim: To analyzed the in vitro the effect of LXR agonist (GW3965) on the synaptic function upon treatment of hippocampal primary cultures or slices with Aβ. Materials and methods: We used primary hippocampal cultures (DIV 15) or hippocampal slices from C57BL/6 mice; cultures were pre-treated with LXR agonist (GW3965, 1 μM) for 18 hours following by exposure to Aβ (200nM) for 6 hours; expression of synaptic proteins (SV2A, P65 PSD95, shank2, NMDA NR1 y AMPA, GLUA2) was analysed by western blotting; dendritic spines and synaptic contacts were analysed by confocal microscopy by using transfection with a GFP plasmid and by immunocytochemistry for Vglut1 and Shank1, respectively; LTP analysis was performed in hippocampal slices by using a 100 pulses of 100 Hz stimulation protocol. Results: Previously we have demonstrated

that LXR agonist treatment of the triple transgenic mouse model of AD rescued the cognitive decline. Tretament with Aβ induced an increased in the expression level of pre and post-synaptic proteins, a decreased in the number of dendritic spines and synaptic contacts and reduces LTP. LXR agonist reverts all these changes, including an increased in the number of dendritic spines and synaptic contacts, regulation of the expression of synaptic proteins and restores LTP. Conclusion: Our results demonstrate that LXR agonist have an impact in the regulation of synaptic function through modulation of expression of synaptic proteins and synaptic plasticity. LXR agonist may be a pharmacological alternative for AD. Acknowledgements: Funded by COLCIENCIAS and DIB-Universisdad Nacional de Colombia.

Title: Novel strategies and screening assays for calcium modulating compounds in Alzheimer's disease models

Authors: *A. LITTLEFIELD[1,2], S. RILEY[2], R. HELFRICH[2], C. BRIGGS[2], N. KAPECKI[2], V. BOTTERO[2], J. BUOLAMWINI[2], R. MARR[2], V. BOTTERO[2], G. E. STUTZMANN[2]; [2]Neurosci., [1]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Alzheimer's Disease (AD) is a progressive neurodegenerative disease with many complex pathophysiological features. Of particular interest to our lab is the presence of increased Ca^{2+} release from ER-localized ryanodine receptors (RyR). This dysregulation in Ca^{2+} homeostasis in AD accelerates many disease features, including synaptic deficits. Previous studies have used dantrolene, an RyR negative allosteric modulator, as a tool compound and demonstrated that RyR stabilization restores Ca^{2+} homeostasis and synaptic integrity in AD mice. In order to address the off-target effects and poor solubility of dantrolene, our lab has synthesized and screened a number of dantrolene analogs for their ability to modulate RyR mediated Ca2+ release in neurons from AD mice and model cells. Several of these structural analogs demonstrate RyR-regulating activity similar or superior to dantrolene and are potential novel lead compounds which can preserve synaptic structure and function in AD. In addition, we

have generated novel structural cores, distinct from dantrolene, that show RyR-modifying properties in cellular models of AD.
The current study aims to utilize various cells lines to test the RyR-Ca2+ modulating compounds in order to examine their pharmacologic properties *in vitro*. Using various expression vectors, the multiple cell lines are developed for calcium channel expression patterns, particularly of the three ryanodine receptor isoforms, RyR1, RyR2, and RyR3, and their calcium release properties. The RyR2 isoform is selectively upregulated in both human early-stage AD patients and in AD mouse models and is of particular interest. Immunocytochemistry and qRT-PCR are used to confirm calcium channel expression patterns, while calcium imaging and electrophysiological approaches are used to characterize functional properties. Preliminary data using an RyR2 expressing mouse neuroblastoma (N2a) dose response assay have identified several novel compounds as potent and selective RyR2-Ca2+ modulators with activity comparable to or better than dantrolene. Those with attractive *in vitro* ADME properties have been tested in brain slice preparations from AD mouse models using whole cell patch clamp recordings and 2-photon calcium imaging. Incubating hippocampal brain slices in these lead compounds (10μM) resulted in normalized RyR-evoked calcium responses in the AD brains, while having no effects on other plasma membrane ion channels, passive or active membrane properties, or action potential properties. Thus our novel compounds could illustrate a potential treatment for AD by restoring Ca^{2+} homeostasis and synaptic integrity.

Title: Ferroelectric gold-iron oxide nanoparticles for the photo-thermal dissolution of protein aggregates - implications in alzheimer treatment.

Authors: *S. HARIKUMAR[1], M. ISLAM[2], J. NOVERON[2];
[1]New Mexico State Univ., Las Cruces, NM; [2]Chem. and Computer Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: Protein aggregates such as beta-amyloid plaques have been implicated in several neurological diseases such as Alzheimer. Developing chemical tools to induce their

disaggregation may have implications for treatment of these conditions. Prior research has shown that photothermal properties of gold nanoparticles (AuNPs) dispense quanta of heat energy that has been applied in the treatment of cancer cells. Similarly, iron-oxide nanoparticles have been used to deliver drugs to an abrasion within the human body. Our research focuses on developing bio-compatible nanoparticles that consist of an iron-oxide core coated with AuNPs which may be further functionalized with peptides to localize on beta-amyloid plaques. These nanoparticles through Rayleigh Scattering may be triggered to dispense quanta of heat energy to break the hydrophobic bonds between the protein agglomerates to dissolve them. We will present the synthesis and characterization of AuNP-Fe_2O_3 nanoparticles and their surfactant derivatives. The electron microscopy and magnetic moment susceptibility data of the nanoparticles will be presented. In-vitro studies to demonstrate the ability of the nanoparticles to dissolve protein aggregates induced by visible light will be discussed.

Title: A small molecule ligand for TrkB/TrkC neurotrophin receptors inhibits Aβ induced neurodegeneration *In vitro* and prevents synaptic impairment in Alzheimer’s animal model

Authors: *T. YANG[1], K. C. TRAN[1], A. Y. ZENG[1], S. M. MASSA[2,3], F. M. LONGO[1]; [1]Neurol. and Neurology. Sci., Stanford Univ., Stanford, CA; [2]San Francisco Veterans Affairs Med. Ctr., San Francisco, CA; [3]Neurol., Univ. of California San Francisco, San Francisco, CA

Abstract: In Alzheimer’s disease (AD) toxic oligomers comprised of forms of beta-amyloid (Aβ) and tau accumulate. TrkB and TrkC receptors are expressed by essentially all neurons affected in AD including those in the hippocampus and cortex, where they promote neuronal survival, neurite outgrowth and synaptic plasticity. Our laboratories have developed a non-peptide small molecule, BC-2, that binds to and activates both TrkB and TrkC, but not the TrkA or p75 neurotrophin receptors. We hypothesized that BC-2 might have effects on degenerative processes induced by Aβ *in vitro* as well as in APP-L/S mice. In mouse hippocampal neuron

cultures, which display synapse formation, BC-2 (1000nM) prevented Aβ-induced inactivation of TrkB, AKT and PKC, blocked loss of pre- and post-synaptic markers and inhibited tau phosphorylation. In addition, BC-2 prevented Aβ-induced tau missorting into dendrites, and MC-1 and Tau22 immunostaining indicated reductions of Aβ-induced tau conformational changes and tau oligomerization. Consistent with the ability of TrkB and TrkC to regulate RhoA and Rac activation, BC-2 inhibited Aβ-induced activation of RhoA and inactivation of Rac; this was associated with normalization of diminished cofilin phosphorylation and protection of dendritic spines. In APP-L/S mice, which show progressive plaque deposition in cerebral cortex and hippocampus beginning at 3-4 months of age, BC-2 was administered via intraperitoneal injection once daily (5 days per week) for three months beginning at 4-5 months of age. BC-2 activated TrkB and TrkC in the hippocampus along with their downstream signaling pathways, which was associated with: decreased tau phosphorylation and aberrant conformations; protection of hippocampal apical and basal dendrites and their synaptic spines; and mitigation of behavioral deficits. These findings are consistent with the known intersections of Trk signaling and AD degenerative signaling networks, and point to the possibility of developing clinically viable small molecule ligands for TrkB and/or TrkC receptors as a therapeutic approach for AD.

Title: The identification of small molecule modulators that increase expression of neuronal survival factor nmnat-2

Authors: J. FRANCIS[1], B. ROTH[2], W. STEBBEDS[1], S. SANYAL[2], R. WILLIAMS[1], G. SMITH[1], M. GECK DO[3], P. JONES[3], *W. J. RAY[2];
[1]BioFocus, LTD, Cambridge, United Kingdom; [2]The Neurodegeneration Consortium, Houston, TX; [3]Inst. for Applied Cancer Sci., Houston, TX

Abstract: Nicotinamide mononucleotide (NAD) adenylyl transferase 2 (NMNAT2) is an essential enzyme for neuronal growth, maintenance and survival. Constant anterograde trafficking of highly labile NMNAT2 from cell body to axon is required to maintain neuronal integrity. Knock-down of endogenous NMNAT2 below a threshold level triggers Wallerian-like axonal degeneration in the absence of injury. Conversely, modest overexpression of NMNAT2 offers protective effects on neuronal degeneration in primary neurons and rescues axonal degeneration in *Drosophila* nerve injury models and a mouse model of tauopathy (rTg4510). Collectively these studies suggest that agents that increase NMNAT2 levels in neurons could have therapeutic potential in neurodegenerative diseases. The mechanisms underlying NMNAT2-mediated neuroprotection remain elusive. There is evidence suggesting the protective effects are afforded by its enzymatic activity that leads to an increase in NAD+ levels and it may act as an enzyme-independent chaperone that assists in clearing neurotoxic misfolded protein aggregates. Here we describe an approach to identify small molecules that enhance NMNAT2 stability and demonstrate neuroprotective effects. We performed a high content image-based high-throughput screen using a stable cell line expressing Flag-tagged NMNAT2 (half-life 100 minutes). Several hits were identified that demonstrated a concentration-dependent increase in levels of Flag-NMNAT2 expression 4 h post-treatment. The lead series of compounds had no effect on the turnover of beta-catenin, another protein rapidly eliminated by the proteasome, or on the membrane localization of CD8, a protein that, like NMNAT2, is palmitoylated. Imaging analyses indicates that this compound increases NMNAT2 expression with the same Golgi-localized subcellular pattern as in untreated controls. Thus the regulation of NMNAT2 is not due to non-selective effects on proteasomal degradation, palmitoylation, or trafficking. Furthermore the increase in NMNAT2 occurred in the presence of cycloheximide, ruling out an effect on transcription. As assessed by western blot, the lead compound enhanced NMNAT2 expression levels by 30-40% in NMNAT2 HEK cells. In agreement with published reports, this modest increase in NMNAT2 was sufficient for biological effect; the compound is neuroprotective in a primary rat dorsal root ganglion NGF withdrawal assay, and completely prevented neurite withdrawal induced by the RhoA-activating toxin CNO3 in human embryonic stem cell-derived neurons. Current studies will delineate the mechanism by which this molecule enhances NMNAT2 expression.

Title: Interaction between proteasomal and lysosomal systems can be modulated to reduce $A\beta_{42}$ effects in hippocampal slice cultures

Authors: *K. G. FARIZATTO[1], U. S. IKONNE[2], H. W. ROMINE[1], M. F. DE ALMEIDA[1], M. F. R. FERRARI[3], B. A. BAHR[1];

Abstract: Intracellular protein clearance decreases with age, thus altering the vital balance between protein synthesis vs. degradation. Accumulating toxic proteins lead to the activation of proteasomal and lysosomal pathways for clearing such species. However, many studies indicate that the two pathways exhibit stress during AD-type protein accumulations. In this study, low concentration Aβ42 was applied to hippocampal slice cultures resulting in reduced proteasome activity (p=0.0196) in correspondence with increased tau phosphorylation and significant loss of synaptophysin. When the slices were treated with the proteasome inhibitor lactacystin, a nearly complete and rapid reduction in proteasome activity was found. Interestingly, during the proteasomal compromise a putative compensatory response by lysosomal enzyme cathepsin B (CatB) was detected, a 50-75% increase in CatB activity. This suggests potential cross-talk between proteasomes and lysosomes as suggested (Pandey et al. 2007, *Nature* 447:860). To further assess the apparent inverse relationship, we used a lysosomal enhancing agent (Z-Phe-Ala-diazomethylketone; PADK) that promotes protein clearance (Butler et al. 2011: *PLoS One* 6:e20501; Bahr et al. 2012: Rejuvenation Res 15:189) to test for proteasomal attenuation. Surprisingly, instead of a decrease PADK appeared to cause a small increase in proteasome activity (control = 98.7±1.7, PADK = 115.3±12.4, N.S.). In slices with Aβ42-mediated proteasomal compromise (34.7±5.2), PADK indeed enhanced the proteasome activity (73.0±10.0, p=0.027), to levels comparable to control slices. Furthermore, PADK also reduced Aβ42-mediated tau phosphorylation by >50%, an event implicated as a consequence of the negative influence on proteasomes and protein clearance efficiency. Such efficiency may involve cross-talk between proteasomes and lysosomes. Together, the results suggest a distinct interaction between proteasomal and lysosomal systems, and they point to potential dual

modulation against protein accumulation pathology linked to Alzheimer's disease and other dementias.

Title: Selection of lead tau oligomer inhibitors for *In vivo* studies

Authors: E. J. DAVIDOWITZ, P. K. KRISHNAMURTHY, P. LOPEZ, C. GLUCHOWSKI, *J. G. MOE;
Oligomerix, Inc., New York, NY

Abstract: There is mounting evidence that tau oligomers have a pathological role in Alzheimer's disease (AD) including leading to the impairment of synaptic function and the spread of pathology. We have undertaken a screening approach to discover small molecule inhibitors that prevent tau oligomer formation at the beginning of the aggregation cascade. Competing programs use methods to select compounds inhibiting the formation of tau fibrils or large aggregates, previously thought to be the most toxic tau species. We hypothesized that by targeting the first step in tau self-association all forms of tau aggregates should be reduced. This work is also highly differentiated from other approaches in that we used full length tau without any mutations that are not relevant to AD. These assays were used to screen a large compound library optimized for drug-like properties. Leads from three chemical series with in vitro IC50 ranging from 300 - 600 nM, molecular weights under 450 Daltons, cLogP 2 - 5, and a polar surface area ranging from 45 to 70 $Å^2$, and which were not toxic to SH-SY5Y neuroblastoma cells, have been selected for further testing of CaCo2 permeability and stability, as well as pharmacokinetic analysis. The best performing candidate compound will be tested in vivo using htau mice. Mice will be treated at 3 escalating doses for 4 months and their brains will be used for biochemical and histological analysis to assess changes in tau oligomer load and efficacy of our treatment paradigm.

Title: Development of Glycosaminoglycan-Interacting Small Molecule (GISMO) compounds for the treatment of Alzheimer's disease

Authors: *P. GREGOR[1], R. BERNAT[1], E. CAMPBELL[1], M. P. MURPHY[2], N. HARRIS[4], R. ZHUK[1], B. F. O'HARA[3], M. FINDEIS[1], J. LIU[1], M. FOLEY[1];
[1]Gismo Therapeut. Inc, Lexington, KY; [2]Dept. of Mol. and Cell. Biochemistry, Sanders-Brown Ctr. for Aging, [3]Dept. of Biol., Univ. of Kentucky, Lexington, KY; [4]Ephraim Katzir Dept. of Biotech. Engin., ORT Braude Academic Col. of Engin., Karmiel, Israel

Abstract: The aim of our program is to develop a novel, disease-modifying, orally active therapeutic agent for Alzheimer’s Disease. According to our hypothesis, amyloid-beta (Abeta) is necessary but not sufficient to cause Alzheimer's Disease alone, and the interaction between Abeta and glycosaminoglycans (GAGs) is an essential process leading to the sequence of events resulting in Alzheimer's Disease. As a result, Abeta interaction with GAGs leads to endo-lysosomal accumulation of GAGs (i.e., Abeta/GAG complex), lysosomal storage and

indigestibility of GAGs, which subsequently leads to lysosomal dysfunction and nerve cell death, ultimately contributing to the development of Alzheimer's Disease.
We have discovered a new class of planar aromatic amine compounds (Harris et al. (2014) Biochim. Biophys. Acta, 1840(1):245), Glycosaminoglycan-Interacting Small Molecules (GISMOs), which uniquely targets GAGs, particularly the heparan sulfate GAGs (HS-GAGs). We now report identification of GISMOs that inhibit interactions between amyloid-beta (Abeta) and HS-GAGs, while having potent biological activity in at least two assays relevant to amyloidosis in nerve cells. A set of Abeta/HS-GAG inhibitors, identified by screening in a molecular interaction assay, were tested for inhibition of Abeta42 and Abeta40 uptake into neuronal SH-SY5Y cells, and a number of inhibitors (>30% Abeta uptake inhibition) were identified. Subsequently, 15 compounds were chosen for neuroprotection studies in primary rat brain neuronal cultures, against toxic Abeta42 and Abeta40. Five lead compounds displayed very good efficacy (>50% reversal of Abeta toxic effects at concentrations as low as 0.1 μM), several of which displayed complete reversal of Abeta40-induced LDH release, and Abeta40 and Abeta42-induced caspase 3/7 activation. The five lead compounds have acceptable in vitro safety (cytotoxicity), selectivity, and other drug-like properties. These lead compounds now enter in vivo validation in animal models of Alzheimer's Disease.
This is the first report of Abeta-HS-GAG inhibitors having significant efficacy in neuroprotection against Abeta40 and Abeta42. These results provide in vitro validation for Abeta/HS-GAG interaction as a drug target as well as justification for further development of GISMO compounds as Alzheimer's Disease therapeutics. GISMOs may also have therapeutic potential in other amyloid neurodegenerative diseases associated with amyloid peptides, i.e., Parkinson's Disease (α-synuclein), Frontotemporal Dementia and other tauopathies (tau) and Amyotrophic Lateral Sclerosis (TDP-43, SOD1).

Title: The mechanism of axonal transport deficit caused by downregulation of O-GlcNAcylation in Alzheimer's disease

Authors: *H. KIM, H. CHOI, W. LEE, I. MOOK-JUNG;
Seoul Natl. Univ. (college of Medicine), Seoul-City, Korea, Republic of

Abstract: Glycosylation with O-linked β-N-acetylglucosamine (O-GlcNAc) is one of the protein post-translational modification that regulates various protein activities. In Alzheimer's disease (AD), protein O-GlcNAc level is downregulated. This downregulation causes harmful effects on cells, especially neuron. Also, axonal transport deficit occurs in AD. This is up to dysfunction of motor and adaptor proteins. Here, we verified that Aβ induced axonal transport deficit was recovered by O-GlcNAcase inhibitor (Thiamet-G). Also the axonal transport related protein altered O-GlcNAc level in Aβ treated cells, as well as in transgenic mouse model were targeted. Site mutation was constructed to silence O-GlcNAcylation on the protein. This construct was used for discovering mechanisms of between O-GlcNAcylation downregulation and axonal transport deficit in AD. This study discover relationship with O-GlcNAc and axonal transport in AD, and it is expected to be support development of specific therapeutic strategy.

Title: A CRISPR-Cas9 based strategy to target the Swedish APP allele in a familial form of Alzheimer's disease

Authors: *C. I. LOOV[1], B. GYORGY[1,2], S. TAKEDA[1], C. COMMINS[1], M. ZABOROWSKI[1], D. MU[1], A. VOLAK[1], L. LANNFELT[3], C. A. MAGUIRE[1], B. T. HYMAN[1], X. O. BREAKEFIELD[1], M. INGELSSON[1,3];
[1]Neurol., Massachusetts Gen. Hosp., Charlestown, MA; [2]Howard Hughes Med. Inst., Boston, MA; [3]Dept. of Publ. Health, Mol. Geriatrics, Uppsala Univ., Uppsala, Sweden

Abstract: Mutations in the *amyloid precursor protein* (*APP*) gene cause early-onset forms of Alzheimer's disease. The *APPswe* mutation leads to an increased beta-secretase cleavage of

APP, resulting in higher levels of amyloid-β (Aβ) 40 and Aβ42 in both brain and peripheral tissues, such as fibroblasts. The development of gene editing tools such as the clustered regularly interspaced short palindromic repeats (CRISPR) system offers novel possibilities to selectively target and disrupt alleles with disease-causing mutations through double-stranded breaks and mismatch repair. In this study we aimed to use the CRIPSR-Cas9 system to target *APPswe* in order to reduce Aβ levels. Three different *APPswe*-directed and one *APPwt*-directed gRNAs were designed. Each gRNA was tested individually together with the Cas9 linked to green fluorescent protein (GFP) into fibroblasts from two mutation carriers and two non-mutation carriers. Transfected (GFP+) cells were separated from non-transfected (GFP-) cells by FACS and replated for additional culturing. Upon confluency, the cells were cultured for 48h in serum-free media before the media was saved for Aβ analysis and cells collected for DNA extraction. Sanger and next generation sequencing showed that the respective gRNAs had varying degrees of specificity against the *APPswe* and *APPwt* alleles, respectively. The longest *APPswe* gRNA (SW1) showed the highest efficacy and almost completely eliminated the mutated allele (99.92%) while conserving the wt allele. Moreover, the media from the fibroblasts showed the predicted decrease of both Aβ40 and Aβ42, as measured by ELISA. Next, the SW1 *APPswe* gRNA and Cas9 were packaged into separate adeno-associated viruses that were used to co-transduced primary neuronal cultures from embryos of the Tg2576 *APP* mouse model. Although these transgenic mice carry multiple copies of the *APPswe* gene, next generation sequencing showed that approximately 3-4% of the *APPswe* alleles were disrupted in the transduced neurons. Taken together, our data indicate that the CRISPR-Cas 9 system can be used to selectively target an *APP* mutation causing Alzheimer's disease and efficiently decrease the production of Aβ in cells carrying such a mutation.

Abstract: Alzheimer's disease is associated with abnormalities in several neurotransmitter pathways, especially the glutamatergic system. Overactivation of glutamate receptors, particularly NMDA, may contribute to neurodegeneration. Memantine, an activity-dependent NMDA receptor antagonist with moderate-affinity, produces neuroprotection and has been used for the treatment of Alzheimer's disease. However, in the late stage of the disease, the NMDA receptor system is hypoactive and stimulation of the NMDA system may mitigate the cognitive decline. In the present study, we have found that the novel tricyclic pyrone compounds CP2 and TP70 with similar structures differentially modulated the glutamatergic system. Using extracellular recordings of rat hippocampal brain slices, CP2 (1-10μM) inhibited the basal field EPSP, blocked the induction and maintenance of long-term potentiation (LTP) induced by high frequency stimulation. Both CP2 and memantine (10μM) comparably inhibited the NMDA receptor-mediated EPSP in a reversible and activity-dependent manner. In contrast, TP70 (1-10μM) caused a long-lasting enhancement of the NMDA receptor-mediated EPSP (133.6±9.5% of control in 10μM) and increased the magnitude of NMDA-dependent LTP (246.7±20.7% vs 191.4±17.5% in control) with little effects on basal EPSP predominantly mediated by AMPA receptors. Furthermore TP70 restored the Aß-42 oligomer-impaired LTP. Aß-42 oligomer (0.1 μM) alone decreased the magnitude of LTP (145.3±10.9%), while co-application with TP70, LTP (180.1±17.5%) was maintained towards the control level. Interestingly, despite the differential modulation on the excitatory neurotransmission and synaptic plasticity, CP2 and TP70 each (25mg/kg, p.o. over 3 months of treatment) reduced cerebral amyloid load by approximately 30% in Alzheimer's disease transgenic mouse brains of both 5xFAD and APP-PS1 revealed by histopathological studies. These results suggest that CP2 may protect against excitotoxicity and may potentially be developed as a therapeutic targeting glutamatergic hyperactivity to decelerate neurodegeneration. TP70 can stimulate the NMDA receptor system and may form the basis for the development of a potential therapy to alleviate the loss of memory associated with the dysfunctional glutamatergic system in Alzheimer's disease.

Title: Neuroprotective effets of Liraglutide against chronic endoplasmic reticulum-stress

Authors: *T. PANAGAKI, C. HOLSCHER;
Biomed. and Life Sci., Lancaster Univ., Lancaster, United Kingdom

Abstract: Alzheimer's disease (AD) has been emerging as the most prevalent and socially disrupting malady of the elderly, with more than 44 million cases worldwide currently developing dementia. The molecular determinants underlying the disease onset and progression remain poorly understood while existing treatments solely provide a short-lived symptomatic relief. Improved understandings of AD etiopathogenesis along with the discovery of disease-modifying drugs are now the pharmacologic research priorities. Accumulating evidence suggests that the persistent endoplasmic reticulum (ER) stress may drive impairments in neuronal integrity and function. The ER stress engages a homeostatic signaling network that orchestrates various processes - from protein quality control and energy homeostasis to inflammation and cell differentiation - to control organelle homeostasis and cell fate. Pharmacological or genetic attenuation of ER stress has successfully restored pathological features and behavioral impairments of diverse animal models of neurodegenerative disorders, rendering ER stress a potent target for therapeutic intervention. Here, we examine whether the glucagon-like peptide 1 (GLP1) analogue Liraglutide can combat the persistent ER stress in the neuroblastoma SH-SY5Y cell line. Chronic treatment with thapsigargin, a non-competitive inhibitor of sarco/ER Ca^{2+}-ATPase, significantly reduced cell proliferation and impaired 5-bromo-2'-deoxyuridine (BrdU) incorporation and 2,3-Bis-(2-methoxy-4-nitro-5-sulphophenyl)-2H-tetrazolium-5-carboxanilide (XTT) metabolism *in vitro,* accompanied by an abnormal increase in lactate dehydrogenase (LDH) levels in the culture supernatant, indicating increased cell death. The impairments in cell physiology further correlate with an increase in the expression levels of the ER luminal stress protein BiP, the apoptosis-related transcription factor Chop and the ER resident caspase 12 (CASP12). Liraglutide co-treatment alleviates the ER stress-induced impairments in cell proliferation and viability and abnormal rise in cytotoxicity. It further attenuates the upregulated expression of the ER stress markers BiP, Chop, and CASP12. To conclude, persistent ER stress detrimentally affects neuronal cell fate, which can be prevented by Liraglutide. Liraglutide is currently in clinical trials in Alzheimer’s patients, and the results presented here and previously demonstrate that the drug shows promise to improve disease progression.

Title: Design and development of a small molecule therapeutic targeting both beta-amyloid and tau misfolding

Authors: ***D. F. WEAVER**[1], S. BANFIELD[2], C. BARDEN[1], A. BHATTACHARYA[2], K. KESKAR[1], E. LU[2], M. REED[2], B. SWEETING[2], M. TAYLOR[2], Y. WANG[2], F. WU[2], A. YADAV[2], S.-P. YANG[2];
[1]Krembil Res. Institute, UHN, Toronto, ON, Canada; [2]Treventis Corp., Toronto, ON, Canada

Abstract: Clinically, Alzheimer's disease (AD) manifests as progressive deterioration in memory and cognition; pathologically, these symptoms arise from cytotoxic protein misfolding, primarily oligomerization of beta-amyloid (Abeta) and tau. To rationally discover a disease modifying drug for AD via exploitation of a druggable target, we devised an in silico 3D molecular model designated as CCM (Common Conformational Morphology), where CCM is the abnormal protein shape common to both beta-amyloid and tau that predisposes to their proteopathic misfolding. Next, a library of 11.8 million compounds was filtered for CNS properties and screened in silico against CCM leading to 3,082 hits. Based on these hits, more than 620 prototype compounds were synthesized, culminating in the identification of the TRV200 class of compounds, which underwent extensive analogue synthesis (>500 analogues) to enable structure-activity optimization. The TRV200 class consists of novel, brain-penetrant small molecules capable of preventing the sporadic or templated misfolding of monomeric proteins, thereby blocking the generation of neurotoxic and synaptotoxic transient oligomeric species (OAbeta, Otau). Single compounds within the TRV200 class block oligomerization of both Abeta and tau (IC50 < 1 μM) in a dose-dependent manner as exhibited in vitro using biotin-amyloid and biotin-tau assays. In surface plasmon resonance studies, TRV200 compounds show selective binding to monomeric Abeta. Compounds show attenuation of tau misfolding by mass spec techniques and are also active in cell-based tau aggregation assays. Compounds exhibit in vivo brain bioavailability, engaging/reducing both Abeta and tau targets in transgenic mouse models (APP-PS1, Tg4510); e.g., a TRV200 class compound decreases Abeta oligomer concentrations within interstitial fluid by 40% within 72 hrs of administration and tau oligomer

concentrations by 35% within 7 days of oral dosing. These compounds also rescue both synaptic function and behavioural deficits in APP-PS1 mice in long-term potentiation, radial arm water maze and fear conditioning testing, following 8 weeks of administration (30 mg/kg po od n=13). Lead compounds from the TRV200 class demonstrate favourable drug metabolism-pharmacokinetic (DMPK) properties such as high liver microsome stability and low CYP inhibition and induction. The compounds are non-genotoxic and show low off-target promiscuity (receptor profiling, protein-protein inhibition, hERG). Thus, we have developed a new class of drug-like, orally bioavailable, brain-penetrant small molecules capable of simultaneously inhibiting both Abeta and tau oligomerization.

Title: P53-mediated senescent neurons trigger apoptosis of healthy bystanders by modulating the metabolic microenvironment in the brain

Authors: ***H. CHOW**[1,2], K. HERRUP[1];
[1]Div. of Life Sci., The Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong; [2]Inst. for Advanced Study., The Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong

Abstract: Aging is the greatest risk factor for AD yet its molecular mechanisms are not well understood. One clue we have been pursuing is that excessive cellular senescence correlates with premature aging phenotypes. For example, both neurofibrillary tangles and neuritic components of the plaques of AD patients show strong immunoreactivity for markers of senescence such as p16(INK4A). Our preliminary findings in human AD and related mouse materials revealed substantial number of neurons show signs of p53-mediated senescence triggered by aberrant p25/β-catenin stabilization. These senescent neurons have lost significant number of neurites, but are functionally "undead" and in this state they are capable of triggering apoptosis in nearby, otherwise healthy, neurons. An additional major correlate of the aging process is altered metabolic regulation. Here again there is a p53 connection as sustained stabilization of p53 impedes the usage of glucose by suppressing glycolysis, and at the same time enhances the usage of glutamine thus sustaining TCA cycle intermediates and glutathione synthesis in senescent neurons. These changes reshape the metabolic microenvironment, depleting the availability of glutamine for the bystander neurons, and rendering them hypersensitive to different types of stress. Further, pharmacological inhibition of p53, or supplementation of glutamine, prevented the bystander killing triggered by senescent neurons. Together, our observations suggest that p53-stabilization induces neuronal senescence and bystander apoptosis by modulating the metabolic microenvironment in the brain. The larger implication of these findings is that pharmacological inhibition of nuclear p53 activities and glutamine supplementation may benefit to the treatment of AD.

Title: Epigenetic modulation of synaptic resistance to amyloid-beta

Authors: *O. ZOLOCHEVSKA[1], R. WOLTJER[2], G. TAGLIALATELA[1];
[1]Neurol., UTMB, Galveston, TX; [2]Neuropathology Core of the Layton Aging & Alzheimer's Dis. Ctr., OHSU, Portland, OR

Abstract: Alzheimer's Disease (AD), the sixth leading cause of death in the US, is the most common form of age-associated dementia, accompanied by synaptic loss at early stages, and neuronal death at late stages of the disease. Oligomeric aggregates are considered to be the most toxic species of the two hallmark misfolded proteins in AD, amyloid beta (Abeta) and tau, capable of targeting and disrupting synapse and thus driving cognitive decay. However, certain individuals (here referred to as Non-Demented with Alzheimer's Neuropathology - NDAN) are capable to withstand the toxicity caused by Abeta and tau, and thus preserve cognitive competency despite the presence of AD neuropathology. Understanding the involved mechanism(s) would reveal new, effective treatment targets. We have previously shown that the post-synaptic density (PSD) of NDAN subjects is capable of rejecting Abeta, thus shielding synapses from its toxicity and, therefore, preserving cognitive ability. We have now completed the proteomics analysis of PSD fractions of hippocampi of control, AD and NDAN subjects and found that 31 unique proteins are significantly different between AD and NDAN PSDs. Ingenuity pathway analysis (IPA) was then performed to determine the canonical pathways, interactions among networks and upstream regulators. Several microRNAs were identified by IPA as potential drivers of the changes we have observed at the PSDs. Among these, we confirmed that microRNA-485, -4723 and -149 are differentially expressed in AD vs control and NDAN brains. Specifically, microRNA-485 and -149 are upregulated in AD, while microRNA-4723 is inhibited. Therefore, we hypothesize that changes in microRNA have an important role in either synapse protection or sensitization to Abeta binding. In order to test our hypothesis, we used a cellular model (differentiated SH-SY5Y cells) to determine if modulation of such microRNA had an effect on the ability of Abeta to associate with synaptic elements. SH-SY5Y cells were transfected with miRNA-4723 mimic and microRNA-485 inhibitor, and then treated with HiLyte Fluor 647-labeled Abeta oligomers. Abeta binding was evaluated using flow cytometry. Taken together, our findings suggest that there is a unique regulation of microRNA in NDAN which could be responsible for protection of synapses from Abeta toxicity, thus contributing to retention of cognitive ability.

Abstract: A key aspect of our discovery platform for novel in vivo probes and drug candidates is the use of informatics and curated databases of small molecules with in vivo CNS data in animals or humans as well as in vitro molecular property profiling. The limited number of small molecules falling within this in vivo relevant molecular space provides a filter for initial synthetic chemistry efforts. Pharmacological screens on initial compounds provide an additional, project-specific filter for recursive medicinal chemistry refinement. The decision tree terminates non-essential synthetic efforts and focuses on optimization in single target and functional discovery. Functional approach deliverables are now in the investigational new drug (IND) enabling or early clinical stage for Alzheimer's (AD) and brain injury. The case study presented here is for the established but technically challenging p38aMAPK target. Briefly, we exploited the CNS scaffold aminoarylpyridazine, a viable molecular fragment (PDB 4ZTH). Our experimental approach used high-resolution crystallography of small molecule-kinase complexes and safety pharmacology screens. The first compound synthesized and tested, MW069a (PDB 4EWQ), had a promising in vitro and in vivo profile but lacked the desired kinase specificity and safety pharmacology potential. Med chem refinement delivered second generation in vivo probes (MW108, PDB 4F9W ; MW181, PDB 4F9Y) with the desired isoform selectivity and improved safety potential. At this stage we also needed to use the platform to address and revise prevailing dogma about active site targeting of PK inhibitors. Pharmacokinetic optimization and safety pharmacology drove the final stage of med chem optimization that yielded MW150 (PDB 4R3C). MW150 is an isoform selective p38aMAPK inhibitor candidate with excellent in vivo exposure and safety in preclinical drug development. A regulatory compatible drug production scheme is available. Efficacy in AD models and an autism susceptibility model, combined with target engagement and pharmacodynamic marker analyses, document the MW150 potential as a candidate for development. The results address the translational gap between the knowledge that PKs are critical players in CNS disease progression and the unmet need for highly selective and CNS-active PK inhibitors that are viable candidates for future clinical drug development.

Title: Enhancement of cGMP signaling rescues LTP in Alzheimer diseased synapses: a high throughput analysis

Authors: *G. A. PRIETO[1], C. T. DANG[2], C. W. COTMAN[2];
[1]Inst. for Memory Impairments and Neurolog. Disorders, Irvine, CA; [2]Inst. for Memory Impairments and Neurolog. Disorders, Univ. of California, Irvine, Irvine, CA

Abstract: Maintaining and even improving cognitive function in early Alzheimer' disease (AD) is a major goal of modern medicine. However, no effective treatments for cognitive decline currently exist. Because it is generally accepted that cognitive decline is due to synaptic dysfunction, the initial evaluation of therapeutics is commonly based on the analysis of long-term potentiation (LTP), a cellular correlate of learning and memory. Phosphodiesterases inhibitors (PDEi), which prevent the breakdown of second messengers cAMP and cGMP, represent a potential treatment strategy for memory decline and have been recognized as therapeutic targets for cognitive improvement and AD. Here we use our novel method to track chemically-induced LTP in isolated synaptosomes ('*Fluorescence Analysis of Single-Synapse Long-Term Potentiation*', FASS-LTP) for drug evaluation in cryopreserved brain samples from AD cases. We simultaneously tested 7 selective PDEi. In parallel, we tested forskolin (adenylyl cyclase activator, AC_{activ}) and a novel guanylyl cyclase activator (GC_{activ}), as well as functionally relevant combinations of PDEi with AC_{activ} or GC_{activ}. Thus, a total of 18 treatments were simultaneously tested on basal conditions and after cLTP. We found that, when combined with GC_{activ}, inhibition of cGMP-specific PDEi rescued cLTP in synaptosomes from AD cases ($P < 0.05$). Basal levels of potentiated synapses were not affected by any drug treatment. These data

show that FASS-LTP is a sensitive and efficient approach for drug screening in human synapses, a previously unattainable goal. Notably, a molecular target were discovered to be the cGMP signaling pathway, suggesting that synaptic plasticity in the AD brain may be rescued by cGMP-specific PDEi.

Title: Blocking the interaction between EphB2 and ADDLs by a small peptide rescues impaired synaptic plasticity and memory deficits in a mouse model of Alzheimer’s disease

Authors: ***C. GAO**, X.-D. SHI, K. SUN, R. HU, N. SUN, J.-R. HAO, Y. HAN, L.-C. ZHANG; Xuzhou Med. Col., Jiangsu, China

Abstract: Soluble amyloid-beta (Aβ) oligomers, also known as Aβ-derived diffusible ligands (ADDLs), are thought to be the key pathogenic factor in Alzheimer's disease (AD). But there is still no effective treatment for preventing or reversing the progression of the disease. Targeting N-methyl-D-aspartic acid (NMDA) receptors trafficking and its regulation is a new strategy for AD early treatment. Aβ oligomers have been found to bind to the fibronectin type III repeats (FN) domain of EphB2 to trigger EphB2 degradation, thereby impairing the normal functioning of NMDA receptors and resulting in cognitive deficits. Here, we identified for the first time the

interaction sites of the EphB2 FN domain with ADDLs by applying peptide array method, based on which to design and synthesize four candidate peptides (Pep21, Pep25, Pep32 and Pep63) that might be able to block EphB2-ADDLs interaction. Among them, Pep63 was screened out to be the most effectively one to inhibit the binding between EphB2 and ADDLs. We found that Pep63 not only rescued the ADDLs-induced depletion of EphB2 and GluN2B-containing NMDA receptors from the neuronal surface in cultured hippocampal neurons, but also improved impaired memory deficits in APPswe/PS1dE9 (APP/PS1) transgenic mice as well as the phosphorylation and surface expression of GluN2B-containing NMDA. Together, these results suggest that blocking the EphB2-ADDLs interaction by small interfering peptides may be a promising strategy for AD treatment. **Acknowledgements:** This work was supported by the National Natural Science Foundation of China (Grant No. 81273489, 81471101, and 81300930), the Natural Science Foundation of Jiangsu Province (Grant No. BK2012582 and BK20130232), the Education Department of Jiangsu Province (Grant No. 12KJA180008 and 14KJB320025), and the Qing Lan Project of Jiangsu Province.

Title: Attenuations of learning and memory impairments in aged and transgenic mice models of Alzheimer's disease by mild stress

Authors: C. LEE[1,3], J.-H. JANG[3], *G. PARK[2];
[1]Inst. of Pharmaceut. Sci., [2]Col. of Pharm., Kyungpook Natl. Univ., Daegu, Korea, Republic of; [3]Sch. of Med., Keimyung Univ., Daegu, Korea, Republic of

Abstract: Stress is regarded as one of the critical risk factors for neurodegeneration leading to learning and memory deficits. Although several researchers have reported that mild stress could enhance cognitive functions, its underlying molecular mechanisms are not clearly verified. In this study we have investigated the effect of mild restraint stress (MRS) for 28 days (4h/day) against the learning and memory dysfunction in aged model mice as well as triple transgenic

model mice of Alzheimer's disease (3xTg AD) by conducting diverse behavior tests and molecular analyses. MRS improved mean escape latency, the time taken to find the platform during training trials in Morris water-maze test. In addition, the neuropathological markers for AD such as accumulation of beta-amyloid peptide and hyperphosphorylation of tau protein were mitigated by MRS. MRS effectively decreased ratio of pro-apoptotic Bax to anti-apoptotic Bcl-2, the representative proteins involved in apoptosis. To elucidate the neuroprotective mechanism of MRS, we have examined the molecules involved in the oxidative stress and inflammation. MRS attenuated the lipid peroxidation and protein oxidation through up-regulation of antioxidant enzymes via modulating redox-sensitive proteins such as NF-E2-related factor 2 (Nrf2) and p66(Shc). MRS also attenuated the pro-inflammatory responses by suppressing expression of cytokines such as TNF-α in aged mice. Moreover, MRS increased the expression of brain-derived neurotrophic factor by phosphorylation of cAMP response element-binding protein in 3xTg AD mice. Taken together, these findings suggest that MRS may have beneficial effects for the learning and memory impairments during neurodegenerative process by decreasing neuropathological markers of AD and oxidative stress as well as inflammatory responses, and increasing neurotrophic factors of regeneration.

Title: Impaired object processing in 3xtg, 5xfad and app/ps1 mouse models of alzheimer's disease: going beyond "object recognition"

Authors: ***S. D. CREIGHTON**[1], D. PALMER[1], V. F. PRADO[2], M. A. M. PRADO[2], B. D. WINTERS[1];
[1]Psychology, Univ. of Guelph, Guelph, ON, Canada; [2]Robarts Res. Inst., Univ. of Western Ontario, London, ON, Canada

Abstract: Object recognition evaluates declarative-like memory in rodents and is sensitive to cognitive deficits in transgenic mouse models of Alzheimer's disease (AD). Object recognition, however, is not a unitary process, and there are many uncharacterized facets of object processing that have relevance to AD. To elucidate the specific nature of object processing deficits in transgenic mouse models of AD, we are systematically evaluating performance on tasks that manipulate different types of object information: object identity (ie., object recognition *per se*: OR), spatial processing (object location; OL), temporal processing (temporal order; TO), and multisensory perceptual integration (multisensory object oddity; MSO) in 12-month-old male and female 3xTG, 5xFAD and APP/PS1 mice. Preliminary results are consistent with a multifaceted impairment in object processing. Specifically, 3xTG males were impaired on open-field OR when the retention delay was 5min or 3h, whereas females were selectively impaired at 3h. However, when spatial and contextual cues were minimized, using a modified Y-apparatus, both 3xTG males and females had intact OR at 5min. Conversely, 5xFAD males were impaired on open-field OR at 5min and 3h, but selectively impaired at 3h on Y-apparatus OR, whereas 5xFAD females were impaired on open-field and Y-apparatus OR at 5min and 3h. OL was impaired in 3xTG males, females and 5xFAD females at 5min and 3h. TO was impaired in 3xTG females at 3min. MSO was impaired in 3xTG males, females and 5xFAD females, despite intact basic visual and tactile object perception. Our results reveal dissociations across transgenic AD strains, sex, and type of object information processing, and should ultimately help to clarify the relationship between specific aspects of AD pathology and "object recognition" impairment.

Abstract: Postoperative cognitive dysfunction (POCD) occurs more frequently in the elderly and has characteristics in common with other neurodegenerative diseases such as Alzheimer's Disease (AD). Neuroinflammation and abnormal tau protein phosphorylation or mislocation is known to be strongly associated with development of AD. Cholinergic system manipulation has been considered a potential strategy in the treatment of this disease. This study investigates the contribution of surgical trauma to and the effect of the cholinergic agonist varenicline on the development of POCD. Aged male C57BL/6N mice (18-month-old, 40.86 ± 5.54 g) were divided into control (CON), sevoflurane only (SEVO) and laparotomy (LAP) groups, all three groups either treated with vehicle (normal saline) or varenicline, which was administrated orally and daily from one day before treatments continuously for 13 days. Cognitive function was assessed by Novel Objective Recognition test (NOR) and Y-maze analysis, and locomotor activity by the Open Field Test (OFT), motor function by Rotarod test on postoperative day 14. Inflammatory cytokine mRNA expression from the liver, frontal cortex and hippocampus were assessed by q-PCR at 4h postoperatively in three groups. Data were analyzed by One-Way ANOVA followed by Turkey's post hoc test, and $p < 0.05$ was considered as statistically significant. Locomotor activity and motor function were not affected by laparotomy or varenicline with no difference found in the frequency of crossing the square and central duration in OFT, or in latency to fall in Rotarod test. Cognitive dysfunction was observed in LAP group when compared with SEVO group. There was an increase in latency and error number in the Y-maze test, and a lower discrimination index in NOR. However, these changes were reversed by varenicline. Hepatic mRNA levels of IL-1β, TNF-α, IL-6 and MCP-1 were significantly increased in LAP group compared with SEVO group. IL-1β, IL-6 and MCP-1 were significantly elevated in the hippocampus in LAP group. Immunoflurescent intensity of GFAP-positive astrocyte was higher and there was more activated microglia in CA1 and DG regions of the hippocampus in LAP group at 14 d postoperation. Varenicline reduced this high level of immunoreactivity of astrocyte and microglia. There was significant hyperphosphorylation of tau protein (AT8) in both cytosol and nucleus in LAP group. Varenicline decreased tau protein phosphorylation in both regions. Neuroinflammation and tau protein hyperphosphorylation may play important role in the development of cognitive dysfunction induced by laparotomy and varenicline improved cognition by reversing these changes.

[2]Anaesthesiology, HKU, Hong Kong, China

Abstract: Alzheimer's disease (AD) is one of the most common types of dementia without effective pharmacological treatment. Increasing evidences have shown that physical training could counteract the deterioration of cognitive functions in both human and animal models. However, the underlying mechanism and the responsible molecule for exercise related neuroprotection remain largely unknown. FGF21 is an endogenous metabolic regulator for glucose and lipid which is primarily expressed in liver, muscle, adipose tissues and brain. Recently, FGF21 has been shown to possess important role in mediating insulin signaling activities, neuroprotection and cognition and can be regulated by exercise. In current study, AD animals received 1 month endurance training and the effect of exercise on AD was investigated. Memory function, insulin signaling activities and tau phosphorylation in brain were examined after exercise training. Also, the effect of endurance training on FGF21 gene expression in both peripheral organs and brain were also examined.
For exercise protocol, mice were trained and run on an automatic rotarod instrument for 30 minute per day and 5 times per week. After 1 month training, memory function was examined by novel object recognition test and a modified Y-maze. Insulin signaling activities and tau phosphorylation in frontal cortex were examined by Western blotting. Gene expression of FGF21 in liver, abdominal adipose tissues, soleus muscle and cortex was examined by real time PCR.
After 1 month endurance training, 3x transgenic mice were shown to improve the cognitive performance in novel object recognition test and Y-maze test. Significant improvement of insulin signaling activities and decreased tau phosphorylation were observed in frontal cortex of AD mice after 1 month endurance training. At the same time, mRNA expression of FGF21 in liver, muscle and fat tissues were increased but not in the brain. These results implicated that exercise exerted neuroprotection and induced peripheral FGF21 induction in AD animal model. Further experiments are needed to confirm the role of exercise induced peripheral FGF21 in terms of counteracting AD.

Title: Infusion of the neuroprotective peptide PACAP27 into mouse hippocampi prevents learning and memory deficits elicited by the cyclooxygenase product of inflammation prostaglandin J2

Authors: ***J. A. AVILA**[1,3], M. KIPROWSKA[2,4], T. JEAN-LOUIS[2,4], P. A. SERRANO[1,3], P. ROCKWELL[2,4], M. E. FIGUEIREDO-PEREIRA[2,4];

Abstract: Upregulation of cyclooxygenase-2 has emerged as an important determinant of the cytotoxicity associated with neuroinflammation in Alzheimer's Disease (AD). Prostaglandins (PGs) are major products of cyclooxygenases, but their role in neurodegeneration is poorly understood. PGD2 is the most abundant prostaglandin in the brain and increases the most under pathological conditions. Specifically, cortical neurons in AD brains were shown to exhibit accelerated PGD2 production. PGD2 is unstable and is converted to the highly neurotoxic prostaglandin J2 (PGJ2) by spontaneous dehydration. To study the *in vivo* effects of PGJ2 we established a mouse model of neuroinflammation. PGJ2 (16.7ug/2ul/week, for 3 weeks) was bilaterally microinfused into the CA1 hippocampal region of old (53 weeks) and young (12 weeks) mice. Following one week of post-surgery recovery, all mice underwent a 12-day training period on the radial 8-arm maze (RAM) to assess spatial learning and memory. Our data revealed significant spatial learning and long-term memory deficits in old PGJ2-treated mice, compared to the other three groups. Hippocampal Fluoro-Jade C staining identified a significant increase in degenerating neurons in the CA3 region of old PGJ2-treated mice, indicating a progressive spread of damage from the site of injection to the adjacent sub-region. Golgi-immunohistochemical analysis identified a significant deficit in the expression of plasticity-related spine types, stubby and filopodia, within CA1 dendrites of old-PGJ2 treated mice

compared to the young-PGJ2 condition. This deficit occurred concomitantly with a significant increase in colocalization of synaptic markers GluA2/PSD-95 within these spine types, indicating a deficit in maturation of spines via disrupted molecular trafficking and turnover. Our findings indicate that PGJ2, as a product of inflammation, can initiate neurodegeneration as well as facilitate its progression within the hippocampus in an age-dependent manner, thus mimicking processes that are highly relevant to AD pathology. We also assessed the efficacy of elevating endogenous cAMP as a therapeutic intervention in our model. Accordingly, a group of old mice received PGJ2 injections at the same time as PACAP27, a lipophilic neuroprotective peptide that raises intracellular cAMP. PACAP27 treatment ameliorated PGJ2-mediated learning and memory deficits on the RAM. We propose that this pre-clinical mouse model is highly valuable to identify and optimize therapeutics that suppress the neurotoxic effects of inflammation as a strategy to prevent or delay the progression of AD.

Title: Cerebral vascular pathologies and executive dysfunction in a new animal model of age-related cognitive impairment

Authors: *A. ELHARRAM, N. CZEGLEDY, B. BENNETT, D. ANDREW;
Pharmacol. and Toxicology, Queen's Univ., Kingston, ON, Canada

Abstract: Oxidative stress causes tissue damage in a number of models of vascular cognitive impairment (VCI) and in age-related Alzheimer's disease (AD). We have developed a novel oxidative stress-based mouse model of *age-related* cognitive impairment based on gene deletion of aldehyde dehydrogenase 2 (ALDH2). ALDH2 is important for the detoxification of endogenous aldehydes such as 4-hydroxynonenal (HNE), a lipid peroxidation product formed during oxidative stress that can form protein adducts, altering cell function. $Aldh2^{-/-}$ mice exhibit oxidative stress, and many VCI- and AD-like pathologies including a progressive decline in recognition and spatial memory, increased anxiety- and depressive-like pathologies, aortic

endothelial dysfunction and arterial hypercontractility, HNE adduct formation and age-related increases in amyloid-β (Aβ) in cerebral microvessels, and a loss of blood-brain barrier integrity and cerebral vascular microbleeds. In contrast to AD, VCI has been characterized by early and significant declines in attention and executive function, a term that encompasses a broad range of higher cognitive processes such as: reasoning, planning, cognitive flexibility, sequencing, response inhibition, and abstract concept formation. In order to further evaluate $Aldh2^{-/-}$ mice as a possible model of VCI, attention and executive dysfunction was assessed using the attentional set-shifting task. Cerebrovascular function was also examined using laser Doppler flowmetry, and systolic and diastolic abnormalities of the heart were assessed to determine correlations between cerebrovascular flow and brain pathologies. Further validation of $Aldh2^{-/-}$ mice as an oxidative stress-based animal model of cognitive impairment and age-related VCI will complement current rodent models and will allow greater insight into the pathogenesis and mechanisms of VCI.

Abstract: The CVN mouse model of Alzheimer’s disease (AD) is characterized by extensive amyloid deposition, expression of hyperphosphorylated tau, and significant neuronal loss. Twelve-month-old CVN mice exhibit impaired spatial memory, as gauged by their inferior performance in the 2-day radial-arm water maze test compared to wild-type (WT) animals. However, their behavior in more translational cognitive tasks has not been thoroughly investigated. We assessed learning and cognitive flexibility of 5-6-month-old CVN mice and their age-matched WT counterparts in a touch screen Visual Discrimination/Reversal (VDR) task, where animals have to learn which one of the two simultaneously displayed stimuli is

correct and subsequently re-learn upon a switch of contingencies. There was no effect of genotype on the number of sessions required to complete instrumental pretraining. Furthermore, CVN and WT animals did not differ in the rate of VD acquisition in terms of the number of days to achieve criterion, number of trials completed, number of errors made, and number of received correction trials ($P < 0.05$ in all comparisons, Mann-Whitney test). However, after the contingency of reward dispensation was switched from the previously correct to previously incorrect stimulus response, CVN mice displayed impaired reversal learning. Analysis of response accuracy across 12 sessions revealed a significant effect of genotype ($F(1,27) = 10.9$, $P = 0.0027$) and session ($F(11,297) = 62.83$, $P < 0.0001$), but no significant interaction between these two factors ($F(11,297) = 0.92$, $P = 0.519$). Furthermore, CVN mice made significantly more errors and received a significantly higher number of correction trials during the 12 reversal sessions. As reversal learning depends on the integrity of prefrontal cortex, we analyzed the metabolic profile in this brain region by 1H magnetic resonance spectroscopy (1H-MRS) using a 11.7 T small animal MRI system. We observed lower levels of the neuronal marker N-acetyl aspartate and glutamate in the brain of CVN mice, whereas myo-inositol concentration was increased. We have previously detected similar changes in the hippocampus of 12-month CVN animals. Furthermore, changes in these metabolites are qualitatively similar to alterations seen in the brain of AD patients. Our results suggest that highly translatable touch screen tests sensitively detect cognitive consequences of AD-like pathology in the brain of relatively young CVN mice. Furthermore, our data indicate that in addition to previously documented hippocampal disturbances, some behavioral impairments in this AD model may be explained by dysfunction of the prefrontal cortex.

Title: Fus1 KO female mice have olfactory, spatial and association memory impairments and sleep/awake cycle disturbances in adult age: a new model for sAD

Authors: *G. CORONAS-SAMANO[1], K. L. BAKER[1,2], A. V. IVANOVA[3], J. V. VERHAGEN[1,2];
[1]The John B. Pierce Lab., New Haven, CT; [2]Dept. Neurobiology, Yale Sch. of Med., New Haven, CT; [3]Dept. of Surgery, Yale Sch. of Med., New Haven, CT

Abstract: Aging is a complex biological process in humans characterized by a progressive impairment of sensory function, motor skills and cognition over time. Mitochondrial dysfunction has been proposed to play a critical role in the aging process, in which overproduction of reactive oxygen species (ROS) induces oxidative *damage* to cellular macromolecules. Hence, mitochondrial dysfunction has been implicated in chronic and neurodegenerative-disorders such as sporadic Alzheimer's disease (sAD). Fus1/Tusc2 is a mitochondrial tumor suppressor protein regulating numerous mitochondrial activities. Fus1 knockout (KO) in mice results in increased ROS production, mitochondrial dysfunction, chronic inflammation and premature aging. Our group has previously demonstrated that 10 months old (mo.) Fus1 KO female mice showed olfactory dysfunctions in the habituation-dishabituation test and also in the long term memory digging test. Here, we show that Fus1 KO mice is a novel useful animal model for studying accelerated aging. We tested if the Fus1 KO mouse model shows AD related symptoms early in life including olfactory deficits, reference and working memory decline, circadian disruptions, depression and anxiety. We tested female adult Fus1 KO (n=23) and the WT background 129sv (n=14) mice starting from 4 mo. over a 3 month period. Animals were tested for the following behavioral tests: olfactory habituation/dishabituation, short- and long-term memory (all incl. sniffing), hidden cookie, open field, light-dark box, passive avoidance, reduced-stress Morris water maze, circadian sleep/awake cycle, nesting and sucrose preference test. All data were objectively scored using Noldus video analysis. Our data suggests that Fus1 KO mice did not habituate to social odor (urine) over minutes to hours. They did not improve their latency in finding the hidden cookie. In the Morris water maze KO mice did not learn the location of the platform (training session) and did not improve their behavior by the fifth day (testing day). In the light-dark box test, Fus1 KO mice spent more time switching between boxes in comparison with their WT counterparts and showed shorter latency in passive avoidance test. The KO mice slept longer in the dark cycle as compared to WT mice. Fus1 KO mice did not show depression or coherent anxiety symptoms. These findings support the hypothesis that mitochondrial dysfunction in Fus1 KO mice negatively affects cognition and other functions that parallels sAD. Thus, Fus1 KO mice is a useful model for studying aging and aging-associated disorders such as AD characterized by memory decline and increased ROS production.

Title: Novel murine resource to identify genetic modifiers of Alzheimer's disease

Authors: *S. M. NEUNER[1], L. A. WILMOTT[1], T. M. SHAPAKER[1], M. J. HUENTELMAN[2], C. C. KACZOROWSKI[1,2];
[1]Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN; [2]Neurogenomics, Translational Genomics Res. Inst., Phoenix, AZ

Abstract: Mutations in the amyloid precursor protein or presenilin genes are known to cause familial Alzheimer's disease (FAD). However, there is a wide variation in the age at onset (AAO) of FAD, suggesting additional genes are involved in determining when a patient will develop disease. Uncovering genetic modifiers of the AAO of FAD is of critical importance, as even delaying the onset of symptoms by 5-10 years would significantly reduce the human burden and costs associated with FAD. In order to systematically identify these modifiers, we generated a novel panel of genetically diverse mice harboring five causal FAD mutations in APP and PSEN1 (5XFAD transgene). We have phenotyped this panel, termed the AD-BXDs, across the lifespan and have found that the genetic background of each individual strain has a profound effect on the penetrance of FAD mutations on cognitive traits. Specifically, the AAO of spatial working memory deficits varied widely, ranging from 4 months of age (susceptible strains) to greater than 16 months of age (resilient strains). This translates to approximately 26-60+ years of age in humans, a time frame consistent with the variation in AAO recently observed in human FAD patients (Lee et. al. 2015). In addition, the severity of long-term contextual fear memory deficits at 14 months of age varied, with resilient strains performing on-par with 6-month-old controls while susceptible strains exhibited almost complete memory failure. Through genetic interval mapping, two significant quantitative trait loci containing gene variants that modify AAO and severity of memory deficits were identified. Positional candidates were involved in functions including neuronal nitric oxide signaling and regulation of immune response, providing a novel list of genes that may be effectively targeted to delay the onset of AD. Current work in the lab is aimed at validating a functional role for our top candidates through gain and loss of function studies using viral-mediated gene therapy and genome editing technologies. Since recent work by Lee and colleagues suggest genetic modifiers of AAO in FAD families also

influence AAO in sporadic late-onset AD (LOAD) cases, we hypothesized that genetic modifiers identified here would influence the development of LOAD in human populations. In support, we have identified variants in four of our leading candidates that were significantly associated with LOAD using the TGen2 cohort. Overall, results here are poised to significantly advance our understanding of how individual genetic variation contributes to susceptibility to multiple forms of AD, and demonstrate the utility of the AD-BXD panel as a novel resource for the study of AD genetics.

Title: Genetic modifiers of non-cognitive symptoms of Alzheimer's disease using a novel transgenic murine panel

Authors: S. NEUNER[1], L. WILMOTT[1], K. O'CONNELL[2], *C. C. KACZOROWSKI[1]; [1]Dept. Anat. and Neurobio., [2]Dept. of Physiol., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Alzheimer's disease, the most common form of dementia in the elderly, often presents with a wide range of non-cognitive comorbidities, including physical frailty, weight loss, and blood glucose regulation (i.e., diabetes). Although a majority of AD research focuses on the neurobiological mechanisms underlying the cognitive deficits seen in AD, these non-cognitive symptoms are often a considerable source of burden for both patients and their caregivers and can drastically affect quality of life. There is evidence that the development of non-cognitive symptoms can be influenced by an individual's genetic makeup, so the identification of precise genes involved is critical both for understanding disease pathophysiology and developing therapeutics to treat symptoms. Our lab recently generated a novel panel of genetically diverse mice harboring five causal mutations in APP and PSEN1 (5XFAD transgene), termed the AD-BXD panel, and has demonstrated that genetic background significantly modulates the penetrance of FAD mutations on cognitive symptoms. We hypothesized that genetic background would also modulate non-cognitive symptoms associated with FAD, so in order to systematically

identify modifier genes, we comprehensively phenotyped AD-BXD mice across the lifespan for a number of non-cognitive traits. Overall, 5XFAD mice exhibited a more severe sensorimotor decline from 6 months of age to 14 months of age and gained less weight then their non-transgenic (Ntg) littermates, reminiscent of the increased physical frailty observed in human AD patients. In addition, 5XFAD mice exhibited a significant decrease in blood glucose levels from 6 months of age to 14 months of age, suggesting an inability to maintain glucose levels. However, the extent of each of these effects was modulated by strain background. Genetic interval mapping identified quantitative trait loci associated with sensorimotor decline, weight curve across the lifespan, and blood glucose levels at 6 months of age, providing a novel list of candidate genes that can potentially be targeted to treat non-cognitive comorbidities associated with FAD. Recent work by Lee and colleagues (2015) has demonstrated that genetic modifiers of the age at onset of FAD also influence the age at onset of sporadic late-onset AD (LOAD), so it reasonable to speculate that genetic modifiers identified here may also influence the development of non-cognitive symptoms associated with LOAD. Overall, results here provide insight into additional symptoms associated with Alzheimer's and are poised to provide a more complete understanding of the genetics of multiple types of AD.

Title: Cognitive deficits in a rodent model of normal pressure hydrocephalus

Authors: *D. L. POETA[1], H. A. BOUNDS[1], I. T. PEREIRA[1], P. M. KLINGE[3], R. D. BURWELL[1,2];
[1]Cognitive, Linguistic and Psychological Sci., [2]Neurosci., Brown Univ., Providence, RI;
[3]Neurosurg., Rhode Island Hosp., Providence, RI

Abstract: Normal pressure hydrocephalus (NPH) is a cerebrospinal fluid (CSF) disorder resulting from abnormal CSF circulation and its accumulation in the ventricles of the brain. The accumulation of CSF results in enlarged ventricles (ventriculomegaly) and damage to

surrounding brain tissue. NPH patients exhibit cognitive and motor deficits (reviewed in Peterson et al. 2016). Cognitive signs include impairments of memory, attention, and executive function. Motor deficits include alterations in gait. Although these deficits are well documented in NPH patients, there are limited studies addressing the cognitive impairments in animal models of NPH. Previously, the rat kaolin model of adult NPH was shown to cause significant ventriculomegaly and associated brain pathology involving hippocampal structures (Klinge et al, 2003). In the present study, we employed this rat kaolin model to examine the cognitive impairments associated with the disease.
The major goal of the study was to identify a memory task that was sensitive to the kaolin procedure and that was suitable for tracking the emergence of memory deficits during the development of NPH. Thus, we selected a recognition memory task that permits repeated testing, the 3-dimensional spontaneous object recognition (SOR) task. The SOR task has become the preferred experimental paradigm to investigate neurobiological mechanisms of recognition memory in rodents (Ennaceur and Delacour, 1988). In a pilot behavioral study, we compared the performance of 3 control rats with 6 NPH rats on the SOR task at 2, 4, and 6 weeks after the kaolin procedure. Control rats showed normal recognition memory at all time points by exploring the novel object more that the familiar object. This was evident in a positive discrimination ratio (DR) significantly greater than zero. DRs near zero indicate impairment in recognition memory evident in the lack of preference for the novel object. NPH rats showed significantly positive DRs at 2 weeks, but at 4 and 6 weeks DRs were not significantly different from zero indicating deficits in recognition memory. Further confirming the model, NPH rats showed impairments in gait evident in a shorter stride length and a wider base of support compared with control animals. In future experiments, we will employ versions of the SOR task that are sensitive to pathology in the hippocampus, parahippocampal, and prefrontal cortices (Ameen-Ali et al., 2015), regions known to be affected in NPH.

Abstract: Patients with Alzheimer's disease (AD), a common dementia among the aging population, often also suffer from depression. This comorbidity is poorly understood. Although most forms of AD are not genetically inherited, we have identified a new human mutation in the carboxypeptidase (CPE)/neurotrophic factor-α1 (NF-α1) gene from an AD patient that caused memory deficit and depressive-like behavior in transgenic mice. This mutation consists of three adenosine inserts, introducing 9 amino acids, including 2 glutamines into the mutant protein, herein called CPE-QQ. Expression of CPE-QQ in Neuro2a cells demonstrated that it was not secreted, but accumulated in the endoplasmic reticulum and was subsequently degraded by proteasomes. Overexpression of CPE-QQ in rat hippocampal neurons resulted in cell death, through increased ER stress and decreased expression of pro-survival protein, BCL-2. Transgenic mice overexpressing CPE-QQ did not show difference in the processing enzyme activity of CPE compared with wild type mice. However, the transgenic mice exhibited poor memory, depressive-like behavior, severely decreased neurites in the hippocampal CA3 region and medial prefrontal cortex indicative of neurodegeneration, hyperphosphorylation of tau at Ser^{396}, and diminished neurogenesis in the dentate gyrus at 50 week old. All these pathologies are associated with AD and the latter with depression. Interestingly, the younger CPE-QQ mice (11 week old) did not show deficits in neurite outgrowth and neurogenesis. This study has uncovered a human CPE/NF-α1 gene mutation that could lead to comorbidity of dementia and depression, emphasizing importance of this gene in cognitive function.

Abstract: Improved healthcare comes with a cost of increased prevalence of dementia as the population ages. Alzheimer's disease is the most prevalent cause of dementia in elderly people (2). To study the neuropathology resembling Alzheimer's disease in laboratory animals, intracerebroventricular (ICV) streptozotocin (STZ) injection is a commonly used method which engenders several pivotal molecular traits of this malady such as oxidative stress, neuroinflammation, amyloid plaque formation, and tauopathy (3). In the present study, we evaluated recognition memory in ICV STZ-injected Wistar albino rats by using a novel object recognition task which enables estimation of global (concurrently cortical and hippocampal) short-term and long-term memory as well as the memory retention. To this aim, two groups (n=8 in each) of animals received either artificial cerebrospinal fluid or STZ (3 mg/kg). Two weeks after this intervention, the recognition test, comprising a habituation phase, in which animals are left to move freely for 5 minutes, and 3 diverse 5-minute-long test phases as familiarization, short-term memory, and long-term memory, was performed. Data were analyzed by two-tailed Student's t-test and $p<0.05$ was considered significant. Two identical objects were used in the familiarization phase, and no place preference was observed ($p>0.05$). One of the objects was changed with the novel object after one hour (short-term phase). ICV STZ-injected rats displayed significantly less exploratory behavior around the novel object than the controls ($t=6.99$, $df=14$, $p<0.01$) which indicates impaired short-term memory. Twenty-four hour after the familiarization, in the long-term memory phase, the familiar object was placed onto the other location and a different novel object was put on the previously familiar location to eliminate spatial cues. Interestingly, there was no statistical significance between the animals in this phase ($p>0.05$). According to these results, we assume that ICV STZ administration did not disrupt memory acquisition (working memory in other words) that is interpreted by preserved long-term memory, but it devastated short-term memory retention. However, this finding seems to be related to a difficulty of memory recall rather than of short-term memory storage.

Title: Surgery causes exaggerated postoperative cognitive decline in high fat diet induced obese mice

Authors: *X. FENG[1], M. V. CONTRERAS[2], S. KOLIWAD[2], M. MAZE[3];
[1]Anesthesia and Perioperative Care, [2]Med., [3]Anesthesia and Perioperative care, Univ. of California, San Francisco, San Francisco, CA

Abstract: Introduction: We have demonstrated that neuroinflammation following surgery produced cognitive decline in previous studies (1-4). Furthermore, we have identified deficiencies in the resolution of inflammation induced by aseptic trauma in the rat model of metabolic syndrome (5,6). In this study we would like to investigate whether surgery could cause exaggerated postoperative cognitive decline in high fat diet induced obese (DIO) mice Methods: Young mice (5-6 weeks old) were fed with high fat diet or control diet for 8 weeks before surgery (tibial fracture) till sacrifice. For the behavioral study, trace fear conditioning (TFC) training was performed 30 minutes before surgery, and TFC testing was performed on the 3rd day postoperatively. Mice were sacrificed 3 days postoperatively, plasma and hippocampus were harvested for detecting LXA4 and LTB4, and neuroinflammation, respectively. Results: Postoperative cognitive decline was exaggerated in DIO mice. High fat diet induced much high neuroinflammatory response to surgery and decreased systemic LXA4 level. Discussion: The neuroinflammatory and cognitive responses to peripheral surgery are exaggerated in DIO mice. DIO mice may be a useful preclinical model in which to investigate therapeutic strategies to prevent and/or ameliorate exaggerated postoperative cognitive decline and other postoperative complications in which inflammation fails to resolve.

Title: Midkine modulates striatal gliosis and cognitive impairment induced by amphetamine: Evidence for a stimulus-dependent regulation of neuroinflammation by midkine

Authors: *G. HERRADON, R. FERNÁNDEZ-CALLE, C. PÉREZ-GARCÍA, E. GRAMAGE, M. VICENTE-RODRÍGUEZ;
Pharmacol. Lab, CEU San Pablo Univ., MADRID, Spain

Abstract: Midkine (MK) is a cytokine with important functions in inflammatory processes in peripheral organs in different pathological conditions. Despite amphetamine-induced striatal astrogliosis, a hallmark of this drug's neurotoxic effects, is increased in MK knockout (MK-/-) mice, the possible role of MK in neuroinflammation is not yet fully understood. To fill this gap, we have studied astrogliosis and microglia activation induced by amphetamine in MK-/- and wild type (WT) mice. Animals received 4 injections (i.p.) of amphetamine (10 mg/kg) or saline (control, 10 ml/kg), allowing between injections a 2 hour interval. Four days after last amphetamine injection, astroglia and microglia were examined in immunohistochemistry studies

using antibodies against GFAP and Iba-1, respectively. We found that amphetamine-induced microglial response and astrocytosis are significantly enhanced in the striatum of MK-/- mice. This counteractive effect of MK against amphetamine striatal gliosis seems to be region-specific since it is not observed in the hippocampus. To test the possibility that MK regulates microgliosis and astrocytosis independently of the inflammatory stimulus, we assessed the effects of lipopolysaccharide (LPS, 0.5 mg/kg, i.p.) in MK-/- and WT mice. Surprisingly, LPS-induced striatal astrogliosis was blocked by genetic inactivation of MK, suggesting a differential regulation of astrocytosis by MK depending on the inflammatory stimulus. Since early onset of amphetamine-type drugs abuse is associated with a wide range of adverse outcomes in adulthood including cognitive deficits, we also tested long term effects of periadolescent amphetamine treatment (3 mg/kg i.p., daily during 10 days) in a memory task in MK-/- and WT mice. Within two weeks after cessation of treatment, significant deficits in the Y-maze test were only observed in amphetamine-pretreated MK-/- mice. However, 26 days after last administration we did not find significant differences between genotypes. The data presented here demonstrate for the first time that MK is an important modulator of amphetamine-induced striatal neuroinflammation. The data also suggest that the modulatory effects of MK in neuroinflammation depend on the inflammatory stimulus and the brain area considered. In addition, our data demonstrate that periadolescent amphetamine treatment in mice results in transient disruption of learning and memory processes in absence of endogenous MK.

Title: Human very low density-lipoprotein induces neuronal inflammation and cognitive dysfunction in mice

Authors: *S.-L. CHEN[1], H.-C. LEE[1], M.-C. CHOU[1], L.-Y. KE[1], C.-L. LAI[1], C.-H. CHEN[2], C.-K. LIU[1];
[1]Kaohsiung Med. Univ., Kaohsiung, Taiwan; [2]Baylor Col. of Med., Housto, TX

Abstract: Present epidemiologic findings indicate that dyslipidemia is associated with accelerated onset and progression of neuronal degeneration and cognitive impairment. Abnormal lipids, in particular electronegative very low density lipoprotein (VLDL), which circulates abundantly in the plasma of patients with the metabolic syndrome (MetS), is toxic to microvascular endothelial cells. We hypothesize that plasma VLDL from MetS patients (MetS-VLDL) plays a role in neurodegeneration by eliciting inflammation and damage of the neuronal tissue. To test the hypothesis, MetS-VLDL and VLDL isolated from normal control subjects (nVLDL) were used in both *in vitro* and in *vivo* settings.
In primary microglial cultures, addition of MetS-VLDL but not nVLDL (both 5 μg/mL) induced significant TNF-α secretion and microglial activation within 24 hours. In wild-type B6 mice, daily tail-vein injections of nVLDL or MetS-VLDL (15 μg/g/3 times/week) induced significant cognitive dysfunction in 6 weeks, as evaluated by Y-Maze task (n=12, P=0.027). In medial prefrontal cortex brain sections, mild to moderate microglial activation was found in both nVLDL (118%, P=0.053) and MetVLDL (135%, P<0.0001) groups, compared with saline treatment. Moreover, the number of activated macrophages adjacent to brain microvessels was increased mildly by nVLDL (120%, P<0.05) and MetS-VLDL (171%, P<0.0001). These data suggest that long-term exposure to excessive human VLDL can induce perivascular microglial inflammation associated with concomitant cognitive dysfunction in mice. MetS-VLDL, which is rich in electronegative VLDL subfractions, exacerbates the pathological changes of neuronal inflammation. Our findings provide new insights into the link between lipid abnormality and neurodegeneration.

Title: Synergistic effects of BDNF-TrkB and Norepinephrine signaling in treating cognitive dysfunction in a mouse model of Down syndrome

Authors: *R. PONNUSAMY[1], B. MEDINA[2], K. SUMANTH[2], S. MOGHADAM[2], H. BAKKER[2], M. BAKTIR[2], F. S. MOJABI[2], A. FAHIMI[2], M. W. MCNERNEY[1], A. SALEHI[2,3]; [1]Psychiatry, VA Palo Alto, Palo Alto, CA; [2]Psychiatry, Palo Alto Veterans Inst. For Res., Palo Alto, CA; [3]Psychiatry, Stanford Sch. of Med., Palo Alto, CA

Abstract: Down syndrome (DS) or trisomy of human chromosome 21, affects around 400,000 individuals in the US. In addition to varying degrees of learning disability, all adults with DS will develop Alzheimer's disease (AD)-related pathology by the age of 40 years. This makes DS a good model to study molecular mechanisms of cognitive dysfunctions in AD. Previously, we provided evidence that increasing brain norepinephrine (NE) levels and/or improving β2 adrenergic signaling can restore cognitive function in the Ts65Dn mouse model of DS. Moreover, a number of recent studies suggest that there is an interaction between Beta adrenergic receptors and BDNF-TrkB signaling. We hypothesized that increasing Beta adrenergic signaling along with BDNF-signaling can have synergic effects and thus more effectively mitigate cognitive dysfunction. Adult Ts65Dn mice and their controls were given 8 weeks of physical exercise (PE) on a treadmill with or without a long acting β2 adrenergic agonist. These mice then were subjected to various behavioral testing procedures including open field, novel object recognition, and contextual fear conditioning. We found that combining PE and improving NE signaling in Ts65Dn mice had far more superior effects on cognitive function than either treatment alone. Our results provide an unprecedented opportunity to develop a new therapeutic strategy for restoring cognitive functions in both DS and AD.

Title: Metformin improves memory in diabetic mice and the SAMP8 mouse model of Alzheimer's disease

Authors: *S. A. FARR[1], M. L. NIEHOFF[2], M. W. BERGIN[2], E. C. ROESLER[2], R. KOEHLER[2], G. N. SHAH[3], J. E. MORLEY[4];

Abstract: BACKGROUND
There is a growing body of evidence showing an increased risk of Alzheimer's disease (AD) in people with diabetes. Diabetes and AD have common features including abnormal protein processing, abnormalities in insulin signaling, dysregulated glucose mechanism, oxidative stress, the formation of advanced glycation end products, and activation of inflammatory pathways. Metformin, a mainstay of diabetic treatment, may play a neuroprotective role through increased neuronal viability, protection against oxidative imbalance, and attenuation of AD-like pathology. The purpose of the current study was to determine if metformin had an effect on learning and memory in diabetic mice and in the SAMP8 mouse model of AD.
METHODS
In study 1, we examined the effect of metformin on cognition in diabetic mice. Ten week old CD-1 mice were given streptozotocin (150/mg/kg/i.v) to induce diabetes and then treated with metformin for 8 weeks. Behavioral testing started after 4 weeks of treatment. Mice were tested in T-maze foot shock avoidance, novel object recognition and Barnes maze. In study 2, we examined the effect of metformin on learning and memory in the SAMP8 mouse model of AD. Starting at 11 months of age SAMP8 mice were administered metformin daily for 8 weeks. After 4 weeks of treatment the mice were tested in T-maze foot shock avoidance, object recognition and Barnes maze. At the end of treatment brain tissue was collected for mitochondrial BAX analysis.
RESULTS
In study 1, metformin improved T-maze acquisition at both doses and T-maze retention at 200 mg/kg compared to vehicle treated diabetic mice. The mean time spent exploring the novel object was also significant for both doses of metformin in the novel object recognition task. In the acquisition phase of the Barnes maze, treatment with both doses of metformin showed significant improvement in time to target compared to vehicle treated diabetic mice. In study 2, metformin, 20 mg/kg and 200 mg/kg, improved both acquisition and retention in T-maze foot shock avoidance, retention in object recognition, and acquisition in the Barnes maze (20mg/kg). Metformin improved mitochondrial BAX at 20 mg/kg.
CONCLUSIONS
The current studies show that treatment with metformin in STZ-induced diabetic CD-1 mice and in the SAMP8 mouse model of AD was associated with improved learning and memory compared to their respective vehicle treated control mice, suggesting that metformin may play a neuroprotective role in both diabetes and AD. Metformin also decreased mitochondrial BAX in the SAMP8 mice suggesting a positive effect on the mitochondria. The current results suggest that metformin may have therapeutic potential for AD.

Title: Probing the effects of kale, arugula, and dandelion greens on the hippocampus and memory in obese pre-diabetic C57BL/6 mice.

Authors: ***B. TENG**[1], D. FOSTER[1], L. BANNER[2];
[2]Biol., [1]California State Univ. Northridge, Northridge, CA

Abstract: The United States is facing a diabetes epidemic. As the 7th leading cause of death and afflicting nearly 10% of the population, diabetes is well studied and its complications are conspicuous, including a battery of neurodegenerative diseases such as Alzheimer's and other cognitive degradation. Diet-induced obesity is an increasingly common occurrence that predisposes individuals to type-2 diabetes and contributes to complications including those of the nervous system and the immune system. Increased body mass is associated with an elevated risk for neurodegeneration and dementia and changes in hippocampal plasticity and spatial learning among others have been documented. While the exact mechanism has yet to be fully understood, neuro-inflammation is thought to be an important factor in impaired cognitive function. Cytokines involved in the inflammatory response are elevated in brains of animals fed a high fat diet (HFD) and a variety of anti-inflammatory/anti-oxidant treatments can reduce this expression and alleviate cognitive changes. What is not well understood is how the progressive nature of cognitive degradation, as measured by memory loss, manifests itself early in the pre-diabetic stage. Cognitive degradation may be ascribed to neuro-inflammation and differences in diet may either aggrandize or temper its severity. Specifically, we are interested in seeing if adding kale, arugula, or dandelion to an existing obesity inducing diet may taper neuro-inflammation and thus stymie cognitive decline.
To address this issue, C57BL/6 mice were fed either a control (10% fat) or high-fat diet (HFD)(60% fat) for 16 weeks until the high-fat group reached a pre-diabetic stage. After 16 weeks, mice on a HFD weighed significantly more than the control mice, displayed elevated blood glucose levels, and showed deficits in spatial learning. During weeks 17 to 25, the diets of

all the mice were supplemented daily with 1.0 gram of fresh kale, arugula, or dandelion. Consumption of the greens had no effect on the weights of either group. During the green diet period the mice were subjected to multiple repetitions of memory tests, such as the Morris Water Maze, Barnes Maze, and Social Recognition Test, to test for changes in their memory abilities. Our preliminary data from the Morris Water Maze demonstrates that animals fed a high fat diet supplemented with arugula or dandelion performed much better than those on a high fat diet alone or HFD plus kale. At 25 weeks the hippocampi were removed and are being analyzed for a variety of inflammatory and neuronal markers.

Title: Reduced hippocampal functional connectivity with prefrontal cortex during a spatial task in an AD mouse model

Authors: ***S. DING**[1], S. M. NEUNER[1], L. A. WILMOTT[1], T. M. SHAPAKER[1], K. M. S. O'CONNELL[1,2], C. C. KACZOROWSKI[1,2];
[1]Dept. of Anat. and Neurobio., UTHSC, Memphis, TN; [2]Neurosci. Inst. UTHSC, Memphis, TN

Abstract: Both hippocampus (Hip) and medial prefrontal cortex (mPFC) play a critical role in learning and memory. The functional connectivity between the Hip and PFC is thought to be critical for working memory performance and formation of long-term memories, as increased synchronization of neural oscillations of Hip and PFC local field potential (LFP) signals strongly correlate with task performance. Human Alzheimer disease (AD) patients exhibit reductions in the functional connectivity of Hip with other memory relevant brain regions, however, it is unclear whether these changes are a cause or consequence of disease. The 5XFAD mouse model of AD recapitulates deficits in learning and memory observed in AD patients, including deficits in spatial working memory, although changes in functional connectivity in this model have not been examined. We hypothesized that, like human AD patients, Hip-mPFC coherence is

disrupted in the 5XFAD model. To test this hypothesis, custom designed shank electrodes were implanted into Hip and mPFC (both prelimbic cortex (PL) and infralimbic cortex (IL)) of 8-10 month old sex-balanced 5XFAD and wild-type (WT) mice. Following five days of post-surgical recovery, LFP signals of Hip and mPFC were recorded while they were awake and resting quietly in their home cage (resting state) or on the Hip-dependent T-maze task. Hip-mPFC coherence of AD and WT mice was compared in different LFP frequency bands: delta (1-3Hz), low theta (3.01-7Hz), high theta (7.01-12Hz), beta 1 (12.01-20Hz), beta 2 (20.01-30 Hz), and gamma (40-60Hz). Analysis of our results indicated that during the resting state, there was no significant difference in the Hip-mPFC coherence across all frequency bands measured in WT and AD mice. However, the task-specific increase in the coherence of Hip-mPFC in delta and theta frequency bands in WT mice was significantly reduced in age-matched AD mice. These results demonstrate that the 5FXAD model adequately recapitulates deficits in Hip-mPFC coherence observed in human AD patients. Ongoing experiments in the laboratory aim to establish whether these changes occur prior to or after the onset overt memory deficits, and to determine mechanisms mediating changes in Hip-mPFC functional connectivity.

Title: Non-invasive early detection of neuroprotection by high-field MRI in periventricular leukomalacia: a preclinical study

Authors: *W. C. PIERRE[1,2], L. AKAKPO[3], I. LONDONO[1], F. LESAGE[3], P. POULIOT[3], G. A. LODYGENSKY[1,2];
[1]Ctr. De Recherche Du CHU Sainte-Justine, Montreal, QC, Canada; [2]Pharmacol., Univ. de

Montréal, Montreal, QC, Canada; [3]Electrical Engin., École Polytechnique de Montréal, Montreal, QC, Canada

Abstract: Introduction: Preterm inflammation-induced white matter injury (WMI) is associated with well-known neurocognitive impairments. Early monitoring of neuroprotection with a non-invasive tool such as magnetic resonance imaging (MRI) could greatly improve the development of therapeutic approaches. Among neuroprotective agents, Anakinra, an antagonist of interleukin-1 receptor (IL-1Ra), has previously showed beneficial effects in an animal model of WMI. Objective: Using diffusion tensor imaging (DTI) as a non-invasive monitoring tool, we evaluated the early neuroprotective effect of IL-1Ra in neonatal rats subjected to WMI. Methods: P3 Rat pups received LPS (1mg/kg) or sterile saline injections in the corpus callosum. A subset was treated with three i.p. injections of IL-1Ra (2 mg/kg). 24h post-injection, 13 animals (7 sham, 3 LPS, 3 LPS+IL-1Ra) were imaged on a 7 tesla scanner. DTI was acquired using spin echo standard sequence with dual scheme with b-values of 0 and 700 s/mm^2 with a voxel resolution of 230 x 120 x 600 µm. ROIs were placed on the ipsilateral cingulum. Kruskal-Wallis test was used for statistical comparisons. Results are normalized with the sham group. Apoptosis and inflammatory status were assessed in the three groups. Results: In accordance with previous results (Lodygensky et al. Pediatric Res 2014), LPS injection causes a decrease in diffusivity in the acute phase. This decrease is significantly limited for animals that underwent IL-1Ra injections. Fractional anisotropy did not come out as a reliable biomarker for assessing acute WMI. Primary blind qualitative evaluation of apoptosis revealed a sharp decrease in fractin expression in treated animals. Furthermore, IL-1Ra treatment decreased RNA expression of pro-inflammatory genes iNOS, IL-1 and IL-6. Conclusion: DTI allowed early detection (in the 24h post-injury) of neuroprotective effect of IL-1Ra which correlated with a reduction of pro-inflammatory gene expression. More animals are currently being scanned with thorough quantitative immunohistochemistry analysis and evaluation of pro- and anti-inflammatory gene expression. Our results suggest MRI is a non-invasive tool allowing early monitoring of therapeutic response in neonates.

Table 1:ROIs analysis for the different diffusion scalar maps extracted from the diffusion tensor.

DTI Scalar Map	LPS (n=3)	LPS+IL-1Ra (n=3)	p-value
Mean Diffusivity	-42.38 %	-24.14 %	**0.0258**
Axial Diffusivity	-38.04 %	-20.34 %	**0.0129**
Radial Diffusivity	-46.32 %	-27.61 %	**0.0336**
Fractional Anisotropy	48.73 %	45.99 %	0.2893

Title: Liraglutide ameliorates intracerebral insulin resistance in "Brain Diabetes" rats

Authors: *A. S. SHINGO[1], T. KANEBAYASHI[2], S. KITO[3], T. MURASE[1];
[1]Okinaka Mem. Inst. For Med. Res., Minato-Ku, Tokyo, Japan; [2]Biopathology Inst., Ohita, Japan; [3]Shonan-Fujisawa Tokushu-kai Hosp., Kanagawa, Japan

Abstract: Intracerebrally streptozotocin injected rats (STZ-3V rats), what we call "Brain Diabetes" rats, show impaired spatial cognition and are considered a model of Alzheimer's disease. On the other hand, it has been established that insulin receptors are widely distributed throughout the brain including the hippocampus. Besides, insulin biosynthesis within the brain, especially in the hippocampus has been confirmed. In this study, we examined phosphorylation state of IRS-1(insulin receptor substrate-1) in the STZ-3V rat hippocampus and effects of liraglutide (a GLP-1 receptor agonist) on the IRS-1 phosphorylation. As methods, phosphorylation state of IRS-1 in the hippocampus of STZ-3V rats was examined by immunohistochemistry before and after 0.037ug/kg liraglutide administration. As the results, in the hippocampus of STZ-3V rats, a decrease of tyrosine phosphorylation accompanied by an increase of serine phosphorylation was observed. Administration of liraglutide induced improvement of tyrosine/serine phosphorylation ratio. It is concluded that in the "Brain Diabetes" rats there was an elevation of insulin resistance that was inhibited by liraglutide administration. The results suggested possibility of liraglutide as a therapeutic drug against Alzheimer's disease.

Title: Suppress sodium channel activity as a new potential therapeutic target for Alzheimer's disease

Authors: *S. LI[1], X. WANG[1], C. Y. JIANG[1], X. G. ZHANG[1], Q. H. MA[2], J. ZHAO[1];
[1]Dalian Med. Univ., Liaoning, China; [2]Soochow Univ., Suzhou, China

Abstract: Aberrant increases in neuronal network excitability may contribute to the cognitive deficits in Alzheimer’s disease (AD). However, the mechanisms underlying hyperactivity are not fully understood. Using patch clamp techniques, we found elevated neuronal excitability due to modulation of the voltage-gated sodium channel by amyloid beta (Aβ1-42). Immunohistochemistry and western blot results showed that the intrinsic neuronal hyperexcitability of human amyloid precursor protein (APP) / presenilin 1 (PS1) transgenic mice might be due to an increased expression of voltage-dependent sodium channels subtype. Blocking the overexcitation of the neural network with lamotrigine (LTG), which is a sodium channel blocker applied in a broad-spectrum treatment of epilepsy, suppressed abnormal spike activity, prevented the loss of spines, synaptophysin immunoreactivity, and neurons, and thus attenuated the deficits in synaptic plasticity and learning and memory in APP/PS1 transgenic mice. Scorpion venom heat-resistant peptide (SVHRP) extracted from nature product Buthus martensii Karsch (BmK) venom could rescue the learning and memory deficits in AD animal model. The mechanism might be related with suppressing sodium channel currents and inhibiting the neuronal excitability. Moreover, the levels of brain-derived neurotrophic growth factor (BDNF) were enhanced in the brains of APP /PS1 mice by the chronic both SVHRP and LTG treatment. Therefore, these observations demonstrate that LTG or SVHRP attenuates AD pathology through multiple mechanisms, including modulation of abnormal network activity, reduction of the generation of amyloid beta and upregulation of BDNF. This study has brought sodium channel blocker as a new strategy, especially the potential application of antiepileptic drugs (AEDs), in AD therapy.

Title: The impact of midazolam on the expression of the circadian rhythm protein Per2

Authors: *J. J. GILE, D. SEHRT, B. SCOTT, T. ECKLE;
Anesthesiol., Univ. of Colorado, Denver, CO

Abstract: Critical care units are a major cause of a disrupted circadian rhythm in patients. Interestingly, circadian disruption is frequently associated with the occurrence of delirium having a high impact on outcome and mortality in the critically ill. It has been shown that prolonged exposure to benzodiazepines (such as midazolam) and, to a lesser extent opiates, contributes to the development of delirium. Here we tested the effect of midazolam and other sedatives on the expression of the circadian rhythm protein Period 2 in different organs from mice. All animal experiments were performed in accordance with the APS/NIH guidelines for the use of laboratory animals. Expressional levels of Per2 were assessed by real-time RT-PCR in different organs from mice using midazolam, propofol, fentanyl, ketamine or isoflurane. Midazolam caused a significant downregulation of Period 2 in all organs investigated. The other sedatives had no effect or little on Per2 expression with the exception of ketamine, which increased Per2 in the lung and decreased Per2 in the liver. Midazolam consistently downregulates Per2 in different mouse organs. As midazolam has been found to play a critical role in the development of delirium we suggest that midazolam mediated downregulation of Per2 represents a potential mechanism in the development of delirium. Further studies using a mouse model for delirium will be necessary to further elucidate the underlying mechanism.

Title: Gross Motor Skills, PET imaging study and trajectory analysis of hemiparkinsonian rats after dopamine supply restitution through a TiO_2DA implant placed in striatum.

Authors: *D. A. VÁZQUEZ MATÍAS[1], G. VALVERDE AGUILAR[3], R. MAYEN DÍAZ[2], H. GONZÁLEZ SÁNCHEZ[2], S. HERNANDEZ CASTRO[2], A. MONZÓN MIRELES[2], P. VERGARA ARAGÓN[2];

Abstract: The aim of this study was to assess the effect produced by the placement of a dopamine releasing reservoir in the striatum of hemiparkinsonian rats on the gross motor alterations, imaging evaluation, and trajectory behavior. Methods: 50 male Wistar rats divided in four groups: A) 8 Sham rats, B) 12 hemiparkinsonian rats induced by administration of the 6-OHDA neurotoxin (8µg/4µl) via stereoscopic surgery in left substantia nigra (Lx), C) 20 hemiparkinsonian rats induced alike Lx rats, and later placement of a dopamine reservoir made of titanium dioxide (Lx+TiO2DA) and D) 10 rats only with placement of the dopamine reservoir (TiO2DA). 180 days after hemiparkinsonism induction in the groups Lx and Lx+TiO2DA, all the groups underwent to apomorphine induced rotational test to evaluate the damage in the dopaminergic system, gross motor performance and path were analyzed in the open field test. Positron Emission scans were performed on left and right striatum measuring the uptake of the tracer 11[C]-DTBZ to obtain a measurement of the nigrostriatal pathway. Once finalized the evaluations the data was analyzed by one-way ANOVA and multiple comparisons Tukey's test; p values < 0.001 were considered significant. Results: Apomorphine rotational behavior showed an increased number of spins in Lx compared to Sham, Lx+TiO2DA and TiO2DA Groups: 295.2 ± 10.1 vs 4.4 ± 0.8, 30.1±4.2 and 11.0±2.9. Lx+TiO2DA and TiO2DA do not present differences compared to the Sham Group. Open field test revealed a decrease in gross motor activity assessment in Lx animals vs Sham, Lx+ TiO2DA and TiO2DA groups: 16.1±2.8 vs 106.5±4.6, 97.5±7.6 and 122.2±5.8. Lx+TiO2DA and TiO2DA do not present differences compared to the Sham Group. At the day 180, Sham animals follow a path close to the open field walls, Lx animals either move to the center of the field or remain immobile in one place. Lx+TiO2DA use to move surrounding the field and visit the center occasionally. TiO2DA animals move fast

around the field and usually visit the center. PET scans disclosed on the left striatum an increase of uptake in the injured animals compared to implanted and Sham animals. The right striatum displayed the same pattern. Conclusion: This study has revealed an effective dopamine supply restitution by the implantation of a titanium dioxide dopamine reservoir, which is evident by the improvement of Lx+TiO2DA animal's performance in the rotational behavior and open field test; as well as, an enhancement demonstrated on 11[C]DTBZ uptake in Lx+TiO2DA animals, which suggest a recovery in the dopaminergic striatal innervation.

Title: Regulated GDNF delivery shows transient neuroprotective effect

Authors: *L. QUINTINO[1,2], L. BREGER[2], M. LUNDBLAD[2], C. ISAKSSON[2], C. LUNDBERG[2];
[1]Wallenberg Neurosci. Ctr., Lund, Sweden; [2]Lund Univ., Lund, Sweden

Abstract: Glial cell-line derived neurotrophic factor (GDNF) is a therapeutic factor for the treatment of Parkinson's Disease (PD). However, overexpression of GDNF in the brain causes side-effects. Our group has used destabilizing domain technology to induce GDNF (GDNF-DD) expression in vivo. Induction of gene expression would enable GDNF to protect neurons while turning off the expression of GDNF would prevent side-effects. The aim of this study was to determine how long the neuroprotective effect of GDNF-DD could be maintained after GDNF-DD expression was turned off. To achieve this, lentiviral vectors expressing GDNF, GDNF-DD or regulated yellow fluorescence protein (YFP-DD) were delivered to the striatum of rats. Three

days after vector delivery, GDNF-DD and YFP-DD expression was turned on for 9 weeks. Three weeks after vector delivery the animals were lesioned with 6-OHDA. Groups of animals were analysed for behaviour, amperometry and their brains were processed for histology at several timepoints. Six weeks after lesion, while GDNF-DD expression was induced the GDNF group had 75% remaining neurons in the substantia nigra (SN). The GDNF-DD group had 50% remaining neurons whereas the YFP-DD group had only 18% remaining neurons in SN. While at later weeks, when expression was turned off, the GDNF group maintained the level of neuroprotection, while the GDNF-DD group lost the neuroprotective effect to levels comparable to the YFP-DD group This study indicates that while constant overexpression of GDNF has deleterious effects, there needs to be a fine regulation of GDNF to maintain the therapeutic effect.

Title: Antisense oligonucleotide reduction of human alpha-synuclein accumulation in dopamine and serotonin neurons prevents early dysfunctions in a mouse model of Parkinson's disease

Authors: D. ALARCON-ARIS[1], E. RUIZ-BRONCHAL[1], A. MONTEFELTRO[2], F. ARTIGAS[1], *A. BORTOLOZZI[3];
[1]IIBB - CSIC - IDIBAPS, Barcelona, Spain; [2]nLife Therapeut., Granada, Spain; [3]IDIBAPS, Barcelona, Spain

Abstract: Multiple convergent lines of evidence implicate α-synuclein (encoded by *SCNA*) in the pathogenic of Parkinson's disease (PD). α-Synuclein is a protein that accumulates in the brain of patients with sporadic PD. Likewise, whole locus multiplications and point mutations in

the α-synuclein gene cause a familial form of PD. Previously, we developed a mouse model that overexpress wild-type human-α-synuclein in the AAV5 vector (donated by MJF foundation) in dopamine (DA) neurons of the substantia nigra compacta (SNc) and ventral tegmental area (VTA) as well as in serotonin (5-HT) neurons of the raphe nuclei (RN). These mice showed increased human-α-synuclein mRNA levels in the ipsilateral SNc (278% of sham mice) and RN (290% of sham mice), but they did not display any loss of tyrosine hydroxylase-positive DA neurons or tryptophan hydroxylase-positive 5-HT neurons at 16 weeks post-injection. Moreover, reduced DA and 5-HT release paralleled with development of α-synuclein-positive axonal swelling in striatum, hippocampus and cerebral cortex were found in the AAV5 model. In addition, AAV5 mice exhibited motor deficits at 8 weeks post-infection into SN and depressive-like behaviors (tail suspension and forced swim tests) at 4 weeks post-infection into RN. Here, we evaluated whether reducing human α-synuclein expression in the mesencephalic nuclei prevented early dysfunctions in the AAV5 model. We used a conjugated antisense oligonucleotide targeting intracellular human α-synuclein (ASO1337) selectively in DA and 5-HT neurons. Mice overexpressing human α-synuclein in the SNc/VTA or RN were treated intracerebroventricularly with ASO1337 (30 or 100µg/day) during 28 days using osmotic minipumps implanted subcutaneously. Control groups received vehicle or nonsense ASO sequence (ASO1227) in the same conditions. ASO1337 reduced dose-dependent the human α-synuclein mRNA levels (vehicle: 0.76±0.04; ASO1337 30µg/day: 0.46±0.05; ASO1337 100µ/day: 0.35±0.03, arbitrary units), whereas endogenous α-synuclein and γ-synuclein expression remained unaltered. Immunohistochemistry analysis confirmed these results showing the reduction of human α-synuclein protein density. Furthermore, recovery of striatal DA release could be achieved by reduction of human-α-synuclein expression in SNc/VTA. Recent data showed that intracerebroventricular ASO1337 infusion (100µg/day, 28 days) also decreased human α-synuclein mRNA expression in the RN of AAV5 mice compared to control groups. Our study indicated that the ASO-induced reduction of intracellular α-synuclein accumulation selectively in DA and 5-HT neurons using ASO molecules represents an optimal PD therapy.

Title: Pramipexole combined with transfection of the BDNF gene restores motor coordination in a bilateral model of Parkinson disease in the rat.

Authors: *A. N. BENITEZ[1], P. REYNA[1], A. ESPADAS[1], A. SIERRA[1], V. ANAYA[3], B. FLORÁN[1], D. MARTÍNEZ-FONG[2], J. ACEVES[1];

Abstract: Pramipexole mediates its therapeutic action on motor deficits in Parkinson's disease mainly via dopamine D3 receptors of the direct and indirect striatofugal pathways. It has also a protective action inducing the expression and secretion of BDNF, which promotes the survival of dopaminergic neurons and enhances dendritic arborization. Here we assessed the immediate and long-term effects of Pramipexole in a bilateral model of PD to test its impact on motor and non-motor behavior. Pramipexole was administered continuously during 4 ½ months via osmotic pumps and the BDNF gene was transfected to the dopamine nigral neurons using a non-viral transfection method (Gonzalez-Barrios et al., 2006). After one month of the 6-OHDA lesion, we tested the acute effect Pramipexole (1 mg/Kg). It restored locomotor and ambulatory activity, walking speed and motor performance evaluated by the rotarod and beam tests, thus showing that Pramipexole controls the motor deficits induced by the bilateral lesion. Since the therapeutic efficacy of Pramipexole eventually wears off, we evaluated the effect of its chronical and continuous administration combined with the non-viral BDNF gene transfection into the remaining nigral neurons, to assess whether it could modify the course of the parkinsonian condition. The combined treatment restored the motor performance, recovering the crossing time in the beam test and the overall rotarod performance to values similar to those of control normal rats. Untreated animals showed none recovery. The motor recovery was observed starting at 1.5 months of the combined treatment and lasted even 2 months after Pramipexole withdrawal. The bilateral lesioned rats showed a permanent reduced ambulation in the open-field compared with normal rats. The combined treatment did not recovered the ambulation to normal. Since the open-field test evaluates anxiety in a novel environment, these results suggested that the combined treatment did not control the anxiety associated with the dopamine lesion. This assumption was confirmed using the burying test to assess anxiety. The test revealed that the bilateral lesion significantly increased the burying time and that the combined treatment did not reduced the time to normal, indicating that it did not control the anxiety produced by the lesion. Diazepam reversed the anxiety of the treated group but not that of the untreated one. Results suggest that the combined treatment induces plastic changes that result in a permanent recovery of motor behavior, but it did not control the anxiety associated with the dopaminergic depletion.

Abstract: It is now widely accepted that compensatory mechanisms are involved during the early phase of Parkinson's disease (PD) to delay the expression of motor symptoms. However, the neurochemical mechanisms underlying this presymptomatic period are still unclear. Objective: Determine the effects that an implant TiO2DA inserted in the caudate in a rat model hemiparkinsonism on motor behavior and its correlation with the in vivo binding of [11-C] raclopride to D2 dopamine receptors in the basal ganglia of rats with hemiparkinsonism. Each rat underwent a PET study, before and after of treatment with microimplant. Material and methods: Male Wistar rats (250-300gr) were used, which were randomly divided into 4 groups: a) Sham b) Lesioned (Lx); c) Lx+implant; d) Implant. Post-lesion for 21 days anxiety behavior and locomotor activity of the rats of each group through the open field test was evaluated. The test was conducted in an acrylic box (with transparent walls and floor), whose floor is divided with painted black lines forming's squares and illuminated with floodlights. The test was recorded for five minutes; the following measurement parameters were assessed: total distance traveled and the number of crossed lines marked on the floor. The tests were recorded. In each group analysis of microPET was done, each rat underwent a PET study, before and after of treatment with microimplant. Results: The implant induced an increase in the in vivo binding of [11C] raclopride in the striatum of hemiparkinsonian rats. This observation indicates that there is a higher amount of transporters bound to striatal dopamine; higher dopamine levels were found in the Lx+Imp group than in the Lx group as well as a larger number of dopaminergic neurons in striatum in the histological analysis. Conclusions: This observation indicates that in hemiparkinsonian rats, the microimplant with dopamine produce an increase in extracellular

levels of dopamine sufficiently to inhibit raclopride binding, this effect probably due to dopamine release from TiO2DA matrix implanted in caudate nucleus.

Title: Addressing limb use asymmetry in the unilaterally dopamin depleted parkinsonian rat by combining optogenetics and microdialysis in freely-moving animals

Authors: ***P. K. BHUPAL**[1], J. LYNN[2], J. TURNBULL[1], J. HOVATER[1], K. ANDERSON[1], T. ARVOY[1], K. HOOLSEMA[1], T. LEDY[1], T. TIBBE[1], K. NICHOLSON[1], E. BURKETT[1], M. SANDSTROM[1];
[1]Neurosci., Central Michigan Univ., MT Pleasant, MI; [2]Wayne State, Detriot, MI

Abstract: Optogenetics is an emerging tool in neuroscience that can provide temporally accurate neuronal stimulation of select populations of neurons and to date the large majority of experiments have used this in the context of single-unit electrophysiology. Yet an emerging concern is that the phasic control of dopamine (DA) release in the context of replacement therapy for Parkinson's disease may provide both improved movement control and prolonged therapeutic success. Our laboratory has been designing a way to address the value of phasic DA release within the striatum of otherwise unilaterally DA-depleted rats. To accomplish this we will combine the use of optogenetics with light-sensitive DA-releasing cell transplants and microdialysis for DA measurement in freely moving rats. Initially such DA source cells will be generated from mesenchymal stem cells and transfected with channelrhodopsin II, and our capacity to stimulate controlled levels of DA from these cells will be tested in-vitro. Subsequently such DA source cells will be transplanted into the striatum of a unilaterally DA-depleted rat in order to demonstrate light-stimulated-DA-release-related behavioral symmetry restoration. There are two ways to demonstrate the value of phasic release in the context of replacement therapy for Parkinson's disease. One would be to show that standard basic tonic release is insufficient to restore controlled behavior, and the other would be to show that induced phasic release engaged in an *as-needed* manner is capable of supporting complex movement behaviors. Our technique should be able to address both of these concerns.

Title: The neuroprotective potential of intranasal DNSP-11 in an intrastriatal 6-hydroxydopamine rat model: a behavior and cellular study

Authors: ***C. M. FOX**[1], M. SPENCER, 18018[2];
[1]Biol. Sciences/Neuroscience Program, [2]Neurosci. Program, Moravian Col., Bethlehem, PA

Abstract: Using both *in vitro* and *in vivo* studies, glial cell line-derived neurotrophic factor (GDNF) became known as one of the more promising neurotrophic factors in its ability to protect dopamine neurons against neurotoxic insult in animal models of Parkinson's disease (PD). The proprotein version of GDNF has been post-translationally processed into a dopamine neuron stimulating peptide, known as DNSP-11. DNSP-11 has been shown to be neuroprotective against TaClo, MPP+ and an intranigral 6-hydroxydopamine (6-OHDA) lesion in rat models of PD. This research project used a different approach to introducing DNSP-11 into the animal model prior to the lesion. An intranasal DNSP-11 technique was used to assess the protection of nigral dopamine neurons against the more progressive intrastriatal lesion of 6-OHDA. Twenty Fisher 344 rats were divided into the following groups: citrate + 6-OHDA and DNSP-11 + 6-OHDA. Citrate or DNSP-11was delivered intranasally 5 days per week for 8 weeks postlesion. The foot fault and cylinder tests were performed to assess behavior improvements following treatment. Brain tissue was processed for tyrosine hydroxylase immunocytochemistry and dopamine cell survival in the substantia nigra was quantified.

Abstract: The aim of this study was to assess the effect produced by the placement of a dopamine releasing reservoir in the striatum of hemiparkinsonian rats on fine motor performance, and describe the histological findigs in striatum after 180 days of treatment. Methods: 50 male Wistar rats divided in four groups: A) 8 Sham rats, B) 12 hemiparkinsonian rats induced by administration of 6-OHDA (8µg/4µl) via stereoscopic surgery in in left substantia nigra (Lx), C) 20 hemiparkinsonian rats induced alike Lx rats, and later placement of a dopamine reservoir made of titanium dioxide (Lx+TiO2DA) and D) 10 rats only with placement of the dopamine reservoir (TiO2DA). 21 days after hemiparkinsonism induction in the groups Lx and Lx+TiO2DA, all the groups underwent to apomorphine induced rotational test to evaluate the damage in the dopaminergic system. Additionally, after 180 days of dopamine reservoir placement, skilled reaching was measured using the Eshkol - Wachman scale. Once finalized the evaluations, animals were slaughtered to obtain the brains and the neuron density was analyzed by optical microscopy. Data was analyzed by one-way ANOVA and multiple comparisons Tukey´s test; p values < 0.001 were considered significant. Results: Apomorphine rotational behavior showed an increased number of spins in Lx compared to Sham, Lx+TiO2DA and TiO2DA Groups: 295.2 ± 10.1 vs 4.4 ± 0.8, 30.1±4.2 and 11.0±2.9. Lx+TiO2DA and TiO2DA do not present differences compared to the Sham Group. Measurement of successfully reached pellet attempts revealed a diminishment of reached pellets in Lx animals compared to Sham, Lx+TiO2DA and TiO2DA groups: 8.0±0.4 vs 16.1±0.6, 12.1±0.6 and 13.75±0.6. Lx+TiO2DA animals didn't show differences in skilled reaching task either with Sham or TiO2DA groups.

Histological analysis revealed significant changes in the neuronal populations in striatum where Lx group showed less population than Sham, Lx+TiO2DA and TiO2DA Groups; as well as, when the location of the reservoir was analyzed, it didn't display histopathological data suggesting chronic inflammatory changes, such as cellular edema, gliosis or mononuclear infiltrate in the tissue surrounding the reservoir. Conclusion: Behavioral results in rotational and skilled reaching demonstrate the improvement produced by the dopamine reservoir in Lx+TiO2DA animals reducing the number of spins and increasing the Eshkol-Wachman score compared to Lx animals who displayed a poor performance during both test. Histological analysis demonstrate that the reservoir do not present significant tissue alterations.

Abstract: Cell replacement therapy holds tremendous promise for the treatment of neurodegenerative diseases such as Parkinson's Disease (PD). However, the lack of a reliable and suitable source of donor cells has limited the widespread application of this treatment modality in the clinic. The advent of induced pluripotent stem cell (iPS) technology has opened up the

possibility for autologous cell therapy. Based on the knowledge that iPS can inherit certain properties of their parental somatic cells via epigenetic transmission, we postulate that deriving iPS from tissues that inherently display reduced immunogenicity and that are genetically pristine could generate an ideal universal donor cell for allogeneic transplantation. The human umbilical cord is an immuno-privileged organ that mediates interactions across the feto-maternal interface. Additionally, its relative nascence implies that it accumulates less somatic mutations compared to adult cells. Capitalizing on these beneficial properties, we derived transgene integration- and feeder-free iPS from cells isolated from the subamniotic lining of the human umbilical cord. Designated as Cord Lining iPS (CLiPS), these iPS showed robust trilineage differentiation either by teratoma formation or directed differentiation in vitro. We further demonstrated that CLiPS can be directed to differentiate into dopaminergic (DA) neurons, the specific neuronal subtypes lost in PD. Transplantation of neuroprogenitor cells (NPCs) primed towards DA fate into the brains of 6-hydroxydopamine induced mouse PD model suggests that these cells can robustly engraft and survive for up to a month in an immunocompetent C57/BL6 mice in the absence of pharmacologic immunosuppression. Furthermore, these NPCs showed efficient differentiation into tyrosine hydroxylase immunoreactive DA neurons. We showed using [18F]FE-PE2I PET imaging that CLiPS-derived NPCs restored dopamine reuptake function in lesioned brains 6 months after transplantation. Behavioral assays revealed statistically significant recovery of motor deficits in transplanted mice. In contrast, no engraftment or behavioral recovery was observed in mice transplanted with human adult iPS-derived NPCs. In summary, we provide proof-of-concept evidence that CLiPS can be used as a source of donor cells for allogeneic cell replacement therapy of PD and potentially other neurodegenerative disorders.

Title: Optogenetic inhibition of STN rescues motor defects in parkinsonian rodents.

Authors: *T. NGUYEN-VU[1], L. LEUNG[2], A. ALLAWALA[2], C. ARNOLD[2], D. ZWILLING[2], R. SAWATZKI[2], M. KAPLITT[2];
[1]Neurobio., [2]Circuit Therapeut., Menlo Park, CA

Abstract: Parkinson's disease is a motor neurodegenerative disorder characterized at least in part by hyperactivity of the subthalamic nucleus (STN). Although deep brain stimulation (DBS) targeted to the STN is a therapeutic option, its underlying mechanism continues to be a subject of debate. While DBS mimics the effects of destructive lesioning, there is also evidence to support the belief that DBS changes firing patterns, or even drives STN firing. Certain DBS effects have also been ascribed to stimulation outside of the STN in the zone incerta. Using optogenetics, we tested whether functional lesion of the STN can provide therapeutic rescue in 6-OHDA induced hemi-parkinsonian rodents. We confirmed functional inhibition of STN by electrophysiological optrode recording in anesthetized and awake head-fixed rodents. In freely moving hemi-parkinsonian rodents, we were able to show therapeutic rescue of motor function by optogenetic inhibition of the STN. The efficacy of this motor rescue was titratable, in that it was dependent on the intensity of the light and was apparent through multiple behavioral assays. Optogenetic inhibition of the STN in 6-OHDA lesioned rodents attenuated the pathological ipsilateral rotation evoked by amphetamine treatment, and induced contralateral rotation in the absence of any drug treatment. In the same hemi-parkinsonian rodents, light treatment also increased motor activity in an open field assay, improved gait in the catwalk assay, and normalized forelimb preference in the cylinder assay. These results support STN inhibition as a potential therapeutic strategy for treatment of Parkinson's disease.

Title: A dopamine release from microimplant with nanopores and its effects on neuron density and behavior in a hemiparkinsonian rat model.

Authors: *R. GONZALEZ-TREJO[1], S. HERNANDEZ CASTRO[2], V. E. ACEVES SIERRA[2], G. VALVERDE AGUILAR[3], P. VERGARA ARAGÓN[2];
[1]Phisiology, Univ. Nacional Autónoma De Mexico, Ciudad de Mexico, Mexico; [2]Facultad de

Medicina. Univ. Nacional Autonoma de Mexico, Ciudad de Mexico, Mexico; [3]CICATA LEGARIA. Inst. Politécnico Nacional, Ciudad de Mexico, Mexico

Abstract: The purpose for this study was to evaluate the effects produced by a TiO2 microimplant made with nanoporos able to release dopamine molecules, which is placed in caudate nucleus, over motor impairment and neuronal density in Substantia Nigra, and determine whether there is a correlation between neuronal density and gyrus behavior test. Materials and Methods: 40 male Wistar rats divided in 4 groups were utilized: A) 10 control rats: (Control), B) 10 injured rats by 6-OHDA 8μg/4μl through stereoscopic surgery in left and right median forebrain bundle: (Lx), C) 10 rats with the same lesion and the colocation of a micro-implant made of titanium dioxide: (Lx+TiO2DA), and D) 10 rats only with the colocation of micro-implant: (TiO2DA). 21 days after the injury all groups were underwent to the rotational induced test with apomorphine (0.05 mg/kg, sc) during 50 minutes in order to determine damage in dopaminergic system, this test was performed again 360 days after the colocation of the micro-implant. Once finalized the test, the animals were slaughtered to obtain the brains and the neuron density was analyzed by optical microscopy. p values <0.0001 were considered significant. Results: In the rotation induced test, the following results were found at 360 day: the Lx group showed more twists than control, Lx + TiO2DA and TiO2DA groups: control vs Lx (4.4±2.6 vs 301.3±19.0), control vs Lx+TiO2DA (4.4±2.6 vs 31.8±14.9), Lx vs Lx+TiO2DA (301.3±19.0 vs 31.8±14.9), Lx vs TiO2DA (301.3±19.0 vs 9.5±7.1), and Lx+TiO2DA vs TiO2DA (31.8±14.9 vs 9.5±7.1). Analysis of neuronal density in left Substantia Nigra were found 5 significant results, where groups with implants and control had a higher neuronal density than injured groups: Control vs Lx (8.3 ± 1.5 vs 0.5 ± 0.5), control vs Lx + TiO2DA (8.3 ± 1.5 vs 5.7 ± 1.0) , Lx vs Lx + TiO2DA (0.5 ± 0.5 vs 5.7 ± 1.0), TiO2DA vs Lx (0.5 ± 0.5 vs 9.5 ± 1.5), Lx + TiO2DA vs TiO2DA (5.7 ± 1.0 vs 9.5 ± 1.5). On the right side were found 3 significant results where the implanted and control groups had a higher neuronal density than injured groups: Control vs Lx (8.8 ± 1.2 vs 4.8 ± 0.8), Lx vs Lx + TiO2DA (4.8 ± 0.8 vs 7.8 ± 1.5) and Lx vs TiO2DA (4.8 ± 0.8 vs 9.6 ± 3.0). The Pearson correlation between neurons of both left and right Substantia Nigra in the induced rotational behavior showed a negative association with coefficient: r = -0.9458; r = -0.9641 for each case. Conclusion: The present results indicate that microimplant gets reverse engines changes produced by the lesion with 6-OHDA in rats with hemiparkinsonism, as observed in the Lx + TiO2DA group which decreased their number of rotations, likewise the Lx + TiO2DA rats showed a higher neuronal density than Lx rats.

Title: TiO_2DA micro-implant can reverse the motor skill alterations caused by 6-OHDA in the reaching for single pellet in a hemiparkinson rat model.

Authors: *P. VERGARA-ARAGON[1], G. VALVERDE AGUILAR[2], R. GONZALEZ TREJO[3], H. GONZALEZ SANCHEZ[4], M. PALOMERO RIVERO[5];
[1]Facultad De Medicina, Mexico DF, Mexico; [2]CICATA LEGARIA. Inst. Politécnico Nacional, Ciudad de Mexico, Mexico; [3]Facultad de Medicina. Univ. Nacional Autonoma de Mexico, Ciudad de Mexico, Mexico; [4]Fisiología. Facultad de Medicina. UNAM, Ciudad de Mexico, Mexico; [5]Inst. de Fisiología Celular, Ciudad de Mexico, Mexico

Abstract: Introduction: Neurodegenerative diseases such as Parkinson's can cause severe motor deficits in skilled forelimb use in both humans and rats. These deficits are typically analyzed in a reach-to-eat paradigm. Therefore, rats serve as an excellent tool to monitor the development of deficits after neurological insults and the single pellet reaching test is a paradigm that involves detailed rating and analysis of qualitative aspects of the reaching movement itself. Objective: The purpose of this research was to evaluate the temporal stability of dopamine in a titanium dioxide matrix (TiO2/DA) in vivo and in vitro and to determine if this micro-implant TiO2DA/DA can reverse motor skill alterations caused by 6-OHDA in the reaching for single pellet in a hemiparkinson rat model. Material and Methods: Sixty four Wistar rats were used, divided into 4 groups: Sham, Lx (hemiparkinsonian), Lx + micro-implant, and micro-implant only. Induced rotation test and single-pellet reaching task were performed on days 0, 1, 21, 90, 180 and 360 days after the insertion of the micro-implant in caudate nucleus. Previously the states of dopamine oxidation were evaluated using infrared spectroscopy. Results: It was possible to evidence stabilization of dopamine molecules 720 hours in vitro and at least during the 360 days that the implant remained in the rat's brain. Significant differences were shown between the Lx group and the control in all the applied tests. Significant differences were also found between the Lx and the Lx+Imp groups, with reports of improvement in the implanted group; Less induced rotations and better performance in the fine motricity assessment (reaching task).These results suggest that probably dopamine was released from its reservoir in the striatum; evidenced by a significant gross motor skill improvement during the 360 days of the experimental evaluation. This motor skill improvement was associated with the presence of dopamine coming from the dopaminergic that was successfully stabilized. Conclusion: Microimplant placement (TiO2DA) in hemiparkinsonian rats improved fine motor skill task, probably due increased levels of dopamine in caudate nucleus. These findings are promising for

the use of these micro-implants as alternative treatment for humans with Parkinson's disease in the near future. Advantages of this treatment are its easy and fast elaboration, microscopic size, low cost, less invasive application, and immediate benefits on the motor disturbances presented by the animals with hemiparkinsonism.

Title: Evaluation of the effects of the treatment with gm1 ganglioside in a model of parkinsons disease in rats

Authors: *D. A. SANTOS, III[1,2], P. OLIVEIRA[2], L. BRITTO[2];
[1]Inst. of Biomed. Sci., Univerty São Paulo, São Paulo, Brazil; [2]Univ. São Paulo, São Paulo, Brazil

Abstract: Several evidences have featured the beneficial effects of the GM1 ganglioside in the treatment of neurological lesions. GM1 has also been studied for treatment of neurodegenerative diseases, mainly because of its neuroplastic and neuroprotective functions. The aim of this study was to analyze the possible effects of GM1 ganglioside on the Parkinson's disease model induced by unilateral intra-striatal injection of 6-hydroxydopamine (6-OHDA). Wistar rats (3 months old, approx. 300g) were divided into 3 groups (5-6 animals): control, 6-OHDA, and 6-OHDA + intracerebroventricular (ICV) GM1. In order to promote the lesion, 6 µg/µL of 6-OHDA were stereotaxically administered by microinfusion in the striatum, with two injections of 0.5 µL at 2 different coordinates. GM1 (30 mg /kg dosis) was injected ICV together with 6-OHDA. Seven days after injury, brains were collected for analysis by immunoblotting in the midbrain and striatum. The expression of tyrosine hydroxylase (TH) in the striatum significantly decreased in

group 6-OHDA compared to controls (50.7%, $p<0.01$). The group treated ICV with GM1 showed a significant increase compared to the 6-OHDA group (51.6%, $p<0.01$), recovering the TH expression to the control level. In the midbrain TH expression also decreased significantly in the 6-OHDA group (ca. 51.8%, $p<0.05$) and appeared to be recovered by GM1. Glial fibrillary acidic protein (GFAP) expression in the striatum showed an increase after 6-OHDA (57.9%, $p<0.01$), and showed a decrease in the group treated with GM1 when compared to the group 6-OHDA (36.3%, $p<0.01$). Similarly, in the midbrain GFAP expression showed an increase after 6-OHDA compared with the control (68.0%, $p<0.01$), and the GM1 treated group showed a significant decrease compared with the 6-OHDA group (36.2%, $p<0.05$). Caspase-3 expression in the striatum significantly increased in the 6-OHDA group compared to controls (70.8%, $p<0.01$) and significantly decreased in the group treated with GM1 compared to group 6-OHDA (45.1%, $p<0.05$). In the midbrain there was an increase of caspase-3 expression in the 6-OHDA group (65.6%, $p<0.05$), which was unaltered by treatment with GM1. We suggest that the GM1 ganglioside exerts neuroprotection in the 6-OHDA model of Parkinson´s disease when injected ICV.

Title: Virally-mediated RNA-interference of alpha-synuclein is well-tolerated and effective in animal models of PD

Authors: Y. KIM[1], A. MILLER[1], L. LINS[1], M. KEISER[2], R. BOUDREAU[1], B. DAVIDSON[2], *N. S. NARAYANAN[1];

Abstract: Parkinson’s disease is a neurodegenerative disease that has no disease-modifying therapy. Alpha-synuclein is postulated to play a key role in disease pathogenesis. Aggregation of the protein alpha-synuclein in insoluble fibrils leading to cellular toxicity in dopamine neurons in humans and in animal models of PD. Here, we use virally-mediated RNA-interference to selectively and specifically reduce alpha-synuclein expression and demonstrate tolerability and

neuroprotection. Previous similar approaches however also induced inflammation and reduced expression of tyrosine hydroxylase. Here we focused on the toxicity due to potential off targeting effect. First, we used a specificity-focused siRNA design algorithm, siSPOTR to identify 8 siRNA sequences with minimal off-targeting potential. After testing these sequences *in vitro*, one RNA-interference sequence (miSyn4) showed maximal protein knockdown potential. To test specificity *in vivo*, AAV vector with miSyn4 was designed and injected in the substantia nigra of mice and rats. miSyn4 was robustly expressed and did not detectably change neurochemistry, dopamine neurons, glial proliferation or animal behavior. We injected AAV-miSyn4 into *Thy1-hSNCA* mice over expressing alpha-synuclein and found significant alpha-synuclein RNA knockdown in both midbrain and cortex. Co-injection of AAV-hSNCA and AAV-miSyn4 demonstrated effective reduction of hSNCA and rescue of SNCA-mediated behavioral deficits. Together, downregulation of SNCA based on RNA interference has therapeutic potential and could be safe and effective for patients with Parkinson's disease.

Title: Zeb013 rescues motor impairments in a mouse model of levodopa-induced dyskinesia

Authors: *R. L. VAZ[1], D. CHAPELA[1], J. E. COELHO[2], L. V. LOPES[2], N. D. AFONSO[1], T. F. OUTEIRO[3], S. SOUSA[1];
[1]Technophage SA, Lisboa, Portugal; [2]Inst. de Medicina Mol., Lisboa, Portugal; [3]Faculdade de Medicina, Univ. de Lisboa, Lisboa, Portugal

Abstract: Parkinson's disease (PD), the second most common neurodegenerative disease, is known for cardinal motor symptoms that include bradykinesia, resting tremor, muscular rigidity and postural instability. Levodopa (L-dopa) is a powerful treatment for the motor symptoms in PD. However, its effectiveness decreases over time and the non-responsive periods to this therapeutic approach increase in advanced stages of the disease. The lack of alternative

therapeutic options for these periods, together with an aggravation of the symptoms is major concern. Novel animal models that recapitulate this advanced stage of the disease are needed in order to enable the development of new therapeutic strategies. Here, we report Zeb013 as a new alternative therapeutic option for PD. Zeb013 was selected in an *in vivo* screen using a 6-hydroxydopamine zebrafish model that enables the identification of compounds rescuing locomotor deficits. We then developed a rodent model that mimics the non-responsive periods of L-Dopa, so that the selected compound could be further investigated in a pre-clinical model. When chronically treated with L-Dopa, this mouse model exhibited an aggravation of gait impairments, and Zeb013 was able to rescue this condition. In the future, we will further investigate the mechanism of action of Zeb013, and gain insight into the molecular underpinnings of advanced stages of PD.

Title: A novel dual GLP-1 GIP analogue protects the brain in the MPTP mouse model of Parkinson's disease

Authors: *C. HOLSCHER[1], C. JI, Jr.[2], G. XUE, Jr.[2], G. LI[2];
[1]Lancaster Univ., Lancaster, United Kingdom; [2]Neurolog. hospital, Shanxi Med. Univ., Taiyuan, China

Abstract: Glucagon-like peptide 1 (GLP-1) is a growth factor that shows neuroprotective properties. We have shown previously that the GLP-1 mimetics that are currently on the market

as treatments for type II diabetes show neuroprotective effects in animal models of Parkinson's disease (PD). Recently, the GLP-1 mimetic exendin-4 (Bydureon) has shown remarkable effects in a clinical study of PD patients, demonstrating the potential of these drugs. The sister incretin growth factor Glucose-dependent insulinotropic polypeptide (GIP) also has shown protective effects in PD animal models. Here we show that novel dual agonists that activate both GLP-1 and GIP receptors protect the brain in the MPTP mouse model of PD. MPTP was injected once-daily (20mg/kg i.p.) for 7 days, and the dual agonist was once-daily for 14 days (50nmol/kg i.p.). The novel dual agonist reduced or reversed most of the MPTP induced motor impairments in the rotarod, catalepsy, and in a muscle strength test. The number of tyrosine hydroxylase (TH) positive neurons in the substantia nigra (SN) was reduced by MPTP and increased by the drug. The ratio of anti-inflammatory Bcl-2 to pro-inflammatory BAX signaling as well as the activation of the growth factor kinase Akt was reduced by MPTP and reversed by the new drug. The PI3k inhibitor had only limited effect on the drug effect. Importantly, levels of the neuroprotective brain derived neurotropic factor (BDNF) were reduced by MPTP and enhanced after drug treatment. The activation of a chronic inflammation response in the brain by MPTP was much reduced by the drug (astroglia and microglia activation). The results show superior effects over single GLP-1 analogues and suggest that this new dual agonist drug class is more protective in PD than exendin-4 in the clinic.

Title: Beta and gamma oscillatory activity in the subthalamic nucleus, anterior cingulate cortex, and ventral medial prefrontal cortex in the awake hemiparkinsonian rat

Authors: *A. R. WEISS, C. DELAVILLE, K. B. DUPRE, E. BRAZHNIK, N. NOVIKOV, J. R. WALTERS;
Neurophysiological Pharmacol. Section, NINDS, Bethesda, MD

Abstract: Exaggerated beta oscillatory activity is observed in the motor circuits of Parkinson's disease (PD) patients and animal models of PD. This activity has been hypothesized to contribute to motor dysfunction in PD. We have previously observed significant increases in spectral power in the 25-40 Hz high beta range in local field potentials (LFP) recorded in the subthalamic nucleus (STN), substantia nigra pars reticulata, and motor cortex of parkinsonian rodents associated with motor function. Further, it has been hypothesized that deep brain stimulation and L-DOPA medication reduce motor and non-motor symptoms by disrupting this excessive beta oscillatory activity. However, the extent to which non-motor networks contribute to this high beta activity and the impact of pathological oscillatory activity in influencing the cognitive deficits of PD are not well understood.
This study used 6-OHDA-lesioned, hemiparkinsonian rats performing a circular treadmill walking task to compare synchronized STN LFP activity with activity in the ventral medial prefrontal cortex (mPFC) (i.e., the infralimbic and prelimbic cortices), and the anterior cingulate cortex (ACC, dorsal mPFC), areas involved in cognitive processes. Electrode bundles were implanted in the STN, the ACC, and the ventral mPFC of rats with unilateral dopamine cell lesions. LFP and spiking activity were recorded during epochs of treadmill walking in control animals and 21 days after dopamine cell lesion.
Data show increases in 29-36 Hz high beta LFP spectral power in the STN and ACC and coherence between these regions after dopamine depletion. In contrast, recordings from the ventral mPFC 21 days after lesion did not show peaks in this beta frequency range. Furthermore, ACC, ventral mPFC, and STN showed peaks in the low gamma frequency range in LFP power - the ACC with a mean peak frequency at approximately 57 Hz and the ventral mPFC and STN at 51 Hz - during treadmill walking before and 21 days after dopamine depletion.
These results suggest that the STN integrates activity from mPFC circuits in a manner that varies with behavioral state, oscillatory frequency, and the integrity of the dopamine system. Our results may help to gain further insight into the significance of excessive beta oscillatory activity in PD and its influence on motor and cognitive systems.

Title: Effects of inhibitory DREADD in the substantia nigra pars reticulata on cortical high beta and high gamma LFP oscillations and behavior in hemiparkinsonian rats

Authors: *K. B. DUPRE, C. J. LOBB, H. C. BERMUDEZ CABRERA, J. R. WALTERS, M. A. COHEN;
Neurophys/Pharmacol Sec, NIH NINDS, Bethesda, MD

Abstract: Loss of dopamine is associated with increased synchronization and oscillatory activity in the basal ganglia in both Parkinson's disease (PD) patients and animal models of PD. Our lab has previously observed increases in LFP power in the 25-40 Hz range in the substantia nigra pars reticulata (SNpr) and motor cortex (MCx) in the hemiparkinsonian rat during treadmill walking, as well as increases in power in the 70-120 Hz range in the MCx during L-DOPA-induced dyskinesia. These findings suggest that the SNpr may play a role in cortical high beta and high gamma LFP activity during bradykinesia and dyskinesia. To study this, hemiparkinsonian rats (n=5) received infusion of the inhibitory DREADD virus, AAV2/8-hSyn-hM4D(Gi)-mCherry, into the SNpr and implantation of electrodes targeting MCx and SNpr. Post-histological analyses revealed DREADD virus expression in the SNpr with some spread to surrounding areas. Similar to our previous work, exaggerated high beta LFP power in the MCx and SNpr and coherence between these regions were observed during treadmill walking. At 3-4 weeks post-surgery, clozapine-N-oxide (CNO; 1.0 mg/kg, i.p.), which stimulates receptors expressed in DREADDs transfected neurons, caused a significant reduction in cortical high beta LFP activity during treadmill walking compared to before CNO. This suggests that inhibiting basal ganglia output may disrupt the propagation of high beta activity observed in the basal ganglia-thalamocortical circuit during bradykinesia. After L-DOPA priming (12 mg/kg, s.c., once daily for 7 days), rats received saline or CNO 15 min prior to L-DOPA (6 mg/kg, s.c.). Similar to our previous findings, cortical high gamma LFP oscillations and abnormal involuntary movements (AIMs) were significantly increased following L-DOPA, regardless of pre-treatment. Interestingly, CNO pre-treatment caused significant increases in both cortical high gamma LFP power and AIMs from approximately 110-160 min post-L-DOPA compared to saline pre-treatment. CNO-mediated inhibition of the SNpr may enhance and extend L-DOPA-mediated inhibition of basal ganglia output, leading to further disinhibition of the thalamus, which would excite the MCx, resulting in exaggerated high gamma activity and dyskinesia. Ongoing DREADDs experiments are further investigating the contribution of the SNpr to cortical high beta and high gamma oscillations during bradykinesia and dyskinesia, as well as the spiking activity of SNpr and MCx under these conditions.

Title: Changes in neuronal activity of cortico-basal ganglia-thalamic networks induced by dopaminergic manipulations

Authors: *N. IVICA, U. RICHTER, I. BRYS, P. PETERSSON;
Integrative Neurophysiol. and Neurotechnology, Lund Univ., Lund, Sweden

Abstract: The basal ganglia are comprised of several subcortical nuclei that are interconnected with the cerebral cortex, thalamus, and brainstem and are thought to be particularly involved in processes relating to action selection and the execution of goal-directed movements. In the cortico-basal ganglia-thalamic circuitry dopamine plays an important role in maintaining the normal function in movement control. This is evident for example in the symptomatology of Parkinson's disease, where the death of a large fraction of the dopaminergic cells in the midbrain leads to severe motor dysfunctions. In order to investigate how disruptions in dopamine signaling affect the neurophysiological activity in the cortico-basal ganglia-thalamic loop, we have here acquired large-scale neuronal recordings in rodents prior to and following acute and chronic interference with the transmission of this neuromodulator. Acute pharmacological interventions include both the blockage of dopamine synthesis from tyrosine using alpha-methyl-p-tyrosine (AMPT) and antagonism of dopaminergic receptors (either type D1R or D2R, or D1R+D2R). Chronic dopamine depletion was obtained by unilateral medial forebrain bundle 6-OHDA lesions. Neuronal recordings in female Sprague-Dawley rats were obtained simultaneously in 16 different regions of the cortico-basal ganglia-thalamic loop (8 per hemisphere), sampling both local field potentials and single cell activity under the different experimental conditions. In local

field potential recordings we could confirm the previously reported relative increase in power in the beta-band. In particular, the exaggerated beta was found in experiments with chronic depletion as well as with AMPT, D1R+D2R antagonist and D2R antagonist, however, the increase was not as clear for the D1R antagonist alone. At the same time, all acute interventions had very similar behavioral effects, i.e. in all animals drug-induced catalepsy could be confirmed in direct tests. Analysis of unit activity suggested complex patterns of changes in firing rate in the different structures, indicating simple rate models stemming from the concept of opposing effect in the direct and indirect pathway are not sufficient to capture the observed data. These data provide for the first time a detailed description of both the acute and chronic effects of disrupted dopamine signaling on the neurophysiological activity in the cortico-basal ganglia-thalamic loop.

Title: Selective targeting of striatal 5-HT_{1A} auto- or hetero-receptors to alleviate L-DOPA-induced dyskinesia in hemi-parkinsonian rats.

Authors: *S. M. MEADOWS[1], C. TASBER[1], N. E. CHAMBERS[1], M. CONTI[1], E. SHEENA[1], M. A. VARNEY[2], A. NEWMAN-TANCREDI[2], C. BISHOP[1];
[1]Binghamton Univ., Binghamton, NY; [2]Neurolixis Inc., Dana Point, CA

Abstract: L-DOPA is the standard treatment for the akinetic motor symptoms of late-stage Parkinson's disease (PD), however chronic treatment leads to abnormal involuntary movements, known as L-DOPA-induced dyskinesia (LID). Modulation of aberrant striatal dopamine (DA) release from serotonin (5-HT) terminals, via 5-HT_{1A} receptor stimulation, has been shown to attenuate LID severity in rodent and non-human primate models. Clinically, previously-used 5-HT_{1A}R agonists have only been modestly effective at reducing LID and may worsen PD motor symptoms and increase liability for 5-HT syndrome. In recent years, the highly selective G-protein biased 5-HT_{1A}R agonists F13714 and F15599 have been employed to target either pre-synaptic auto-receptors or cortical hetero-receptors, respectively. The present study utilized these compounds to better understand the role of distinct striatal 5-HT_{1A}R populations in dyskinetic, hemi-parkinsonian rats. In Experiment 1, a cohort of rats received systemic injections of vehicle, F13714 (0.01 or 0.02 mg/kg, s.c.), or F15599 (0.06 or 0.12 mg/kg, s.c.) 5 minutes prior to L-

DOPA (6 mg/kg, s.c.) in a within-subjects counterbalanced design. In Experiment 2, a second cohort of rats received bilateral striatal cannulations concurrent with DA lesion. After L-DOPA priming, animals were split into two equally dyskinetic groups, one that received intrastriatal microinjections of F13714 (0, 2 or 10 μg in 1 μL) and another receiving F15599 (0, 10, or 30 μg in 1 μL), 5 minutes prior to systemic L-DOPA (6 mg/kg, s.c.) administration. LID and 5-HT syndrome were rated in both experiments, but motor performance was only rated in Experiment 1. Results from Experiment 1 showed that whilst both compounds effectively reduced dyskinesia without interfering with the therapeutic effects of L-DOPA, stimulation of 5-HT_{1A} autoreceptors induced marked 5-HT syndrome in these acute administration experiments. Striatal microinjections in Experiment 2 yielded a similar pattern of effects, suggesting that these compounds work via striatal 5-HT_{1A}Rs to reduce LID. This study implicates differential roles for striatal 5-HT_{1A} auto- and hetero-receptor populations in the therapeutic effects of non-specific 5-HT_{1A}R agonists on LID expression and suggests the promise of selective 5-HT_{1A}R targeting for clinical LID treatment.

Title: Pathological firing patterns in substantia nigra pars reticulata neurons after acute or chronic dopamine deprivation in the 6-OHDA rodent model of Parkinson´s disease

Authors: *V. CACERES CHAVEZ[1], R. HERNÁNDEZ-MARTÍNEZ[2], J. PÉREZ-ORTEGA[1], M. A. HERRERA-VALDÉZ[3], E. GALARRAGA[1], J. BARGAS[1];
[1]Neurociencias, Inst. De Fisiología Celular, UNAM, México D.F, Mexico; [2]Neurol., Duke Univ. Med. Ctr., Durham, NC; [3]Facultad de Ciencias, UNAM, México D.F, Mexico

Abstract: During Parkinson's disease, dopamine deprivation produces modifications on several synaptic inputs connecting *substantia nigra pars reticulata* (SNr) neurons (e.g., Ibañez-Sandoval

et al., 2007; Aceves et al., 2011), these changes in turn produce changes in the firing patterns in the neurons of the SNr. This feature may represent the cellular basis of a major pathological sign of the disease in both animal models and patients: correlated firing and anomalous synchrony in basal ganglia output neurons. In the present work, we perform whole cell recordings of SNr neurons in mouse brain slices from healthy and parkinsonian subjects. The firing pattern of SNr neurons in control conditions is mostly regular and tonic. After either acute blockade of D1 and D2 dopamine receptors with their respective selective antagonists (sulpiride and SCH23390) or after the lesion of the dopaminergic neurons with 6-OHDA, the firing pattern of SNr neurons becomes irregular and bursty. Because under control conditions TRP cationic and T type calcium channels have been implicated in the generation of firing of SNr neurons, we decided to determine whether on pathological conditions they remain as an important component of the firing machinery. Here, we confirm that hypothesis. Given that SNr neurons are the first target of the *substantia nigra pars compacta* dopaminergic neurons, we propose that we can assay Parkinson's disease pharmacological treatments evaluating their effects in the firing pattern of these neurons.

Title: D1R-D3R dopamine receptor stimulation alters downstream signaling in the semi-parkinsonian rat: implications of the D1R-D3R heteromer

Authors: *K. E. LANZA[1], S. MEADOWS[1], M. DEAK[1], C. BISHOP[1], S. FERRÉ[2]; [1]Psychology, Binghamton Univ., Binghamton, NY; [2]Natl. Inst. on Drug Abuse, NIH, Baltimore, MD

Abstract: Parkinson’s Disease (PD) is a neurodegenerative disorder characterized by nigro-striatal dopamine (DA) cell loss resulting in pronounced motor deficits. DA replacement therapy first with DA agonists and subsequently L-DOPA, initially reduces motor symptoms, but eventually patients experience loss of treatment efficacy and abnormal involuntary movements (AIMs) develop. The DA D1 receptor (D1R), expressed on the medium spiny neurons of the direct pathway, has been strongly implicated in dyskinesia and changes in D1R signaling associated with dyskinesia development and expression. DA D3 receptors (D3R) have also been

shown to play a role in dyskinesia development though D3R mechanisms are less understood. More recent work has suggested an interplay between D1R and D3R. In vitro, co-localization of D1R with D3R in the form of a heteromer synergistically enhances select downstream substrates, such as extracellular signal-regulated protein kinase (ERK 1/2) in its phosphorylated form (pERK 1/2). In the unilateral 6-hydroxydopamine rat, D1R and D3R agonists dose-dependently induce dyskinesia and importantly, their co-administration induces synergistic expression of dyskinesia. To better understand how D1R-D3R co-activation leads to in vivo alterations in downstream signaling, we monitored levels of ERK1/2 and pERK1/2 after individual or collective administration of D1R and/or D3R agonists. To do so, adult male Sprague-Dawley rats were given unilateral DA lesions to the medial forebrain bundle. Three weeks later, rats were given daily L-DOPA (6 mg/kg; s.c.) for 2 weeks to establish stable dyskinesia expression. Rats were then treated with either vehicle, the D1R agonist SKF38393, the D3R agonist (+)PD128907 or a combination of both and dyskinetic behaviors were measured. Thirty minutes later, striatal tissue was harvested and later analyzed via western blot. Initial findings indicate pronounced behavioral synergy and treatment-dependent changes in cellular signaling, supporting the induction of pERK1/2 as a cellular consequence of D1R-D3R interactions in the DA-depleted striatum.

Title: Spatiotemporal inhomogeneity of pathological beta activities in the motor cortex of hemi-parkinsonian rats

Authors: *Z. YU[1], W. ASAAD[2,3], A. NURMIKKO[1], I. OZDEN[1];
[1]Sch. of Engin., [2]Neurosci., Brown Univ., Providence, RI; [3]Rhode Island Hosp., Providence, RI

Abstract: Excess beta-band power (13-30Hz beta oscillations) in the local field potentials (LFPs) of the motor cortex and in several basal ganglia nuclei is the most prominent feature of Parkinsonian pathophysiology. However, it is not known how and to what extent pathological beta activity might override the functional activity in the motor cortex. Specifically, the spatiotemporal dynamics of pathological neural activity within the Parkinsonian motor cortical microcircuits have not been characterized at suitable spatial resolution. To address this question, we utilized microelectrode arrays (MEAs, 400μm electrode pitch) implanted unilaterally (6x6 MEA) or bilaterally (two 5x5 MEAs) into the anterior forelimb area of motor cortices in 6-OHDA-induced hemi-Parkinsonian rats. Recordings were obtained during free behavior or while animals performed a harnessed lever pressing task. In short, animals were conditioned to press a lever with their right forelimb upon onset of a light cue to receive a reward. LFPs were extracted from MEA recordings and their spatiotemporal dynamics were examined with spectral, correlation, and coherence analyses. Unilateral 6-OHDA lesions led to stereotypical asymmetrical motor deficits such as akinesia and rotational bias. Accompanying motor deficits, elevated beta-band power in LFPs was observed on the lesioned side of motor cortex. Interestingly, these beta oscillations appeared intermittently only at certain locations as distinct spatial activity patterns. A linear discriminant analysis showed that the beta band power at some recording sites was indistinguishable from control levels. However, further analysis indicated that these sites could be distinguished from control sites by their phase coherence. We found, within the lesioned motor cortex, excess phase coherence at the beta band between pairs of recording sites. The beta synchrony was not distributed uniformly; it was more pronounced between sites with higher beta power. We note that the motor cortex has been tested as an alternative modulation target for Parkinson's disease, e.g. by transcranial magnetic stimulation. In our microcircuit work, the observed variations in beta-band power and phase synchrony across the motor cortex implied the presence of inhomogeneity in the extent of cortical Parkinsonism; and hence, might offer a route to potential therapeutic benefit via differential neuromodulation at different motor cortical sites. Such modulation paradigm could potentially allow more specific control of motor cortical activity, and thereby motor symptoms, while reducing interference of stimulation on eloquent functional motor activity.

Title: Cell-type specific pallidal stimulation provides long-lasting relief of immobility in a model of Parkinson's disease

Authors: *K. J. MASTRO[1], K. T. ZITELLI[1], A. M. WILLARD[2], K. H. LEBLANC[3], A. V. KRAVITZ[3], A. H. GITTIS[2];

Abstract: In Parkinson's disease (PD), the external segment of the globus pallidus (GPe) is a key contributor to the induction, propagation and maintenance of network dysfunction within the basal ganglia. In the classical rate model of basal ganglia dysfunction, the loss of dopamine shifts the balance of the two functionally opposing pathways: motor-facilitating direct and motor-suppressing indirect. An overactive indirect pathway leads to the cardinal symptoms of PD: bradykinesia and immobility. To test the efficacy of pallidal stimulation to reduce indirect pathway activity and alleviate parkinsonian motor symptoms, we used an optogenetic approach to modulate activity in the GPe in a global, or cell-selective manner. Our results demonstrate that global increases or decreases in GPe activity are minimally effective at restoring movement in bilaterally dopamine-depleted mice, but in contrast, cell-specific stimulation strategies were highly effective. Specifically, activation of Parvalbumin-positive (PV-GPe) neurons, or inhibition of Lim homeobox 6-positive (Lhx6-GPe) neurons restored movement to near pre-lesion levels. Intriguingly, this behavioral rescue did not cease at the end of stimulation, but persisted for hours. At the end of the 4-hour experiment, all mice still exhibited near pre-lesion levels of locomotion. For comparison, we tested the ability of direct-pathway stimulation to rescue movement in bilaterally-depleted mice. Behavioral recovery as a result of direct pathway stimulation was neither as robust, nor as persistent as cell-specific manipulations in the GPe. In future experiments, we will use in vivo electrophysiology within the output nucleus of the BG to observe circuit-level alterations before, during and after the optogenetic stimulation. In summary, these results demonstrate that cell-specific activation of PV-GPe or inhibition of Lhx6-GPe neurons provide a long-lasting recovery in motor function and establish the existence of two functionally distinct cell populations in the GPe.

Title: Dopamine depletion alters striatal histone acetylation in the MPTP-induced mouse model of Parkinson's disease.

Authors: *G. L. LEMIEUX, É. PEPIN, G. BUREAU, M. CYR;
Med. Biol., Univ. Du Québec À Trois-Rivières, Trois-Rivière, QC, Canada

Abstract: Parkinson's disease (PD) is a chronic progressive neurodegenerative movement disorder characterized by a profound and selective loss of nigrostriatal dopamine (DA) neurons. Clinical manifestations of this complex disease include motor impairments involving resting tremor, bradykinesia, postural instability, gait difficulty and rigidity. The molecular adaptation of striatal neurons to DA deficiency, mostly accountable for the motor manifestations, remains poorly understood. Epigenetic modifications of histone proteins exert fundamental roles in developmental processes and their deregulation is suspected in the progression of diverse human disorders. Acetylated and deacetylated histones are considered epigenetic tags within chromatin by relaxing or tightening chromatin structure, subsequently increasing or decreasing gene transcription levels. In the present study, we verify whether acetylation of histone proteins play a role in the molecular adaptation of striatal neurons and the impaired motor behavior associated with DA depletion. The neurotoxin MPTP was acutely administered to adult mice using 4 injections of 20 mg/kg, i.p., every 2 hours. Mice were sacrificed 1 or 7 days after MPTP injections. To evaluate motor manifestations, we performed 7 days after treatments the beam, wire suspension and pole tests in vehicle and MPTP-treated mice. Impaired motor abilities were observed in the MPTP-treated mice in all tests; but statistical significance was reached only in the wire suspension test. Degrees of DA-depletion were estimated by the evaluation of tyrosine hydroxylase (TH) levels in the striatum using western blot technique. We observed a 45% and a 60% reduction in striatal TH levels in mice sacrificed 1 and 7 days after MPTP injections, respectively. Modification of histone acetylation was assessed in the striatum of mice following MPTP treatments by western blot. Elevated levels of lysine 9-acetylated histone H3 (H3K9ac) were observed in MPTP mice 1 day after injections. In MPTP-treated mice sacrificed 7 days after injections, levels of H3K9ac were even more important and reached statistical significance. These preliminary results indicate that DA depletion triggers epigenetic modification of histone proteins in the striatum of MPTP-treated mice. Although conclusion about the relationship between PD, motor manifestations and striatal histone acetylation would need further investigations, studying epigenetic mechanisms will be helpful to understand the etiology of PD which is essential for therapeutic strategies of this disease.

Title: Progression of physiological changes in the basal ganglia following bilateral gradual or acute administration of 6-hydroxydopamine in mice

Authors: ***A. M. WILLARD**[1], K. J. MASTRO[2], A. H. GITTIS[1];
[1]Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA; [2]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Parkinson's disease (PD) is characterized by the gradual loss of dopamine in the basal ganglia that produces dramatic changes in circuit physiology and ultimately motor function. In humans, levels of dopamine degenerate at a rate of ~11% over the course of 10-20 years where motor deficits do not appear until a significant amount of dopamine is lost. Despite abundant evidence for the gradual loss of dopamine in humans, most studies utilizing neurotoxin ablation of dopamine neurons use acute, unilateral administration to understand PD physiology. Though many of these studies are instrumental in our understanding of basal ganglia circuit dysfunction, the period over which dopamine is lost may be a necessary component for the brain to adapt and therefore more closely recapitulate the physiological characteristics found in the patient population. Based on recent behavioral evidence (Willard et al., 2015), the rate at which dopamine is depleted can impact the degree of motor preservation at late stages. We hypothesized that the gradual decline in dopamine may alter the way in which the basal ganglia adapt to the new brain state and may challenge current descriptions of parkinsonian physiology. In this study, we compared the neural activity within basal ganglia nuclei of awake head-restrained mice that had undergone gradual or acute bilateral dopamine depletion with 6-hydroxydopamine administration in the medial forebrain bundle. Further investigation utilizing gradual bilateral dopamine depletions could aid in uncovering potential compensatory maintenance of neural activity within the basal ganglia, and enhance our understanding of the role of dopamine in basal ganglia function.

Title: Computer Simulation of GBA related pathways with implications for Parkinson 's disease

Authors: *I. IKEDA[1], J. W. RYAN[2], T. J. SWEENEY[3], A. D. LEE[1], B. BEHROUZ[1]; [1]Neuroinitiative, Jacksonville, FL; [2]NeuroInitiative, Jacksonville, FL; [3]Neuriniative, Jacksonville, FL

Abstract: Since the discovery of the link between the glucocerebrosidase (GBA) gene and Parkinson's disease (PD), a substantial amount of attention has been directed towards the mechanisms by which the glucocerebrosidase protein (GCase) and lysosomal dysfunction contribute to α-synuclein pathology and PD. Research into this area has identified a consistent, inverse, and bidirectional relationship between GCase activity and α-synuclein protein concentration, although a specific biochemical relationship has yet to be elucidated. GCase is a lysosomal hydrolase that is active in a dynamic degradative process known as the glycosphingolipid salvage pathway, critical for the recycling and re-synthesis of new lipids. Interestingly, deficient GCase activity results in Gaucher Disease (GD) in an autosomal recessive manner. We used the Simulation Environment for Experimental Design (SEED) to model and simulate, at a pathway level, the molecular interactions of GCase and sphingolipid metabolism. *In Silico* protein content was quantified following various knock out and overexpression models within this pathway and data was visualized and quantified, allowing for the modeling of GCase related abnormalities such as those observed in PD and GD. Additionally the degradative pathway of short chain glycosphingolipids was represented by SEED allowing for the basic modeling of abnormalities in a number of lysosomal storage disorders (e.g GM1 gangliosidosis or Tay Sachs disease).

Title: Adressing mitochondrial dysfunction in iPSC derived neurons from GBA1 associated Parkinson's disease patients

Authors: *D. C. SCHÖNDORF, L. K. SCHWARZ, D. INVANYUK, M. ZARANI, S. DE CICCO, T. GASSER, M. DELEIDI;
Neurodegeneration, DZNE Tübingen, Tuebingen, Germany

Abstract: Heterozygous mutations in the *β-glucocerebrosidase* (*GBA1*) gene represent the most common genetic risk factor for Parkinson's disease (PD) known to date. Even though mitochondrial dysfunction has been described to play a role in the disease, it is still unclear whether a loss of glucocerebrosidase enzymatic activity or a gain of function of the misfolded enzyme contributes to disease pathogenesis. In order to study the role of *GBA1* loss of function in PD, we generated *GBA1* knock out ($^{-/-}$) induced pluripotent stem cells (iPSCs) using CRISPR–Cas9 technology. To this end, a deletion was introduced in both copies of the *GBA1* gene in iPSCs from healthy individuals as well as PD patients with *GBA1* mutations. Multiple KO lines from each subject were selected and differentiated into midbrain dopaminergic (DA) neurons. No significant differences in DA neuronal differentiation potential were observed between *GBA1*$^{-/-}$ iPSCs and corresponding isogenic controls. *GBA1* PD and *GBA1*$^{-/-}$ neurons showed increased production of reactive oxygen species, impaired respiration and reduced mitochondrial membrane potential compared to wild type isogenic controls. Next, we assessed energy metabolism in iPSC-derived neurons and investigated the therapeutic effect of targeting mitochondrial function in GBA-PD.
Our data suggest that mitochondrial dysfunction plays a role in the pathogenesis of GBA-PD, thereby providing a tool for the development of therapeutic strategies for PD.

Title: Inhibition of glucosylceramide synthase alleviates aberrations in synucleinopathy models

Authors: *S. SARDI, C. VIEL, J. CLARKE, A. RICHARDS, H. PARK, J. DODGE, J. MARSHALL, B. WANG, S. CHENG, L. S. SHIHABUDDIN;
Genzyme, a Sanofi Co., Framingham, MA

Abstract: Mutations in *GBA*, the gene encoding glucocerebrosidase, are associated with an enhanced risk of developing synucleinopathies such as Parkinson's disease (PD). Recent studies have also demonstrated that genetic variation in *GBA* can impact the progression of PD. Patients harboring mutations in *GBA* present higher prevalence and severity of motor and non-motor symptoms. However, the precise mechanisms by which mutations in *GBA* increase PD risk and exacerbate its progression remain unclear. Here, we investigated the merits of glucosylceramide synthase (GCS) inhibition as a potential treatment for synucleinopathies. A Gaucher-related synucleinopathy mouse model ($Gba^{D409V/D409V}$) was treated with an orally available brain-penetrant GCS inhibitor, Genz-667161 for 8 months. This intervention prevented CNS substrate lipid accumulation. Most notably, treatment with the GCS inhibitor slowed the accumulation of hippocampal aggregates of α-synuclein, ubiquitin and tau, and improved the associated memory deficits. The effects of the GCS inhibitor were also studied in a mouse model overexpressing α-synuclein, *PrP-A53T-SNCA,* and harboring wild type alleles of *GBA*. Treatment of *PrP-A53T-SNCA* mice with Genz-667161 for 6.5 months reduced membrane-associated α-synuclein in the CNS and ameliorated cognitive deficits. Collectively, the data indicate that inhibition of GCS can modulate processing of α-synuclein and reduce various α-synuclein entities, thereby reducing the progression of synucleinopathies in mice with and without mutations in *GBA*. The present study provides supporting evidence for the clinical development of brain-penetrant GCS inhibitors in PD and other synucleinopathies.

Title: Cortical evoked potentials generated by deep brain stimulation

Authors: ***K. KUMARAVELU**[1], C. S. OZA[1], C. E. BEHREND[1,2], W. M. GRILL[1,3,4,5]; [1]Biomed. Engin., [2]Sch. of Med., [3]Electrical and Computer Engin., [4]Dept. of Neurobio., [5]Dept. of Surgery, Duke Univ., Durham, NC

Abstract: Parkinson's disease (PD) is associated with abnormal neural activity in the basal ganglia and cortex. Subthalamic nucleus (STN) and globus pallidus (GP) deep brain stimulation (DBS) are both effective in suppressing PD motor symptoms by altering cortical activity, however the anatomical pathways responsible for this modulation remain unclear. Cortical evoked potentials (cEP) generated by STN or GP DBS are a key biomarker encoding the response of cortex to subcortical stimulation. The goal of this study was to determine the neural origin of STN and GP DBS induced cEP. We performed M1 electrocorticography (ECoG) recordings with skull mounted screws during 4.5 Hz STN and GP DBS in healthy awake rats. We then used a detailed biophysical model of the thalamocortical (TC) network (Traub et al. 2005) to decipher the neural origin of the cEP signal.

The predominant in vivo STN DBS induced cEP pattern (n=7/16 rats) included short latency positive (P1), intermediate latency negative (N1), and long latency positive (P2) responses. Major features of the STN DBS induced cEP response pattern in rats matched well with those from humans (Walker et al. 2012), although there were differences in peak latencies between the rat and human cEPs. STN DBS was simulated in the computational model by activating axons of layer 5 pyramidal neurons and by injecting inhibitory postsynaptic current into thalamus (TH) mimicking activation of antidromic (corticospinal, CS) and orthodromic (STN-entopeduncular nucleus-TH) pathways respectively. Model-based STN DBS cEPs matched remarkably well in vivo responses. P1 and N1 responses were due to the direct and rebound activation of L5 pyramidal neurons, respectively, while polysynaptic activations of L5 and L2/3 pyramidal neurons resulted in the long latency response. Orthodromic activation produced an inhibitory effect on TH and reduced the amplitude of the long latency response.

GP DBS induced cEP (n=6/11 rats) exhibited P1, N1, P2 responses similar to STN DBS, however the magnitude and latency of response components were different. GP DBS was simulated in the computational model by stimulating axons of L5 pyramidal and TH neurons

mimicking activation of CS and TC fibers in the internal capsule. P1 response in model cEP was due to the direct activation of L5 pyramidal neurons, while trans-synaptic activations of L2/3 and L6 pyramidal neurons generated N1 and P2 responses.
Establishing the anatomical pathways responsible for cortical modulation during STN and GP DBS lays a foundation for better understanding of therapeutic targets and thereby optimizing DBS electrode placement.

Title: Neurolincs imaging - illuminating human motor neuron biology

Authors: *S. FINKBEINER[1], .. NEUROLINCS CONSORTIUM[2], J. OSTERLOH[1];
[1]Gladstone Inst. of Neurolog. Dis., San Francisco, CA; [2]NIH, Bethesda, MD

Abstract: The goals for NeuroLINCS are to empirically determine key features that distinguish cellular states and to develop models for predicting how cells respond to perturbagens. We are interested in human iPSC-derived neurons from people with and without motor neuron disease. Using robotic microscopy (RM), we can identify and track individual cells over time and quantify the relationship between intermediate changes in cellular physiology and eventual fate. This quantitative molecular phenotyping enables us to construct multivariate predictive models of fate, which we will integrate with data generated from other NeuroLINCS sites, to provide comprehensive molecular "signatures" for our cell types of interest. Here, we present new image analysis techniques and cellular reporters that are illuminating new features of human motor neurons from patients with SMA and ALS, including those from sporadic patients and others with mutations in C9ORF72 and SOD1.

Title: Answer ALS: Establishing a clinical and comprehensive multi-omics signature for ALS employing induced pluripotent stem cell derived motor neurons from 1000 sporadic and familial ALS patients nationwide

Authors: *J. D. ROTHSTEIN[1], M. CUDKOWICZ[3], C. SVENDSEN[4], N. MARAGAKIS[2], J. D. BERRY[3], L. THOMPSON[5], S. FINKBEINER[6], J. VAN EYKE[4], E. FRAENKEL[7], E. MOSMILLER[2], S. VAUGHN[3], T. THOMPSON[5], S. FARR[1], E. BAXI[1];

Abstract: ALS, like many other neurodegenerative diseases, likely represents a collection of different subtypes of patient populations and molecular etiologies. Over a dozen different genetic mutations cause familial ALS (fALS) and fALS is clinically indistinguishable from the far more common sporadic ALS. Disappointingly, no new drug treatments have been found to be reproducibly successful in large clinical trials since the first and only FDA approved drug, more than 20 years ago. Using approaches gleaned from personalized medicine approaches in cancer, Answer ALS was conceived and organized as a comprehensive multi-omics approach to ALS to ascertain, at a population level, the various clinical-molecular- biochemical subtypes of ALS. The overall organization was built on the collaborative NIH initiated NeuroLinc's consortium. Specifically, ALS patients nationwide are being enrolled at 6 University clinics distributed throughout the USA and longitudinally followed with deep clinical data collection. In addition,

patients wear a personal health monitoring device with a linked Android/iOS app collecting 24/7 data on motor activity, sleep activity, heart rate, motor performance and learning "games", voice and pulmonary function. The iPS derived neurons are centrally generated from a novel, rapid and highly reproducible specific differentiation protocol. Whole genome sequencing, transcriptomics, epigenomics, proteomics, metabolomics, lipomics, high content imaging and longitudinal high throughput single cell analysis are collected on the patients iPS motor neurons also employing standardized and parallel cultures. Integrated clinical and biological signatures are being generated using bioinformatics, statistics and computational biology to establish patterns that may lead to a better understanding of the underlying mechanisms of disease. The data acquired in this consortium effort is open source and freely available online to academic and commercial researchers along with the library of patient derived iPS cells, all without IP restrictions. Ultimately the data will be analyzed using deep machine learning algorithms performed in collaboration with partner organizations. The overall goal of this comprehensive individualized clinical and biological national effort will be to identify biological subsets of ALS which will inform future clinical trials, help develop therapies targeting the proper molecular pathway for the right patient subgroup, provide a platform of human patient derived authentic neurons for use in patient subgroup drug discovery and appropriate biomarker and/or pharmacodynamic markers for use in clinical trials.

Title: Proteomic analysis of motor neurons from induced pluripotent stem cells: ALS and SMA

Authors: ***V. J. DARDOV**[1,2], V. VENKATRAMAN[2], R. HO[2], A. D. MATLOCK[2], .. NEUROLINCS CONSORTIUM[3], C. SVENDSEN[2], J. VAN EYK[2];
[1]Biomed. Sci., [2]Cedars Sinai, Los Angeles, CA; [3]NIH, Bethesda, MD

Abstract: Amyotrophic lateral sclerosis (ALS) is an adult onset neurodegenerative condition in which loss of upper and lower motor neurons occurs, while Spinal Muscular Atrophy (SMA) affects only the lower motor neurons and occurs in infants and young children. In both diseases, there is loss of neurons due to cell death which ultimately leads to impaired muscle function. Determining if and how these two diseases are linked at the molecular level can be investigated by employing cell wide proteomic analysis to determine the effects of single genetic perturbations (C9 and SMN1) that drive the ALS and SMA disease phenotype. Ideally the molecular profile of affected motor neurons in disease would be interrogated in vivo, but this is challenging and precludes experimentation to deduce cause and effect. iPSC derived motor neurons allow for the interrogation of the discrete molecular effects of specific genetic perturbations within the context of human genomic backgrounds upon which disease is made manifest, and furthermore enables chemical and environmental perturbations to further elucidate molecular pathology in ALS. The goal of this study was to identify disease specific molecular signatures characteristic of known disease phenotypes including neuronal cell death in an iPSC-derived motor neuron model of ALS and SMA. We have generated motor neuron precursors (iMNs) from the iPSCs derived from healthy human patients as well as those with SMA and ALS, (n=4/group). We hypothesize that by quantitative proteomic analysis we will elucidate the disease specific pathways and through bioinformatics analysis, be able to link the convergent and divergent pathways that lead to MN cell death in both ALS and SMA when compared to control. In this study, we used the cutting edge proteomic approach, Data Independent Acquisition Mass Spectrometry (DIA-MS, also referred to as SWATH), and by first constructing a iMN sample specific DIA peptide assay library we used a targeted analysis approach to quantitate 3934 proteins across the 12 iMN samples. Our quantified proteome included key neuronal markers, such as MAP2, DCX and Snap25 and enriched protein classes include vesicle coat proteins, SNARE proteins, and non-motor microtubule binding proteins. Future studies include fingerprinting the molecular pathology of the disease at earlier stages in culture by comparing this set of iMN data to its iPSC counterpart in an effort to tease out any pathways that are affected by cell maturation and development, as well as reveal disease specific pathways that can then be associated with single genetic perturbations.

Abstract: Amyotrophic lateral sclerosis (ALS) is a severe neurodegenerative disease impacting motor neurons in the brain and spinal cord, with ensuing paralysis and death. With the advancements in human induced pluripotent stem cell technologies, there is a unique opportunity to define the molecular networks that govern cellular responses to disease. Through the NeuroLINCS consortium, a series of molecular, cellular and data analytic approaches are being used to generate cell signatures from human brain cells derived from unaffected individuals and subjects with ALS or spinal bulbar muscular atrophy (SMA). We first used differentiated motor neurons from individuals with an ALS-causing hexanucleotide repeat expansion in *C9orf72* to investigate how this dominant mutation affects the epigenomic landscape that may drive transcriptomic dysregulation. iPSC-derived motor neurons from ALS and control patients were analyzed using total RNAseq to define changes in gene expression and alterations in exon usage and splicing. In parallel, ATAC-Seq, which reveals regions of open chromatin, was performed to identify epigenomic changes in the disease state versus control. In order to gain mechanistic insights into the relationship between chromatin accessibility and gene expression changes, we developed a tool called AChroMap (accessible chromatin mapper of transcriptional regulators), which allows one to determine relevant transcriptional regulators for a set of genes across disease states. We have applied AChroMap to identify potential important regulators in the context of the *C9orf72* expansion that may drive transcriptional changes and contribute to potential disease related phenotypes. These approaches will be expanded to integrate proteomic, lipidomic, and metabolomic data, as well as whole genome sequencing, single cell imaging, and functional cellular readouts with various perturbations, and all of these data will be made available to the scientific community through NeuroLINCS and Answer ALS to further elucidate the pathogenic mechanisms in ALS motor neurons.

Title: Banking and distribution of motor neurons derived from induced pluripotent stem cells: A focus on motor neuron disease

Authors: *B. C. SHELLEY[1], B. MANDEFRO[1], L. SHUE[1], M. BANUELOS[1], D. WEST[1], L. ORNELAS[1], D. SAREEN[1], C. N. SVENDSEN[1], .. NEUROLINCS CONSORTIUM[2]; [1]Board of Governors Regenerative Med. Inst., Cedars-Sinai Med. Ctr., Los Angeles, CA; [2]NIH, Bethesda, MD

Abstract: There are many challenges involved in the production of valuable, consistent cell products that may be used to model diseases across different laboratories. We have addressed some of these challenges by creating a Production Core for human induced pluripotent stem cell (iPSC)-derived motor neurons that have been optimized for disease modeling studies and translational work. In particular, we are focusing our efforts on producing banks of motor neurons derived from patients with motor neuron diseases such as amyotrophic lateral sclerosis (ALS) and spinal muscular atrophy (SMA) using cutting-edge differentiation techniques for derivation and banking. Here, we describe our banking and quality control methodology with a focus on batch-to-batch consistency. Key aspects to the process include: standard operation procedure development and implementation, the initiation of a laboratory information management system (LIMS) for tracking manufacturing metadata throughout the growth process, and quality control measures such as short tandem repeat (STR) testing and immunocytochemistry for key motor neuron markers. Alongside these differentiation protocol optimizations, we are also developing genome-wide methods to assay global mRNA and protein expression in these cells. These analyses aim to sensitively gauge technical variability across batches, assess similarities to in vivo motor neurons, and detect biologically meaningful differences between disease and control conditions. Accounting for all these factors is critical for effective motor neuron-disease modeling.

Title: Uncovering mechanisms of toxicity in C9ORF72 ALS.

Authors: *J. OSTERLOH[1], S. FINKBEINER, 94158[2];
[1]Inst. for Neurolog. Dis., [2]Gladstone Inst., San Francisco, CA

Abstract: Amyotrophic lateral sclerosis (ALS) is an incurable motor neuron (MN) disease that affects approximately 30,000 people in the USA. It manifests clinically as progressive muscle weakness and atrophy and results in fatal respiratory failure typically within 5 years of onset. Expansions of hexanucleotide repeats in the C9ORF72 gene are the leading cause of ALS, accounting for 8% of sporadic and 40% of familial ALS cases. However, the underlying mechanisms driving MN death due to C9ORF72 expansions are unknown. Three hypotheses regarding the mechanism of motor neuron death have emerged: (1) loss of normal C9ORF72 function; (2) sequestration of RNA-binding proteins by transcribed hexanucleotide repeats; and (3) expression of toxic dipeptide repeats translated from the hexanucleotide sequence. Here, we use Robotic Microscopy to assess the relative contributions of each potential mechanism to cell death, as both expression of transcribed but not translated GGGGCC repeats and translated non-GGGGCC dipeptide repeats are both highly toxic. Together, this powerful longitudinal, single-cell analysis provides novel insights into the specific cellular dysfunctions and dynamics that drive cell death due to C9ORF72 expansions.

Title: Maturation of iPSC-derived motor neurons co-cultured with brain microvascular endothelial cells in micro-engineered ALS-Chip.

Authors: *S. SANCES[1], G. VATINE[1], R. BARRILE[2], D. WEST[1], A. LAPERLE[1], R. HO[1], C. LUCCHESI[2], C. HINOJOSA[2], N. WEN[2], J. KERNS[2], G. A. HAMILTON[2], C. N. SVENDSEN[1]; [1]Cedars Sinai Med. Ctr., West Hollywood, CA; [2]Emulate, Inc., Boston, MA

Abstract: Traditional *in vitro* systems used in human stem cell-based modeling of neurodegenerative diseases such as Amyotrophic Lateral Sclerosis (ALS) possess inherent limitations for biological and pathological relevance. Studies have revealed that stem cell-derived neural tissue is unable to mature fully *in vitro*. This fetal-like immature phenotype presents a challenge when studying genetic contribution to adult-onset pathogenesis *in vitro.* Here, we hypothesize that iPSC-derived motor neurons (MNs) can better mature through enhanced endogenous media conditioning and the addition of developmentally relevant, non-neuronal cell types in co-culture. To address this hypothesis, we developed a micro-engineered co-culture system, termed "ALS-Chip". Calcium imaging and patch electrophysiology were used to characterize the functional effects of micro-media volumes on the neuronal maturation of induced pluripotent stem cell (iPSC)-derived MNs originating from non-disease control and ALS patients. We then developed a robust co-culture paradigm with iPSC-derived brain microvascular endothelial cells (BMECs) that forms a functional blood brain barrier across a porous membrane separating two distinct culture chambers. We interrogated the contribution of BMEC co-culture to MN maturation through morphology, transcriptomic analysis and electrophysiology. In addition, we introduced laminar flow in the ALS-Chip and studied the transcriptional effects of flow on both cell types and compared this to a traditional 96-well culture. The establishment of this novel ALS-Chip *in vitro* modeling strategy permits further studies into ALS disease mechanisms and blood brain barrier-related therapy development.

Title: C9orf72 G_4C_2 HRE-mediated nucleocytoplasmic trafficking defects alter autophagic targeting

Authors: *J. R. MANN[1], A. M. GLEIXNER[1], M. R. MARKS[1], U. B. PANDEY[2], C. J. DONNELLY[1];
[1]Neurobio., [2]Pediatrics, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Working in conjunction with the ubiquitin-proteasome system (UPS), the autophagy-lysosomal pathway (ALP) plays a crucial role in the targeted degradation of damaged or aggregated proteins and dysfunctional organelles (1). Dysregulation of the ALP has been implicated in the pathogenesis of Amyotrophic Lateral Sclerosis (ALS), a progressive and fatal neurodegenerative disease affecting motor neurons of the brain and spinal cord (2). The G4C2 hexanucleotide repeat expansion (HRE) in C9orf72 is the most common genetic cause of familial and sporadic forms of ALS, accounting for up to 30% of familial and 8% of sporadic cases (3). Toxicity associated with expression of this C9orf72 HRE has recently been linked to impairments in nucleocytoplasmic trafficking that result in the nuclear retention of RNA species and sluggish import of proteins destined for the nucleus (3-4). Interestingly, these nuclear import defects correlate with enhanced levels of cytoplasmic TDP-43, a pathological hallmark of roughly 97% of all ALS patients (5-6). While the exact mechanisms underlying these nuclear transport defects remains unclear, both G4C2 RNA and dipeptide repeat protein products of the repeat expansion have been linked to this dysfunction. Given the role of autophagy in the degradation of aggregated cytoplasmic proteins (7), it is possible that C9orf72-mediated mislocalization of aggregate-prone proteins such as TDP-43 may alter the degradation profiles of autophagosomes responsible for delivering cytoplasmic components to the lysosome for degradation. We developed a simple immunoprecipitation-based method to isolate pure and intact autophagosomes and found that these LC3-positive autophagosomal vesicles contain diverse protein and RNA species. Using this technique in conjunction with screening

methodologies, we assessed how G4C2 RNA, C4G2 RNA, and their repeat-associated non-ATG translation (RANT) protein products altered the autophagosome degradation profiles in cell culture and iPSC neurons. In addition, we tested whether expression of WT and ALS-linked mutant TDP-43 and FUS proteins revealed common autophagosomal targets. Alterations in degradation profiles are currently being confirmed in ALS-patient CNS tissue regions that show G4C2/C4G2 RNA foci or RANT protein accumulation. The data generated from this work will be used to catalog unique and common targets of the ALP among genetic subtypes of ALS.

Title: Assessment of FG nup function in C9ORF72 ALS

Authors: *A. GLEIXNER[1], A. LUCE[1], J. R. MANN[1], M. R. MARKS[1], U. PANDEY[2], C. J. DONNELLY[1];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Pediatrics, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive and fatal neurodegenerative disease characterized by the degeneration of the motor neurons and interneurons in the brain and spinal cord. The majority of ALS occurs sporadically (sALS; 90%) with no family history. Genetic studies of patients with a family history of ALS, familial ALS (fALS; 10%) have been studied to identify ALS-causing mutations within the human genome. Despite 32 known ALS-causing mutations, a G_4C_2 repeat expansion in the first intron of the *C9orf72* gene has been identified as the most common known genetic cause of both fALS and sALS comprising 30% and 8% of cases, respectively. A molecular mechanism conferring neurotoxicity for the repeat

expansion mutation is the generation of toxic G_4C_2 RNAs that sequester RNA binding proteins and the accumulation of dipeptide repeat proteins (DPRs) through the non-canonical repeat associated non-ATG translation (RANT) pathway. Recent studies show that the expression of G_4C_2 or arginine-rich DPRs, products of the *C9orf72* repeat expansion, dramatically alter the nucleocytoplasmic transport pathway. This results in the nuclear retention of RNAs and the reduction in the rate of nuclear import of proteins that contain a classical nuclear localization sequence (NLS) and the cytoplasmic enrichment of TDP-43. Moreover, components of the nuclear pore complex (NPC) were identified as potent modifiers of both nuclear transport defects and neurodegeneration in C9orf72 ALS *Drosophila* models. The NPC functions to regulate transport of molecules >40kDa across the nuclear membrane. It is comprised of thirty different nucleoporins and approximately half of the nucleoporins contain intrinsically disordered phenylalanine-glycine repeat domains (FG domains). FG Nups comprise the selective barrier of the NPC and their dysfunction alters the compartmentalization of nuclear and cytoplasmic proteins. Loss of some FG nucleoporins (FG nups) have been shown to modulate degeneration in C9ORF72 ALS *Drosophila* models. In this work, we begin to address the role of FG Nups in C9orf72 ALS pathobiology. Here, we employed a genetic screen in RNA and DPR *Drosophila* models of C9orf72 ALS and iPSC motor neurons to determine FG Nups important for C9orf72 mediated neurodegeneration. Next we assessed how C9orf72 RNA and/or DPR products alter FG Nup biology including stability and post-translational status. Finally, we determine if modulating FG Nup function and contributes to or rescues nucleocytoplasmic trafficking deficits in C9ORF72 ALS.

Title: Defining the pathways responsible for the nuclear export of g4c2 rna in c9orf72 als/ftd ipsc neurons

Authors: *M. R. MARKS[1,2], J. R. MANN[1,2], A. M. GLEIXNER[1,2], C. J. DONNELLY[1,2]; [1]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [2]Live Like Lou Ctr. for ALS Res., Univ. of Pittsburgh Brain Inst., Pittsburgh, PA

Abstract: The G_4C_2 repeat expansion in the *C9ORF72* gene has been identified as the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD), diseases that cause the degeneration of motor neurons and/or cortical neurons of affect patients. The C9ORF72 hexanucleotide repeat expansion is thought to act through a gain of function mechanism where the G_4C_2 RNA and/or its dipeptide repeat protein products (DPRs) impair the function of nuclear pore complexes (NPC). This leads to increased nuclear retention of cellular RNAs and a reduction in the nuclear import of proteins containing a classical nuclear localization sequence (NLS). Recent studies have revealed that genetic correction of nucleocytoplasmic transport via the enhancement of protein import is neuroprotective to G_4C_2-expressing *Drosophila.* Furthermore, studies in *Drosophila* expressing an intronic G_4C_2 sequence suggest nuclear retention of G_4C_2 RNA is neuroprotective. Taken together, these data indicate that the nuclear export of G_4C_2 RNA might be a key toxic mechanism that underlies C9ORF72 gain of function neurotoxicity. Here we aim to study the mechanism of G_4C_2 RNA nuclear export employing iPSC motor neurons from C9ORF72 ALS patients. The G_4C_2 RNA has been shown to form hairpins and G-quadruplex structures and might therefore highjack a number of nuclear export pathways for similar structured RNAs. To test this, we modulated critical components of the export machinery for mRNA, tRNA, snRNA, miRNA, and rRNA and assessed G_4C_2 RNA foci localization and DPR accumulation. In addition, we evaluated whether reducing the nuclear export of G_4C_2 RNA rescues nucleocytoplasmic trafficking defects previously observed in C9ORF72 iPSC neural cultures. Thus, if inhibiting G_4C_2 RNA export rescues these defect, it may act as a novel strategy for therapeutic development for C9ORF72 ALS/FTD.

Title: Determining the minimum neuroprotective dose of n6-cyclopentoadenosine that prevents seizure after exposure to soman and vx nerve agents.

Authors: *T. P. THOMAS[1], T.-M. SHIH[2];
[1]Army Res. Lab., Aberdeen Proving Ground, MD; [2]US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD

Abstract: Nerve agents, such as soman (GD) and VX, produce toxic effects via acetylcholinesterase inhibition. Current medical countermeasures display limited efficacy in preventing seizure and neuropathology. Previously, we showed that N6-cyclopentoadenosine (CPA), an agonist for the A1 adenosine receptor (AR), effectively prevented seizure and neuropathology at 55-60 mg/kg (intraperitoneally) in a GD seizure rat model. Although CPA was neuroprotective at that high dose, there were unwanted side-effects such as sedation and depression of cardiac output. This study aimed to determine if lower doses of CPA could prevent GD-induced seizure with fewer side-effects. Therefore, we conducted a dose escalation experiment to determine the minimum effective dose of CPA that prevented excitotoxicity after GD exposure for 24 hrs. Specifically, rats received CPA at 25, 30, 40, 50, or 60 mg/kg 1 minute after a 1.6xLD_{50} dose of GD. For control, rats received saline (i.e., 0 mg/kg CPA). Full protection from GD seizure was only achieved at 60 mg/kg (N=10). At 0, 30, 40, and 50 mg/kg, seizure rates were 100% (N=12), 67% (N=6), 50% (N=4), and 40% (N=5) respectively. Although CPA at 40 and 50 mg/kg did not prevent 100% seizure, all rats survived until the study's endpoint (at 24 hrs)-a significant improvement over the control group (0% survival). Whereas rats receiving 0 mg/kg CPA displayed severe cholinergic symptoms (e.g., salivation), hypersecretions were suppressed by CPA treatment at doses ≥ 40 mg/kg. Consequently, peripherally administered CPA may provide compressive protection by mitigating both peripheral and central cholinergic crises. Since the efficacy of neuroprotectants may vary between G and V nerve agents, we also evaluated CPA's efficacy against a challenge of VX at 1.6xLD_{50}. Investigation started by comparing the effects of CPA 0 mg/kg (control) to 60 mg/kg after VX. Twelve of the 14 controls experienced seizure and 7 survived 24 hrs. CPA at 60 mg/kg provided complete protection from seizure, and 10 of the 13 rats survived 24 hrs. Moreover, rats receiving 60 mg/kg treatment did not display peripheral signs. The success of 60 mg/kg of CPA prompted a dose reduction study where CPA was lowered until seizure activity was detected. In

all, we tested 60, 50, 40, 30, 20, 10, and 5 mg/kg CPA. Seizure was only detected in rats receiving CPA at 5 mg/kg. At that dose, 50% of the rats experienced intermittent seizure activity. The minimum effective dose that prevented all VX seizure was 10 mg/kg. The mechanism for CPA's marked efficacy at significantly lower doses for VX vs. GD requires further study. Although the doses differ, CPA proved to be a highly protective treatment strategy for both G and V agents.

Title: Brief exposure to isoflurane as a post-exposure treatment against organophosphate chemical threat agents.

Authors: *J. KRISHNAN[1], J. R. MOFFETT[2], T. H. FIGUEIREDO[2], A. P. APPU[2], P. ARUN[2], M. F. BRAGA[2], A. M. NAMBOODIRI[2];

Abstract: Organophosphate poisoning is a significant world health problem, claiming thousands of lives per year through intentional and unintentional pesticide exposure. Potential for a terrorism based release scenario has made the situation worse. Organophosphate based chemical threat agents (CTA) exert their toxic effects through cholinergic over-activation during the initial phase. However, if not treated immediately, shifts to a glutamatergic phase which can lead to status epilepticus (SE), irreversible neuronal degeneration and long term CNS damage. Prognosis for any CTA-based post exposure treatment is poor since most drugs fail to inhibit the post exposure phase of non-cholinergic activation. Recently, we have reported that intranasal delivery of obidoxime (OBD) provides almost 100% neuroprotection against lethal dose of paraoxon when administered 5 mins after intoxication. In subsequent studies, we have examined the post exposure time window of effectiveness and found that OBD was not effective at 30 min. During these studies, we have discovered that isoflurane, the anesthetic used for the intranasal delivery, was very effective as a post exposure neuroprotectant. Sprague Dawley rats (250 ±40g) were exposed to lethal dose of paraoxon (4mg/kg) and were randomly assigned to control group and isoflurane treated group with a time course from 10min to 2 hours. Isoflurane treatment involved

2% isoflurane exposure for 3 mins followed by 5% for 1 min in 100% oxygen. All animals exhibited at-least stage 3 seizures, according to modified Racine scale until they were treated with isoflurane. Post exposure Isoflurane treatment decreased seizure severity significantly with the peak effectiveness when isoflurane was given around 30 min post exposure. Animals were euthanized at 24 h following transcardial perfusion using 4% formaldehyde and Fluoro-Jade-C staining was performed in brain slices. There were extensive neuronal degeneration in the surviving untreated control animals 24 hours after paraoxon administration, whereas degenerating neurons decreased significantly in the isoflurane treated groups, with the greatest reduction at around 30 min post treatment period. Dose -response studies indicated that exposure to 2% isoflurane for 3 min followed by 1 min exposure in the -3.5 to 5% range is effective. Studies are in progress to determine the possible mechanisms involved. Our subsequent goal is to develop isoflurane as a post exposure treatment for CNS damage caused by CTA exposure in view of the lack of toxicity due to the brief exposure required, noninvasive nature and attractiveness for field applications in a terrorism scenario.

Title: A brain slice model of gulf war illness allows for mechanistic studies and the search for antidotes

Authors: *P. A. FERCHMIN[1], D. PEREZ[1], M. CARRASCO[1], M. PEREZ LASSALLE[1], H. A. MARTINS[2], V. A. ETEROVIC[1];
[1]Biochem., Univ. Central Del Caribe, Bayamon, PR; [2]Pharmacol. & Toxicology, Univ. of Puerto Rico - Med. Sci. Campus, San Juan, PR

Abstract: Gulf War Illness (GWI) is a neurological syndrome afflicting about 25% of veterans from the Gulf War (1990-1991). The etiology of the GWI are the neurotoxicants to which the

veterans were exposed. The relevant neurotoxicants include traces of sarin, pyridostigmine (PB), N,N-diethyl-meta-toluamide (DEET), and permethrin (Per). Here diisopropylfluorophosphate (DFP), a surrogate of sarin, was included instead of sarin. The objective of the present project was to study the mechanism of GWI with the aim of developing antidotes to alleviate the GWI. The method used was an ex-vivo model which is faster and less costly than classical in vivo models. The neurotoxicity and neuroprotection were assessed by recording population spikes (PS) from acute hippocampal slices. PSs are the sum of the synaptically elicited axon potentials of a population of neurons. Axon potentials are all-or-none robust responses produced by functional neurons. The loss of PSs is an early event that precedes neuronal death which can be prevented by neuroprotective compounds. Remarkably, the neuroprotective and neurotoxic effects observed in slices have repeatedly been confirmed in vivo confirming the usefulness of this method. All the chemicals implicated in the GWI showed toxicity in this hippocampal slice model. The order of toxicity was DFP>PB>Per>DEET. The GWI drugs were tested by application to the slices for 2 hours in μM concentrations followed by 1 hour of the presumed antidotes. GWI drugs decreased the PS in a concentration-dependent manner. However the application of edelfosine, flupirtine or (1S,2E,4R,6R,7E,11E)-cembra-2,7,11-triene-4,6-diol (4R) restored 80-90% of the initial PSs. Edelfosine is an inhibitor of PLC-beta3, flupirtine is an activator the Kv5.2-7 channels and 4R is a neuroprotective, and anti-inflammatory cembranoid developed by our group. Our data suggest that the pivotal component of the GWI neurotoxicity is the over-activation of PLC-beta3 and inhibition of Kv5.2-7 channels. In slices, this causes glutamatergic excitotoxicity and inflammation. A chronic in vivo exposure to GWI drugs will likely cause a pathological lingering glutamatergic excitotoxicity, and inflammation later expressed as a neurological deficit. Paradoxically the symptoms of the GWI continue in the absence of the neurotoxic agents indicating that the GWI is perpetuated by a vicious cycle. We suggest that the GWI symptoms could be ameliorated by reactivation of the Kv5.2-7 channels and decreasing inflammation.

Title: Human chorionic gonadotropin protects the neonatal brain against hypoxic-ischemic neurodegeneration and inhibits glutamate-dependent excitotoxic neuronal cell death

Authors: *R. GALINDO[1], T. Z. MOVSAS[2], R. WEINER[3], D. M. HOLTZMAN[3]; [1]Neurol., Washington Univ. In St. Louis, Saint Louis, MO; [2]Zietchick Res. institute, LLC, Plymouth, MI; [3]Washington Univ., St. Louis, MO

Abstract: Neonatal cerebral hypoxia-ischemia (H-I) is a major cause of perinatal mortality and neurodevelopmental dissability in children although limited effective strategies are available for its prevention and treatment. The placental hormone human chorionic gonadotropin (hCG) is a glycoprotein with potential neuroprotective properties with recent data demonstrating beneficial effects in animal models of adult stroke. In the present study we ask whether hCG acts as a neuroprotectant against the effects of neonatal cerebral H-I. We tested this hypothesis in two ways. First, we used the modified Levine model of newborn H-I to examine the protective effects of in *vivo* hCG in the term-equivalent neonatal mouse. Second, we examined the direct actions of hCG against the neurodegenerative effects of glutamate-dependent excitotoxic neuronal injury *in vitro* utilizing the dissociated hippocampal and cortical neuron preparation. *In vivo* intraperitoneal (IP) injection of 1.5 IU/mg of hCG 18 hours prior to H-I decreased hippocampal and striatal tissue loss by 36% and 29% respectively. In addition, IP hCG administration increased cerebral levels of vascular endothelial growth factor mRNA, a molecule with known neuroprotective actions in the immature brain. The neuroprotective effect of hCG is possibly mediated via a glutamate-dependent mechanism given that *in vitro* administration of hCG at a physiological concentration (2 IU/mL) promoted the survival of immature cortical and hippocampal neurons following glutamate-dependent excitotoxicity. High doses of hCG did not adversely affect neuronal survival, but rather resulted in an increase in neuronal fiber sprouting. The above observations suggest that hCG may be a potential novel neuroprotective agent against the neurodegenerative effects caused by neonatal hypoxic-ischemic brain injury.

Title: $GABA_A$ alpha4beta3delta receptors are a target to supplement standard medical countermeasures for status epilepticus caused by acute soman poisoning

Authors: H. MCCARREN[1], R. YOSHIMURA[2], D. HOGENKAMP[2], C. SMITH[1], *K. W. GEE[2], J. MCDONOUGH[1], T. JOHNSTONE[2,1];
[1]Res. Div., U.S. Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD;
[2]Pharmacol., Univ. of California Irvine, Irvine, CA

Abstract: The neurological outcome of acute organophosphorus (OP) poisoning is a state of chronic uncontrolled epilepsy in the brain (i.e., status epilepticus, SE). Standard medical countermeasures for OP-induced seizures include midazolam, a benzodiazepine (BZ) anticonvulsant with rapid onset of action and reasonable efficacy on the survival rate of victims. However, improvement of seizure control is needed at longer time points after nerve agent exposure to minimize the resulting lethal neuropathology. Soman (GD) exposure is reported to reduce surface expression of synaptic $GABA_A$ receptors ($GABA_AR$) in the hippocampus to impair $GABA_AR$ function. Therefore sufficient receptors responsive to BZs may not be available for receptor modulation after poisoning. We tested whether enhanced function at extrasynaptic delta-subunit containing $GABA_ARs$ could augment the control of nerve agent poisoning. Two high efficacy/high potency modulators of alpha4beta3delta $GABA_ARs$ were tested against pilocarpine-induced seizures in mice and acute GD poisoning in rats. UCI50027 (non-selective neurosteroid) or 2-261 (beta-subunit subtype selective enaminone) were co-injected with 1 mg/kg scopolamine 30 minutes prior to a 416 mg/kg dose of pilocarpine. Mice were placed in individual housing and tremors, clonic seizures, SE, tonic seizures and death were noted. In the GD studies, rats were prepared for brain electroencephalographic (EEG) waveform measurements then placed in chambers to record ~30 min of normal EEG baseline. The animals were then pretreated with the oxime HI-6 (125 mg/kg, IP) and 30 min later challenged with GD (180 ug/kg, SC) at a dose that elicits electrographic seizure activity in 100% of the animals. Twenty minutes following the onset of seizure activity the animals received standard medical countermeasures (0.45 mg/kg atropine sulfate admixed with 25 mg/kg, 2-PAM, IM; 1.8 mg/kg, midazolam, IM) for nerve agent intoxication with or without a test dose of UCI50027 or 2-261. Evaluation and categorization of the EEG response to treatment was performed (4 hrs) and rated by absence of all spiking and/or rhythmic waves. Inclusion of UCI50027 in the standard medical countermeasure terminated seizure activity in test animals and afforded protection from seizures supported by reductions in gamma power and decreases in mean spike frequency.

Alpha4beta3delta $GABA_A$Rs targeted compounds may augment standard medical countermeasures for GD poisoning by enhancing synaptic GABA efficacy of BZs and provide additional efficacy at extrasynaptic $GABA_A$Rs.

Title: Axonal transport, mitochondrial dynamics, and gulf war illness (*In vitro* studies)

Authors: *S. X. NAUGHTON[1], J. GAO[2], C. M. HERNANDEZ[1], A. V. TERRY, Jr[1];
[1]Pharmacol. and Toxicology, [2]Augusta Univ., Augusta, GA

Abstract: The disorder known as Gulf War Illness (GWI) affects about 25-30% of veterans deployed to the Gulf War in 1990-91 and is characterized by a variety of chronic symptoms including neurologic deficits. While a host of potential contributing factors have been implicated, the underlying pathophysiology of the specific symptoms of GWI has not been clearly established, thus limiting the development of effective treatment strategies. One compelling explanation for the neurological-based symptoms is exposure to acetylcholinesterase inhibitors (AChEIs) (Golomb et al., 2008) including organophosphates (OPs). Previous studies in our laboratory have shown that OPs (e.g., chlorpyrifos) can impair the transport of mitochondria in axons as well as lead to alterations in mitochondrial dynamics, suggesting potential mechanisms for the aforementioned neurologic deficits. Here, using a time-lapse imaging technique in cortical neurons, we evaluated chlorpyrifos (CPF) and its oxon metabolite (CPO) across a wide range of concentrations (subnanomolar to micromolar) for effects on fast axonal transport of membrane bound organelles (MBOs) that contained the amyloid precursor protein (APP) tagged with the fluorescent marker, Dendra2 (APPDendra2). 24 hours of exposure to CPF and CPO resulted in a decrease in the velocity of anterograde and retrograde movements of MBOs and an increase in the number of stationary MBOs. These effects of CPO occurred at picomolar (100 pM) to low nanomolar (0.1 nM) concentrations that were not associated with compromised cell viability or cytoskeletal damage. Moreover, the effects of CPO and CPF on axonal transport occurred at concentrations that did not inhibit AChE activity and they were not blocked by

cholinergic receptor antagonists. Given the fundamental importance of axonal transport to neuronal function, these observations may explain some of the long term neurological deficits that have been observed in GWI and in others exposed to organophosphates (e.g., farmers, pesticide applicators). In ongoing studies we are also seeking to elucidate the relationship between axonal transport and mitochondrial dynamics, and to utilize phenotypic screening measures to pursue therapeutic compounds which may reverse OP associated deficits within these domains.

Title: Vascular endothelial degeneration in the rat striatum is associated with prolonged exposure to rotenone

Authors: *Z. K. BINIENDA, B. GOUGH, S. SARKAR;
Natl. Ctr. Toxicological Res/Food and Drug Adm., Jefferson, AR

Abstract: The plant-derived pesticide, rotenone, is a potent mitochondrial toxin that leads to degeneration in striatal nerve terminals and nigral neurons. Rotenone-induced behavioral, neurochemical and neuropathological changes in rats mimic those observed in Parkinson's disease. We previously reported rotenone-induced decreases in tyrosine hydroxylase (TH) in the striatum as well as in the substantia nigra and a time-dependent depletion of striatal dopamine, concomitant with peripheral motor nerve dysfunction following a prolonged exposure. Rats were treated with rotenone at 1 mg/kg i.p. for 37 days. Control rats received vehicle (30% Solutol HS 15 in 0. 9% saline). A loss of dopamine transporter (DAT) and TH in the midbrain was observed along with activation of both microglia and astroglia after rotenone treatment. Here, striatal vascular integrity was evaluated in the same animals using a rat endothelial cell antigen -1 RECA-1 immunostaining method. Rats were perfused after treatment with 4% paraformaldehyde for immunohistochemical analyses. In the rotenone treated animals, RECA-1 immunolabeled endothelial cells were shrunken, regressed and thinner compared to those from vehicle controls. Image analysis using Image J software revealed that the % area of the RECA-1 positive vessels

was 4.53 ± 0.96 in rotenone treated vs. 9.05 ± 0.96 in control rats ($p<0.05$) and the average area was 22.21 ± 1.62 μm in treated vs. 33.51 ± 3.10 μm in controls ($p<0.05$). This study indicates that prolonged exposure to the neurotoxin, rotenone, not only decreases TH and DAT in the striatum but also affects endothelial cells in that area. The sequence of events, i.e., whether endothelial cell degeneration is caused by the neurodegeneration or the neurodegeneration and neuro-inflammation are concomitant with vascular damage has yet to be determined.

Title: Foxo1-mediated inflammatory response after cerebral hemorrhage in rats

Authors: *J. ZHAO, Z. Y. LI, Q. HE, X. ZHAI, Y. YOU, Y. ZHAO, Y. H. HOU; CHONGQING MEDICAL UNIVERSITY, Shanghai City, China

Abstract: The forkhead box O (Foxo) family of transcription factors plays a crucial role in cell apoptosis, immune regulation, and tissue development. Foxo1, as the foremost member of the Foxo family, regulates a wide range of molecular signals in many tissues, including tumor, liver, and brain. This study investigated Foxo1 expression at different time points and in different brain areas, and the role of Foxo1 *in vivo* in regulating inflammatory injury in a rat model of autologous blood-injected cerebral hemorrhage injury. We found that Foxo1 expression peaked at 12 h post-intracerebral hemorrhage (ICH) and in the ipsilateral corpus striatum. Foxo1 knockdown by Foxo1 siRNA decreased ICH injury, improved neurological function, and decreased the expression of inflammatory factors downstream of the Foxo1 pathway, including TLR4, NF-κB, TNF-α, IL-1β, and IL-18. Foxo1 knockdown also decreased the expression and activity of myeloperoxidase, IL-1β, and IL-18. In conclusion, our findings demonstrate that Foxo1 is a key regulator of inflammatory injury in rats after ICH. By identifying the molecular mechanisms of Foxo1/TLR4/NF-κB signaling, we provide a novel rationale for therapeutic approaches to managing inflammatory injury after ICH.

Title: Nanocoffee increases stem cell proliferation and displays neurogenic and neuroprotective effects in stroke models

Authors: *V. DE ALVARENGA GUEDES[1], J.-Y. LEE[1], M. PROVENZANO[3], I. ANTONUCCI[3], L. STUPPIA[3], K. RICHARDS[1], N. TAJIRI[1], C. CAO[2], C. V. BORLONGAN[1]; [1]Dept. of Neurosurg. and Brain Repair, [2]Dept. of pharmaceutical Sci., Univ. of South Florida, Tampa, FL; [3]Dept. of Psychological, Hlth. and Territorial Sci., G. d'Annunzio Univ., Chieti-Pescara, Italy

Abstract: Stroke is a leading cause of death and disability in the world. Despite the clinical relevance of stroke, available treatment options are limited, thereby making the development of novel therapies an urgent need. Epidemiological and animal studies have attributed neuroprotective properties to coffee. In the present study, we used well-established in vitro and in vivo ischemic stroke models to investigate the therapeutic potential of nanosized coffee (nanocoffee). In vitro, we exposed human amniotic-fluid stem cells (AFSCs) or rat primary cortical neurons to oxygen-glucose deprivation (OGD). AFSCs and cortical neurons were treated with different concentrations of nanocoffee and subsequently exposed to the OGD procedure for 90 minutes. Additionally, AFSCs were treated with nanocoffee for 24 hours in the absence of insult (normoxic condition, regular cell culture medium). Cell viability was measured using a calcein AM (Acetoxymethyl) assay. In vivo, adult male Sprague-Dawley rats were submitted to the middle cerebral artery occlusion (MCAo) model, which induces transient unilateral focal ischemia. Rats received a single intrajugular vein injection of nanocoffee or vehicle immediately after the beginning of the artery occlusion. All animals were euthanized 3 days after the MCAo for cresyl-violet staining and immunohistochemistry experiments using ki67 (cell proliferation marker) and doublecortin (neurogenesis marker). We observed that AFSCs ($p<0.01$) and cortical neurons ($p<0.05$) were protected against OGD-induced cell death by the nanocoffee treatment. Additionally, nanocoffee increased AFSCs proliferation under regular cell culture conditions ($p<0.01$). In vivo, we found an increase in both cell proliferation and neurogenesis in the

subventricular zone (SVZ), a neurogenic niche in the mammalian brain, with the nanocoffee treatment (p's<0.05). No significant effects of the nanocoffee treatment were observed on the number of live cells in the peri-infarct area as revealed by the cresyl violet staining. The present study shows that nanocoffee stands as a potent stem cell proliferative agent, displays proliferative and neurogenic effects in the SVZ, and acts as a neuroprotectant in an in vitro stroke model. Our results suggest that nanocoffee has a therapeutic potential in stroke. Studies of nanocoffee mechanisms of action are underway.

Title: Bio activates the canonical wnt pathway to ameliorate neuronal cell death *In vitro* and following intracerebral hemorrhage

Authors: ***J. Y. ZHANG**[1], S. WON[1], Z. Z. WEI[1], Y. ZHOU[2], S. P. YU[1], L. WEI[1,2];
[1]Emory Univ., Atlanta, GA; [2]Neurol., Beijing Friendship Hosp., Beijing, China

Abstract: Hemorrhagic stroke, or intracerebral hemorrhage (ICH), is a devastating medical emergency that accounts for 15% of all stroke cases, but results in 40% of stroke-related mortality. Currently, no effective clinical treatments exist to counteract ICH. In the present investigation, we evaluated 6-bromoindirubin-3'-oxime (BIO) after ICH as a therapeutic candidate. BIO is a selective inhibitor of glycogen synthase kinase 3β (GSK-3β), a key intracellular signaling mediator of multiple pathways. One of the signaling pathways inhibited by GSK-3β is the canonical Wnt/β-catenin system, which is involved in transcriptional regulation of mitogenic and trophic genes, such as c-Myc and brain-derived neurotrophic factor (BDNF). Because BDNF promotes neuronal viability, we hypothesized that activation of the canonical Wnt pathway would confer neuroprotective effects. Specifically, we evaluated whether post-ICH

treatment with BIO could enhance cellular survival. The neuroprotective effects of BIO was firstly examined in primary cortical neuronal cultures subjected to oxygen-glucose deprivation (OGD). Cell death was measured at 24 hrs after OGD using the lactate dehydrogenase (LDH) assay and 3-(4,5-dimethyl-thiazol-2-yl)-2,5-diphenyltetrazolium (MTT) assay. BIO (0.1 - 10 μM, co-applied with OGD) significantly enhanced neuronal viability in a dose-dependent pattern, with the greatest neuroprotection observed at 10 μM. In addition, in primary astrocyte cultures subjected to OGD, activation of the canonical Wnt pathway did not show significant effect on astrocyte death, suggesting that the Wnt pathway is specific for neuronal viability. Next, we implemented BIO administration in an ICH model of adult mice, induced by injections of collagenase IV into the striatum. BIO (150 μL, 4 μM, i.p.) was co-administered during collagenase IV injection, and then the animals were sacrificed at 48 hr post-ICH for immunohistochemistry. In immunohistochemical staining of terminal deoxynucleotidyl transferase dUTP nick end labeling (*TUNEL*), cell death was examined by colabeling with the neuronal marker NeuN and astrocyte marker GFAP. The cytotoxicity was almost exclusively localized to neurons, with astrocytes undergoing minimal cell death. Importantly, BIO successfully ameliorated the magnitude of neuronal cell death and decreased the hemorrhage size and the area of necrotic tissue. Overall, this report provides new evidence for a translational potential of BIO following intractable brain injuries, such as ICH.

Title: Inhibition of RGMa cleavage promotes axonal regeneration and improved neurological deficits after CNS injuries

Authors: ***N. G. TASSEW**[1], A. SHABANZADEH[2], P. BANERJEE[2], P. MONNIER[2];
[1]Toronto Western Res. Inst., Toronto, ON, Canada; [2]Krembil Res. Inst., Toronto, ON, Canada

Abstract: RGMa inhibits outgrowth of many types of CNS neurons through interaction with its receptor, Neogenin. The RGMa/Neogenin pathway is involved in several processes both in the developing and mature CNS, including axon guidance, cell differentiation, cell survival, and

axonal regeneration. RGMa is processed into several fragments by a combination of autocatalytic and proprotein convertase (Furin and SKI-1) enzymatic cleavages. The ensuing membrane bound and soluble fragments interact with Neogenin and inhibit axonal outgrowth. Since RGMa is upregulated at the lesion site after CNS injury, we hypothesized that treatment with SKI-I inhibitor will prevent its activation following CNS injuries. The present study examined the therapeutic effects of SKI-1 inhibitor (PF 429242) in optic nerve crush and middle cerebral artery occlusion (MCAO) models. We show that inhibition of RGMa cleavage leads to axonal regeneration in optic crush model, and reduced infarct volume and improved neurological deficits following cerebral ischemia.

Title: Effect of GW4869 in serum free DITNC1 astrocyte culture

Authors: *P. R. GUDA[1], S. RAY[2], O. A. KHAN[2], D. TRISLER[2,3,5], C. T. BEVER, Jr[2,4,5], T. K. MAKAR[2,4,5];

Abstract: Astrocytes play a major role in the central nervous system (CNS). Astrocytes secrete pro-inflammatory cytokines in different neurodegenerative diseases. Astrocytes grown in serum-deprived (SD) media can cause apoptosis by elevating different apoptotic proteins. Furthermore, astrocytes secrete exosomes, membrane-enveloped Nano vesicles. Exosomes communicate cell to cell by transporting genetic material, proteins and lipids and subsequently regulating functions of targeted cells .Exosome release is decreased by the inhibition of sphingomyelinase2, an important enzyme responsible for formation of ceramide from sphingomyeline, by using GW4869. In DITNC1 cells, it is found that GW4869 treatment (72 hr,40uM) effectively prevented apoptotic cell death under SD conditions. Our objective is to determine the neuroprotection role of GW4869 on SD DITNC1 astrocyte cell line where cell death occurs in an

apoptotic manner by inhibiting exosome release. 40 μM GW4869 was used in serum free media of DITNC1 cell culture. The cells were incubated for 72 hours in SD with and without GW4869 treatment. Interestingly, we found the level of endothelin1 (ET1) was significantly increased in serum free media and that cytokine levels were decreased after GW4869 treatment. We also found that Bax, cleaved-caspase 3, cleaved-caspase 9, apoptotic markers and ET1, an inflammatory molecule, were increased in SD cells and that all of these parameters were reduced after GW4869 treatment. Furthermore, we observed that the Drp1, mitochondrial fission marker, expression was significantly increased in SD cells and was suppressed by GW4869 treatment. In the same experimental condition, in the cell medium exosome content was downregulated in SD cells by GW4869 treatment compared to without drug treatment. Exosomes were isolated from the cell supernatant by centrifugation at 100,000 g for 2 hour. Exosome markers GAPDH and CD63 were determined by western blot analysis. Our results suggest that GW4869 increases cell survival by preventing exosome release and indicate nSMase2 as a potential drug target for astrocyte associated neuroinflammatory diseases. Collectively, our findings suggest That GW4869 can be used for anti-inflammation and neuroprotection.

Title: NF-kB S-nitrosylation in excitotoxicity

Authors: *A. CAVIEDES, K. CORVALAN, B. MATURANA, U. WYNEKEN;
Univ. De Los Andes, Las Condes, Chile

Abstract: Introduction: Excitotoxicity, i.e. neuronal death by excessive NMDA receptor activation, neuronal Ca^{2+} overload and nitric oxide (NO) synthesis, is a prominent mechanism leading to cell death (Sandoval et al. 2011, J Neurochem 118:760). NO leads to proteins S-nitrosylation. We postulate that in hippocampal (i.e. vulnerable neurons) and cortical neurons (i.e. more resistant neurons), a differential set of proteins involved in cell death regulation is S-nitrosylated following an excitotoxic challenge. **Materials and methods:** To pull down hippocampal S-nitrosylated proteins, the biotin switch method was applied. Proteins were

identified by mass spectrometry and validated by Western blots. Viability test were performed with the Trypan blue exclusion test. **Results:** From a total of 863 proteins, 744 were detected only in one of the culture conditions. S-nitrosylation levels in hippocampal and cortical cultures were compared by Western blots: S-nitrosylation of the scaffolding protein PSD-95 and of the NMDA receptor subunit GluN2A increased after NMDA incubation in cortical and hippocampal cells. S-nitrosylation of the scaffolding protein SAPAP4 increased only in cortical cells, while S-nitrosylation of the NF-κB subunit p65 increased in cortical cells (i.e. its transcriptional activity was potentially inhibited) while it decreased in hippocampal cells. Moreover, the NF-κB inhibitor 6-(Phenylsulfinyl)tetrazolo[1,5-b]pyridazine prevented hippocampal neuronal death while it had no effect on viability of cortical neurons. **Conclusion:** The results reveal a notable specificity of NO targets that is cell-type dependent. Bi-directional regulation of protein S-nitrosylation and especially, of NF-κB pathway components, may constitute a major mechanism able to control excitotoxicity-related cell death. Title: EPO neuroprotection and MAPK signalig pathway in excitotoxic brain injury model mediated by MSG

Authors: *S. F. CORNELIO-MARTINEZ[1,2], M. RIVERA CERVANTES[2], C. BEAS ZARATE[2];
[1]Neurobiología Celular, Ctr. Universitario De Ciencias Biológicas Y Agro, Zapopan, Mexico;
[2]Biologia Celular y Mol., Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Glutamate (Glu) is the main excitatory neurotransmitter in Central Nervous System (SNC). It has been show that play important role in many brain processes including differentiation, migration, survival, learning, plasticity memory and behavior. It function through two main types of Glu receptors (GluR), ionotropic and metabotropic. Excessive activation of GluR may excite nerve cells to their dead in a process referred as excitotoxicity. Thus Glu has also been implicated in neurodegenerative disorders like cerebral ischemia, traumatic brain injury, Huntington's disease, Alzheimer disease and epilepsy. These receptors triggering not only a significant Ca2+ influx but also the activity of transduction-signal cascade where the activation

of MAPK may promote S-phase entry of neurons, which leads to cell death. There are several in vitro and in vivo studies reporting neuroprotective effect of erythropoietin (EPO), through the activation of anti-apoptotic, anti-oxidant, and anti-inflammatory pathways as well as through the stimulation of angiogenic and neurogenic events. The main purpose of this work was to evaluate the MAPK signal cascade after the administration of excessive MSG, and determine the neuroprotective effect of EPO after excitotoxicity mediated through MSG. We evaluate the activation of MAPK cascade and the neuroprotective effect of EPO in the hippocampus of neonate male Wistar rats. First we evaluate the activation of MAPK signal cascade at 5, 6, 7 and 8 postnatal days (PD) after the administration of MSG at 1, 3, 5 and 7 PD using a selected PCR arrays, including MAPK signal pathway (PARN-061A) Rat Microarray MAP Kinase Signaling Pathway. Then we administered three different doses of EPO (250UI/kg body weight (bw), 500UI/kg bw and 1,000UI/kg bw) intravenously at 8 PD and determine the cell viability at 14 PD using Nissl technique, because it has been demonstrated that some regions of the hippocampus were more susceptible to cell damage at this age. Results of this work demonstrated that after the administration of MSG the MAPK signal cascade is activated and some of the molecular effectors of this cascade like Cdkn2, C-Fos, Ccnd2, Creb, Mapk13, Mapk10, Rac1 and Col1a1were up or down regulated. These molecules are related with cell cycle and may promote S-phase entry of neurons. We also demonstrated that after administration of EPO, cell damage in hippocampal CA1 region decrease compare with those animals that were administered with MSG only and the most effective dose of EPO was 1,000UI/kg bw.

Title: Cell death after experimental hemorrhagic stroke *In vitro* is ferroptotic and necroptotic

Authors: *M. ZILLE[1], S. S. KARUPPAGOUNDER[1], Y. CHEN[1], T. A. MILNER[2], E. A. JONAS[3], R. R. RATAN[1];
[1]Burke Med. Res. Inst., Weill Cornell Med. of Cornell Univ., White Plains, NY; [2]Feil Family

Brain and Mind Res. Inst., Weill Cornell Med. of Cornell Univ., New York, NY; [3]Dept. of Intrnl. Medicine, Section of Endocrinol., Yale Univ., New Haven, CT

Abstract: Intracerebral hemorrhage (ICH) accounts for about 15% of all strokes and has the highest mortality rates among strokes with up to 50% within 30 days after the insult. While direct tissue destruction strikes immediately, secondary injury including perihematoma edema formation, inflammation, and cell death occurs days and weeks following the hemorrhagic event. Hemoglobin and its breakdown product hemin induce toxicity, but it remains unclear how cells die following ICH. The aim of this study was to identify the underlying cell death mechanisms at a pharmacological, biochemical, and morphological level.

We systematically investigated cell death mechanisms after treatment of primary immature cortical neurons with 1.5μM hemoglobin or 100μM hemin. Twenty pharmacological inhibitors of different cell death pathways were studied and cell viability assessed. We confirmed the identified cell death mechanisms using biochemical markers with western blotting and RT-PCR in vitro and in vivo (collagenase ICH model in mice). To assess the morphological phenotype of cell death, we performed electron microscopy determining the number of cells per cell death morphology and mitochondria size.

We found that pharmacological inhibitors of ferroptosis – deferoxamine, N-acteylcysteine, the water-soluble analog of vitamin E, trolox, and U0126 – protected against hemoglobin- and hemin-induced toxicity. Furthermore, necrostatin-1, an inhibitor of necroptosis, also reduced cell death dose-dependently. In contrast, inhibiting caspase-dependent apoptosis, calpains, cathephins, protein or mRNA synthesis, autophagy or mitophagy did not increase cell viability. We then showed that phosphorylation of extracellular signal-regulated kinase 1/2, a marker for ferroptosis, as well as gene expression of receptor-interacting protein 1 and 3, a marker for necroptosis were increased following ICH in vitro and in vivo. Using electron microscopy, we identified that hemin induced a necrotic phenotype with loss of membrane integrity and swelling of organelles, but no shrunken mitochondria characteristic for ferroptosis. To be noted, we did not detect any apoptotic bodies in hemin-treated cells.

Our results suggest that iron overload caused by hemorrhagic stroke in vitro shares features of ferroptotic and necroptotic cell death, but not caspase-dependent apoptosis or autophagy. Distinct mechanisms of cell death imply different therapeutic approaches. Current studies are exploring the relevance of these in vitro findings to rodent models of hemorrhagic stroke.

Title: The pharmacological occupancy of the aryl hydrocarbon receptor and its effects on the kynurenine pathway

Authors: *L. G. GARCIA[1], R. CASTAÑEDA-ARELLANO[1], F. PEREZ-SEVERIANO[2], D. GONZÁLEZ-ESQUIVEL[2], R. O. GONZÁLEZ[3], G. ELIZONDO[1], J. SEGOVIA-VILA[1]; [1]CINVESTAV, D.F., Mexico, Mexico; [2]Inst. Nacional de Neurología y Neurocirugía, Mexico City, Mexico; [3]Univ. Autónoma Metropolitana, Mexico City, Mexico

Abstract: L-kynurenine (Kyn) is a key element of the tryptophan metabolism; it is enzymatically converted by kynurenine aminotransferase II (KAT II) to kynurenic acid (KYNA), which acts as an antagonist to the NMDA receptor-glycine site. Kyn is also an endogenous ligand of the aryl hydrocarbon receptor (Ahr), a transcription factor that regulates the expression of various genes. Interestingly, KYNA levels are reduced in several brain regions of Huntington's disease patients. Previously, we reported that KYNA levels are increased in the brains of *Ahr*-null mice and this induces a neuroprotective effect against neurotoxic insults. Based on these results, we decided to determine whether the pharmacologically- induced occupancy of Ahr had effects on KYNA bioavailability. We used TCDD, a powerful Ahr agonist and resveratrol an antagonist of the Ahr, to assess their effects on cerebral KYNA levels. TCDD was used in a single acute dose because of its toxic side effects, whereas resveratrol was administrated for six weeks. We found that both TCDD and resveratrol increased the striatal levels of KYNA in $Ahr^{+/+}$ mice, whereas it had no effect on $Ahr^{-/-}$ mice, indicating that increased KYNA is a consequence of occupying the Ahr. This strongly suggests that modulating Ahr activity could be neuroprotective. Therefore, we injected quinolinic acid (QUIN) into the striatum of both $Ahr^{+/+}$ and $Ahr^{-/-}$ mice previously treated with resveratrol or vehicle, and observed a neuroprotective effect in resveratrol-treated mice, presumably caused by increased KYNA. These data suggest that the pharmacological occupancy of Ahr could be an interesting therapeutic alternative to protect neurons.

Sch., Boston, MA; [9]Drug Discovery & Develop., Ever Neuro Pharma, Oberburgau, Austria

Abstract: Gold Nanoparticles (AuNPs) are used for treatment of cancer with whole body hyperthermia (WBH) therapy. Furthermore, nanodelivery of drugs using AuNPs for the treatment of Alzheimer's disease is also suggested. However, the safety and efficacy of AuNPs with regard to cellular toxicity is still not well known. Previous experiments from our laboratory showed that AuNPs depending on their sizes and route of administration could induce profound neurotoxicity in normal rats. Thus, 5 and 10 nm AuNPs induced blood-brain barrier (BBB) breakdown, edema formation and neuronal and glial cellular changes. However, 40-50 nm AuNPs in identical doses did not induce any apparent brain pathology. Interestingly, acute WBH

(at 38° C for 4 h) alone induces BBB breakdown, edema formation and cellular injury in healthy. However, repeated WBH for 1 or 2 h daily for 1 week at 38 °C did not result in brain pathology. Thus, it would be interesting to know weather a combination of AuNPs in acute or repeated WBH could further aggravate brain damage in healthy animals.
Male Wistar rats (age 20 to 25 weeks) were subjected to WBH at 38° C in a Biological Oxygen Demand (BOD) incubator (relative humidity 45-47 %; Wind velocity 20-26 cm/sec) either for 4 h or repeated heat exposure for 1 h daily for 1 week. In separate group of rats AuNPs (ca. 50 nm) was administered (5 mg/kg, i.p.) once daily for 1 week subjected to WBH either for 4 h or repeated 1 h heat exposure daily for 1 week. On the 8th day, BBB breakdown to Evans blue albumin (EBA) and radioiodine ($^{[131]}$-Iodine) and brain edema formation using water content was examined in several brain regions. Neuronal changes were examined using Nissl or H&E stain and glial cell activation was demined by immunohistochemistry of glial fibrillary acidic protein (GFAP) immunoreactivity.
Rats treated with AuNPs alone did not exhibit brain pathology after 1 week. However AuNPs intoxicated rats subjected to 4 h WBH exhibited 2-to 4-fold increase in BBB breakdown, 1.5 to 2-fold higher brain swelling and 2- to 4-folds greater increase in neuronal and glial cell injuries. On the other hand, AuNPs did not exhibit brain pathology in repeated WBH rats up to 5 days. However, on the 8th day marked increase in BBB breakdown, edema formation and cellular injuries were seen in the cerebral cortex, hippocampus, cerebellum and brainstem. Interestingly, treatment with TiO2-nanowired cerebrolysin (2.5 ml/kg, i.v.) 2 h after a 4 h WBH session, or once daily in repeated WBH group significantly prevented brain pathology on the 8th day in AuNPs treated animals. These observations are the first to point out that cerebrolysin could be used as an adjuvant therapy with AuNPs in WBH for acute or chronic cancer therapy.

Title: Potential protective effect of dexmedetomidine on ketamine-induced damage in embryonic neural stem cells

Authors: *Q. YIN, F. LIU, S. LIU, M. G. PAULE, C. WANG;
Div. of Neurotoxicology, Natl. Ctr. for Toxicological Research, FDA, Jefferson, AR

Abstract: Ketamine, an antagonist of *N*-methyl-D-aspartate (NMDA) receptors in the brain, is a commonly used pediatric general anesthetic. Evidence that ketamine can induce neural damage especially in the developing brain has been widely accumulating. Dexmedetomidine (Dex), a sedative and analgesic, is a selective agonist of the α_2-adrenergic receptor. It has been proposed that Dex is capable of ameliorating the neurotoxic effects of other general anesthetics but the underlying mechanisms contributing to this protection are still unclear. Embryonic neural stem cells (NSCs) were harvested from GD14 rat fetuses, cultured in neural stem cell growth medium for seven days, then exposed to different concentration (0.1nM,1nM,10nM,100nM,1μM,10 μM and 100 μM) of Dex with or without ketamine (10 μM) for 3, 6 or 24 hours. Mitochondrial viability, LDH release, and cellular reactive oxygen species (ROS) were evaluated using MTT, LDH and ROS assays, respectively. Our preliminary data indicate that no significant toxicological effects of Dex were observed in these embryonic NSCs: While the potential protective effects of Dex are still under investigation, the early dose-response and time-course data suggest that Dex may serve as protective agent against ketamine-induced neurotoxicity.

Title: Metallothioneins: new therapeutic targets in lysosomal storage disorders

Authors: *E. CAVALCA[1], M. CESANI[2], M. PEVIANI[1], D. PELLIN[3], C. DI SERIO[3], A. BIFFI[4];
[1]Dana Farber Cancer Inst., Boston, MA; [2]San Raffaele Telethon Inst. for Gene Therapy, Milan, Italy; [3]Universita' Vita Salute San Raffaele, Univ. Ctr. for Statistics in the Biomed. Sci., Milan, Italy; [4]Dana Farber/Boston Children's Cancer and Blood Disorders Ctr., Boston, MA

Abstract: Lysosomal Storage Disorders (LSDs) comprise more than 40 diseases, mostly characterized by neurodegeneration. For many LSDs current therapies are not effective in treating the neurologic symptoms, due to the impossibility to target the brain. The family of Metallothioneins (MTs) has been described as neuroprotective therapeutic tools for acute and chronic brain diseases acting mostly as anti-oxidant, but so far they have never been proposed for

the treatment of LSDs. We have recently showed that MT family is a reliable and sensitive marker for LSDs, being highly expressed in the peripheral circulation and more importantly in brains of patients and mice affected by LSDs. Moreover we demonstrated that in LSD patients and animal models MTs decrease to pre-symptomatic levels after treatment. All together these observations suggest a putative reactive and protective role of MTs that still needs to be further dissected. Aim of our work is to investigate the therapeutic use of MTs for alleviating neurologic damage in LSDs. To assess the benefit of constitutively high levels of MTs on LSD background, the mouse model of Globoid Cell Leukodystrophy (GLD), affected by a severe and rapidly progressive brain disease, was cross-bred with a transgenic mouse over-expressing MT1 in all tissues. Interestingly enough, the survival of MT1-GLD transgenic mice was slightly increased as compared to normal affected GLD mice. When dissecting the consequences of MT over expression in GLD mice, the most profound effect we observed was a rescue of Purkinje cells from degeneration and apoptosis. This effect was associated to i) a change of microglia phenotype towards an anti-inflammatory status with an increase of Arginase1 and CD206 expression paralleled by a decrease of IL1β and TNFα expression and ii) a reduction of oxidative stress in microglia cells as shown by quantification of ROS levels in these cells. The direct correlation of these events is currently under investigation, but we may speculate on the key anti-apoptotic and anti-oxidative role of MTs in protecting Purkinje neurons, as also suggested by a transcriptome analysis on cerebella of our models in which we further detailed the involvement of these pathways. We are now testing the same MT-overexpressing strategy in Late Infantile Neuronal Ceroid Lipofuscionosis (LINCL) mouse model, known to be affected by severe neurodegeneration. We have currently under behavioural evaluation MT-NCL mice that show a delayed disease progression as compared to NCL mice, resulting also in an improved survival. Overall, these data may pave the way for exploiting MT features for a therapeutic approach for neurodegenerative LSDs.

Title: Dendrite versus axon regeneration in central nervous system repair: which way to grow?

Authors: *L. MOONS[1], A. BECKERS[2], L. ANDRIES[2], J. VAN HOUCKE[2], I. BOLLAERTS[2], I. VAN HOVE[2], L. DE GROEF[2], K. LEMMENS[2];
[2]Biol., [1]KU Leuven, Leuven, Belgium

Abstract: Despite intensive research, successful regeneration and subsequent functional recovery of the injured or diseased mammalian central nervous system (CNS) can still not be evoked. One essential component of the neuronal circuitry might have been overlooked for decades: the dendrites.
During development of the retinofugal system, there is a distinct temporal window for axon *versus* dendrite outgrowth, in which axogenesis precedes dendritogenesis. Whether this recapitulates in the damaged adult CNS remains elusive, but loss of dendritic arborization and connectivity is being recognized as one of the first stages of neurodegeneration, also in glaucoma. Notably, this immediate retraction of dendrites after optic nerve damage might reflect an attempt to repeat the ordered developmental program in adult organisms. As axonal regeneration cannot yet be induced successfully in mammals, we investigated this intriguing hypothesis in the spontaneously regenerating zebrafish, which provides a unique model in the quest for crucial molecules and signaling pathways contributing to successful CNS regeneration. Using a combination of state-of-the-art molecular, biochemical and morphological tools, we were able to show that similar as in mammals, dendritic shrinkage occurs after optic nerve crush (ONC) in adult zebrafish. However, this is only temporal here and quickly followed by a recovery phase in which dendrites regain their length, morphology and synaptic connectivity. Strikingly, pharmacological approaches that counteract this temporal dendritic pruning, result in a reduced RGC axonal regrowth and optic tectum reinnervation. A detailed spatiotemporal characterization of the axonal and dendritic regeneration processes in fish subjected to ONC indeed revealed that axonal and dendritic outgrowth are antagonistic processes and one occurs at the expense of the other.
Overall, our findings disclosed that transient RGC dendritic shrinkage is necessary to induce spontaneous axonal regeneration in the adult zebrafish, and thus that the orderly developmental program of neurite outgrowth repeats. Currently ongoing investigations aim to shed light on how dendritic shrinkage/remodeling contributes to axonal regeneration in the injured zebrafish retinotectal system and to elucidate key molecular signals that regulate these processes, thereby contributing to the development of novel regenerative strategies promoting repair in human age-related neurodegenerative diseases such as glaucoma, but also Alzheimer's and Parkinson's disease.

Title: Protective mechanisms of Lycium barbarum polysaccharide in a murine hepatic encephalopathy model

Authors: *L. JINGJING[1,2], L. HUANG[2], Y. LV[2], C. REN[2], J. XIAO[2], K.-F. SO[3];
[1]Jinan Univ., Guangdong, China; [2]Jinan Univ., Guangzhou, China; [3]The Univ. of Hongkong, Hongkong, China

Abstract: Hepatic encephalopathy (HE) is a systematic dysfunction syndrome with metabolic disorders of the central nervous system (CNS) which is caused by severe liver damages and/or portosystemic shunt. HE has complicated pathological mechanisms and can seriously threatens patients' life. Lycium barbarum polysaccharide (LBP) is a biologically active extract which can regulate immune- and neuroendocrine-functions. In this study, we aimed to investigate the protective mechanisms of LBP in a murine HE model. We established this model by an intraperitoneal single dose injection of 400 mg/kg thioacetamide (TAA) in C57BL/6 mice. LBP (5 mg/kg) was intragastrically administered for once a day. Behavioral, biochemical and molecular tests were used to investigate the mechanisms. We also conducted cell experiment by culturing the rat normal hepatocyte line BRL-3A to examine the protective effect of LBP. We found that LBP significantly improved liver functions and cognitive performance of mice by suppressing hepatic/raphe/hypothalamus apoptosis, necrosis, oxidative stress and inflammation. MAPK and autophagic pathways played critical roles in those processes. In line with previous findings, amelioration of hyperammonemia contributed to the neuronal/hepatic protective properties of LBP. Furthermore, by using BRL-3A cell model, we confirmed that increased serum levels of pro-inflammatory cytokines and ammonia secreted from damaged liver were the major causes of brain damages. In conclusion, we proposed that LBP is a promising nutraceutical supplement for the daily prevention and clinical amelioration of HE.

Title: Thymoquinone protects neurons in intracerebro-ventricular kainic acid model of temporal lobe epilepsy by enhancing the gliosis and BDNF and VEGF levels

Authors: *H. UPTON, M. S. RAO;
Dept. of Anat., Kuwait Univ., Jabriya, Kuwait

Abstract: Temporal lobe epilepsy (TLE) is the most common type of epilepsy among other types of epilepsies. During the early phase after status epilepticus, there will be a significant neuronal death, gliosis and increase in neurogenesis in the dentate gyrus (DG). A few recent studies and our earlier studies have indicated the neuroprotective role of thymoquinone (TQ), the active component of nigella sativa oil in intracerebro-ventricular kainic acid (ICV-KA) model of temporal lobe epilepsy. TQ is shown to be a promising anticonvulsant for epilepsy treatment. Although thymoquinone, showed to be effective in restraining ICV-KA induced epileptic changes in the hippocampus and hippocampal neurogenesis, its mechanisms of actions have not previously been studied. Objective of the present study was to investigate the mechanisms of actions of thymoquinone (TQ) in neuroprotection in intra-cerebro-ventricular kainic acid (ICV-KA) model of temporal lobe epilepsy in young rats. Male Wistar rats (4months old) were divided into three groups: (1) Normal control (NC, n=12), (2) lesion only (LO, n=12), and (3) lesion + thymoquinone (L+TQ, n=12). Rats in the control group remained undisturbed. Rats in the lesion only group received a kainic acid lesion bilaterally in the hippocampus (0.5µg/ventricle). Rats in the lesion + Thymoquinone group were treated with thymoquinone (10mg/kg) intraperitoneally, 3 hours before lesion and daily thereafter for four days. On 5th post-lesion day rats in all groups were anesthetized and perfused with 4% paraformaldehyde. Brains were dissected and processed for cresyl violet, Flurojade-B staining and NeuN, OX-42 and GFAP immunostaining. Fresh hippocampal tissues were dissected and processed for Western blot analysis (GFAP) and analysis of BDNF and VEGF. Results of the study showed significantly decreased neurodegeneration, in the KA+TQ treated rats compared to lesion only group. Astrocyte number and GFAP content and microglial cells were significantly increased in TQ treated group ($p<0.01$) compared to control and lesion only group. Further, TQ treatment also increased the levels of BDNF and VEGF in the hippocampus ($p<0.01$) in TQ treated group. We conclude that TQ protects the neurons by increasing the astrogliosis and increasing the release of neurotrophic factors.

Title: Insulin-like growth factor binding protein 6 released from human mesenchymal stem cells confers neuronal protection

Authors: *M.-S. CHANG, H.-J. JEON, J.-H. SHIN, J. PARK;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Human bone marrow-derived mesenchymal stem cells (hMSCs) are a desirable cell source for cell-based therapy to treat nervous system injuries due to their ability to differentiate into specific cell types. In addition to their multipotency, hMSCs render the tissue microenvironment more favorable for tissue repair by secreting various growth factors. Our previous study demonstrated that hMSCs secrete many growth factors, including several insulin-like growth factor binding proteins (IGFBPs). Among them, IGFBP6 with high-affinity binding to IGF-2 inhibits the growth of IGF-2-dependent tumors by inhibiting IGF-2. However, relatively little is known about the function of IGFBP6 in the nervous system. Here, we elucidated the protective effects of IGFBP6 secreted by hMSCs on H_2O_2-injured primary cortical neuron cultures and LPC-injured organotypic spinal cord slice cultures. Treatment of H_2O_2-injured cortical neurons with conditioned media from hMSCs (hMSC-CM) increased phosphorylation of Akt and reduced both cell death and nuclear translocation of Bax. A blocking antibody against IGFBP6 abolished this hMSC-CM-mediated neuroprotective effect in both injured cortical neuron cultures and spinal cord slice cultures. In addition, treatment with cyclolignan PPP, an inhibitor of the IGF-1 receptor IGF-1R, significantly inhibited neuronal protection by hMSC-CM. These findings demonstrate that hMSC-CM-mediated neuroprotection is attributed to IGF-1R-mediated signaling by IGFBP6. Our study provides insight into the mechanism by which hMSC administration may promote recovery from nerve injury.

Title: The role of Brain-Derived Neurotrophic Factor in the protection of hippocampal neuron networks after glutamate-induced excitotoxicity

Authors: *K. M. O'NEILL[1,2], B. L. FIRESTEIN[1];
[1]Cell Biol. & Neurosci., [2]Biomed. Engin., Rutgers, the State Univ. of New Jersey, Piscataway, NJ

Abstract: In traumatic brain injury (TBI), the physical injury causes mechanical damage to nervous tissue and activates a chemical cascade, resulting in glutamate-induced excitotoxicity (GIE). Despite improved knowledge of the mechanisms of TBI, there is still no agreed-upon treatment for GIE. In particular, N-methyl-D-aspartate receptors (NMDARs) have been implicated in GIE: overactivation of NMDARs leads to excessive levels of intracellular calcium levels, increased rate of cellular events, and excitotoxicity. However, attempts to use NMDAR antagonists as a therapy for TBI have failed. Thus, we are employing a different approach by using brain-derived neurotrophic factor (BDNF) as a neuroprotective agent because it is a pro-survival factor and is overexpressed in neurons that survive injuries, such as ischemia. BDNF prevents chromatin condensation following excitotoxic insult and preserves protein levels of axonal, dendritic, and excitatory synaptic markers. While valuable, these studies lack a functional component to demonstrate that BDNF ensures that neuronal activity is still properly integrated at the network level. To record network activity, dissociated hippocampal neurons from E18 rat embryos are cultured on 64-electrode microelectrode arrays (MEAs). MEAs non-invasively record local field potentials from the group of neurons contacting each electrode. Network parameters, such as spiking (overall) activity, bursting (organized) activity, and synchronization, are collected for the entire culture as well as each electrode. Comparisons are made over time to determine the effects of injury and recovery. Previously, our laboratory used MEAs to examine changes in network activity of cortical neurons after excitotoxic injury with and without drug treatment. The current work suggests that hippocampal neurons are more

sensitive to glutamate-induced injury than cortical neurons: injuring hippocampal neuron cultures for 30 min with 100 μM glutamate abolishes bursting activity at 24 hr after injury, whereas injury with 30 μM has no effect and 60 μM trends toward decreasing bursting. Therefore, we used 30 μM (minimal injury) and 60 μM (moderate injury) for all experiments. For recovery treatments, 50 ng/mL BDNF was chosen because treatment with this concentration, and not 25 ng/mL, significantly increases synchronization. Finally, our results demonstrate that BDNF trends toward conferring protection, as measured by synchronization, to hippocampal networks at 24 hr after injury with 30 μM glutamate and at 72 hr after injury with 60 μM glutamate. These results suggest an optimal window for BDNF treatment after excitotoxic injury associated with TBI.

Title: The effects of exercise pattern and intensity on Flk-1 and Flt-1 expression in the hippocampus

Authors: *M. STEVENSON, V. K. BEHNKE, V. G. BELTRONE, H. E. HOBSON, R. A. SWAIN;
Psychology, Univ. of Wisconsin- Milwaukee, Milwaukee, WI

Abstract: Exercise produces neurovascular changes in the brain, which can be neuroprotective and support ischemic stroke recovery (Austin et al., 2014). Exercise exerts these protective effects, in part, by increasing angiogenesis, the growth of new capillaries from preexisting blood vessels (Kerr & Swain, 2011). Increased angiogenesis, following ischemic stroke, highly correlates with improved functional outcomes in animal models and human patients (Hayashi et al., 2003). Understanding how exercise pattern and intensity influence angiogenesis could lead to improved exercise rehabilitation programs following ischemic stroke. One critical factor involved in the regulation of angiogenesis is vascular endothelial growth factor (VEGF) and its receptors Flk-1 and Flt-1. Although exercise is generally found to be beneficial, there are wide variations in the exercise regimens used across experiments. This study standardized these variations. In this study, sixty male rats were divided into six equal groups: Voluntary Exercise-Unrestricted (VX-U), Voluntary Exercise- High Intensity (VX-H), Voluntary Exercise- Low Intensity (VX-L), Forced Exercise- High Intensity (FX-H), Forced Exercise- Low Intensity (FX-

L), and Inactive Control (IC). VX-U, VX-H, and VX-L were be placed in cages with attached running wheels. VX-U remained in these cages for the study duration, but VX-H and VX-L were returned to their home cages after reaching 1,000 revolutions (high intensity) and 500 revolutions (low intensity), respectively. FX-H and FX-L were required to run on a motorized wheel at 11m/min. FX-H and FX-L were returned to their home cages after reaching 1,000 and 500 revolutions, respectively. ICs remained in their home cages during the exercise regimens. All animals were sacrificed at the end of the exercise regimens. Exercising animals were then compared to inactive controls, based on unbiased stereological quantification of Flk-1 and Flt-1 immunohistochemical labeling in the hippocampus. Preliminary findings indicate that voluntary exercise animals, allowed unrestricted access to running wheels, display a greater Flk-1 area fraction in the CA1 region of the hippocampus compared to high intensity forced exercise animals and inactive controls. Animals allowed unrestricted access to running wheels also display a greater Flt-1 area fraction in the DG region of the hippocampus.

Title: Peripheral neurotrophic factors in the regulation of adipose tissue energy expenditure.

Authors: M. BLASZKIEWICZ, E. WOOD, *K. L. TOWNSEND;
Univ. of Maine, Orono, ME

Abstract: In order to maintain proper energy balance and metabolic health, the body must tightly regulate the processes that control energy intake (appetite, food intake, nutrient absorption) as well as energy expenditure (physical activity, basal metabolism, thermogenesis). An important aspect of regulating energy expenditure is the transfer of signals from the brain through sympathetic nerves to activate lipolysis and thermogenesis in white and brown adipose tissues, respectively. Cold-stimulation is able to increase the sympathetic innervation and activation of adipose tissues and thus increase energy expenditure through lipolysis and thermogenesis. The exact mechanisms by which cold (or other stimuli that increase energy expenditure) is able to mediate peripheral nerve plasticity are currently under-investigated and largely unclear. In the current project, we provide new evidence that adipose tissue-resident immune cells, including macrophages, are able to secrete a neurotrophic factor, brain derived

neurotrophic factor (BDNF), in response to cold-stimulation. This release of BDNF likely stimulates sympathetic nerve branching, neurite outgrowth and survival, and synapse formation in order to stimulate energy-expending processes in adipose depots. BDNF SNPs have been associated with human obesity and mice lacking BDNF show extreme energy balance dysregulation. While BDNF is well-studied in the brain, it has been largely uninvestigated in adipose tissues. We have found that deletion of BDNF from the myeloid lineage (including macrophages, using LysM-Cre) results in a severe loss of neural innervation of adipose depots, and a shift in energy balance that leads to increased adipose mass, decreased thermogenesis, and lower energy expenditure. Interestingly, while we hypothesized that loss of BDNF secretion from adipose-resident immune cells would also prevent the process of cold-induced 'browning', or development of brown adipocytes in white adipose depots, we were surprised to observe that LysM-BDNF-KO animals do indeed display browning after cold exposure, but the brown adipocytes are mostly clustered around the vasculature and do not express high levels of uncoupling protein 1 (UCP1), the unique marker for brown adipocytes that confers their thermogenic capacity. In total, our findings support the notion that locally-secreted neurotrophic factors are important for maintaining proper innervation and neural stimulation of energy expending processes in adipose tissues, including the activation of UCP1-mediate thermogenesis.

Title: Brain microvasculature defects and Glut1 deficiency syndrome averted by early AAV9 mediated repletion of the Glucose Transporter 1 protein

Authors: C. B. RUEDA[1], M. TANG[1], G. GAO[3], K. E. ENGELSTAD[1], J. MCCONATHY[4], D. C. DE VIVO[1], *U. MONANI[2];
[2]MNC, [1]Columbia Univ., New York, NY; [3]Univ. of Massachusetts Med. Sch., Boston, MA; [4]Univ. of Alabama, Birmingham, AL

Abstract: Glut1 deficiency syndrome (Glut1 DS) is a severely disabling neurodevelopmental disorder caused by haploinsufficiency of the *SLC2A1* gene and thus reduced levels of its translated product, the Glucose Transporter Type 1 (Glut1) protein. Although one consequence of insufficient Glut1 protein - a paucity of brain glucose - is widely recognized, precisely how this condition results in the complex Glut1 DS phenotype is unclear. Here we demonstrate that reduced Glut1 protein has a profoundly deleterious effect on brain angiogenesis and on the maintenance of the cerebral microvasculature, without compromising the blood-brain barrier. Early, AAV9-mediated repletion of the protein in neonatal Glut1 DS model mice ensures the proper development of the microvasculature of the brain and arrests disease evolution. Augmenting the protein in juvenile mutant mice that have already suffered sustained low brain glucose is less effective in establishing normal brain microvasculature, yet reverses mutant brain glucose concentrations and has a pronounced overall therapeutic effect. In contrast, delayed delivery of the protein - to adult mice - neither reverses defects of the brain capillary network nor rescues the Glut1 DS phenotype. Our results link brain dysfunction in Glut1 DS to novel defects of the cerebral microvasculature, a condition that likely upsets the evolving circuitry of the maturing brain. The results, furthermore, identify a limited postnatal therapeutic window for Glut1 DS, yet suggest that timely reinstatement of the Glut1 protein, even under prolonged conditions of profoundly low brain glucose, can prevent disease. Early repletion of the Glut1 protein may thus constitute the most effective treatment yet for Glut1 DS.

Title: Ppars modulates the anti-inflammatory effects of melatonin in the secondary events of spinal cord injury.

Authors: *I. PATERNITI, M. CAMPOLO, M. CORDARO, D. IMPELLIZZERI, R. SIRACUSA, E. ESPOSITO, S. CUZZOCREA;
Univ. of Messina, Messina, Italy

Abstract: Melatonin is the principal secretory product of the pineal gland and its role as an immumo-modulator is well established. Recent evidence shows that melatonin is a scavenger of oxyradicals and peroxynitrite and reduces the development of inflammation and tissue injury

events associated with spinal cord trauma. Previous results suggest that Peroxisome proliferator activated receptor alpha- α (PPAR-α), an intracellular transcription factor activated by fatty acids, plays a role in control of secondary inflammatory process associated with spinal cord injury (SCI).
With the aim to characterize the role of PPAR-α in melatonin mediated anti-inflammatory activity, we tested the efficacy of melatonin (30 mg/kg) in an experimental model of spinal cord trauma induced in mice by the application of vascular clips (force of 24 g) to the dura via a four-level T5-T8 laminectomy, and comparing mice lacking PPAR-α (PPAR-αKO) with wild type (WT) mice.
The results obtained indicate that melatonin -mediated anti-inflammatory activity is weakened in PPAR-α KO mice, as compared to WT controls. In particular, melatonin was less effective in PPAR-α KO, compared to WT mice, as evaluated by inhibition of the degree of spinal cord inflammation and tissue injury, neutrophil infiltration, pro-inflammatory cytokine expression, NF-κB activation, inducible nitric-oxide synthase (iNOS) expression. This study indicates that PPAR-α can contribute to the anti-inflammatory activity of melatonin in SCI.

Title: Live imaging of innate immune response in neonates reveals differential activation patterns in brain injury and infection

Authors: M. LALANCETTE-HEBERT[1], G. SOUCY[1], J. FAUSTINO[2], Z. VEXLER[3], *J. KRIZ[1];
[1]Laval Univ., Quebec, QC, Canada; [2]Neurol., Univ. of California, San Francisco, CA; [3]Neurol., Univ. of California, San Francisco, CA, Canada

Abstract: Inflammatory response can be a strong contributor to injury evolution in adult central nervous system. Moreover, in immature brain, neuroinflammation episode, triggered by neonatal stroke or systemic infections, can be responsible for long term neurological deficits. However, the potential role of inflammation and immune cells activation in normal brain development is

less characterized. In order to study the role of microglial cells, a CNS specific immune cell type, we took advantage of our live imaging model, the TLR2-luc-GFP mouse. We follow longitudinally the microglial/TLR2 activation in the brain of live animals from postnatal day 6 (PN6) to adulthood. The spatial expression of TLR2 is very dynamic during the first weeks after birth, initially emerging from the whole brain and become more and more restricted to the olfactory bulb at the end of the first month. Furthermore, the identity of TLR2 expressing cells also change during time. In fact, neurons and microglia express TLR2 in early PN age while 28 days after birth, microglial cell is the major cell type expressing it. These results suggest that the spatiotemporal expression of TLR2 can be determinant in the brain response to diverse inflammatory conditions. To test this hypothesis, we first mimic a systemic infection using i.p. LPS injection at PN6 and PN9. The expression of TLR2 is upregulated in the brain in both PN ages 24 hrs after LPS injection. The cytokines profile correlate with the induction of TLR2 seen by live imaging and most pro-inflammatory cytokines like IL-1β, IL-17 and TNFα are upregulated in both time points. On the other hand, we wanted to compare the inflammatory response of immature brains after LPS injection with a model of sterile inflammation like a stroke. To do so, we use intra-cortical injection of IL-1β on PN6 and PN9 pups and follow the inflammatory response by live imaging. To our surprise, the TLR2 activation is downregulated 24 hrs after injection. Once again, the cytokines profile correlates with this downregulation of TLR2 signal. In fact, the major proinflammatory cytokines are decreased. In both pathological models, the immune reaction seems to be more prononced at PN6 when compared to PN9 indicating that the level of maturity of brain and the immune system can be an important component in the outcome of the damage resolution. Those results clearly show that different inflammatory stimuli can initiate contrasting innate immune reaction in immature brain. A better knowledge of the specific spatiotemporal sequence of events after an injury or infection will allow us to better control and adapt the treatment of neonates to minimise long term neurological handicap.

Title: The highly electronegative low density lipoprotein l5 induces the reactive activation and inflammation in bv2 microglia

Authors: *J.-Y. WANG[1], L.-E. YU[2], C.-L. LAI[3], C.-T. LEE[4];
[1]Grad. Inst. of Med., [3]Dept. of Neurol., [2]Kaohsiung Med. Univ., Kaohsiung, Taiwan; [4]Dept. of Nursing, Hsin-Sheng Col. of Med. Care and Mgmt., Taoyuan, Taiwan

Abstract: The patients with cardiovascular diseases (CVD) are often associated with the occurrence of cognitive decline and dementia. Low-density lipoprotein (LDL), which is one of the risk factor for CVD, may play a critical role; further, L5, a electronegative LDL with relatively highest electronegative charge, is the most important candidate. So far, the biological effect of electronegative LDL on microglia reactivity is fully unknown and has not been studied. Here, an in vitro cultured model of BV-2 cell, a murine microglia cell line, was used in this study. We treated the cells with lipopolysaccharides (LPS), L5, L1 (an LDL with lesser extent of electronegativity than L5) and oxidized LDL (an artificially synthesized LDL) and assayed for gliotoxicity and inflammation responses, including the release of inflammation mediators, the expression of inducible stress proteins, the induction of apoptosis and cell migration. The results indicated that L5 stimulates BV-2 cell activation, evidenced by the production of nitric oxide (NO), reactive oxygen species, peroxynitrite and TNF-α, and the induction of inflammatory proteins (e.g., inducible NO synthase, cyclooxygenase-2 and hemeoxygenase-1), consequently initiating an inflammation. Moreover, L5 leaded to apoptosis and potentiated cell migration, detected by DAPI staining and wound-filling assay, respectively. These results suggested that L5 itself has the potential to trigger inflammatory responses and cause eventual death in immune cells, like microglia.

Title: Toll-like receptor 4 priming sensitizes macrophages to oxidant-mediated Cox2 gene expression and PGE2 production

Authors: *Y. ZHANG[1], O. J. IGWE[2];
[1]Univ. of Missouri Kansas City, Kansas City, MO; [2]Univ. of Missouri-Kansas City, Kansas City, MO

Abstract: **Background:** In addition to pathogen associated molecular patterns and damage associated molecular patterns, toll-like receptor 4 (TLR4) can be triggered by various environmental factors, e.g. ozone, atmosphere particulate matter, and ionizing radiation etc. Prostaglandin E2 (PGE2) produced from induction of phospholipase A2 (PLA2), cyclooxygenase 2 (Cox2) and membrane-associated PGE sysnthase-1 (mPGES-1) is a potent proinflammatory mediator.
Objective: This study examined the role of TLR4 priming in mediating oxidant-induced activation of Cox 2 and PGE2 production in macrophages
Methods: Potassium peroxychromate (PPC) and peroxynitrite (PN) were used as prooxidant sources and a TLR4-specific agonist LPS-EK was used to prime or sensitize TLR4. We used primary murine peritoneal macrophages (pM) isolated from C57BL/6 mice expressing TLR4 (TLR4-WT) and B6.B10ScN-*Tlr4* mice with complete deletion of TLR4 (TLR4-KO). pM were sensitized for 4 h with 100 ng/ml LPS-EK, then incubated for another 24 h with fresh medium containing PPC or PN. Intracellular reactive oxygen species (iROS) production was visualized and quantified by fluorescence imaging and flow cytometry, respectively. Total antioxidant capacity within cells was quantified by antioxidant assay kit. We used ELISA to quantify PGE2 released into the media following treatments. The levels of mRNA and protein of phospholipase A2 type V, Cox2, and mPGES-1 were determined by real-time PCR and western blot, respectively.
Results: We found that pro-oxidants treatment increased iROS production and decreased total antioxidant capacity in pM derived from TLR4-WT but not in pM derived from TLR4-KO mice suggesting TLR4 acts as sensor of exogenous oxidants. In addition, we found that treatment with oxidant alone induced a limited increase in PGE2 production. In contrast, pM sensitized with LPS-EK and treated with oxidants exhibited robust Cox2 expression and PGE2 production compared with sensitized pM and vehicle control. The expression levels of mRNA and proteins for PLA2 type V, Cox 2 and mPGES-1 were significantly increased. The induction of Cox2 and subsequent PGE2 production was observed in pM derived from TLR4-WT mice but not TLR4-KO mice.
Conclusions: Taken together, TLR4 priming sensitized primary macrophages to oxidant-induced Cox2 expression and PGE2 production. The data provide a potential mechanism by which prooxidants facilitate human disease states (inflammatory processes in the presence of bacterial LPS). The data further confirms the potential threat posed by the ubiquitous bacterial LPS and oxidative stress.

Neurosci., Lausanne, Switzerland; [5]Physiol., Lausanne Univ., Lausanne, Switzerland; [7]Psychiatric Neurosci., [6]Lausanne Universtiy Hosp., Lausanne, Switzerland

Abstract: Tollip is a ubiquitous protein, originally described as a modulator of the IL-1R/TLR-NFκB signalling pathway. Although this property has been well-characterized in peripheral cells and despite evidence of its expression into the central nervous system, the role of Tollip in neuroinflammation remains poorly investigated. The present study sought to explore the implication of Tollip in the response to an inflammatory challenge using Tollip knockout (KO) mice. The effects of an intranigral injection of lipopolysaccharide (LPS), a TLR4 receptor agonist, on inflammatory markers have been assessed at transcriptional and protein levels. We show that Tollip deletion had no effect on the basal levels of inflammatory markers, but increased susceptibility to LPS-induced neuroinflammation. Indeed, 6 hours post-injection of LPS at a sub-maximal dose (0.1 μg), a significant increase of TNF-α, IL-1β, IL-6 and IFNγ mRNA was observed in the midbrain of Tollip KO mice, whereas this effect did not reach significance for all the analyzed cytokine in WT mice. In addition, Tollip KO mice displayed a higher LPS-induced inducible NO synthase (iNOS) production, as demonstrated by an increase of iNOS mRNA and iNOS protein immunostaining when compared to LPS-injected WT mice. Finally, Tollip deletion aggravated LPS-induced oxidative and nitrosative damages, as indicated by an increase of 8 oxo-DG and nitro-tyrosine immunostaining, respectively. These effects are associated with an increase of NFκB activation in KO mice evidenced using a AAV reporter viral vectors expressing eGFP mRNA under the control of NFκB-responsive transcriptional sequences. In conclusion, these results show that Tollip KO mice have a global tendency to elicit a higher cytokine production associated with a significant increase of oxidative and nitrosative stress. Unexpectedly, viral vector-mediated Tollip overexpression in neurons of the midbrain did not reveal a decrease but an increase of pro-inflammatory cytokines and NFκB activation.

Altogether, these observations reveal a contribution of Tollip in the regulation of the early phase of the neuroinflammation.

Abstract: Introduction: Neurocysticercosis (NCC) is the most common helminthic infection affecting the human central nervous system. It remains, as a disease of epidemiological importance in developing countries, owing to is associated with high morbidity and disability in productive population. It produces a wide range of neurological (motor, sensory, cognitive, etc.) and psychiatric manifestations requiring recurrent hospitalizations. Regarding treatment, the response is variable depending on the location, number and stage of the parasite. Extraparenchymal location of the parasite causes the most severe presentation of the disease, frequently manifested by intracranial hypertension. In these cases, the lack of response to cysticidal drugs occurs in 30-40 % of the patients. In this research we evaluated whether or not non-response to treatment is associated with any immunological features.
General Objective: Evaluate the relationship between the immunological factors and response to treatment in patients with extraparenchymal neurocysticercosis.
Material and methods: Prospective, longitudinal, comparative and analytical study. 16 patients with definitive diagnosis of vesicular extraparenchymal neurocysticercosis were included. Lymphoproliferation assays using *Taenia solium* antigens were performed on PBMC before and after (1 and 4-6 months) treatment. Proinflammatory cytokines (IL-1B, IL-6 y TNFα) were measured on supernatans and CSF, as well as the concentration of albendazol sulfoxide (ASOX) in sera. Patients were evaluated clinically and radiologically (3D IRM, volumetric measurement

of the cysts). The response to treatment was determinated by the volume cyst index (pre treatment/post-treatment volume cyst). Correlations between the response to treatment and immunological parameters were evaluated. As well as its relation to age, gender and ASOX levels.
Results: 16 patients were included and according to the volume cyst index we classified them as 8 responders and 8 non-responders to treatment. Both groups showed similar demographic characteristics (gender, age) and ASOX levels were not significantly different between groups. We found positive correlations between volume cyst index and proinflammatory cytokines in supernatans (IL-1β pre-treatment) (R=0.52, P= 0.03), IL-1β 1 month after treatment (R=0.49, P= 0.05) and IL-6, 1 month after treatment (R=0.65, P=0.007). The non-responder group had a decreased lymphoproliferative response (P=0-004).
Conclusions: An exacerbated inflammatory state before and after cysticidal treatment is associated with a better response to treatment.

Title: Basal expression of immune related genes is attenuated in Pu.1 knockout microglia

Authors: T. YOON, S. KIM, A. DAS, J. CHAI, Y. LEE, K. PARK, K. JUNG, *Y.-G. CHAI; Mol. Biol. & Life Sci., Hanyang Univ., Ansan, Korea, Republic of

Abstract: Microglia are tissue resident macrophages which have important roles in immune system in the CNS. Pu.1 is a transcription factor which organizes cell type specific gene expression pattern in myeloid cells including microglia, and closely related to immune response under the inflammatory stimuli. To investigate the regulatory roles of Pu.1 in microglia, we constructed Pu.1 knockout (KO) BV-2 microglial cell line using CRISPR-Cas9 system and performed comparative transcriptomic analysis between wild type and Pu.1 KO BV-2 cells by the use of web-based analysis programs including IPA. The results showed that the expression levels of 176 genes were significantly altered (75 up-regulated and 101 down-regulated; ±1.5

log2-fold change, 0.05 p-value and q-value thresholds) by Pu.1 KO. The functional annotations presented that the majority of down-regulated genes were related to immune responses, and the analyses on cellular functions and gene networks also predicted that cell activation and immune responses would be repressed in Pu.1 KO cells. In addition, ChIP-qPCR results of representative genes obtained from the analyses showed that Pu.1 binding is related to the expression of those genes. In conclusion, through the transcriptomic analyses and following experiments, we reconfirmed the regulatory roles of Pu.1 in immune responses of microglia, and also presented that Pu.1 plays its regulatory role even in resting state microglia.

Title: SH-SY5Y neurons and BV2 microglia show unique neuro-immune responses to ethanol and TLR agonists that are modified by co-culture

Authors: *C. J. LAWRIMORE, F. T. CREWS;
UNC Chapel Hill, Chapel Hill, NC

Abstract: Introduction: Excessive ethanol (EtOH) consumption causes neuroimmune activation, which is linked to neurodegeneration and addiction. While microglia function as the primary macrophage in brain, neurons are emerging as a novel player in innate immune signaling. In order to investigate cell-type-specific immune signaling, neuron-like SH-SY5Y and microglia-like BV2 were treated with EtOH or agonists to TLR3 or TLR4, and cell lysates/media were examined for cytokine expression. To determine whether communication between the two cell types modifies immune signaling, cells were also co-cultured prior to treatments.
Methods: BV2 microglia and SH-SY5Y neurons were treated with either TLR3 agonist PolyI:C (50ug/mL), TLR4 agonist LPS (100ng/mL), or EtOH (100mM) for 24hr. In co-culture groups, BV2 were plated on top of SH-SY5Y using Transwell inserts, allowing for signaling communication without physical contact. Cell lysates and media were analyzed using RT-PCR and ELISA, respectively. Gene expression data is shown as % control for respective cell-type and culture condition.

Results:
SH-SY5Y neurons alone showed no response to LPS. However, when co-cultured with BV2 microglia, LPS increased SH-SY5Y cell mRNA of TNFα, IL-1β, and MCP1 (1763%, 2877%, and 752% respectively, $p<0.05$), and increased MCP1 release in media. PolyIC increased TNFα, IL-1β, and MCP1 (9094%, 47402%, and 3287% respectively), with co-culture potentiating TNFα and IL-1β (48738% and 67144% respectively), while MCP1 displayed a dampened increase (2048%). EtOH had no effect on TNFα or IL-1β, but MCP1 was decreased in cells alone (42% of control) and co-cultured (43%). EtOH increased HMGB1 release and decreased MCP1 release in cells alone, and in co-cultured cells both MCP1 and HMGB1release was decreased.
In BV2 microglia, LPS increased mRNA expression of TNFα IL-1β and MCP1 (440%, 1162%, and 340% respectively, $p<0.05$). PolyIC increased TNFα and IL-1β (725% and 1351% respectively) but not MCP1. EtOH increased TNFα and IL-1β (121% and 184% respectively) and HMGB1 release. Co-culture with SH-SY5Y enhanced LPS-induced TNFα, IL-1β and MCP1 (971%, 15521%, and 1065% respectively). PolyIC, co-culturing increased MCP1 (212%), but dampened TNFα and IL-1β responses (483% and 737%). Co-culturing blocked EtOH-induced TNFα and IL-1β, and decreased MCP1 (33±1.3%) and released HMGB1.
Conclusions: Co-cultured BV2 microglia and SH-SY5Y neurons display altered neuro-immune responses. In the presence of microglia, SH-SY5Y neurons become responsive to LPS. Future experiments will examine mechanisms underlying microglia-neuron communication.

Title: Wakeful EEG correlates of systemic lipopolysaccharide

Authors: *M. I. BANKS[1], M. DARRACQ[2], C. N. MURPHY[3], S. M. GRADY[2], R. D. SANDERS[2];
[1]Dept. of Anesthesiol., [2]Anesthesiol., [3]Physiol. Grad. Training Program, Univ. of Wisconsin, Madison, WI

Abstract: Introduction: Neuroinflammation is associated with cognitive and behavioral anomalies, but the mechanisms linking inflammation to changes in brain activity are unclear. Lipopolysaccharide (LPS) from gram negative bacteria is a common model for systemic inflammation in experimental animals. In young people, controlled administration of LPS induces an inflammatory state characterized by behavioral lethargy and depression but increased alpha and beta power in the EEG. We sought to model these apparent contrasts in the behavioral and EEG responses by studying LPS-induced changes in brain electrical activity in wakeful young mice.
Methods: All procedures were approved by the UW-Madison Animal Care and Use Committee and conform to APS/NIH guidelines. Six mice (1 male; BL6 background; 12-20 wks old) were instrumented with bilateral parietal and frontal skull screw EEG electrodes under aseptic surgical conditions. After 5-7 days recovery, mice were given sham intraperitoneal (IP) saline injections, and 2 days later IP injections of LPS (125 ug/kg). Animals were tethered to a lightweight headstage during the experiment, but otherwise free to move in the recording chamber. Data were collected for 1 hr prior and 4 hrs post-injection. EEG signals were subjected to spectral analysis and average power computed in the δ (1-4 Hz), θ (4-10Hz), α (10-20 Hz), β (20-30 Hz) and γ (30 – 100Hz) bands during movement defined by EMG activity and confirmed via video recording. Power in each band was normalized to the average total spectral power in the control condition. Statistical comparisons (paired t-tests) were between the post-injection:control ratios of normalized band power for saline versus LPS.
Results: There was little effect of saline injection on relative power in any frequency band (median across animals of ratio to control at one hour after injection = 0.76, 0.96, 0.84, 1.0 & 1.0 for δ, θ, α, β & γ, respectively). By contrast, dramatic and significant increases in α & β band power were observed following injection of LPS (median ratio to control at one hour after injection = 2.4 & 15, respectively; $p<0.05$), while variable increases were observed for δ, θ & γ bands (4.5, 1.8 & 1.2, respectively). The increase in α & β power was rapid, occurring within 0.5 hr of injection, while the variable increases in other bands were delayed.
Conclusions: LPS injection into mice is a promising model for neuroinflammatory effects on brain activity in wakefulness confirmed by spontaneous movement. Our future goal is to investigate the neural circuits underlying the observed changes to inform the neuropsychiatric consequences of acute and chronic illness.

Title: RNS60 nanobubble treatment reduces inflammation and Abeta plaques in aged APP/PS1dE9 mice

Authors: *Q. SHI[1], B. LIU[1], A. S. M. HUNG[2], K. LE[1], B. CALDARONE[3], S. GHOSH[4], R. WATSON[4], C. A. LEMERE[1];

NeuroBehavior Lab. and Dept. of Neurol., Boston, MA; [4]Revalesio Corp., Tacoma, WA

Abstract: RNS60 (Revalesio Corp., Tacoma, WA) is generated by electrokinetic modification of normal saline and contains an oxygen-filled nanobubble core surrounded by layers of positive and negative electrical charges or “charge stabilized nanostructures”. Previous studies by others have demonstrated that early treatment with RNS60 promotes anti-inflammatory effects and protects against Alzheimer’s disease (AD)-related neurodegeneration and memory decline in the 5XFAD mouse model (Roy et al., 2014; Modi et al., 2014). Here, we asked whether RNS60 would be beneficial in aged, plaque-rich AD transgenic (Tg) mice. Sixteen month-old male APP/PS1dE9 Tg mice were treated with 300 µl intraperitoneal (i.p.) RNS60 (n=13) or Normal Saline (NS; n=8) 3 days per week for 10 weeks. Wildtype (WT) control littermates were treated with i.p. NS (n=8). At 18.5 months of age, learning and memory were significantly impaired in NS-treated Tg mice in Contextual Fear Conditioning (CFC; learning only) and Water T Maze (WTM) compared to NS-treated WT mice. RNS60 treatment resulted in a modest increase in freezing time during CFC training (p=0.059; shock 2) compared to NS-treated Tg mice but had no effect on acquisition or reversal learning in the WTM in the aged mice. RNS60 treatment led to a significant reduction in Aβ42 plaque immunoreactivity in cortex and hippocampus but no change in Aβ levels by ELISA compared to NS-treated Tg mice. Longitudinal ^{18}F-GE180 TSPO microPET imaging before and after treatment showed reduced glial activation in RNS60- vs. NS-treated Tg mice. Immunoreactivity with multiple microglia/macrophage markers was significantly reduced in the hippocampus of RNS60-treated Tg mice compared to NS-treated Tg mice, while astrocyte staining was non-significantly reduced. RNS60 treatment reduced cerebral pro-inflammatory proteins, TNFα and iNOS, and increased anti-inflammatory proteins, IL-10

and YM-1, in RNS60-treated Tg mice compared to NS-treated Tg mice. Hippocampal synaptic puncta density and synaptic protein levels were modestly but significantly increased in RNS60-treated Tg mice compared to NS-treated Tg controls but were significantly lower than NS-treated WT mice. Mature-BDNF, p-CREB and p-ERK, but not ERK1/2 levels, were significantly increased in RNS60-treated Tg mice compared to NS-treated Tg mice. Phospho-GSK3β was increased in RNS60-treated Tg mice, indicating reduced GSK3β kinase activity. In conclusion, RNS60 treatment in aged, plaque-rich AD mice reduced inflammation and plaque load, and modestly improved learning but not memory. This suggests the potential for better recovery with earlier treatment.

Title: TLX as a protective modulator against IL-1β-induced impairment in hippocampal neurosphere growth

Authors: ***C. O LEIME**[1], J. F. CRYAN[1,2], Y. M. NOLAN[1];
[1]Anat. and Neurosci., Univ. Col. Cork, Cork, Ireland; [2]Alimentary Pharmabiotic Ctr., Cork, Ireland

Abstract: Hippocampal neurogenesis is the process by which new neurons are produced from neural stem cells (NSCs) and is involved in some forms of memory and emotion regulation. Sustained proliferation of NSCs within the hippocampus is a key factor in maintaining normal hippocampal neurogenesis. The pro-inflammatory cytokine IL-1β is an important mediator of neuroinflammation and is elevated in conditions associated with hippocampal dysfunction such as Alzheimer's disease and major depression. Evidence now demonstrates that IL-1β suppresses the proliferation of NSCs. TLX is an orphan nuclear receptor known to regulate NSC proliferation and it has been recently shown that IL-1β reduces TLX expression in proliferating NSCs. We investigated whether a restoration of TLX expression in hippocampal NSCs can prevent the anti-proliferative effects of IL-1β on these cells. Embryonic day 18 rat hippocampal neurospheres were transfected with a lentiviral vector (LV) overexpressing either TLX (OEX) or

Green Fluorescent Protein (GFP) as a control. The formation and growth of the neurospheres were measured in the presence or absence of IL-1β (recombinant protein) for 5 days *in vitro* (DIV). While IL-1β did not impair neurosphere formation it significantly impaired neurosphere growth after 3DIV ($p<0.05$). Early results indicate that TLX overexpression (in the absence of IL-1β) increased neurosphere growth compared to control treatment. Moreover, overexpression of TLX also attenuated the IL-1β-induced reduction in neurosphere growth. This effect appears to be TLX specific as this attenuation is not observed in the LV-GFP-treated neurospheres in response to IL-1β. Analysis is currently being carried out to assess the effects of IL-β and TLX(OEX) on the cellular phenotypes in neurospheres and on their proliferative capacity.

Title: Kinematic analyses of gait deficits in a mouse model of multiple sclerosis: Alterations in ankle movement predict the degree of spinal cord injury

Authors: *M. FIANDER[1], N. STIFANI[4], T. AKAY[2], G. S. ROBERTSON[3];
[1]Pharmacol., [2]Med. Neurosci., [3]Psychiatry & Pharmacol., Dalhousie Univ., Halifax, NS, Canada;
[4]Inst. de reserches cliniques de Montreal (IRCM), Montreal, QC, Canada

Abstract: Experimental autoimmune encephalomyelitis (EAE) is the most widely used animal model for multiple sclerosis (MS). Symptoms of EAE resemble those observed in MS patients, including loss of motor coordination and paralysis. The primary behavioural measure of EAE disease severity is a 5-10 point scale that reflects qualitative aspects of neurological function.

This ordinal scale provides very limited information about the extent and specific nature of motor disabilities exhibited by EAE mice. In view of these limitations, we compared three methods of assessing motor function in EAE mice: clinical scoring, rotarod and kinematic gait analysis. We have found that rotarod performance and clinical scores were strongly correlated during the acute phase of EAE (15 days post-immunization; dpi; r=-0.8), however, the strength of this correlation weakened at 22 and 29 dpi (r=-0.33 and r=-0.44, respectively). These findings indicate clinical scores are unable to accurately measure the recovery of motor function from peak disease (15 dpi) to chronic EAE (22 and 29 dpi) and that mice with similar clinical scores often vary substantially in their rotarod performance. To assess motor dysfunction from a biomechanical perspective, kinematic gait analysis was performed. Briefly, a high-speed camera that captured 250 frames per second was used to record mice walking on a treadmill. Kinematic analysis of sagittal joint angles (hip, knee and ankle) was then performed on these recordings. There were a variety of changes in the kinematic parameters of EAE mice that varied substantially between animals. In order to simplify the kinematic data, we calculated the root mean square (RMS) of the difference in joint angles between baseline and post-immunization time points for EAE mice. The RMS difference of the ankle and knee joints sensitively detected changes in EAE mice and correlated well with other behavioural measures of disease severity. We then correlated clinical score, rotarod performance and RMS difference of the hip, knee and ankle joints with white matter loss in the spinal cord. Clinical scores and rotarod performance only weakly correlated with white matter loss (r=0.38 and r=-0.43, respectively). By contrast, the RMS difference for the ankle correlated remarkably well with white matter loss (r=0.95) indicating that changes in ankle kinematics are exquisitely sensitive to white matter damage in the spinal cord. These findings indicate kinematic gait analysis is a highly sensitive method for assessing neurological deficits in EAE mice that should facilitate the identification of treatments which promote functional recovery in MS.

Title: Mri-guided focused ultrasound gene delivery to the brain using an astrocyte-specific promoter in a mouse model of alzheimer’s disease

Authors: *D. WEBER-ADRIAN[1], J. W. Y. CHAN[1], J. SILBURT[1], Z. NOROOZIAN[1], K. SHAH[3], A. BURGESS[2], S. RIDEOUT[2], S. KÜGLER[4], K. HYNYNEN[2], I. AUBERT[1]; [1]Brain Sci. Research, Biol. Sci., [2]Physical Sci., Sunnybrook Res. Inst., Toronto, ON, Canada; [3]Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada; [4]Neurol., Georg-August-Universität Göttingen, Göttingen, Germany

Abstract: Previous studies have demonstrated an increase in glial fibrillary acidic protein (GFAP) expression surrounding amyloid-β (Aβ) plaques in a mouse model of amyloidosis. Harnessing the GFAP promoter to strongly express a transgene in response to Aβ pathology may provide a useful strategy for gene therapy for Alzheimer's disease (AD). Gene therapy offers promise for the treatment of AD; however, the blood brain barrier (BBB) is a challenge for non-surgical delivery of transgenes to the brain. Here, MRI-guided focused ultrasound (MRIgFUS) is used to mediate delivery of an adeno-associated virus (AAV) gene construct from the blood to the brain using a cell-specific GFAP promoter. We hypothesize that AAV-mediated gene delivery under control of the GFAP promoter will result in enhanced transgene expression within the vicinity of Aβ plaque, in which reactive astrogliosis is occurring. A transgenic (Tg) mouse model of amyloidosis and wild-type mice were used. MRIgFUS allowed for transient and local permeabilization of the BBB, thereby facilitating AAV delivery from the bloodstream to FUS-targeted cortical and hippocampal regions. Results indicated that the GFAP promoter is selective for gene expression in astrocytes in the central nervous system, but not in the peripheral system. Transgene expression in Tg animals was compared between FUS-targeted brain regions with and without Aβ plaque, using either a GFAP or ubiquitous promoter. Amount of transgene expression was further compared between Tg and wild-type animals. The GFAP promoter demonstrates a heightened gene expression rate in areas of high Aβ plaque deposition with reactive astrocytes. The next step is to reduce gene expression in the periphery.

Neurosciences, Ctr. for Brain Res., Med. Univ. of Vienna, Vienna, Austria

Abstract: Surgery often leads to cognitive impairments, yet the mechanisms whereby systemic injury affects the central nervous system (CNS) remain unclear. Pain is a critical component after surgery and associates with poor functional outcomes. Understanding the role of pain signaling after surgery may help us defining novel interventions for common postoperative complications like delirium and postoperative cognitive dysfunction. Using a murine model of orthopedic surgery we show that tibial fracture selectively triggers cold allodynia and up-regulates nerve injury and inflammatory markers in the primary somatosensory system, including dorsal root ganglia (DRGs) and spinal cord. At 24 h after injury activating transcription factor 3 (ATF3), neuropeptides galanin and neuropeptide Y (NPY), brain-derived neurotrophic factor (BDNF), non-neuronal markers ionized calcium binding adaptor molecule 1 (Iba1), glial fibrillary acidic protein (GFAP) and CX3CR1, were differentially elevated in DRGs. We compared these changes to an established model of complete transaction of the sciatic nerve to evaluate the temporal relationship of these markers. In the CNS we describe a distinct increase in BDNF protein levels in the mossy fibers at 24 h using immunohistochemistry but with no changes in mRNA levels in the granule cells, monitored by both in situ hybridization and RTqPCR. These changes in hippocampal BDNF were paralleled by a reduction in neurogenesis. Our findings indicate that bone fracture in mouse causes, in addition to selective cold allodynia, an unexpected effect on BDNF signaling, selectively in the hippocampal granule cells, resulting in presynaptic accumulation of this growth factor in the mossy fibers, tentatively due to attenuated/blocked release. Overall this apparently novel mechanism may underlie cognitive and mental deficits as often observed after surgery or critical illness.

Title: Astrocyte-targeted production of either IL6 or IL10 influences peripheral nerve regeneration after facial nerve axotomy

Authors: *G. MANICH[1], N. VILLACAMPA[2], B. ALMOLDA[2], I. CAMPBELL[3], B. GONZÁLEZ[2], B. CASTELLANO[2];
[1]Dept. of Cell Biology, Physiol. and Immunol., [2]Autonomous Univ. of Barcelona, Bellaterra, Spain; [3]Sch. of Mol. Biosci., Sydney, Australia

Abstract: The facial nerve axotomy (FNA) is one of the most well-described models of peripheral nerve injury, and is mainly characterized by retrograde degeneration of motor neurons in the facial nucleus (FN), glial activation and axonal regeneration. After facial transection, the surviving motor neurons undergo a process of axonal regeneration that starts around 28 day post-injury (dpi) and leads to functional recovery of the facial muscle kynesis. Previous studies performed in our group with transgenic mice strains producing either IL6 or IL10 under the GFAP promoter (GFAP-IL6Tg and GFAP-IL10Tg mice) have shown that these cytokines are able to modulate the CNS response after FNA. Importantly, a decrease of neuronal survival was observed in GFAP-IL6Tg mice respect to wild-type (WT) after 21 dpi, while GFAP-IL10Tg mice showed an increase in motor neuron survival. However, the effect of both cytokines in axonal regeneration has not been explored yet. The objective of this study is to investigate the effects of IL6 and IL10 production in nerve regeneration after FNA. To accomplish this aim, GFAP-IL6Tg and GFAP-IL10Tg adult mice and their respective WT controls underwent FNA. Motor neuron survival was analysed on cryostat sections stained with toluidine blue at 42 dpi. To assess axonal regeneration, 4% solution of Fluoro-Gold (FG), a retrograde fluorescent marker, was injected at 35 dpi in the whiskerpads of both hemispheres, and motor neuron labeling was evaluated at 42 dpi. In addition, the regeneration-associated molecule CD44 was studied from 3 to 28 dpi. Our observations revealed a decrease in the total number of FN motor neurons in the injured side respect to the contralateral side at 42 dpi in all experimental groups. However, no significant differences on neuronal survival were found when comparing the respective experimental groups. In contrast, FG analysis revealed a lower number of regenerating motor neurons targeting the vibrissae in GFAP-IL6Tg mice than in their WT littermates, while GFAP-IL10Tg motor neurons did not show any differences in FG labeling respect to WT. Finally, the study of CD44 showed a decrease at all time-points analyzed in GFAP-IL6Tg mice and an

increase of this molecule in the GFAP-IL10Tg mice at 14 and 28 dpi respect to the WT. In conclusion, our findings indicate that astrocyte-targeted production of either IL6 or IL10 has not a direct impact on long-term neuron survival but may affect the nerve regeneration process after FNA. Further studies are necessary to elucidate the mechanisms of both IL6 and IL10 cytokine production in the dynamics of peripheral axonal regeneration and to assess their influence in target reconnection.

Title: Role of inflammation in impaired autophagy and mitophagy in aging brain

Authors: ***L. L. DUGAN**[1], Q. TANG[2], P. DEMEDIUK[2], J. SASKOWSKI[2];
[1]Dept Medicine/Geriatrics & Vanderbilt Brain Inst., [2]Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Autophagy is the choreographed set of processes that eukaryotic cells use to deliver cytoplasmic components to lysosomes for degradation. Autophagy is a highly evolutionarily conserved system activated in response to nutrient deprivation or cellular stress to allow macromolecules to be recycled, and damaged organelles to be degraded and removed. Despite its name (*self-eating*), autophagy is predominantly cytoprotective, and has emerged as a key determinant of lifespan and broad anti-aging effects in organisms ranging from yeast to mammals. Because aging is associated with low-grade inflammatory pathway induction in humans and animal models, we asked whether inflammation might impair autophagy in aging brain. We found large aggregates of p62 deposited throughout hippocampus and cortex by, as well as increased p62 levels on Western blot in aged wild-type mice. p62 specifically targets protein "cargo" to phagosomes for ultimate lysosomal degradation, but is, itself, degraded in lysosomes, thus providing a marker for effective lysosome activity. Accumulation of p62 in brain was observed in the presence of *increased* LC3B II expression by immunofluorescence and Western blot, consistent with inhibition of autophagic flux at the level of lysosomes. In addition,

we observed co-localization of multiple other proteins with p62 aggregates, suggesting a general defect in lysosomal proteolysis. Among these were key mitophagy proteins pink1 and parkin, frequently localized to structures resembling partially degraded mitochondria, suggesting impaired mitophagy as well. Ineffective mitophagy is associated with increased inflammation, and in turn, inflammatory induction of NADPH oxidase (Nox) has been reported to directly impair lysosome activity, so we exposed neuronal cultures to either LPS or interleukin-6 (IL-6), and found that both pro-inflammatory mediators caused increased levels of both p62 and LC3B II, thus reproducing the flux inhibition observed *in vivo*. Inhibition of Nox rescued autophagic flux in pilot experiments, studies which are continuing. If age-related inflammation impairs autophagy by inhibiting lysosomes, these results could link inflammation with Alzheimer's and other neurodegenerative diseases in which protein clearance is impaired.

Title: Astrocyte-targeted IL10 production modifies the microglial/macrophage proliferation rate and regulates the infiltration of monocyte-derived macrophages

Authors: ***M. RECASENS TORNÉ**[1], K. SHRIVASTAVA[1], B. ALMOLDA[1], I. CAMPBELL[2], B. GONZÁLEZ[1], B. CASTELLANO[1];
[1]Autonomous Univ. of Barcelona, Bellaterra, Spain; [2]Sch. of Mol. Biosci., Sydney, Australia

Abstract: When CNS homeostasis is altered, microglial cells become rapidly activated, proliferate and release a broad range of molecules, including cytokines. Among the plethora of molecules involved in the regulation of microglial activation and monocyte infiltration, cytokines are considered crucial. Although production of interleukin-10 (IL10) by activated astrocytes and microglia has been demonstrated after different types of injuries, the specific role played by IL10 modulating microglial cells remains unclear. Hence, the objective of this study was to evaluate the effects of transgenic astrocyte IL10 production on microglial activation associated with CNS axonal anterograde degeneration. For this purpose, unilateral perforant pathway transection (PPT) was performed in transgenic mice GFAP-IL10Tg and their corresponding wild types (WT) littermates. At 2, 3, 7, 14 and 21 days post-lesion (dpl), animals were intracardiacally perfused

and the hippocampal areas of projection processed for immunohistochemistry (IHC), flow cytometry and ELISA. Our results showed that the non-lesioned GFAP-IL10Tg animals showed an increase in the number of microglial/macrophages (monitored with Pu.1 IHC) compared to WT. After PPT, the cell density was higher in GFAP-IL10Tg than in WT. However, the GFAP-IL10Tg mice showed an important reduction of microglial proliferation (phosphohistone-3 IHC) correlating with a decrease of the expression of macrophage colony -stimulating factor receptor (M-CSFR) and IL5, both molecules are involved in the microglial proliferation. Hence, since the increase of Pu.1+ cells observed in GFAP-IL10Tg was not due to microglial proliferation, we analyse the evolution of microglial/macrophage population after PPT. Flow cytometry revealed that the increase in microglia/macrophage cell density observed in GFAP-IL10Tg was due to a specific increase of $CD11b^{+}/CD45^{high}$ population showing a decrease of MHCII, ICOSL and CD11c expression. Another interesting result is that GFAP-IL10Tg mice showed an increase of $CD11b^{+}/CD45^{high}$/Ly6C cells assuming that the number of infiltrated cells was higher than WT. Correlating with this results, the expression levels of IP10 (chemokine involved in cell recruitment) were higher in GFAP-IL10Tg than WT. No differences were found in microglia/macrophage cell death between Tg and WT animals. In conclusion, this study demonstrated that astrocyte-targeted IL10 production induces 1) an important reduction of microglial proliferation 2) an increase of microglial/macrophages cell density 3) an increases in the number of infiltrated cells.

Title: Astrocyte turnover in a mouse model of LPS-induced brain inflammation

Authors: M. LEE, C. TREXLER, A. NATH, *J. P. STEINER;
NINDS Translational Neurosci. Ctr., Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: The elimination of the latent reservoir can be critical to achieving HIV eradication. Astrocytes are generally considered as long-lived cells with low rates of cell turnover, thus

serving as a long-term reservoir for HIV infection. However, no detailed studies of the degree to which astrocytes proliferate or die have been reported. Here, we determined the turnover rate of astrocytes and determined if the turnover rate can be accelerated in an inflammatory condition. The rate of turnover of cells can be measured in terms of the time between mitosis and death, or between two mitoses. We designed a BrdU pulse-chase experiment to track cell proliferation and death. The experiment was carried out with male C57BL/6 mice about 6 weeks of age when the experiment began. Mice received four injections of BrdU administered three hours apart. Half of the mice received a single injection of LPS 1 h after the first BrdU injection to stimulate brain inflammation. The other half received an injection of PBS as a control. Brain tissues were collected at day 1, 2, 3, 5, 7, 14, 28, 42, 56 and 70 after the first BrdU injection. Four mice were euthanized at each time point. Our data provides strong evidence for moderate astrocyte turnover in the mouse corpus callosum. LPS treatment shortened the astrocyte turnover period. Additionally, the short entry time for GFAP+ BrdU+ cells indicates that mature astrocytes may be capable of replicating, as glial progenitor cells take several weeks to mature into GFAP+ astrocytes after dividing. These results support the idea that an inflammatory response can increase astrocyte turnover, thus providing a new potential mechanism for HIV treatment.

Title: Isolated microglia express activation markers after binge alcohol exposure in adult rat

Authors: ***H. PENG**, K. NIXON;
Pharmaceut. Sci., Univ. of Kentucky, Lexington, KY

Abstract: Microglia activation and neuroinflammation are common features of neurodegenerative conditions, including alcohol use disorders (AUDs). When activated, microglia span a continuum of diverse phenotypes ranging from classically activated, pro-inflammatory (M1-like) microglia to alternatively activated, growth-promoting microglia/macrophages. Identifying microglia activation states is critical for understanding the

role of microglia in the pathogenesis of AUDs. In this study, male adult rats were gavaged with 25% (w/v) ethanol or isocaloric control diet every 8 hours for 4 days following a modified Majchrowicz protocol, which resulted in an 8.5 ± 1.1 g/kg/d ethanol dose. Rats were sacrificed 2 days after alcohol exposure since previous studies show that indices of microglia activation peak at this time. Microglia were isolated from hippocampus and entorhinal cortex by Percoll density gradient centrifugation. Cells were labeled with microglia surface antigens for activation and analyzed by flow cytometry. Consistent with prior studies, isolated cells yielded a highly enriched population of brain microglia (>95% pure) as evidenced by staining for the microglia antigen CD11b. We compared ethanol's effects on the activation markers (MHC-II, CD86, and CD32) expressed on microglia isolated from the entorhinal cortex and hippocampus of adult rats. Results revealed that ethanol increased the expression of MHC-II, CD86, and CD32 compared to controls. MHC expression increased from 2.5%±0.3 (control) to 19.0%±9.9 (ethanol) in the entorhinal cortex and from 5.3%±2.2 (control) to 21.5%±3.9 (ethanol; $p<0.05$) in the hippocampus. CD32 expression increased from 16.5%±13.2 (control) to 62.3%±4.1 (ethanol) in the entorhinal cortex and from 10.5%±6.3 (control) to 56.8%±3.2 (ethanol; $p<0.05$) in the hippocampus. CD86 expression increased from 2.1%±0.2 (control) to 18.1%±9.5 (ethanol) in the entorhinal cortex, and from 4.3%±1.9 (control) to 20.7%±2.7 (ethanol; $p<0.05$) in the hippocampus. These data support that flow cytometric analysis of isolated, enriched microglia can quantitatively measure microglia polarization state, which complements our published findings in immunohistochemistry and ELISA. Understanding microglia phenotype will be especially critical in pharmacologically reducing or redirecting neuroinflammatory signaling in the treatment of AUDs. Title: Comparative study of melatonin against the inmunomodulators treatments (interferon beta and glatiramer acetate) in a model of experimental autoimmune encephalitis

Authors: *E. J. RAMOS GONZALEZ[1], O. BITZER QUINTERO[2], L. RAMIREZ JIRANO[2], G. ORTIZ[2];

Abstract: INTRODUCTION
Multiple sclerosis (MS) is a chronic autoimmune demyelinating disease of the central nervous system (CNS) leading to neuroinflammation; the animal model of MS is the experimental autoimmune encephalitis (EAE), which is also an autoimmune disease of the CNS. MS classically has been treated with immunomodulators such as interferon beta (IFN-beta) and glatiramer acetate (GA). Melatonin (MLT) is known for its role in many physiological processes, within which highlights the modulation of the immune system, which could be related to the suppression of autoimmune diseases, including EAE.
MS is a chronic inflammatory demyelinating disease of the CNS leading to a cumulative and irreversible damage. To date, there have been no studies comparative of immunomodulatory treatments (IFN - beta and AG) classically prescriben to treat MS and MLT in the animal model (EAE) according to the signs and symptoms observed clinically and expression of proinflammatory cytokines.
OBJECTIVE
Compare the immunomodulatory effect of the administration of melatonin against treatments commonly used in MS (IFN-β and AG) in a murine model of experimental autoimmune encephalitis.
METHODS
Experimental study with male Sprague Dawley adult rats; experimental groups (8): control, EAE, IFN-β, AG, MLT, EAE-IFNß, EAE-AG, EAE-MLT with 16 animals per group; Dosage: IFN-β 8000U every third day, AG 0.5mg/ kg daily and MLT 10mg/ kg daily for 12 days; scale neurological evaluation: grado0 = normal rat, grade 1 = partial loss of tonicity of the tail, grade 2 = loss of tonicity of the tail, grade 3 = unsteady gait and mild paralysis, grade 4 = paralysis of hind limbs, grade 5 = moribund or death. The expression of these proinflammatory cytokine TNF-α, IL-1β and IL-12 was evaluated in cerebrospinal fluid with real time PCR.
RESULTS
Administering INF-β, AG and MLT produces an attenuation of clinical signs and symptoms of EAE to a different scale and at different times for each experimental group.
No expression of proinflammatory cytokines under any of the therapeutic interventions of the experimental groups is observed.
CONCLUSION
Melatonin administration exhibits immunomodulatory effects compared to the treatments used in multiple sclerosis.

Title: The effects of insulin impairments in cx3cr1 knockout mice on neuroinflammation

Authors: *A. S. MURTISHAW[1], M. M. BOLTON[2], J. W. KINNEY[2];
[1]Neurosci., UNLV Neurosci. Doctoral Student, Las Vegas, NV; [2]Psychology/Neuroscience, Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: Alzheimer's disease (AD) and vascular dementia (VaD) are the two most common forms of dementia. Inflammation and insulin signaling perturbations have emerged as important risk factors associated with both AD and VaD. Data have also demonstrated an interaction between alterations in insulin signaling and inflammation. Many studies support the relationship between AD-VaD and metabolic disorders, particularly diabetes mellitus. Fractalkine (CX3CL1) is a chemokine that has been shown to protect the brain from the damaging consequences of chronic inflammation by interacting with its obligate receptor (CX3CR1) on microglia. Additionally, recent studies have demonstrated that the CX3CL1/CX3CR1 system plays a regulatory role in pancreatic β-cell function and insulin secretion. Our lab has previously demonstrated a low-dose, staggered administration of streptozotocin (STZ) results in hyperglemcia, cognitive impairments, and increased neuroinflammation. To further explore the relationship that fractalkine plays with insulin signaling we administered our low-dose, staggered STZ protocol in CX3CR1 knockout mice to evaluate if the alterations in AD related pathologies and neuroinflammation previously observed are altered in the CX3CR1 KO mice. Animals were run through a standard behavioral and health screen before beginning novel object recognition and cued and contextual fear conditioning. Following completion of behavioral training, brains were removed for biochemical examination. The hippocampus, cortex, and hypothalamus were investigated for markers of inflammation, histopathological alterations relevant to AD, and cerebrovascular abnormalities associated with VaD.

Abstract: Early life brain inflammation has been proposed to play important roles in the development of neurodegenerative disorders in adult life. Our previous studies showed that interleukin-1β (IL-1β), a proinflammatory cytokine, plays an important role in mediating dopaminergic neuronal injury in the neonatal rat brain. To examine whether neonatal IL-1β exposure enhances dopaminergic neuron susceptibility to rotenone neurotoxicity at adult ages, Sprague-Dawley male rats at postnatal day 5 (P5) were pre-treated with IL-1β (1 μg/kg) via intracerebral injection, and then challenged with rotenone through subcutaneous mini-pump infusion (1.25 mg/kg per day for 14 days) at P70. A single IL-1β exposure resulted in motor function deficits during the developmental period but were spontaneously recoverable by P70. Single IL-1β exposure also suppressed tyrosine hydroxylase (TH) expression in the substantia nigra (SN) at P70. A low dose of rotenone treatment, which itself does not induce motor deficits in rats, resulted in Parkinsonism-like symptoms including bradykinesia, akinesia and rigidity in rats with neonatal exposure to IL-1β, but not in those without the neonatal IL-1β exposure. Neonatal IL-1β exposure also enhanced adult susceptibility to rotenone-induced loss of dopaminergic neurons as indicated by reduced numbers of TH+ cells in the SN, and axonal impairment as indicated by decreases in the number of Fluoro-Gold (FG)+ nigrostriatal projecting neurons in P98 rats. These results suggest that perinatal neuroinflammation may enhance adult susceptibility to develop neurodegenerative disorders triggered by environmental toxins at an ordinarily non-toxic or sub-toxic dose. Our model may be useful for studying mechanisms involved in the pathogenesis of nonfamilial Parkinson's disease.

Title: An evaluation of $gaba_b$ receptors in modulating neuroinflammation

Authors: ***M. M. BOLTON**, A. S. MURTISHAW, K. N. CALVIN, J. W. KINNEY; Psychology, Univ. of Nevada Las Vegas Dept. of Psychology, Las Vegas, NV

Abstract: Alzheimer's disease (AD) is characterized by the accumulation of beta-amyloid plaques (Abeta) and neurofibrillary tangles consisting of hyperphosphorylated tau. In addition to these two core pathologies, neuroinflammation has been observed in AD patients and preclinical animal models of AD. Considerable evidence has demonstrated the sustained inflammatory response, in particular chronic microglia activation promotes Abeta production as well as the hyperphosphorylation of tau through the sustained release and increased levels of several proinflammatory cytokines. These data make understanding the mechanisms driving the inflammatory response and treatment of the inflammation an important target in AD research. In addition to aberrant microglia functioning, the loss of a number of aspects of GABAergic signaling, including $GABA_B$ receptors have been reported in clinical AD populations and animal models of AD. As microglia express functional $GABA_B$ receptors and their activation on microglia appear to provide an anti-inflammatory effect, GABA signaling may decrease proinflammatory cytokine production, serving as a vital anti-inflammatory cascade. Therefore, we sought to investigate the role of $GABA_B$ in neuroinflammation related to AD pathogenesis. In two separate, non-transgenic inflammation mouse models we evaluated the behavioral and biochemical effects of a $GABA_B$ agonist baclofen. Following behavioral testing in novel object recognition and cued and contextual fear conditioning, we examined tissues for number of activated microglia, proinflammatory and anti-inflammatory cytokines, and AD related pathological changes. These projects were performed to evaluate behavioral and/or biochemical

modulation of the inflammatory response that may be beneficial. Our data demonstrate that baclofen treatment was able to modify the immune response and alter both behavioral deficits and AD related pathologies.

Title: Nlrp3 mediates systemic and neurologic inflammatory changes resulting from rotenone exposure in mice

Authors: *E. M. MARTINEZ[1], J. M. SULLIVAN[2], A. YOUNG[2], L. WANG[3], Y. PATANKAR[2], B. BERWIN[2], M. C. HAVRDA[2];
[1]Cancer Center/Pediatrics, Dartmouth-Hitchcock, Hanover, NH; [2]Geisel Sch. of Med., Lebanon, NH; [3]Med. Col. of Wisconsin, Millwaukee, WI

Abstract: Neuroinflammation is thought to contribute to the progression of neurodegenerative diseases such as Alzheimer's (AD) and Parkinson's (PD). The pesticide rotenone, a mitochondrial toxin, has been identified as a risk factor for the development of PD. Synuclein pathology and neuroinflammation have been observed in the brainstem in mice following rotenone exposure but the molecular mechanisms are unclear. Pro-inflammatory "inflammasomes" are multi-protein complexes that react to intracellular stress and initiate inflammation. NLRP3, a key component of the NLRP3 inflammasome complex, and polymorphisms in *NLRP3* are associated with late onset AD and gastro-inflammatory disorder Crohn's disease. Reports of NLRP3 inflammasome activity in AD and evidence that misfolded synuclein can activate NLRP3 in vitro suggest that the NLRP3 inflammasome has an important role in the development and progression of PD. To determine whether Nlrp3 has a role in the development of Parkinsonism or neuroinflammation, wild-type (WT) and *Nlrp3*$^{-/-}$ mice were exposed to intragastric rotenone over a 6 month time course and evaluated using longitudinal behavioral studies and serologic assays. We observed progressive *Nlrp3*-dependent Parkinson's-like motor abnormalities, progressive *Nlrp3*-dependent suppression of the chemokine eotaxin, and significant elevation of Cxcl1 during the time course of rotenone exposure. Post-mortem

multiplex analysis of brain extracts also identified a significant elevation of Cxcl1 in WT mice exposed to rotenone. In vitro analysis identified a robust *Nlrp3*-dependent induction of Cxcl1 in mixed glial cultures. We determined that rotenone-induced Cxcl1 expression was limited to astrocytes in these primary cultures but that induction of astroglia Cxcl1 was enhanced in the presence of microglia after rotenone exposure. While *Nlrp3* expression was detected primarily in CD11b+ microglia the canonical executors of inflammasome activity, IL1B and IL18, were not significantly induced by rotenone. Further experiments will be conducted to determine how microglia enhance astroglia Cxcl1 thereby improving our understanding of how environmental exposure to disease associated toxins could be translated into systemic and neurologic inflammation.

Title: Mild chronic intermittent hypoxia increases oxidative stress and inflammation in brain regions at risk for neurodegeneration

Authors: *B. SNYDER[1], B. SHELL[2], J. CUNNINGHAM[2], R. L. CUNNINGHAM[2];
[1]Univ. of North Texas Hlth. Sci. Ctr., Ft Worth, TX; [2]UNT Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Age is the highest risk factor for the development of neurodegenerative diseases (ND), such as Alzheimer's disease (AD) and Parkinson's disease (PD). As life expectancy increases, the incidence of ND and associated healthcare costs are projected to rise accordingly. Currently, no cure exists for ND and diagnosis occurs at advanced stages, which foreshadows a financial healthcare crisis. Therefore, early identification of patients at risk for ND may provide opportunities for more effective therapies. Since ND is associated with increased oxidative stress (OS) and inflammation, these markers could be used to identify patients at risk for ND. Multiple environmental factors can be an oxidative stressor, and thus exacerbate ND risk. One such

environmental factor that increases OS is sleep apnea (SA). Severe SA has been well established as a common ND comorbidity. However, it is unknown if mild SA induces OS and associated neuroinflammation in areas associated with ND. To model mild SA in rats, chronic intermittent hypoxia was used. Male rats were exposed to six minute chronic intermittent hypoxia (CIH) cycles, during which oxygen levels were rapidly decreased from normal room air oxygen levels of 21% to 10% and held for 90 seconds. Oxygen levels were then rapidly returned to normal room air levels. This protocol repeated for eight hours a day during the light phase for seven days. Plasma and tissue from brain regions associated with ND were collected and tested for levels of OS and inflammation, using Advanced Oxidative Protein Products (AOPP) and multiplex immunoassays, respectively. Regions of interest were hippocampus (HIPP), entorhinal cortex (ETC), substantia nigra (SN), rostral ventrolateral medulla (RVLM), and solitary tract nucleus (NTS). Plasma OS markers and inflammation were elevated in rats exposed to CIH compared to control rats. Dysregulation of inflammatory markers was observed in the RVLM, NTS, and SN. This may contribute to an altered homeostasis, increasing the risk of ND. Increased inflammation was associated with OS in ETC, a brain region associated with early AD, whereas no effects were observed in the HIPP, a brain region associated with later stages of AD. Therefore, mild CIH can contribute to processes involved in early ND pathology by elevating OS and inflammation in critical brain regions.

Title: Microglia progenitors are influenced by physiological stimuli *In vitro* and *In vivo*

Authors: *G. A. GARDEN, M. ALOI, W. SU, R. DODGE, III, T. LE, J. KANG, J. WEINSTEIN;
Univ. of Washington, Seattle, WA

Abstract: Microglia are myeloid cells derived from embryonic yolk sac and migrate into the CNS early in embryogenesis. Adult microglia participate in a variety of physiological processes and pathological responses in adult CNS. Two recent studies have demonstrated that

pharmacological or genetic depletion of adult microglia invokes repopulation from a previously unknown Nestin expressing microglia progenitor population. Here we demonstrate that Nestin expressing CD11b^{pos}/Iba-1^{neg} microglia progenitors reside in the normal adult brain and constitute a substantial portion (10-15%) of the total resident myeloid population. Microglia progenitors can be cultured and further differentiated *in vitro* in a manner that recapitulates the molecular signatures observed during embryogenesis. Cultured microglia progenitors exposed to cytokines including interferon gamma, Interleukin-1 beta and tumor necrosis factor beta suppress Nestin expression and increase expression of mRNAs specifically associated with mature microglia. Nestin^{pos}/CD11b^{pos}/Iba-1^{neg} cells were also isolated from the mixed glial cultures employed to generate cultured neonatal microglia, demonstrating that microglia progenitors in neonatal animals are similar to those observed in adults. To determine if inflammatory stimuli influence microglia progenitors *in vivo*, we performed 15 min. unilateral middle cerebral artery occlusion followed by reperfusion (MCAO/R), a stimulus known to induce an inflammatory reaction and ischemic preconditioning without infarction. Microglia progenitor proliferation was significantly induced ipsilateral to 15 minute MCAO/R 72 hours later. We observed an increase in the number of both microglia progenitors and differentiated microglia ipsilateral to MCAO/R at this time point. Microglia (CD11b^{pos}/F480^{pos}/CD45^{int}) isolated from the cortex ipsilateral to MCAO/R also demonstrated gene expression profiles strongly associated with the induction of cellular proliferation. Taken together, these findings demonstrate that microglia progenitors are a distinct population of CNS cell that generate new microglia *in vitro* and can be recruited to participate in an *in vivo* inflammatory response.

Title: Cellular expression of L and H prostaglandin D synthases in rat and mouse brain

Authors: *E. ALVAREZ[1,2], D. LO[3], J. SERRATS[4], C. ARIAS[2], B. PEARCE[2], P. SAWCHENKO[2];

Abstract: D- and J-series prostaglandins (PGs) are active in the central mechanisms of sleep, nociception, thermoregulation and inflammation. They represent one arm of the cyclooxygenase-dependent synthetic pathways from PGH_2, catalyzed by two terminal enzymes, lipocalin- and hematopoietic-prostaglandin D synthases (L- and H-PGDS, respectively). These enzymes are structurally and functionally distinct, and there remains uncertainty regarding their cellular localization and regulation in brain. Because prior studies in our laboratory implicated D/J-type PGs in anti-inflammatory interactions between vascular cell types in immune-to-brain signaling, we used immuno- and hybridization histochemical methods to clarify the PGDS distributions in rat and mouse brains. In rat, L-PGDS-immunoreactivity (ir) and mRNA were seen under basal conditions in the leptomeninges and associated with blood vessels throughout the brain. A majority of vascular cells and a minority of meningeal ones co-stained for the macrophage differentiation antigen, ED2, identifying them as perivascular and meningeal macrophages, respectively. Vascular L-PGDS+ cells never co-labeled for the endothelial cell marker, RECA1. Vascular and meningeal labeling for H-PGDS was also extensively colocalized with the ED2 antigen in both meninges and vasculature, and was seen in activated Iba1-ir microglia surrounding a locus of mechanical damage (cannula track). Both enzymes' expression was mildly upregulated in the early hours following an inflammatory challenge (100 µg/kg LPS, i.p.). A similar overall pattern of results was seen in mouse brain, except that we consistently failed to find evidence for vascular expression of H-PGDS mRNA or protein under either basal or stimulated conditions. These findings identify perivascular macrophages as a likely source of D/J prostaglandins in a position to engage in local, anti-inflammatory interactions with cerebrovascular endothelial cells in immune-to-brain signaling.

Title: The anti-inflammatory role of 4R cembranoid

Authors: W. I. VELEZ[1], F. A. MORALES-VIAS[1], M. LEBRÓN-DAVILA[1], V. WASHINGTON[2], P. A. FERCHMIN[1], *V. A. ETEROVIC[1];
[1]Biochem., Univ. Central Del Caribe, Bayamon, PR; [2]Biol., Univ. of Puerto Rico, San Juan, PR

Abstract: The cembranoid (1S, 2E, 4R, 6R, 7E, 11E)-cembra-2,7,11-triene-4,6-diol (4R) is a natural compound found in tobacco leaves that has been shown to significantly decrease the infarct volume in a rodent model of ischemic stroke. There is evidence that this effect is mediated through alpha 7 nicotinic acetylcholine receptors (a7). The purpose of this study was to determine if 4R treatment decreases inflammatory cytokines and if a7 receptors are involved in this effect. This could explain 4R's beneficial role in reducing brain damage after stroke. C57BL/6J wild type and a7 knockout (a7ko) mice received 6mg/kg of 4R dissolved in DMSO subcutaneously 90 min before an intraperitoneal injection of 1mg/kg LPS. Two hours later blood was collected and cytokines measured by flow cytometry. An LPS time-curve performed in wild type mice showed that TNFalpha peaked at 1 hr, while IL-6, IL-10, and MCP-1 peaked at 2 hrs. LPS treatment significantly increased the levels of all 4 cytokines in both wt and a7ko mice compared to mice receiving saline. Wt mice receiving either vehicle + LPS or 4R + LPS had significantly lower TNFalpha, MCP-1, and IL-10 cytokine levels compared to those receiving LPS alone. However, in the a7ko mice only the vehicle + LPS group had significantly lower levels of IL-6, TNF, MCP-1, and IL-10 compared to the LPS group. Cytokine levels in the 4R + LPS group were not significantly different from those in the LPS group in these mice. T-test analyses showed significant differences between wt and a7ko mice with regard to IL-6 (3,605 ± 1340 versus 10,021 ± 5,100, respectively) and Il-10 (62 ± 36 versus 863 ± 200, respectively) cytokine levels. These data show that cembranoid 4R lowers LPS-induced TNF, MCP-1 and IL-10 levels by an a7-dependent mechanism.

Title: Evaluation of the effect of monocyte locomotion inhibitor factor in motor recovery and acute phase gene expression in rats with traumatic spinal cord injury

Authors: *J. S. HERRERA GARCÍA[1,2], A. IBARRA ARIAS[3,4], L. BLANCAS ESPINOZA[1], E. GARCÍA VENCES[3], A. FLORES ROMERO[4], R. SILVA GARCÍA[1];

Abstract: After spinal cord injury (SCI) occurs, self-destructive mechanisms that cause immediate and chronic neurodegenerative process are triggered; they could harm motor, autonomic, and sensitivity functions. Several works have studied the effects of this inflammatory response and state that the balance between benefic and damaging effects depends in its intensity, in addition, mayor secondary damages occur during the acute phase. There's no fully restorative therapy for SCI, but strategies for modulating inflammation provided evidence that rehabilitation after SCI may be possible. Monocyte locomotion inhibitor factor (MLIF) is a pentapeptide that regulates inflammatory molecules expression and increases the expression of proliferation, angiogenesis, vasculogenesis, and axonal guidance genes *in vitro*. In this context, it is necessary to know the effect of the MLIF on the expression in genes related to neuroprotection, degeneration, and inflammation, in an *in vivo* model. The aim of this study was to evaluate whether MLIF exerts a neuroprotective effect that promotes motor recovery by modulating the acute phase gene expression in rats subjected to SCI. Two experimental designs using 60 Sprague Dawley female rats divided in 5 groups: Sham; PBS; 1, 3 and 7 MLIF applications. All groups underwent a laminectomy at T9 level and a controlled moderated lession was followed by the application of MLIF or PBS as corresponding. The first application of MLIF (200 μg) or PBS were administered in the injury site and subsequent MLIF applications intraperitoneally every 24 hrs. In the first experimental design, the motor ability of the rats treated was tested during 8 weeks using the "BBB" scale. MLIF showed significant differences relative in comparison to the control group (α=0.01). Groups with multiple doses showed better motor recuperations than the group with only one dose. In the second experimental design, 3hrs after the last treatment in each group rats were sacrificed and 1 cm of spinal cord from the injury site was obtained; RNA was purified and microarray analysis expression studies were performed. The modification of expression of different gene families was observed. In qPCR, it was found that MLIF modulates DIVA, Pax6, and XIAP anti-apoptotic genes selectively in the three treatments; while, Casp3 had a lower expression and iNOS had a higher expression, however, it can be argued that when correlating the long-term behavior of individuals, the anti-apoptotic stimulus significantly promotes neuronal survival, thus improving the motor recuperation in rats subjected to a SCI model.

Title: Dexmedetomidine modulates immune responses and improves recovery after rat spinal cord injury (SCI)

Authors: *J. Z. PAN[1,3], Y.-W. CHANG[3], A. LIN[2,3], S. LEE[2,3], J. SACRAMENTO[2,3], J. GAO[1,3], Z. SUN[1,3], J. BRESNAHAN[2,3], M. MAZE[1], M. BEATTIE[2,3];
[1]Dept. Anesthesia, [2]Dept. of Neurolog. Surgery, Univ. of California, San Francisco, San Francisco, CA; [3]Brain and Spinal Injury Ctr., San Francisco, CA

Abstract: Background
Catecholamines, that are released early after acute spinal cord injury (SCI) as part of the sympathetic nervous system response to injury, stimulate splenic adrenergic receptors and promote monocyte migration into the injury site. Splenectomy immediately prior to SCI leads to reduced monocytes at the injury epicenter, decreased lesion size and better behavioral outcome (Blomster et al., 2013). Attenuation of the sympathetic response improves outcome in experimental stroke, another model of acute neurologic injury (Ajmo et al., 2009). Dexmedetomidine (DEX), a sedative that is commonly used for critically ill patients, including those with spinal trauma, is a sympatholytic agent by virtue of its highly selective alpha-2 adrenergic agonist activity. We hypothesize that DEX can improve functional outcome after SCI by modulating the neuro-immune response.
Methods
Long-Evans female rats received i.p. injection of DEX (25 μg/kg) following unilateral C5 contusion injury (75 kdyne) or C5 laminectomy only. DEX was given at 0, 2, 4, 6h following SCI on the first day and daily single dose on 2d, 3d, 4d and 5d thereafter. Animals were sacrificed at 6h, 24h or 7d after injury. Grooming score and forepaw placement tests were performed on 2d and 7d after SCI to evaluate behavioral recovery. In all groups, spinal cord, serum, and spleen tissues were harvested and analyzed for inflammatory markers. Flow cytometric analysis of peripheral leukocytes was also performed.
Results
Inflammatory markers were assessed in local injured spinal cord tissue at 6h, 1d and 7d post SCI. Compared to injury control, IL-6 was significantly reduced at all three time points, while TLR-4 is down-regulated at 6h after DEX treatment. As a marker for macrophage and microglia, CD11b

expression is decreased in DEX treated group. Further, DEX enhances the expression of Arginase-1 at both 6h and 1d, which suggests its ability to promote an anti-inflammatory response and tissue repair. In a time course study of blood monocyte using flow cytometry, percentage of peripheral CD11b/c positive cells are quickly elevated at 6h, peaked 1d after injury and slowly approach baseline over weeks. At 6h post SCI, these cells are significantly reduced by DEX. However, DEX seems to have no effect on these cells at later time points (1 and 7 days). In behavioral tests, there is a trend of improvement in grooming score and weight support by ipsilateral forelimb in the DEX treated animals.
Conclusions
As a highly selective α2-adrenergic agonist and sympatholytic agent, dexmedetomidine seems to improve functional recovery after acute SCI and modulates both local and systemic immune responses.

Title: Neovascularization by mechanical barrier disruption procedure infusing systemic erythropoietin in mild ischemic rat model

Authors: *G. PARK, E. CHOI, Y. KWON, B. YUN, K.-E. LEE, J. LEE, J. HONG;
Dept. of Neurology, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: BACKGROUND: Stroke is one of the most disabled diseases and neovascularization is a promising strategy for acute ischemic stroke. To achieve a successful backward neovascularization from the external cranium with enriched environment, we simply combined mechanical barrier disruption (MBD) on the skull with systemic erythropoietin infusion under the brain ischemic condition. Therefore, this combination is hypothesized by two beneficial modes: (1) MBD is for a new vessel detour from the outside, (2) systemic erythropoietin (EPO) is a boosting drug for vessel maturation without regression. METHODS: Mild ischemic animal model was established by subjecting male Sprague-Dawley rats (250-270g) to bilateral internal carotid artery ligation (bICAL). They were intraperitoneally injected with recombinant human EPO (5000 U/kg) or saline for 3 days and were performed as a 2.5±0.5 mm burr-hole operation on the right side. MBD groups with or without EPO were compared in histology, gene

expressions using quantitative real-time polymerase chain reaction, and postmortem angiography using the india ink stain at 3 phases: 4 (early, T1), 7 and 14 (intermediate, T2), 28 and 84 days (late, T3). RESULTS: Compared to contralateral side without MBD (left), ipsilateral side with MBD showed a successful neovascularization after 14 days (T2): Extra- and intracranial anastomoses were shown in a postmortem angiography at 14 days and vessel density (RECA-1^{+}) was gradually increased since T2. Compared to contralateral MBD side during T1, ipsilateral MBD side showed an increase of pro-angiogenic (angiopoietin 2), inflammatory factors for vessel permeability, and activated M1 type microglia (Iba-1+/CD16/32^{+}). However, there was a suppression of inflammatory responses (those with EPO) in T1. Compared to MBD without EPO group during T3, MBD with EPO group showed the increases of functional and structural vessel maturation (RECA-1^{+}/SMA^{+}/$NG2^{+}$) along with upregulating relevant genes and activated M2 type-microglia (Iba-1^{+}/$CD206^{+}$). Minocycline (45mg/kg) infusion for consecutive 4 days (MIC, inflammatory inhibitor during T1) showed a decreased expression of inflammatory factors and a decreased angiogenesis at T3, even in MBD with EPO group. CONCLUSIONS: Our data suggest that EPO contribute to a long-term stability for angiogenesis representing pro-angiogenic and anti-inflammatory properties, especially under the MBD status. This new method augmenting neovascularization without its regression can reflect a novel therapeutic strategy for ischemic stroke victims.

Title: Differential effects of rapamycin treatment on recurrent synaptic excitation of hilar inhibitory interneurons after focal brain injury in mice

Authors: *C. R. BUTLER[1], J. A. BOYCHUK[1,2,3], B. N. SMITH[1,2,4];
[1]Physiol., [2]Epilepsy Ctr., [3]Ctr. for Advanced Translational Stroke Sci., [4]Spinal Cord and Brain Injury Res. Ctr. (SCoBRIC), Univ. of Kentucky, Lexington, KY

Abstract: Traumatic brain injury (TBI) is among the most common causes of acquired temporal lobe epilepsy (TLE). Multiple forms of synaptic reorganization occur in the dentate gyrus after

brain injury, which may contribute to TLE development. A murine model of TBI using controlled cortical impact (CCI) injury was used to examine the effect of daily rapamycin treatment (3 mg/kg) on excitatory synaptic reorganization of dentate granule cells (DGCs) and CA3 pyramidal neurons after CCI injury. Increased doublecortin immunolabeling was observed in the ipsilateral DGC layer 2 weeks after CCI injury and mossy fiber sprouting was evident 8-13 weeks post-injury in the ipsilateral hemisphere. Daily rapamycin treatment reduced both the increased doublecortin immunolabeling and mossy fiber sprouting in the ipsilateral dentate gyrus. Using mice that express GFP in a subset of inhibitory neurons (FVB-Tg(GadGFP)4570Swn/J; i.e., GIN mice), whole-cell patch-clamp and on-cell recordings in vitro detected an increase in spontaneous EPSC frequency and action potential firing rate of surviving GFP+ hilar interneurons ipsilateral to CCI injury, relative to cells contralateral to the injury. Relative to CCI injury alone, daily rapamycin treatment for 8-12 weeks after CCI injury resulted in a reduction in the increase in sEPSC frequency and spontaneous firing rate of GFP+ hilar interneurons, but these measures were not normalized to control levels. After CCI injury, GFP+ hilar interneurons ipsilateral to injury exhibited increased evoked responses to glutamate photostimulation of both DGCs and CA3 pyramidal neurons, relative to contralateral and sham controls. Rapamycin treatment reduced responses of ipsilateral GFP+ hilar interneurons to glutamate photostimulation of DGCs, but did not reduce the increased response to glutamate photostimulation of CA3 pyramidal neurons. Rapamycin treatment therefore suppresses synaptic reorganization of DGCs, but not CA3 pyramidal cells after CCI injury. Ongoing experiments using glutamate photolysis will test the hypothesis that rapamycin treatment suppresses excitatory axon sprouting of DGCs, but not other neurons ipsilateral to CCI injury.

Title: Enduring erythropoietin repair of cerebral microstructure and diffusion abnormalities following severe infant traumatic brain injury in rats

Authors: *L. L. JANTZIE[1], S. ROBINSON[2];
[1]Neurol., Univ. of New Mexico Dept. of Pediatrics, Albuquerque, NM; [2]Pediatric Neurosurg., Johns Hopkins Univ., Baltimore, MD

Abstract: Traumatic brain injury (TBI) is a leading cause of death and severe morbidity for infants who are born healthy. Despite the high prevalence and incidence of lifelong deficits from TBI suffered by infants, no targeted treatment currently exists to actively promote repair. Using a translatable preclinical model of infant TBI, we hypothesized that diffusion tensor (DT) magnetic resonance imaging (MRI) could be used to quantify outcomes and potential efficacy of the neuro-reparative agent erythropoietin (EPO). To this end, controlled cortical impact (CCI) was performed on postnatal day 12 (P12) rats of both sexes. Anesthetized rats underwent left parietal craniectomy and 0.6mm impact. On post-injury day (pid) 1, injured rats were randomized to 6 doses of intraperitoneal erythropoietin (EPO) 3000U/kg/dose or vehicle (sterile saline) over pid 1-8. Ex vivo MRI was performed on a 4.7T MRI scanner at P15, P45 and P90, and quantified by observers blinded to injury and treatment status. DTI investigation reveals bilateral widespread injury and significant abnormalities of functional anisotropy (FA), axial (AD) and radial diffusivity (RD) developing acutely from P15 through P45 in multiple gray and white matter structures following CCI. Specifically, FA is decreased, and AD and RD increased, in the corpus callosum, and hippocampus and thalamus ipisilateral to CCI compared to sham (n=6-8/group, $p<0.05$ for all). Notably, treatment with EPO reversed changes in AD and RD throughout the white matter, overlying cortex and AD in thalamus both ipsilateral and contralateral to CCI (two-way ANOVA with post-hoc correction, $p=0.011$ and $p=0.029$, respectively). Impaired diffusivity in white and gray matter was sustained at P90, with increases in AD and RD concomitant with reduced structural coherence in the corpus callosum, lateral white matter and cortex. Notably, EPO treatment provided sustained repair of AD and RD microstructural abnormalities bilaterally (i.e. corpus callosum RD: CCI-veh $4.0\pm0.29x10^{-4}$ vs. CCI-EPO $3.4\pm0.02x10^{-4}$ mm^2/s, $p=0.03$). Together, these data indicate that EPO, administered in an extended post-injury dosing paradigm congruent with its mechanisms of action, proved efficacious in reversing microstructural and sustained diffusion abnormalities in developing rats. These data support the use of age-appropriate preclinical models with human clinical trial-compatible imaging biomarkers and outcome measures.

Title: Erythropoietin reverses cognitive deficits in a model of infant traumatic brain injury

Authors: *A. OPPONG[1], L. L. JANTZIE[2], S. ROBINSON[1];
[1]Pediatric Neurosurg., Johns Hopkins Univ., Baltimore, MD; [2]Neurol., Univ. of New Mexico Dept. of Pediatrics, Albuquerque, NM

Abstract: Traumatic brain injury (TBI) is a leading cause of death and severe morbidity for infants who are born healthy. No targeted treatment currently exists to actively promote repair after early TBI, despite the high incidence of chronic, debilitating deficits. Using a translatable preclinical model of infant TBI, we hypothesized that touchscreen cognitive testing could be used to quantify outcomes and potential efficacy of the neuro-reparative agent erythropoietin (EPO). Controlled cortical impact (CCI) was performed on postnatal day 12 (P12) rats of both sexes. Anesthetized rats underwent left parietal craniectomy and 0.6mm impact. On post-injury day (pid) 1, injured rats were randomized to 6 doses of intraperitoneal erythropoietin (EPO) 3000U/kg/dose or vehicle (sterile saline) over pid 1-8. Similar to the Cambridge Neuropsychological Test Automated Battery (CANTAB) in humans, a touchscreen platform was applied to assess multiple cognitive domains. Beginning at P35, rats were trained on a touchscreen operant platform by blinded investigators. Following successful training, rats performed visual discrimination (VD) and reversal tasks to assess executive function and cognitive flexibility (n=6-8/group, two way ANOVA with Bonferroni correction). Results indicate that Sham, CCI and CCI-EPO rats are able to successfully perform VD with each group requiring a similar number of sessions to passing criteria and committing similar numbers of discrimination errors. However, when assessing reversal learning, only 57.1% of CCI animals successfully passed criteria compared to 100% of Sham and 83.3% of CCI animals treated with EPO. Notably, CCI animals committed significantly more errors and required more correction trials (1114±132) compared to Sham (730±95) and CCI-EPO (652±61, $p<0.05$ for all), concomitant with increased perseveration (all $p<0.05$). Reaction and magazine latencies were similar for each group and did not differ between VD and reversal platforms. Taken together, EPO treatment ameliorates deficits on a touchscreen platform, including error reduction and perseveration, and restores cognitive flexibility. To our knowledge, this is the first demonstration using the highly-translatable, sophisticated cognitive testing of the touchscreen platform for TBI. EPO, administered in an extended post-injury dosing paradigm congruent with its mechanisms of action, proved efficacious in reversing functional impairment after TBI in developing rats.

Title: Effects of intraventricular cdnf, manf and gdnf injections on neuroblast proliferation and migration after cortical stroke in adult rats

Authors: *K.-Y. TSENG[1], J. ANTTILA[1], K. MATLIK[1], A. DOMANSKYI[1], M. SAARMA[1,2], R. TUOMINEN[2], M. AIRAVAARA[1];
[1]Helsinki Univ., Inst. of Biotech., Helsinki, Finland; [2]Fac. of Pharm., University of Helsinki, Helsinki, Finland

Abstract: Objective: Mesencephalic astrocyte-derived neurotrophic factor (MANF) and cerebral dopamine neurotrophic factor form a novel evolutionally conserved family of neurotrophic factors. Previous studies have shown that glial cell line-derived neurotrophic factor (GDNF) and MANF pretreatment reduce ischemic brain injury and promote behavior recovery, and that GDNF induces neurogenesis after striatal stroke. The purpose of this study was to study the effects of MANF, CDNF and GDNF treatments on neurogenesis in stroke rats. **Material and Methods:** Adult rats were subjective to 90 minutes middle cerebral artery occlusion (MCAO) and divided into four groups based on their neurological scores. Recombinant human MANF, CDNF, GDNF proteins (10 µg) or phosphate buffered saline (PBS) was administrated to rats via intraventricular injections on days 3, 7, 10 post-stroke. Proliferating cells were labeled with 5´-bromo-2´deoxyuridine (BrdU) injections from day 4 to day 10. Fourteen days after stroke rats were perfused and brains collected for immunohistochemistry. **Result:** Stroke increased the number of doublecortin+ cells in the ipsilateral SVZ post-stroke. GDNF increased BrdU+ cells in ipsilateral SVZ and the number of doublecortin+ cells in the striatum. MANF did not have effect on number of BrdU+ cells in the SVZ but it increased number of doublecortin+ in the corpus callosum and the peri-infarction zone. We did not observe effects with CDNF. **Conclusion:** Taken together, these data suggest that intraventricular injections of MANF after post-stroke promoted the migration of endogenous neuroblasts from the SVZ to the lesioned cortex in adult rats of stroke.

Title: Promoting post-stroke plasticity with local delivery of brain-derived neurotrophic factor

Authors: *J. M. OBERMEYER[1], A. TULADHAR[2], S. L. PAYNE[1], C. M. MORSHEAD[3], M. S. SHOICHET[1,2,4];
[1]Chem. Engin. and Applied Chem., [2]Inst. of Biomaterials and Biomed. Engin., [3]Surgery, [4]Chem., Univ. of Toronto, Toronto, ON, Canada

Abstract: Stroke is a devastating neurological event, affecting approximately 5 million people each year. As there is currently no treatment that will regenerate damaged brain tissue, stroke survivors suffer from permanent disabilities and memory loss that greatly impact quality of life. Administration of a known agent of plasticity, Brain-Derived Neurotrophic Factor (BDNF), has the potential to facilitate the rearrangement necessary to compensate for stroke-induced deficiencies; however, delivery of this protein to the brain remains a challenge[1]. We have previously developed a biocomposite composed of a hyaluronan and methyl cellulose hydrogel (HAMC) and poly(lactic-co-glycolic acid) (PLGA) nanoparticles in order to circumvent the blood brain barrier and provide local, sustained release of therapeutics[2]. In this work, we optimize this biocomposite for the delivery of BDNF and evaluate efficacy of this delivery strategy in a rat model of stroke injury.
BDNF was encapsulated in PLGA nanoparticles using a double emulsion technique. These nanoparticles were mixed with hyaluronan and methyl cellulose to create the PLGA-HAMC biocomposite and the release of BDNF from this system was studied *in vitro*. To measure the extent of penetration of locally delivered BDNF into stroke-injured brain tissue, endothelin-1 was used to create stroke lesions in male Sprague-Dawley rats and the biocomposite was injected onto the surface of the cortex above the lesion. Animals were sacrificed at 13 and 20 days post-injury and enzyme-linked immunosorbant assay (ELISA) was used to measure BDNF concentration in the tissue.
In vitro, the release of BDNF from the HAMC hydrogel alone reached completion by three days,

whereas BDNF release from the PLGA-HAMC system was sustained out to 28 days with no initial burst release. A dorsal root ganglion bioassay revealed that the BDNF released from this system was still bioactive at each sample time point. *In vivo*, BDNF diffused from the biocomposite on the surface of the cortex into the tissue and was detectable above endogenous levels at all depths tested.
The PLGA-HAMC delivery system achieved sustained, local release of bioactive BDNF to the stroke-injured rat brain. Ongoing studies will evaluate the effect of locally
delivered BDNF on synaptic plasticity and functional recovery in the endothelin-1 rat model of stroke.

Title: Dihydropiridine calcium channel antagonist (Nilvadipine) is potential drug against repetitive mild TBI

Authors: *A. MORIN, B. MOUZON, S. FERGUSON, F. CRAWFORD;
Roskamp Inst., Sarasota, FL

Abstract: Traumatic brain injury (TBI) is the recognized cause of disability in various population groups including military/veterans and athletes, and has long been known as a risk factor for neurodegenerative disorders such as Alzheimer's disease (AD). Currently, there is no efficient treatment for TBI due to complex and diverse neuropathological processes occurring after injury. However, we propose that certain drugs which are used to ameliorate AD conditions may also show positive changes in TBI. For this purpose, we are testing nilvadipine, calcium channel blocker (CCB), in a mouse model of repetitive mild TBI (r-mTBI). Nilvadipine is known

as an anti-hypertensive drug, but was also shown in our laboratory as AD preventive drug via reduction of Aβ accumulation, and is now under clinical trial, Phase III in Europe. To verify nilvadipine effects after r-mTBI, we are using aged htau mice (expressing all six isoforms of human tau) which show age-related tau pathological features. Animals subject to five hits with an inter-injury interval of 48hrs or r-sham in order to control for the effects of repeated anesthesia followed intraperitoneal (IP) injections of nilvadipine during 21 days. A battery of behavioral tests is currently ongoing to assess cognitive impairments. Rotarod showed positive performance of motor function in nilvadipine treated mice compared to vehicle only group. Barnes Maze and optomotor response were used to assess spatial memory and vision. Moreover, we are planning to collect brain samples 1 week after final injection for immunohistochemistry (IHC) analysis and to look at inflammation level using Iba1, GFAP and APP as biomarkers for activated microglia, astrogliosis and axonal damage, respectively.

Title: The aminopeptidase P2 inhibitor, ST-115, improves functional outcomes after experimental stroke.

Authors: *S. KAJA[1,3,2], S.-Y. TSAI[3], A. ROCKWELL[1], E. SAVARESE[1], V. RAO[2], G. L. KARTJE[3,2], W. H. SIMMONS[2];

Abstract: Stroke remains the fifth leading cause of death and the leading cause of disability in the US. Previous studies have shown that reperfusion injury is positively associated with the extent of stroke damage. There is an urgent clinical need for novel safe and efficacious therapies that prevent the deleterious effects of reperfusion injury. Apstatin is a selective aminopeptidase P2 blocker that has previously been shown to be highly effective in preventing cardiac reperfusion injury. Aminopeptidase P2 is localized at the luminal plasma membrane in

endothelial cells, where it inactivates the peptide hormone bradykinin through hydrolysis. Here we tested the hypothesis whether the apstatin analog, ST-115, can prevent ischemia/reperfusion injury and improve functional outcomes and retinal degeneration in an experimental model for stroke. Male Sprague-Dawley rats (2 months of age) were subjected to experimental stroke surgery by transient (45 min) bilateral occlusion of the common carotid artery and unilateral occlusion of the middle cerebral artery, followed by either 48 hr or 2 wk of survival time. Animals received either saline, or the apstatin analog ST-115 (16 μg/kg), which is 1000-times more potent than apstatin (IC_{50} = 3.7 nM) by intravenous injection immediately prior to initiation of reperfusion. At 48 hrs, ST-115-treated animals showed a highly statistically significant improvement of acute neurological deficits as assessed by the NeuroScore paradigm, which tests abnormal forelimb posture, rearing, and weight bearing (2.3 ± 0.2 and 0.2 ± 0.2; $P<0.01$), and a statistically significant reduction in the volume of ischemia-induced lesions as quantified by TTC staining. In order to test long-term functional outcomes, we assessed the skilled forelimb reaching task in another cohort after 2 wk of survival. ST-115-treated animals performed significantly better than saline-treated controls ($P<0.001$) and showed no statistically significant difference in the reaching score from baseline ($P=0.46$). We further characterized retinal damage, which is clinically associated with stroke and ischemia/reperfusion injury. ST-115 reduced the number of apoptotic retinal ganglion cells (RGCs) from 62.1% to 40.5% ($P<0.01$), as assessed by fluorescent TUNEL staining on frozen sections. Similarly, ST-115 improved retinal thinning and reduced expression of astrocytic and microglial markers, glial fibrillary acidic protein (GFAP) and ionized calcium-binding adapter molecule 1 (Iba1). Our data provide strong proof-of-concept and feasibility data supporting the development of apstatin analogs for targeted therapy against ischemia/reperfusion injury after stroke.

Title: A role for neuropeptide signaling in regulating *C. elegans* response to anoxia

Authors: *S. DOSHI[1], R. G. KALB[1,2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: While the brain is 2% of the body's mass, it utilizes 20% of all consumed oxygen to maintain its energy needs. As a result, the nervous system is very sensitive to oxygen availability, and neurons can alter their metabolic state and activity upon detecting a decrease in oxygen. Neuronal injury caused by reduced oxygen (hypoxia or anoxia) has severe implications in development and adulthood, leading to impaired brain function and even death. In this study, we use the nematode *C. elegans* to understand the molecular regulation of anoxic injury. The worm responds to hypoxia and anoxia using distinct molecular pathways, and while the genetic regulation of the hypoxic response has been well characterized in the worm, less is known about the response to anoxic environments. Here, we find a novel role for neuropeptide signaling in regulating a specific response to anoxia using genetic manipulations afforded by this model organism. Loss of function mutants in neuropeptide maturation (egl-3) as well as neuropeptide release (unc-31) have a significant survival advantage after 48hr anoxia compared to wild-type N2 animals. Tissue-specific loss of egl-3 demonstrates that the nervous system is necessary for this effect, confirming that neuropeptides, and not other peptidergic hormones, mediate this regulatory response. The role of neuropeptide signaling is also specific to anoxic stress as it does not protect against other stressors such as heat or ER stress. This response is independent of many canonical stress resistance factors (daf-16, hsf-1, skn-1). It is also independent other known genes involved in hypoxia and anoxia, such as hif-1 and nsy-1. Others have reported that the homolog of yeast longevity assurance gene 2 (hyl-2), a ceramide synthase, protects *C. elegans* from anoxia as hyl-2 mutants are very poor survivors of anoxic stress. We made double mutants to test whether loss of neuropeptide secretion is dependent on hyl-2 for its protective effect. Our results indicate that hyl-2 is indeed necessary for the protective effect conferred by loss of neuropeptide signaling. Ongoing work aims to describe the mechanistic link between unc-31/egl-3 and hyl-2 in regulating this response. We are also working to define the specific neuropeptide(s) and the cell-types responsible for neuropeptide-mediated death under anoxia. This work sheds light on a novel and specific pathway regulating the response to severe oxygen deprivation, and could have implications for a variety of human conditions including, among others, hypoxic ischemic encephalopathy, stroke and injury to the brain.

Abstract: Traumatic brain injury (TBI) is the leading cause of death and disability in the most active segment of the population. At present, no pharmacological agent is approved for the treatment of TBI. The enormous human suffering and financial burden of TBI provides a compelling rationale for the development of novel agents and approaches to TBI management. Using *in vivo* phage screening in an animal model of TBI, we have identified a novel brain injury targeting peptide (BIP) that, when systemically injected, specifically homes to sites of injury in penetrating and non-penetrating (controlled cortical impact) brain injury models. The target epitope for BIP peptide appears to be within a proteoglycan complex that is upregulated in mouse and human brain injuries. We have used BIP to enhance the accumulation of systemically administered molecules ranging from a drug-sized molecule to nanoparticles to sites of brain injury. BIP-coated nanoparticles containing silencing oligonucleotides provided first evidence of gene silencing in injured brain parenchyma by systemically administered siRNA. Importantly, BIP also showed selective binding to human brain injury lesions, which supports the potential application of this delivery strategy in humans. The effect of targeted delivery of therapeutics using BIP on brain injury is currently being investigated. Together, these findings present a readily accessible and effective targeting strategy for the delivery of therapeutics in clinical management of acute brain injuries.

Title: cPLA2 activation leads to lysosomal damage and autophagy impairment after TBI

Authors: *C. SARKAR[1], S. LIU[2], N. HEGDEKAR[1], J. PETER[1], A. I. FADEN[1], M. M. LIPINSKI[1];
[1]Shock, Trauma and Anesthesiol. Res. (STAR) Center, Dept. of Anesthesiol., [2]Dept. of Orthopaedics, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Autophagy, a lysosome dependent major cellular degradative process, plays important role in maintaining cellular homeostasis particularly in cells like neurons. Autophagic dysregulation has been implicated as one of the major causes of neuronal cell death in several neurodegenerative diseases. Recently we also have demonstrated impairment of autophagy following controlled cortical impact (CCI) induced traumatic brain injury (TBI) in mice. We observed block of autophagosome degradation mainly within neuron at early time point after TBI. Our data indicated that it is at least in part due to lysosomal dysfunction, as evidenced by lower protein levels and enzymatic activity of the lysosomal enzyme, cathepsin D (CTSD) in injured cortex at day 1 after TBI. In the current study we further explored the mechanism of lysosomal defect following TBI. We observed leakage of lysosomal content into the cytosol due to lysosomal membrane damage after brain injury. This correlated with the activation of cytosolic phospholipase A2 (cPLA2), an enzyme that cleaves fatty acyl linkage in the phospholipid of cellular membranes. We observed enhanced phosphorylation of cPLA2 within mouse cortex soon after injury. Furthermore, elevated level of cPLA2 was also observed within

neurons where autophagosomes accumulate following brain injury. Consistently with the possibility that cPLA2 activity may damage lysosomal membranes and inhibit autophagy, block of autophagosome degradation was detected *in vitro* in H4 cells and rat cortical neurons treated with cPLA2 activator ceramide-1-phosphate (C1P). This was due to the lysosomal damage caused by cPLA2 activation as evidenced by lower lysotracker fluorescence in cells treated with C1P. SiRNA mediated knock down of cPLA2 or pretreatment of cells with cPLA2 inhibitor arachidonyl trifluoromethyl ketone (AACOCF3) substantially prevented autophagosome accumulation in C1P treated H4 cells and rat cortical neurons. *In vivo,* we observed significant decrease in accumulation of autophagosomal marker LC3-II and its substrate p62 in the injured mouse cortex when mice were treated before and after CCI with AACOCF3. Taken together these data indicate that cPLA2 activation leads to lysosomal damage causing autophagosome accumulation in the cortex and contributing to neuronal cell death after TBI. Thus we propose, that inhibiting cPLA2 mediated lysosomal damage early after TBI may restore autophagosome clearance and decrease neuronal cell loss.

Title: Diazepam inhibits post-traumatic neurogenesis and blocks aberrant neuronal maturation

Authors: *L. E. VILLASANA[1], A. PETERS[2], R. MCCALLUM[2], G. WESTBROOK[3], E. SCHNELL[1,4];
[1]Anesthesiol. and Perioperative Med., [2]Sch. of Med., [3]Vollum Inst., Oregon Hlth. and Sci. Univ., Portland, OR; [4]VA Portland Hlth. Care Systems, Portland, OR

Abstract: Traumatic brain injury (TBI) robustly increases the generation of adult-born neurons within the dentate gyrus of the hippocampus, a brain region critical for learning and memory. Under healthy conditions, constitutive neurogenesis is important for certain forms of learning and memory, although whether post-traumatic neurogenesis is beneficial or harmful to cognitive restoration has yet to be established. Benzodiazepines, which are frequently administered to severely head-injured patients during hospitalization, target receptors known to modulate constitutive neurogenesis. To investigate whether benzodiazepine administration after TBI affects post-traumatic neurogenesis, we administered diazepam continuously for one week via implanted osmotic pump immediately after a controlled cortical impact (CCI) injury was performed on 2-month old mice. Diazepam administration attenuated the TBI-induced increase in hippocampal neurogenesis without reducing neurogenesis below baseline levels, and did not affect neurogenesis in uninjured control mice. Cell proliferation three days after injury as assessed by bromodeoxyuridine incorporation into dividing cell nuclei was unaffected by diazepam, suggesting that the inhibition of post-traumatic neurogenesis by diazepam may be attributed to changes in survival or differentiation of cells generated after CCI. Neuronal activity within the hippocampus, however, was significantly decreased as assessed by cFos immunohistochemistry. Diazepam exposure also mitigated the dendritic abnormalities previously reported in TBI-induced adult-born neurons, but did not inhibit the enhanced outward migration of new neurons through the granule cell layer. As diazepam selectively attenuated the increase in neurogenesis without affecting baseline levels of neurogenesis, it may be a powerful tool to determine whether the increased generation of neurons born after injury is beneficial or harmful to cognitive recovery.

Title: Combined intervention using acute intrathecal baclofen (ITB) and locomotor exercise provides significant therapeutic outcome in reducing TBI-induced spasticity without adversely affecting cognitive, balance, anxiety, and activity performance

Authors: *P. K. BOSE[1,2,3], J. HOU[2], R. NELSON[1], G. MUSTAFA[2], J. WATTS[1], J. JOSEPH[1], S. TSUDA[2], L. PAGE[5], F. J. THOMPSON[1,2,4];
[1]North Florida/South Georgia VAMC, Gainesville, FL; [2]Physiological Sci., [3]Neurol., [4]Neurosci., Univ. of Florida, Gainesville, FL; [5]Medtronic Neuromodulation,Targeted Drug Delivery R & D, Medtronic Inc, Minneapolis, MN

Abstract: Spasticity is a major health problem for patients with moderate to severe traumatic brain injury (TBI). Following TBI, the onset of spasticity and its secondary muscular and orthopedic sequellae is rapid, and can begin as early as one week following injury. These progressively developing motor disabilities often represent significant barriers for re-entry of TBI patients into the community. However, current federal guidelines preclude the use of ITB therapy for spasticity treatment during the first year following TBI due to insufficient data to determine potential risk associated with early therapies on cognitive function, balance, and motor recovery. Moreover, it is not clear, if acute ITB is safe or provides a therapeutic advantage when combined with locomotor therapy. Therefore, the objective of this preclinical study was to determine the safety and effectiveness of an experimental rehabilitation program that combined ITB and locomotor exercise. In these studies ITB (Lioresal® baclofen injection; 0.8µg/hr) and treadmill locomotor exercise (Tm) were initiated at one week after TBI (450g / 1.5 m), and then continued for 4 weeks. We recently reported that enduring spasticity, balance, anxiety and cognitive deficits were observed and quantitated in this TBI model (Bose et al., 2013). Spasticity, anxiety-like behavior, balance, cognitive, and home caged performances were measured using an elevated plus maze (EPM), rotorod, Morris water maze (MWM), and Noldus Phenotyper, respectively. One month of ITB and Tm combined treatment produced the most significant reduction in spasticity without detectable impact on cognitive, balance, anxiety or activity recovery. In fact, this combined treatment completely blocked early onset spasticity. More importantly, this significant therapeutic benefit persisted even after cessation of ITB therapy. Interestingly, the combined therapy group exhibited significantly reduced MWM latency at the

fourth day of testing, and significantly less anxiety-like behavior in the EPM. Moreover, 12-hour video-tracked activity monitoring data (6pm through 6am) did not show any adverse effects. In fact, ITB+Tm group exhibited home caged behavioral patterns similar to normal animals. These observations indicated that initiating ITB at one week post-TBI was safe, feasible, and effective; and in combination with a Tm therapeutic exercise protocol provided the most effective rehabilitation. These studies also indicate that progressively, a broad spectrum of comprehensive data will reinforce confidence in the safety, feasibility, and efficacy of early intervention treatments with locomotor therapy for TBI-spasticity.

Title: Mild traumatic brain injury in mice causes region specific deficits in oscillatory neuronal activity and functional connectivity that are rescued by the novel cannabinoid type-2 receptor inverse agonist SMM-189

Authors: *D. H. HECK[1], S. S. MCAFEE[1], N. H. GULEY[1], M. G. HONIG[1], N. DEL MAR[1], W. BU[1], S. A. HELDT[1], B. M. MOORE[2], A. REINER[1,3], Y. LIU[1];
[1]Anat. & Neurobio., [2]Pharmaceut. Sci., Univ. of Tennessee, Memphis, TN; [3]Ophtalmology, Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Mild traumatic brain injury (mTBI) typically results from a closed-head insult after a primary blast shock wave, blow to the head, or head acceleration - deceleration during a collision. It is a frequent occurrence during military combat, sports, recreational activities, and vehicular accidents. MTBI can cause long lasting cognitive deficits. Depression and persevering fear are among the most commonly observed deficits in mTBI patients, and they have been reproduced in a focal cranial air-blast model of mTBI in mice (*1, 2*). Although these deficits strongly implicate neuropathology of the medial prefrontal cortex (mPFC) and the hippocampus, abnormalities in these brain regions after mTBI have not been confirmed. We used multi-electrode, multi-site recording techniques in the focal cranial air-blast mouse model of mTBI to investigate the effect of mTBI on oscillatory neuronal activity, coherence and phase-amplitude coupling (PAC) in medial prefrontal cortex (mPFC), the primary somatosensory and primary visual cortex (S1/V1), and the hippocampal CA1 area. We also investigated the effect of mTBI on CA1 sharp wave ripples (SWR) and on SWR evoked responses in the mPFC. Coherence and PAC of neuronal oscillations require precise temporal coordination of neuronal activity within and/or between regions, and we hypothesized that they would be sensitive indicators of cortical and hippocampal connectivity disruption following mTBI (*2, 3*). MTBI caused increased coherence of oscillatory activity at theta to beta (4-30Hz) frequencies within the mPFC and S1/V1, enhanced theta-gamma PAC within the mPFC, caused a downshift of SWR frequency in the CA1 and reduced SWR-evoked LFP activity in the mPFC. Systemic treatment of mTBI mice with the cannabinoid type-2 (CB2) receptor inverse agonist SMM-189 for two weeks after blast rescued most deficits. In the brain, CB2 receptors are selectively expressed on microglia, and SMM-189 acts to bias microglia from the pro-inflammatory M1 state to the pro-healing M2 state. Our findings link mTBI to specific deficits in oscillatory network activity and functional connectivity within mPFC, S1/V1 and hippocampus, and suggest targeting of neuroinflammatory processes as a promising route for the development of treatments for mTBI.

Title: Poly(ADP-Ribose) polymerase-1 causes mitochondrial respiratory dysfunction by regulating PGC-1α

Authors: ***P. LU**[1,2], A. KAMBOJ[1], S. CHOWDHURY[3], P. FERNYHOUGH[3,2], C. M. ANDERSON[1,2];
[1]Neurosci. Res. Program, Kleysen Inst. For Advanced Med., Winnipeg, MB, Canada; [2]Pharmacol. & Therapeut., Univ. of Manitoba, Winnipeg, MB, Canada; [3]St Boniface Hosp. Res. Ctr., Winnipeg, MB, Canada

Abstract: Excitotoxic oxidative stress and DNA damage causes excessive activation of the nuclear enzyme poly(ADP-ribose) polymerase-1 (PARP-1). This leads to mitochondrial dysfunction and neuron death, but the mechanisms of PARP-1-induced mitochondrial damage are poorly understood. Peroxisome proliferator-activated receptor gamma coactivator-1α (PGC-1α) is a master regulator of mitochondrial biogenesis and respiration. PGC-1α activity is influenced by sirtuins, which are nicotinamide adenine dinucleotide (NAD^+)-dependent class III histone deacetylases. Since PARP-1 consumes NAD^+, we hypothesized that PARP-1 leads to mitochondrial dysfunction in neurons by inhibiting sirtuin activity and preventing support of mitochondrial function by PGC-1α. Primary cortical neuron cultures were exposed to the DNA alkylating agent, N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) to initiate pathological PARP-1 activation. A Seahorse Flux Analyzer was then used to assess several facets of mitochondrial function. Beginning 4 hr after MNNG exposure, maximal respiratory rate, respiratory control ratio, and spare respiratory capacity were significantly reduced in a manner partially restored by PARP-1 inhibition (PJ34, 10 μM), PARP-1 deletion (*parp-1*$^{-/-}$ mice) or exogenous replenishment of NAD^+. MNNG caused PARP-1-dependent depletion of NAD^+ levels and commensurate inhibition of sirtuin deacetylase activity. Increased PGC-1α acetylation was also observed, corresponding with reduced PGC-1α binding to nuclear respiratory factor-1 (NRF-1), NRF-1 association with mitochondrial transcription factor A (TFAM) promoter, and TFAM expression. In agreement, mitochondrial DNA copy number and total mass were significantly attenuated by MNNG by a mechanism sensitive to PJ34 or exogenous NAD^+ replacement. Taken together, these data demonstrate that PARP-1 activation causes NAD^+ depletion severe enough to inhibit PGC-1α-directed mitochondrial mass and respiratory capacity in neuron cultures.

Title: Pomalidomide mitigates neuronal loss, neuroinflammation and behavioral impairments induced by traumatic brain injury in the rat

Authors: ***J. WANG**[1], J.-Y. WANG[1], L.-Y. YANG[1], D. TWEEDIE[2], N. H. GREIG[2]; [1]Grad. Inst. of Med. Sci. TMU, Taipei, Taiwan; [2]Drug Design & Develop. Section, Translational Gerontology Branch, Intramural Res. Program,, NIA, NIH, Baltimore, MD

Abstract: Traumatic brain injury (TBI) is a risk factor for neurodegenerative diseases and mortality worldwide. The therapeutic effects and time window of pomalidomide (Pom), an FDA approved immunomodulatory agent, were evaluated in a moderate to severe rat model of TBI induced by controlled cortical impact. Pom (0.5mg/kg, i.v.) or vehicle was administered at 5 or 7 hr after TBI. Neurobehaviors were evaluated using swing test, adhesive removal, modified neurological severity scores and beam walking. Tissue levels of mRNA and protein of pro-inflammatory cytokines such as tumour necrosis factor-α (TNF-α), interleukin-6 (IL-6), interleukin-1β (IL-1β) were measured by reverse transcriptase-qPCR and ELISA, respectively. Our results indicate that post-injury treatment with a single Pom dose within 5 hr significantly alleviated functional impairments caused by TBI. Pom reduced the contision volume, augmented neuronal survival and provided anti-inflammatory effects. In addition, Pom concentration-dependently ameliorated glutamate-mediated cytotoxic effects, H2O2-induced oxidative stress on cell viability and reduced microglial cell activation in vitro. Our data suggest that Pom has therapeutic effects to improve histological and functional outcomes after TBI and reduces neuroinflammatory responses. These findings strongly support the further evaluation and optimization of Pom for potential use clinically in TBI. (supported by MOST 104-2923-B-038-001-MY3, Taiwan).

Title: The antipsychotic drug aripiprazole benefits functional outcome after experimental brain trauma and does not attenuate the benefits of environmental enrichment

Authors: H. L. RADABAUGH, S. BESAGAR, M. J. LAPORTE, P. B. DE LA TREMBLAYE, C. O. BONDI, *A. E. KLINE;
Phys Med. & Rehab, Psych, Safar Ctr. Resuscitation Res., Univ. Pittsburgh, Pittsburgh, PA

Abstract: Introduction: The typical antipsychotic drug (APD) haloperidol (HAL), a D_2 receptor antagonist, has been shown to impede functional outcome after experimental traumatic brain injury (TBI). Furthermore, the deleterious effects persist for up to 3 months after drug withdrawal. Moreover, a recent study showed that HAL reduced the effectiveness of environmental enrichment (EE), a preclinical model of neurorehabilitation. Because agitation is common after TBI, patients are provided APDs so that they can be safely managed. However, many patients in rehabilitation will only experience agitation occasionally and thus will receive APDs intermittently. **Hypotheses**: Aripiprazole (ARIP), a partial D_2 and 5-HT_{1A} receptor agonist, will not impair recovery or reduce the effectiveness of EE regardless of whether administered once every day (i.e., chronic agitation) or once every other day (occasional agitation). **Methods**: Anesthetized adult male rats received a cortical impact of moderate severity or sham injury and were then randomly assigned to EE or standard (STD) housing. Treatments with ARIP (0.1 mg/kg; i.p.) or vehicle (VEH; 1.0 mL/kg; i.p.) began 24 hr after injury and continued once daily for 19 days, or once every other day for the same period. Motor (beam-walk) and cognitive (spatial learning) outcome were assessed on post-operative days 1-5 and 14-19, respectively. **Results**: Motor and cognitive function was significantly improved in the TBI+EE+VEH vs. TBI+STD+VEH group ($p<0.05$). Moreover, the TBI+EE+ARIP groups, regardless of dosing regimen, performed significantly better on all endpoints relative to the TBI+STD+VEH controls ($p<0.05$), but did not differ from one another or from TBI+EE+VEH ($p>0.05$). **Conclusions**: The data replicate previous work from our laboratory showing the EE improves functional outcome after TBI. Furthermore, ARIP, unlike HAL, did not impair recovery or reduce the efficacy of EE, which supports the hypothesis. **Significance**: ARIP is beneficial on its own and does not negate the benefits of rehabilitation (i.e., EE) and thus may be used to control TBI-induced agitation and aggression without compromising recovery.

Title: Chronic vs intermittent administration of the antipsychotic drugs haloperidol or risperidone after experimental traumatic brain injury: Insights into motor and cognitive recovery

Authors: *P. BARRA DE LA TREMBLAYE[1], L. J. CARLSON[1], M. J. LAPORTE[2], C. O. BONDI[1], A. E. KLINE[1];
[1]Physical Med. & Rehabil., [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Preclinical studies have shown that chronic administration of the antipsychotic drugs (APDs), haloperidol (HAL) or risperidone (RISP), impairs neurobehavioral recovery after TBI. However, APDs are often administered intermittently rather than continuously to TBI patients as restlessness and agitation occur irregularly during the recovery phase. The goal of this study was to test the hypothesis that intermittent (1 or 3 times per week) administration of HAL and RISP would produce less deleterious effects on motor and cognitive recovery compared to chronic (daily) administration. Anesthetized adult male rats received a controlled cortical impact (2.8 mm tissue deformation at 4 m/s) or sham injury and then were provided HAL (0.5 mg/kg; i.p.), RISP (0.45mg/kg; i.p.) or vehicle (VEH; 1 mL/kg; i.p.), with administration starting at 24 h after surgery and then either once daily (chronic), or 1 or 3 times weekly for 19 days. Beam-balance/walk and Morris water maze performance were assessed on post-injury days 1-5 and 14-19, respectively. The data revealed that the TBI groups administered HAL or RISP intermittently did not significantly differ from the VEH+TBI group in both motor and cognitive outcome, which is opposite to the chronic (once daily) treatment paradigm, which performed worse in all

behavioral measures compared to the VEH+TBI group ($p < 0.05$). These findings replicate previous reports that chronic administration of HAL or RISP negatively impact motor and cognitive recovery after cortical impact. Additionally, the data expands the research by demonstrating that intermittent administration of HAL or RISP, regardless of whether once or three times a week, did not impair recovery as those groups did not differ from the TBI+VEH-treated controls. The potential clinical implications of these findings suggest that intermittent administration of the APDs HAL or RISP may be safely used to control agitation in TBI patients, without negatively impacting subsequent recovery.

Title: Effects of chronic unpredictable stress on cognitive and depressive-like behaviors following experimental brain trauma

Authors: L. KUTASH, E. MCPEAKE, E. COOLEY, R. ROHAC, I. MARSHALL, J. CHENG, A. E. KLINE, *C. O. BONDI;

Abstract: Traumatic brain injury (TBI) affects 2 million individuals in the United States each year, and many survivors endure long-lasting cognitive impairments associated with frontal lobe disturbances, while also being vulnerable to neuropsychiatric disorders. Clinical and preclinical research has highlighted the importance of chronic stress, particularly when presented in an unpredictable fashion, as a major risk factor for many psychopathological conditions. In the

current study, we are beginning to assess clinically-relevant cognitive-behavioral and anxiety-like dimensions sensitive to both TBI and chronic unpredictable stress (CUS). We hypothesized that moderate TBI produced by controlled cortical impact (CCI) injury, as well as CUS exposure will render cognitive impairments in male rats in an attentional set-shifting test (AST), reduced sucrose preference and open field exploration, as well as blunted weight gain. Isoflurane-anesthetized adult male rats were subjected to a CCI (2.8 mm cortical tissue deformation at 4 m/sec) or sham injury over the right parietal cortex. Following surgery, rats were randomly assigned to receive CUS (21 days starting 5 days post-surgery) or 30 sec of handling (CTRL). Upon cessation of stress, rats were tested for perceived state of anxiety (open field test) and anhedonia (reduced preference of 1% sucrose-water versus regular water overnight). At 4 weeks post-surgery, rats were then tested on the AST, which involves a series of increasingly difficult discriminative tasks to obtain food reward. Preliminary results demonstrate that CUS exposure leads to a 5-10% weight gain reduction compared to CTRL group, yet the combination of TBI and CUS does not seem to negatively impact center exploration in the open field, or sucrose preference (n=8-12/group). We anticipate that TBI will lead to cognitive deficits, as previously reported (Bondi et al., 2014, *J Neurotrauma*), which will be further augmented by CUS exposure. This ongoing project will provide novel outcomes pertaining to cognitive capability, as well as anxiety- and depressive-like symptoms following overlapping chronic stress exposure and the recovery phase of TBI.

Title: Phosphodiesterase 10A inhibition promotes motor recovery in ischemic striatal stroke

Authors: S. Z. BIRJANDI[1], S. NAIR[2], K. SUZUKU[3], H. KIMURA[3], *S. CARMICHAEL[4]; [1]Neurol., David Geffen Sch. of Med. at UCLA, Los Angeles, CA; [2]Neurol., David Geffen Sch. of Med. at UCLAa, Los Angeles,, CA; [3]Takeda Pharmaceut. Co., Osaka, Japan; [4]UCLA Sch. Med., Los Angeles, CA

Abstract: Stroke is one of the leading causes of adult disability in the United States. Physical therapy leads to modest improvements in motor recovery, but there is currently no drug regimen available to enhance recovery after stroke. Phosphodiesterases (PDEs) are the enzymes that degrade the intracellular second messengers, cAMP and/or cGMP. Accumulating preclinical evidence suggests that PDE inhibitors promote learning and memory and attenuate disease progression in several neurologic illnesses. Among the PDE families, PDE10A is unique in its restriction to the basal ganglia/striatum, a common site of human stroke. The use of a PDE10A inhibitor has not been examined in recovery after stroke. Our goal was to test if a PDE10A inhibitor developed with demonstrated effect on brain function leads to improved motor recovery. We hypothesized that a PDE10A inhibitor would promote recovery in striatal but not cortical stroke. Using a murine model of striatal and cortical ischemic stroke, mice were given once-daily intraperitoneal injections of a novel PDE10A inhibitor TAK-063 for 9 weeks starting day 5 post stroke. Behavioral testing was evaluated during the course of drug treatment. After the 9-week drug regimen, the neuroanatomical tracer, biotinylated dextran amine, was microinjected into the motor cortex, and the motor cortical connections were mapped. Brains were also analyzed for relative degrees of gliosis and angiogenesis. In a parallel study, brains were harvested for measurement of brain-derived neurotrophic factor (BDNF), which is downstream of the cAMP signaling cascade. After treatment with 3 mg/kg of TAK-063, improvement in forelimb motor function and gait compared with stroke-only controls was exclusive to the striatal stroke model. No difference in behavior was observed in the cortical stroke model. Daily treatment with TAK-063 led to a significant increase in BDNF in the striatum when compared with stroke-only mice, normalizing BDNF levels to that seen in non-stroke mice. Differences in motor system connections (axonal sprouting) and gliosis and angiogenesis were not observed in either stroke model with TAK-063 treatment. Our findings demonstrate that treatment with TAK-063 has a differential effect on stroke recovery depending on stroke location, and studies are needed to examine potential therapeutic effects for striatial stroke in humans.

Abstract: Traumatic Brain Injury (TBI) is an increasingly common event affecting 1.7 million people annually in the USA alone. TBI is a significant cause of death and disability in the developed world, particularly among young adults. At present, no effective pharmaceutical therapies for TBI are available. Mild TBI (mTBI) is a common neurological event, which accounts for some 80% to 90% of TBI cases. Victims of mTBI frequently manifest cognitive, behavioral and emotional difficulties that can be long lasting. Previous experiments in our laboratory have shown that mTBI may lead to short and long-term cognitive and behavioral deficits as well as apoptotic processes in the brains of mice. The incretins glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) are gastrointestinal hormones that induce glucose-dependent insulin secretion, promote β-cell proliferation and enhance resistance to apoptosis. GLP-1 mimetics are on the market as treatments for type II diabetes and are well tolerated. Both GLP-1 and GIP mimetics have shown neuroprotective properties in animal models of Parkinson's and Alzheimer's disease. Twincretin is a unimolecular, dual action co-agonist with balanced activity at both the GLP-1 and GIP receptors with optimized pharmacokinetics. In this study, we exposed male ICR mice to mTBI using a weight drop concussive head trauma device and administered twincretin in a 7-day regimen of subcutaneous injections starting 30 minutes after the injury. Subsequently, we investigated the effects of twincretin on the cognitive impairments and neuronal degeneration following mTBI. Twincretin ameliorated mTBI-induced visual and spatial memory deficits as measured in the novel object recognition paradigm and the Y-maze paradigm, respectively. These effects were observed at both 7 and 30 days post-mTBI. Using the elevated plus maze we assessed the anxiety-like behavior and well-being of the mice. There were no differences between the groups at both 7 and 30 days following mTBI. These findings show that the results of the novel object recognition and

Y-maze paradigms are not confounded by different levels of anxiety among experimental groups. In addition, neuronal loss was quantified immunohistochemically at 72 hours post-injury by the use of fluoro-Jade B and NeuN within the dentate gyrus on both sides of the brain. Twincretin demonstrated significant mitigation of mTBI induced neuronal degeneration in the dentate gyrus. These findings may offer a new potential therapeutic agent to treat the deficits caused by mTBI. Further studies will continue to investigate the neuroprotective effects and mechanism of action of twincretin.

Title: Comparison of tissue plasminogen activator (tPA) alone and in combination with thrombin inhibitor argatroban in a nonhuman primate model of thromboembolic stroke

Authors: J. SUZUKI[1], Y. ITANI[1], K. YAMANAKA[1], *A. HAMA[2], A. MATSUDA[1], H. TAKAMATSU[1];
[1]Hamamatsu Pharma Research, Inc., Hamamatsu, Japan; [2]Hamamatsu Pharma Res. USA, Inc., San Diego, CA

Abstract: When given early, tissue plasminogen activator (tPA) increases functional recovery following acute stroke by clot lysis and vascular recanalization. However, to achieve efficacy, there is a narrow therapeutic time window in which tPA must be administered. In addition, not all patients respond to tPA, which suggests the need for antithrombotics for the treatment of acute stroke with mechanisms other than that of tPA. Numerous promising treatments that showed significant efficacy in preclinical animal models of acute ischemic stroke have failed clinical trials. A potential limitation of current preclinical studies is the utilization of rodents as the model species. Nonhuman primates are phylogenetically closer to humans than rodents, which could narrow the current translational shortfall between preclinical and clinical findings. Thus, the goal of the current study was to uncover a possible beneficial effect of a combination of argatroban, a thrombin inhibitor, with tPA in a nonhuman primate model of thromboembolic ischemia. A thromboembolic stroke was induced in cynomolgus macaques by injection of blood

clots into the internal carotid artery. One hour following the induction of ischemia, either tPA (0.9 mg/kg) or vehicle was intravenously infused for 1 hour. After completion of tPA infusion, either argatroban (0.6 mg/kg) or vehicle was intravenously infused for 22 hours. Middle cerebral artery blood flow was monitored for 6 hours after ischemia. In addition, brain infarct volume (TTC staining) and functional assessment (Neurological Deficit Score; NDS) were determined 24 hrs after ischemia. Tissue plasminogen activator significantly decreased occlusion time, brain infarct volume and NDS compared to vehicle treatment. Preliminary findings suggest that macaques treated with the combination of argatroban and tPA showed decreased occlusion time, similar brain infarct volume and similar NDS compared to tPA alone-treated macaques. The current study in a nonhuman primate model suggests that the addition of argatroban could enhance recanalization rates, but does not further enhance tissue or functional recovery from a thromboembolic stroke compared to tPA treatment alone. Additional macaques will be tested to confirm the current findings.

Title: Calpain-1 and calpain-2 play opposite roles in traumatic brain injury (TBI) induced neurodegeneration

Authors: ***Y. WANG**, D. LOPEZ, J. TRAN, A. ALSTON, X. BI, M. BAUDRY;
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Traumatic Brain Injury (TBI) is a major cause of death and disability worldwide. The mechanism of injury varies and includes motor vehicle accidents, falls, sport injuries, and gunshot wounds, etc. Among the different types of TBI, penetrating traumatic brain injuries produce the worst outcomes and highest mortality rates. TBI induces neurodegeneration and axonal damage, and the calcium-dependent protease, calpain has been shown to be involved in these events. However, while calpain inhibitors have been tested in several animal models of TBI, there has not been any clinical trial testing the efficacy of calpain inhibitors in human TBI. One important reason for this, could be the lack of knowledge regarding the differential functions of the two major calpain isoforms in the brain, calpain-1 and calpain-2 (aka μ- and m-calpain). In this study, we used the controlled cortical impact (CCI) model in mice to test the specific functions of calpain-1 and calpain-2 in TBI-induced neurodegeneration. Immunohistochemistry with calpain activity markers performed at different time points after CCI in wild-type and calpain-1 KO mice showed that calpain-1 and calpain-2 were sequentially activated around the impact site. While calpain-1 was activated within 0-8 h after CCI, calpain-2 activation was not significant until about 8 h after CCI, peaked at 24 h and was still present at 72 h after CCI. TUNEL and Fluoro-Jade C staining showed enhanced neurodegeneration around impact site in calpain-1 KO mice after CCI, as compared to WT mice, suggesting that calpain-1 is neuroprotective. Systemic injection of a calpain-2 selective inhibitor, NA101, at 1 h or 4 h after CCI significantly reduced calpain-2 activity and neurodegeneration around the impact site, and reduced the contusion volume. Our data indicate that calpain-1 activity is neuroprotective while calpain-2 activity is neurodegenerative after TBI and that a selective calpain-2 inhibitor can reduce TBI-induced neurodegeneration.

Title: Combined inhibition of fyn and c-src reduces brain edema and improves cognitive function following traumatic brain injury in adult rats

Authors: *Z. YE[1,3], F. SHARP[1], K. VAN[2], B. ANDER[1], X. ZHAN[1], B. STAMOVA[1], G. C. JICKLING[1], B. LYETH[2], D. LIU[1];
[1]Neurol., Univ. of California, Davis, Sacramento, CA; [2]Neurolog. Surgery, Univ. of California, Davis, Davis, CA; [3]Dept. of Navy Aeromedicine, Second Military Med. Univ., Shanghai, China

Abstract: Traumatic brain injury (TBI) is often accompanied by intracerebral and intraventricular hemorrhage. We have previously demonstrated that moderate TBI produced by lateral fluid percussion injury (LFPI) produces bleeding into the cerebrospinal fluid (CSF) in the ventricles, which activates Src family kinases (SFKs)[1]. In the current study we explored whether inhibition of SFKs could attenuate TBI-associated brain injury and behavioral deficits. Since several SFK subtypes including Fyn and Src have been reported in brain[2-4], we targeted these SFK subtypes using a newly developed *in vivo* nanoparticle-based siRNA transfection system to inhibit the specific SFK subtypes. One day after injections of nanoparticle-siRNAs (100μg, i.c.v.) for SFK family members Fyn and c-Src into the left lateral cerebral ventricle, Fyn and c-Src mRNAs decreased in rat hippocampus by 22% and 43%, respectively. As compared to vehicle treated TBI controls, the combined si-Fyn and si-c-Src decreased brain water content from 82.7% to 80.64% in ipsilateral cortex, and decreased sodium fluorescence concentration in brain homogenates from 2.4 to 1.5μg/ml ($p<0.05$) in the ipsilateral cortex at 24 hours after TBI. Additional studies are currently underway examining the effects of combined treatment with si-Fyn and si-c-Src on cognitive function assessed at 12 through 16 days after TBI using the Morris Water Maze, and on survival of hippocampal neurons ($NeuN^+$ cells) at 16 days after TBI. These data suggest that combined inhibition of Fyn and c-Src has the potential to improve outcomes following TBI. SFK inhibitors have been well tolerated in cancer patients in clinical trials and the FDA has approved the nanoparticle-based siRNA approach. We propose that combined inhibition of specific SFK subtypes Fyn and c-Src by nanoparticle-based siRNA might improve outcomes of patients with TBI. **Acknowledgements:** This study was supported by NIH grants R01NS089901 (DZL) and NS054652 (FRS). There were no conflicts of interest.

Title: Hyperglycemia-mediated hematoma expansion during intracerebral hemorrhage is attenuated by PGD2 DP1 receptor antagonism

Authors: *A. S. AHMAD[1,2], M. MENDES[1,2], S. ALI[1,2], C. WASSERFALL[3,4], S. DORE[1,2,5]; [1]Dept. of Anesthesiol., [2]Ctr. for Translational Res. in Neurodegenerative Dis., [3]Dept. of Pathology, Immunol. and Lab. Med., [4]Diabetes Inst., [5]Departments of Neurology, Psychiatry, Pharmaceutics, Psychology, and Neurosci., Univ. of Florida, Gainesville, FL

Abstract: The respective importance of PGD2 and its receptor DP1 in the vasculature, the blood, and the brain warrants additional examination of their role in intracerebral hemorrhage (ICH) under hyperglycemic condition. In this study, we first tested the role of hyperglycemia on ICH, and, then, tested the therapeutic potential of DP1 receptor inhibition on functional and anatomical outcomes following ICH in hyperglycemic mice. Wildtype (WT) and DP1-/- C57BL/6 mice were given 2g/kg glucose and then blood glucose and C-peptide levels were monitored up to 3h after the injection. In the second cohort, WT and DP1-/- mice were subjected to hyperglycemia and ICH was induced at 1h after glucose injection by giving a single intrastriatal injection of collagenase to induce ICH. In the third cohort, WT mice were subjected to hyperglycemia and ICH, as described above, followed by treatment with saline or the DP1 receptor antagonist Laropiprant at 1h after ICH induction. Neurologic deficits, brain injury volume, and edema volume were determined at 72h. Furthermore, brain sections from these groups were subjected to Perls' staining and Iba1 and GFAP immunoreactivity to determine the effect of Laropiprant on the modulation of iron levels and gliosis. Acute injection of glucose led to a significant increase in the glucose level in WT and DP1-/- mice. DP1-/- mice exhibited faster clearance of glucose overload compared with the WT mice. Also, WT mice treated with Laropiprant also exhibited faster clearance of glucose. Similar patterns were observed in C-peptide levels of these groups. The injury volume in DP1-/- compared with WT was significantly lower (8.3±1.8 vs 19.3±5.6mm3; $p<0.01$). Moreover, WT mice treated with Laropiprant also exhibited significantly lower brain lesion volume (9.1±3.2 vs 19.3±5.6mm3; $p<0.01$). Interestingly, a significant decrease in Iba1 immunoreactivity and Perls'-labelled iron content was observed in hyperglycemic DP1-/- compared with the hyperglycemic WT mice. Together, the data suggest that blockade of the DP1 receptor improves glucose tolerance/clearance and ameliorate functional and anatomical outcomes following ICH in hyperglycemic condition. Ongoing studies are underway to further investigate optimal therapeutic conditions and mechanisms of action.

Title: Manipulation of Ubiquilin-1 expression in the post-ischemic mouse brain to validate its role in neuroprotection following transient cerebral ischemic stroke

Authors: *Y. LIU[1], H. WANG[2];
[1]Div. of Basic Biomed. Sci., [2]Univ. of South Dakota, Vermillion, SD

Abstract: Stroke is one of the most common causes of adult disability and death and is pathologically associated with oxidative stress, protein damage, and neuronal loss. We previously reported that overexpression of a ubiquitin-like protein, ubiquilin-1 (Ubqln), protects neurons against oxidative stress and ischemia-caused brain injury, while knockout of the gene exacerbates cerebral ischemia-caused neuronal damage and delays functional recovery. Although these observations indicate that Ubqln is a therapeutic target, transgenic manipulation-caused overexpression of Ubqln occurs before the event of ischemic stroke, and it remains unknown whether delayed Ubqln overexpression in post-ischemic brains within a clinically relevant time frame is still beneficial. To address this question, we generated lentiviruses either overexpressing mouse Ubqln or mouse Ubqln-shRNAs. Adult mice were subjected to middle cerebral artery occlusion (MCAO) for 90 minutes and then reperfused for 6 hours before intracerebral injection of the lentiviruses was performed. Mouse motor and sensory behaviors were evaluated at day 1, 3, 5 and 7 days following the ischemia/reperfusion. Our data indicate that post-ischemic overexpression of Ubqln significantly reduces neuronal injury and promotes functional recovery. In contrast, downregulation of Ubqln expression delays functional recovery and increases neuronal injury. To further understand the mechanisms underlying how Ubqln functions, we also isolated protein aggregates from the ischemia/reperfusion insulted mouse brains and found that Ubqln was present in the aggregates. These observations suggest that Ubqln may be a useful candidate for therapeutic intervention for stroke.

Title: Oligodendrocyte response to mechanical injury: role of the Erk1/2 pathway

Authors: *J. KIM[1], P. GOKINA[1], A. ADAMS[1], B. J. PFISTER[2], H. A. KIM[1];
[1]Biol. Sci., Rutgers Univ., Newark, NJ; [2]Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ

Abstract: Impact-accelerated forces to the head causes rapid stretching of the axons through out the brain termed traumatic axonal injury (TAI). Long myelinated axons within white matter tracts are especially vulnerable to the injury and accordingly, chronic myelin loss is a common occurrence after such traumatic brain injury (TBI). While axon pathology associated with TBI has been well elucidated, the molecular efficacy of mechanical force on myelin and oligodendrocyte is not fully understood. Using an in vitro TAI model, we investigated the effects of stretch injury on differentiated oligodendrocytes. Differentiated oligodendrocyte cultures were established on deformable silicone membrane, which was then stretched using computer-controlled air pressure. Within 24 hours after injury, oligodendrocytes at the site of injury lost membrane arborization and MBP expression or exhibited aberrant MBP accumulation. Cell death was not observed indicating that the injury response was induced in viable oligodendrocytes. Stretch injury also induced calcium-dependent Erk1/2 activation in differentiated oligodendrocytes. In vivo, experimental TBI on rat induced Erk1/2 activation in white matter oligodendrocytes within 4 hours after injury, suggesting that Erk1/2 may play a role in mediating the oligodendrocyte response to TBI. To directly assess the impact of Erk1/2 activation on myelin, we generated oligodendrocytes harboring a constitutive active mutant of MKK1 (CA-MKK1), which expression is induced by doxycycline. The CA-MKK1 oligodendrocytes were co-cultured with neurons and allowed to generate myelin, after which Erk1/2 was activated in oligodendrocytes with myelin by doxycycline. Erk1/2 activation resulted in myelin degeneration in viable oligodendrocytes and down regulation of myelin protein expression. In differentiated oligodendrocyte cultures, Erk1/2 activation induced loss of the differentiated phenotype, which was followed by the oligodendrocyte re-entry into the cell cycle. Altogether, our results suggest a role of Erk1/2 in mediating oligodendrocyte response and myelin loss following mechanical injury.

Title: Preclinical and clinical toxicity/safety profiles of sp-8203, a novel neuroprotectant for the treatment of cerebral ischemic stroke

Authors: *H. SONG[1], W.-K. KIM[1], J.-M. RYU[2], B.-S. KIM[2], G.-S. CHO[2], K.-S. BAE[3]; [1]Korea Univ. Med. Col., Seoul, Korea, Republic of; [2]Central Res. institute, Shin Poong Pharm. Co. Ltd, Ansan, Korea, Republic of; [3]Asan Med. Center, Univ. of Ulsan, Seoul, Korea, Republic of

Abstract: The novel neuroprotectant SP-8203 (Shin PoongPharm. Co. Ltd, South Korea) extends the therapeutic time window of tPA in embolic stroke rats by reducing the adverse effects caused by delayed tPA treatment. SP-8203 has successfully completed a Phase 1 clinical trial and is undergoing a Phase 2a clinical trial in ischemic stroke patients. The preclinical and clinical toxicity/safety profiles of SP-8203 are reported here. General toxicity tests in Sprague Dawley rats and Cynomolgus monkeys were performed by MPI Research (USA), Toxikon (USA) and Phase 1 clinical trial by Asan Medical center (Korea). The NOAEL of 4 week repeated dose of SP-8203 was 40 mg/kg/day in rats and 12 mg/kg/day in monkeys. There was no specific safety concerns noted in the preclinical program. A Phase I, single-center, randomized, double-blind, placebo-controlled study to assess the safety, tolerability, and pharmacokinetic of single ascending doses (SAD) and multiple ascending doses (MAD) of SP-8203 was conducted in healthy subjects. For the SAD assessment (n=48), cohorts of 8 subjects were randomly assigned to receive a single dose of either SP-8203 (n=6) or placebo (n=2). The doses were from 10 mg with incremental escalation up to 240 mg. For the MAD assessment (n=24), cohorts of 8 subjects were randomly assigned to receive one dose of either SP-8203 (n=6) or placebo (n=2) daily for 7 consecutive days, and the doses of SP-8203 were 30 mg, 60 mg, and 120 mg. Mild adverse events (AEs) occurred in 4 out of 48 subjects (8.3%) and no serious adverse events (SAEs) occurred, in the SAD assessment. Additionally, AEs were observed in 7 (29.1%) out of 24 subjects in the MAD again with no SAE, demonstrating the safety and tolerability of SP-8203.The pharmacokinetics of SP-8203 has been described in healthy subjects where no accumulation of SP-8203 was demonstrated with repeated dosing. SP-8203 was metabolically most stable in human. Taken together, the series of toxicity/safety assessments showed that SP-8203 is safe and well tolerated at the doses which will be used in the study of SP-8203 treatment

for the cerebral ischemic stroke in man. A Phase 2a proof-of-concept study is underway to evaluate the safety and exploratory efficacy of SP-8203 in combination with tPA in patients with acute ischemic stroke. (HYS and W-KK equally contributed)

Title: Estrogen reduces stroke induced brain damage by differentially altering ASIC1a and 2a expression

Authors: ***M. MUKHOPADHYAY**[1], A. WAHUL[2], P. JHELUM[2], S. CHAKRAVARTY[2], A. BERA[1];
[1]Indian Inst. of Technol., Chennai, India; [2]CSIR-Indian Inst. of Chem. Technol., Hyderabad, India

Abstract: Activation of acid sensing ion channels (ASICs) during cerebral ischemia has been implicated in stroke induced brain damage. Estrogen is known to be neuroprotective against many neurological disorders and stroke. We hypothesise the involvement of ASICs in the estrogen mediated neuroprotection against stroke. We found that while ASIC1a exacerbates ischemic cell damage, ASIC2a subtype is neuroprotective. Increase of ASIC2a expression possibly increases the population of ASIC1a and 2a containing heteromeric channels which have much lower activation pH than homomeric ASIC1a. Thus, shifting of pH_{50} to lower values renders the channel ineffective at the moderate drop of extracellular pH during ischemia. We detected an up-regulation of ASIC2a levels in female mice with intact ovaries following experimental stroke, whereas the levels of ASIC1a went down. This pattern however was not seen in male and ovariectomised mice. Estrogen supplementation in ovariectomised mice reinstated the ASIC2a levels and decreased ASIC1a. This substantiates our hypothesis that estrogen exhibits neuroprotective properties by regulating ASICs.

Title: Enhanced synaptic plasticity in a brain injury model treated with phasic striatal deep brain stimulation

Authors: *H. KATNANI[1], J. ARONSON[2], E. ESKANDAR[2];
[1]Dept. of Neurosurg., [2]Massachusetts Gen. Hosp., Boston, MA

Abstract: We have previously demonstrated that striatal deep brain stimulation (DBS) can enhance functional recovery of mice in a sub-acute phase of traumatic brain injury. We found that brain injured mice, receiving precisely timed stimulation at the reinforcement period of the task, performed significantly better then sham mice on a spatial memory task after 2 days and also reached the same performance level of uninjured mice after 6 days. With the observation of changes in performance occurring on a relatively fast time-scale, we evaluated dynamic neural mechanisms with a short time-constant. Converging evidence suggests that spatial memorization during the reinforcement period relies on early activation of synaptic receptors, which induces structural modifications in pre- and post-synaptic neurons that alters synaptic function. Accordingly, immunohistochemical analysis from our study revealed that stimulated mice had upregulated levels of synapsin-1 and GAP43. The promotion of these proteins with striatal stimulation could therefore be enhancing signal propagation through the striatum and hippocampus, leading to enhanced spatial memory function. In line with this, we utilized molecular biology techniques across multiple control groups to further assess modification of synaptic proteins from punch outs of the striatum, prefrontal cortex, and hippocampus, elucidating if DBS in the striatum is important to altering synaptic plasticity across multiple loci.

Title: Improvement in upper limb function after unilateral, but not bihemispheric, transcranial direct current stimulation.

Authors: *M. K. FLEMING[1], J. C. ROTHWELL[2], L. SZTRIHA[3], J. T. TEO[3,2], D. J. NEWHAM[1];
[1]Ctr. of Human and Aerospace Physiological Sci., King's Col. London, London, United Kingdom; [2]Inst. of Neurol., Univ. Col. London, London, United Kingdom; [3]Dept. of Stroke & Neurol., King's Col. Hosp. NHS Fndn. Trust, London, United Kingdom

Abstract: Transcranial direct current stimulation (tDCS) is a safe and non-invasive brain stimulation technique with the potential to improve upper limb function after stroke. Based on the interhemispheric competition model, ipsilesional primary motor cortex (M1) excitability can be increased with anodal tDCS, contralesional M1 excitability can be decreased with cathodal tDCS or both can be used simultaneously (bihemispheric). The impact of these different electrode arrangements on the efficacy of tDCS, and whether changes are due to callosal connections between cortices, is unclear. This study therefore aimed to investigate the effect of tDCS electrode arrangement on within-session change in upper limb function in chronic stroke survivors and change in transcallosal inhibition (TCI). 24 stroke survivors (range 3 - 124 months post-stroke, 34 - 81 years of age) with persistent upper limb impairment received 20 minutes of 1 mA tDCS while performing a motor sequence learning task. This involved reaching movements with the paretic arm to targets on a monitor in a repeated order. Four tDCS conditions were studied in a crossover design; i) anodal to the ipsilesional M1, ii) cathodal to the contralesional M1, iii) bihemispheric and iv) sham. Upper limb function was assessed before and after tDCS, using the Jebsen-Taylor hand function test (JTT). Changes in TCI were assessed as the duration of the ipsilateral silent period, using transcranial magnetic stimulation. Performance of the motor sequence learning task was unaffected by tDCS. There was a significant effect of tDCS condition on upper limb function as unilateral tDCS (anodal or cathodal) improved JTT time compared to sham ($p < 0.05$), but bihemispheric did not (Fig. 1). There was no effect on TCI ($p > 0.5$), and no relationship between changes in TCI and upper limb function. This indicates that unilateral, but not bihemispheric, tDCS improves upper limb function but that the response to tDCS does not

appear to be driven by changes in TCI. These results have implications for the use of tDCS during upper limb rehabilitation after stroke.

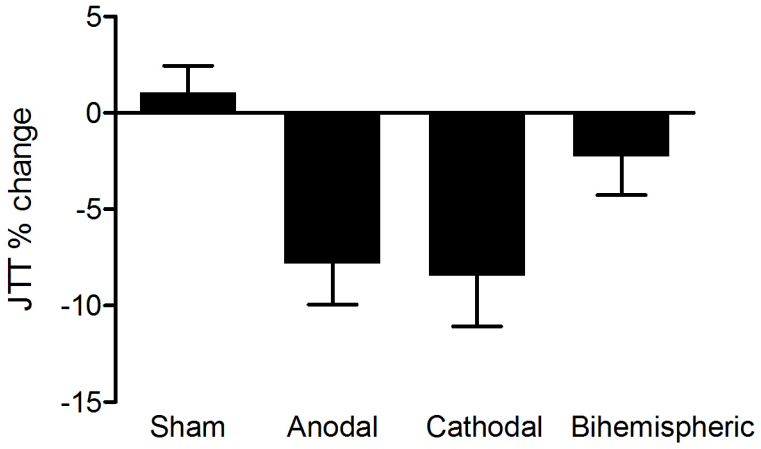

Fig. 1. Percentage change in JTT time for each tDCS condition.

Title: Contralesional rtms and motor training in a single subject with brainstem stroke

Authors: *K. FROST, T. BROBACK, N. CARLSON, C. DAGGETT, M. DALBEC, J. R. CAREY;
Univ. of Minnesota Syst., Minneapolis, MN

Abstract: Background: Repetitive transcranial magnetic stimulation (rTMS) coupled with motor training may improve post-stroke motor recovery. The influence of rTMS on ipsilesional corticospinal excitability is usually assessed using ipsilesional motor evoked potentials

(IpMEPs). However, nearly 40% of individuals with stroke do not have an elicitable IpMEP and are excluded from study samples. Thus, the efficacy of rTMS in this population is unknown. This study explores the influence of primed rTMS in a single subject with no baseline IpMEP amplitude ≥50 μV through the use of functional magnetic resonance imaging, transcranial magnetic stimulation and motor function tests. Methods: The human subject (45 year old male, six years post left pontine stroke) received two randomly applied interventions in a cross-over design with a one-month washout. *Active rTMS+training* included active 6-Hz priming of active 1-Hz principle rTMS followed by one hour of paretic finger tracking training. S*ham rTMS+training* included sham 6-Hz priming of sham 1-Hz principle rTMS to the contralesional primary motor area (M1) followed by one hour of paretic finger tracking training. Outcome measures were M1 and primary sensory area (S1) laterality indices, the probability of eliciting an IpMEP following single pulse and interhemispheric inhibition protocols, box-and-block score and finger tracking score. Due to the single-subject nature of this study, visual analyses were used for all outcomes. Results: *Following active rTMS+training,* the M1 laterality index moved closer to zero, reflecting a trend toward decreasing activation of contralesional M1. The S1 laterality index shifted from positive to negative during non-paretic finger tracking. Box-and-block and finger tracking scores did not change. *Following sham rTMS+training*, the M1 laterality index shifted from negative to positive, reflecting greater cortical activation of ipsilesional M1. The S1 laterality index, box-and-block and finger tracking scores did not change. For both interventions, the probability of eliciting an IpMEP decreased. Conclusions: Neural activation changed its laterization from contralesional to ipsilesional M1 following five days of paretic finger tracking without adjunctive rTMS (i.e. with sham rTMS). However, there was no accompanying functional improvement, possibly because of the short training time. Including active rTMS as an adjunct to motor training did not improve motor function or likelihood of eliciting an IpMEP. We conclude that there was no benefit of coupling contralesional rTMS with motor training in this single subject with no elicitable IpMEP ≥50 μV.

Title: Deep brain stimulation of the entorhinal cortex rescues memory in a rat model of global ischemia

Authors: *E. GONDARD[1], L. TEVES[1], C. HAMANI[1,2], S. K. KALIA[1], M. TYMIANSKI[1], A. M. LOZANO[1];
[1]Neurosurg., Toronto Western Hosp. - Univ. of Toronto, Toronto, ON, Canada; [2]Res. Imaging Ctr., Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Deep brain stimulation (DBS) is a well-established therapeutic modality for the treatment of movement disorders. Stroke is among the most frequent cause of disability in adults worldwide and often results in long-term neurological deficits in various functions including memory. Recently, the potential beneficial effects of DBS have been reported for memory enhancement in rodents and humans. Despite these promising results, DBS has not yet been tested for its ability to improve memory impairments following global ischemia. Using stimulation parameters analogous to clinical high-frequency DBS, we hypothesized that stimulating the neural circuits that underlie learning and memory might improve memory impairments observed in a rat model of global ischemia (GI). Two weeks after the GI induction, rats were bilaterally implanted with electrodes in the entorhinal cortex (EC) and underwent high frequency stimulation for 1 hour. Six weeks after DBS treatment, rats were assessed for changes in locomotor activity in the Open Field and learning and memory using the Morris water maze (MWM). Four different groups were studied: sham-stroke animals with DBS off (CTL-CTL), sham-stroke animals that received DBS (CTL-DBS), GI rats with DBS off (GI-CTL) and GI rats that received DBS treatment (GI-DBS). No differences were observed in the Open Field, suggesting that GI and DBS did not affect locomotion. GI led to a dramatic loss of neurons in the CA1 subregion of the hippocampus, which are known to be essential for spatial learning and memory. GI-CTL rats exhibited memory impairments when tested in the Morris Water Maze. However, when treated with DBS, GI rats crossed the platform area significantly more and spent more time in the quadrant area than GI-CTL rats, suggesting that the memory impairment caused by GI was improved with DBS treatment. Moreover, there was no difference between GI-DBS and CTL-CTL or CTL-DBS groups during the probe test, indicating that DBS of the EC can rescue some memory deficits induced by global ischemia. These results indicate that DBS may be a potential new approach to treat patients suffering from stroke.

Title: Revisiting interhemispheric imbalance in chronic stroke: a tDCS study

Authors: *W. D. BYBLOW[1,2], A. B. MCCAMBRIDGE[3], J. W. STINEAR[2];
[2]Exercise Sci. and Ctr. for Brain Res., [1]Univ. of Auckland, Auckland, New Zealand; [3]Grad. Sch. of Hlth., Univ. of Technol. Sydney, Sydney, Australia

Abstract: At the chronic stage of stroke patients with moderate-severe upper limb (UL) impairment rely on descending commands from the contralesional motor cortex (M1) for controlling both ULs. Although this may seem maladaptive, recent studies have shown that down-regulation of contralesional M1 excitability produces neurophysiological or behavioral deficits. We examined whether anodal transcranial direct current stimulation (a-tDCS) would increase contralesional M1 excitability and improve paretic UL coordination in a circle drawing task. We also explored associations between behavioural change scores and potential biomarkers derived from clinical, neurophysiological and neuroimaging variables. Patients were clinically assessed on measures of UL impairment, function and spasticity, then received a-tDCS, cathodal (c-tDCS) or sham stimulation in randomised order across separate sessions. The target electrode was positioned over contralesional M1 (1 mA, 20 cm^2, 15 min). Contralateral and ipsilateral corticomotor pathway excitability was examined using transcranial magnetic stimulation and motor evoked potentials (MEP). Fractional anisotropy within the posterior limbs of the internal capsules, and basal gamma-amino butyric acid (GABA) concentration in each M1, were assessed with magnetic resonance imaging (30 diffusion directions, b=2000) and spectroscopy (MEGA-PRESS) respectively at 3T. For the group, chronicity was 113 (14-192) months, impairment on the UL Fugl-Meyer scale was 27 (9-58, max 66), Action Research Arm Test scores were 21 (0-57, max 57) and spasticity on the Modified Ashworth Scale ranged from 1-3. Both contralateral ($P = 0.017$) and ipsilateral ($P = 0.092$) MEPs were facilitated after a-tDCS, and accompanied by a trend toward improved circle drawing (aspect ratio, AR) with the paretic UL ($P = 0.085$). The effect of a-tDCS on AR was associated with chronicity ($R = 0.88$, $P = 0.002$) and spasticity ($R = 0.70$, $P = 0.036$) such that those with greater chronicity and spasticity achieved the most benefit from contralesional a-tDCS. The effect of c-tDCS on AR was associated with baseline motor performance ($R = 0.80$, $P = 0.01$) and GABA:Cr ratio within ipsilesional M1 ($R = 0.75$, $P < 0.013$). Contralesional c-tDCS did not suppress corticomotor excitability ($P > 0.24$) or influence

AR (all $P > 0.80$). These findings indicate that further increasing contralesional excitability may benefit some patients. This study identifies potential biomarkers that may be useful for identifying patients who are suitable for contralesional tDCS.

Title: The contribution of intact hemisphere dorsal premotor cortex to paretic arm motor performance after severe stroke

Authors: *R. HARRINGTON[1], E. CHAN[2], A. K. ROUNDS[3], C. J. WUTZKE[4], A. W. DROMERICK[5,6], P. E. TURKELTAUB[6,5], M. L. HARRIS-LOVE[3];
[1]Interdisciplinary Program in Neurosci., Georgetown Univ., Washington, DC; [2]MedStar Hlth. Res. Inst., Hyattsville, MD; [3]George Mason Univ., Fairfax, VA; [4]Washington DC Veterans Affairs Med. Ctr., Washington, DC; [5]MedStar Natl. Rehabil. Hosp., Washington, DC; [6]Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Stroke affects almost one million Americans every year and many are left with long-term effects. One such effect is chronic post-stroke arm impairment, which can drastically affect independence in activities of daily living and quality of life. Existing treatments are of limited efficacy, particularly for patients with relatively severe post-stroke arm impairment. We examined how transcranial magnetic stimulation (TMS) perturbation of several sites within the intact hemisphere [dorsal premotor cortex (PMd), primary motor cortex (M1), and dorsolateral prefrontal cortex (DLPFC)] during a reaching task affected reaching performance. Chronic stroke patients who had not recovered active wrist or finger extension in the affected arm, but

had partial shoulder/elbow movement, participated in the study (n=15). Patients were instructed to, upon seeing a visual 'Go' signal, reach forward as quickly as possible with the affected arm to contact a target placed at approximately waist height and oriented in the horizontal plane. TMS (double-pulse; ISI 25 ms; 120% of resting motor threshold for unaffected biceps) was delivered over M1, PMd, or DLPFC of the intact (i.e. ipsilateral) hemisphere during the reaction time period between the 'Go' signal and the onset of movement. Analysis of hand-path kinematics in trials with vs. without TMS perturbation revealed that perturbation of PMd resulted in a significantly greater reduction in speed of reaching (movement time) than occurred with perturbation of M1 or DLPFC ($p<0.05$). Analysis of hand path parameters showed that stimulation of PMd, but not M1, resulted in a longer overall trajectory of movement ($p<0.05$), a greater decrease in the smoothness of the movement ($p<0.05$), and a larger increase in endpoint error ($p=0.05$). Taken together, these results suggest that PMd of the intact hemisphere can contribute to the speed and trajectory of affected arm reaching movements in patients with severe arm impairment.

Title: High-frequency rTMS improves functional recovery and promotes neurogenesis through BDNF signaling pathways in a rat model of ischemic stroke

Authors: J. LUO[1], L.-Y. ZHANG[1], Z. PEI[2], *H. LIANG[3], W.-J. GAO[3], F. LI[4], X.-Q. HU[1]; [1]Dept. of Rehabil. Med., the Third Affiliated Hospital, Sun Yat-sen University, Guangzhou, China, Guangzhou, China; [2]Dept. of Neurol., the First Affiliated Hospital, Sun Yat-Sen University, Guangzhou, China, Guangzhou, China; [3]Drexel Univ., Philadelphia, PA; [4]Dept. of Neurobio. and Anat., Zhongshan Col. of Medicine, Sun Yat-Sen University, Guangzhou, China, Guangzhou, China

Abstract: Objective: This study was performed to investigate whether high-frequency rTMS can improve functional recovery or promote neurogenesis, and to examine the role of BDNF-TrkB pathways in high-frequency rTMS-induced effects in a rat model of middle cerebral artery occlusion (MCAO).
Methods: A total of 56 adult Wistar rats with MCAO operation were randomly divided into four groups: 20Hz group (n=16), iTBS group (n=16), control group (Sham stimulation group, n=16) and sham-operated group (n=8, filament was not inserted into the artery). The rats were sacrificed 7 or 14 days after evaluating the neurological function. In addition, neurogenesis around the peri-infarction region was examined with immunecytochemical stainings of several specific markers, including Ki67,Nestin,DCX,CD31 and NeuN. Some brain tissues were also used to detect protein levels of BDNF and TrKB with Western blots.
Results: The results showed that 20Hz rTMS and iTBS significantly improved neurological function ($p<0.05$) and reduced infarct volume ($p<0.05$). Moreover, both treatments promoted neurogenesis as evidenced by the increased Ki67/Nestin-positive and Ki67/DCX-positive cells in ischemic hemisphere. These beneficial effects were in conjunction with significant elevated BDNF and TrkB protein levels.
Conclusions: High-frequency rTMS improves functional recovery and promotes neurogenesis possibly through BDNF signaling pathways in ischemic rats.

Title: Activity dependent stimulation of the lateral cerebellar nucleus to promote post-stroke motor improvement

Authors: *C. WATHEN[1], J. COOPERRIDER[2], H. CHAN[2], H. PARK[2], K. BAKER[2], J. GALE[2], A. MACHADO[2];
[1]Lerner Col. of Med., Cleveland Clin. Fndn., Cleveland Heights, OH; [2]Dept. of Neurosciences, Cleveland Clin., Cleveland, OH

Abstract: Deep brain stimulation (DBS) of the lateral cerebellar nucleus (LCN) has been shown to improve motor recovery after ischemic stroke in preclinical models when stimulation is delivered chronically, independent of motor behavior, during the animal's active period. We hypothesize that efficacy may be improved further by pairing stimulus delivery to specific epochs in relation to a rehabilitative motor task. The goal of the present study was to develop a task that would enable activity dependent stimulation in a rodent model. Long-Evans rats were trained on a modified version of the isometric pull task. Rats were trained to wait in front of a slot with the forepaw resting on a capacitive plate before reaching through the slot to grasp and pull a stationary handle. In the first stage of training, with the handle retracted fully out of reach, rats were trained to activate the capacitive plate for progressively longer periods of time prior to receiving a reward. Next, the handle was introduced inside the cage and the rats received a reward only after activating the capacitive plate for a sufficient period of time before interacting with the handle. In subsequent stages, the handle was retracted step-wise out of the cage to its final position and the force threshold required to receive a reward was adaptively increased. Once trained to a pre-specified criterion, rats underwent stroke induction via endothelin-1 injection in the primary motor cortex and electrode implantation in the contralesional LCN. Animals were assigned to receive no stimulation, continuous stimulation, or activity-dependent stimulation (initiated when the rat lifted its forepaw from the capacitive plate and terminated upon handle release). Assessments were performed over a period of four weeks. Sixteen rats were trained on the task. Training to criterion required 37.75±1.2 days (Mean ± SEM). The first stage of training on the capacitor lasted 21±2 days. After introducing the handle, the time required to reach criterion for stroke induction was 16.75±0.5 days. Four animals were excluded and did not undergo stroke induction; 2 for failure to meet criterion, and 2 for interacting with the capacitor with the nose, rather than the forepaw. Following a two week post-stroke recovery period, animals successfully resumed execution of the task. Rats were successfully trained on a multi-step behavioral task that enabled delivery of activity-dependent stimulation. Ongoing studies are aimed to determine if DBS applied only during a critical period of reaching behavior is capable of improving post-stroke motor impairment.

Title: A method for the quantification and visualization of stroke volume lesion using MRI

Authors: *L. COVOLAN[1,2], C. WATHEN[2], J. COOPERRIDER[2], H. BATTAPADY[2], J. CHEN[2], C. ANDROJNA[2], A. MACHADO[2];

Abstract: Determination of stroke volume is an important parameter to be taken into consideration while evaluating behavioral performance during ongoing experiments, such as those in rodent models. The methods we describe below would allow for the quantification and visualization of an ischemic lesion using only free, open source software. Ischemic stroke was induced in a Long-Evans rat by the injection of endothelin-1 in the vicinity of the middle cerebral artery. Several days after stroke induction the subject died, at which time the brain was extracted and preserved in 4% paraformaldehyde. Following preservation, the brain was imaged with the Bruker Biospec 70/20 7T MRI system using the mouse brain array coupled with the standard 86 mm coil (Bruker Corp). Axial, three-dimensional T2 Turbo RARE images were acquired using the following parameters: TE = 40 ms, TR = 1800 ms, SA=1; Image size = 150x150x150 and resolution = 0.173x0.173x0.173 mm. Following image acquisition, stroke volume was calculated using ImageJ (NIH). The image was first aligned within the standard viewing planes and resized. Next, the stroked hemisphere of the brain was reflected across the midsagittal plane. Using the image calculation tool, the two hemispheres were overlaid by subtracting the stroked hemisphere from the healthy hemisphere. Outside of the lesion, this resulted in a null image due to the subtraction of voxels of similar intensity. In the ischemic lesion, however, significant atrophy had taken place resulting in a low intensity signal which did not appreciably change the intensity of the corresponding healthy hemisphere following image subtraction. As a result, in the image resulting from the subtraction of the healthy and stroked hemispheres, the remaining signal corresponded to the stroke lesion volume. The resulting stroke volume image was then saved in the Analyze file type. Volview 3.4 (Kitware Inc, Clifton Park, NY) was then used to visualize the resulting stroke volume. The original T2 Turbo RARE image was first loaded. Next, using the “Merge Volumes” utility, the stroke volume was merged with the original image. False coloring of the stroke volume then allowed for visualization of the

stroke volume in both 2D and 3D. Further refinement of the stroke volume measurement is underway with the implementation of (a) slice-by-slice co-registration, (b) acquisition of higher resolution data sets (or images), and (3) evaluation of alternate MRI sequences (e.g. T1_FLASH_3D).

Title: Behavioral assessment using the pellet tray task in a rodent model of ischemia

Authors: *J. COOPERRIDER, C. WATHEN, A. LIU, H. CHAN, J. T. GALE, K. B. BAKER, A. G. MACHADO;
Cleveland Clin., Cleveland, OH

Abstract: The availability of sensitive and meaningful tools to measure functional recovery after neurological disease is critical to the success of preclinical neurorehabilitation models. The pasta matrix task is a commonly utilized task that our lab has used to measure the rehabilitative effect of deep brain stimulation of the lateral cerebellar nucleus after stroke. Here, we describe a complementary task to the pasta matrix that was designed to require a similar motor pattern, while presenting a greater challenge to the animal and compare it to the more established pasta matrix task. Rats were trained on both the pasta matrix task and a lab-built pellet tray task. Both tasks require the animal to reach through a narrow aperture to grasp and retrieve pasta or pellets with the paw contralateral to the presented food. Pasta is presented upright in a grid pattern and must be broken to be retrieved, while pellets must be grasped and retrieved without dropping. Individual performance in naïve animals was significantly correlated between the tasks. Animals then underwent a small, endothelin 1-induced cortical ischemic injury. Following stroke, rats showed a significantly greater deficit on the pellet tray task compared to the pasta matrix task across the 15 subsequent post-stroke assessment days, and performance on the two tasks was no longer correlated. The pellet tray task can be constructed from easily attainable and inexpensive components and provides a sensitive supplemental or alternative measure of post-injury motor deficit.

Title: Activation of ventral attention network by transcranial direct current stimulation for a patient with unilateral spatial neglect

Authors: *Y. TAKAMURA[1], K. IKUNO[2], S. FUJI[2,1], S. OHMATSU[1], S. MORIOKA[3], N. KAWASHIMA[4];

Ctr. for Persons with Disabilities (NRCD), Tokorozawa, Japan

Abstract: Unilateral spatial neglect (USN), a common neurological syndrome following right hemispheric lesions, has become evident as a widespread attention network disorder. We previously revealed hyperactivity of the frontal cortex as a neural mechanism underlying the compensatory strategy during recovery process after USN. While an optimal level of compensatory strategy is necessary to avoid neglect behavior in daily life, excess attention bias toward neglected space may lead adverse effects, such as reduced tolerance and suppression of the bottom-up attention. The subject of this case study was a 42-year-old man who had suffered extensive infarction of the right hemisphere by the obstruction in internal carotid artery 10 months earlier. In spite of a severe neglect in the daily living, the patient gradually recognize his neglect behavior. At the participation of this study, he clearly had excess attention bias toward neglected space. In order to optimize an involvement of compensatory strategy, we here attempted to apply combined intervention of temporo-frontal transcranial direct current stimulation (tDCS) and visual stimuli on PC display. We hypothesized that neuromodularoty intervention of tDCS induce elicitation of ventral attention network, and might result a reduction of the excess frontal activity. Anodal and cathodal electrodes were placed at right temporal and

frontal cortex, and the stimulus intensity was set to 2mA. Based on the BAB design (two weeks of each phase), the B/A phase consists of visual stimuli real/sham tDCS for 20 minutes in a session. In order to evaluate an extent of gaze and it's cortical mechanisms, EEG was recorded when the patient performed eye pursuit-based choice reaction task. At the beginning of intervention, the patient clearly showed extensive leftward gaze shift which accompanied with the increased in theta-band power in the frontal cortex even at rest. Interestingly, degrees of leftward gaze shift was improved after neuromodulatory intervention, and these alteration accompanied the reduction of frontal theta-band power. The present results imply that task-dependent and tDCS-induced elicitation of the ventral attention network might activate bottom-up attention and then effectively work to reduce excess frontal activity.

Title: Analysis of visual search pattern during free viewing of horizontally flipped image: Novel approach for the evaluation of visuospatial neglect

Authors: *S. OHMATSU[1,2], Y. TAKAMURA[1,2], M. IMANISHI[2], M. OSAKA[2], T. TOMINAGA[2], S. MORIOKA[1], N. KAWASHIMA[3,1];

Abstract: Eye tracking has been regarded as one of effective tool for identifying the behavioral aspect of unilateral spatial neglect (USN) which is a common neurological syndrome following right hemisphere lesion. In the present study, we attempted to develop an intuitive evaluation for USN behavior with the analysis of gaze distribution during free viewing of a pair of horizontally flipped images. 26 patients with right hemisphere damage participated in this study, and was divided into with and without neglect symptom (USN group: n=12, RHD group: n=14) based on the score of behavioral inattention test (BIT). The patients were asked to view nine pairs of horizontally flipped images represented on eye tracker mounted PC display (Tobii TX60, Tobii Inc., Sweden). Since a pair of flipped image has, one hand, similar consisting elements, the other hand, the right-left-reversed spatial location of the include item, we tested if the neglect symptom affect to a symmetry of the gaze distribution between a pair of image. In order to quantify an

extent of gaze shift, pixel from left end to right end was normalized as from -1 to 1, and then calculated asymmetry index (AI) as the median of eye trajectories of a pair of flipped images for the first 0.5 seconds (AI_{first}) and later 4.5 seconds (AI_{search}). The results clearly revealed that USN group showed significantly larger extent of rightward gaze shift (AI tended close to 1) as compared to RHD group. Both of AI_{first} and AI_{search} showed statistically significant correlation with BIT score, suggesting that (1) the analysis in free viewing of flipped image effectively demonstrate neglect behavior and (2) initial fixation point largely affected to later "biased" visual search. Our proposed method would be a simple and effective method for the evaluation of an extent of neglect behavior.

Title: Dissociative evaluation of neglect behavior and attention deficit based on the spatial distribution of reaction time in patients with unilateral spatial neglect

Authors: *N. KAWASHIMA[1], Y. TAKAMURA[2], S. OHMATSU[2], H. ABE[3], K. IKUNO[4], K. TANAKA[5], A. MANJI[6], T. TOMINAGA[7], S. MORIOKA[2];
[1]Nat'l Rehab Ctr. Japan, Tokorozawa, Japan; [2]Kio Univ., Nara, Japan; [3]Kohnan Hosp., Sendai, Japan; [4]Nishi-Yamato Rehabil. Hosp., Nara, Japan; [5]Shizuoka Rehabil. Hosp., Shizuoka, Japan; [6]Saitama Misato Rehabil. Hosp., Saitama, Japan; [7]Murata Hosp., Osaka, Japan

Abstract: Unilateral spatial neglect (USN) is a common neurological syndrome following predominantly right hemisphere damage. While USN is classically regarded as a parietal syndrome, it has become evident as a widespread attention network disorder. We here aimed to propose a dissociative evaluation between spatial neglect and attention deficit based on the characteristics of the spatial distribution of the reaction time. We also focused on the aspect of the ventral attention network disruption which cannot be evaluated by paper-based neuropsychological test. 144 right-brain-damaged patients participated, and were categorized into three subgroups based on the score of the behavioral inattention test (BIT): (1) USN++ (n=47) with a BIT score below the cut-off (<131); (2) USN+ (n=59) with a BIT score above the cut-off (>131) but with experience of neglect in daily life and/or a previous history of USN; (3) RHD (n=38) with a right hemisphere disorder without neglect. Trail marking test A (TMT-A)

was also evaluated. The subjects were asked to perform a touch panel-based pointing task toward circles (7 columns x 5 rows) on a PC monitor, and the reaction time to each object was recorded. In order to quantify the spatiotemporal characteristics of the reaction time, the total average of all objects (RT_{mean}) and the ratio between right and left side (L/R_{ratio}) were calculated. The result demonstrated that RT_{mean} has a strong relevance to TMT-A ($r=.56$, $p<0.01$), and L/R_{ratio} has a statistically significant correlation with BIT ($r=-.31$, $p<0.01$). Since BIT reflect not just neglect but attention deficit, there was a strong correlation between BIT and TMT-A ($r=-.73$). On the other hand, L/R_{ratio} showed weak correlation with RT_{mean} ($r=.24$), suggesting that these two parameters distinctly reflect the aspect of neglect and attention deficit, respectively. Interestingly, increase of L/R_{ratio} (prolongation of reaction time for left targets) was clearly shown in most of patients in USN+ groups, suggesting that our proposed method have potential as a sensitive probe to judge subtle neglect that cannot be detected by a paper-based neuropsychological test. These results suggest that spatial distribution of reaction time might be a useful tool not only for the evaluation of USN, but also for the dissociative evaluation between neglect and attention deficit.

Title: A neural-interface to boost motor function after stroke

Authors: ***L. GUO**[1,2], D. S. RAMANATHAN[1,3], T. GULATI[1,2], S.-J. WON[1,2], A. K. HISHINUMA[1,2], K. GANGULY[1,2];

Abstract: Introduction. Stroke is the leading cause of permanent and long-term disability worldwide, and it is crucial to develop strategies to improve rehabilitation. Recent work from our lab has found that perilesional low frequency (LF) oscillatory dynamics were abolished after stroke and then reinstated after motor rehabilitation. Importantly, a subset of the animals did not experience recovery and continued to have persistent deficits. This study aimed to further characterize and develop a method to therapeutically modulate LF dynamics in animals with poor recovery. Direct current stimulation (DCS) has been used to modulate ongoing neural dynamics and excitability. We thus examined the hypothesis that DCS can boost task-related LF dynamics and enhance motor function, by testing the effects of brief on-demand DCS delivered to the perilesional cortex in animals with poor recovery.
Method. Long Evans rats were trained on a skilled forelimb reach-to-grasp task. After performance stabilized, we induced a focal photothrombotic stroke in the forelimb motor cortex. We then implanted microwire arrays in the rostral perilesional cortex, and recorded local field potential (LFP) and single unit activity during motor rehabilitation to investigate the associated oscillatory dynamics. We assessed the neural effects of DCS by recording neural activity during epidural DCS under anesthesia in healthy Long Evans rats. To probe behavioural effects of DCS, we induced stroke in a separate group of rats and compared performance with DCS, no stimulation, sham and alternating current (AC) stimulation applied during motor execution (i.e. after recovery had plateaued).
Results. Recovery after stroke was associated with an increase in power, inter-trial coherence and spike-field coherence (SFC) in the LF band. DCS was effective at modulating LF dynamics, increasing LF power and SFC in anesthesized rats. Furthermore, DCS, compared to no, sham and AC stimulation, improved task performance in rats with chronic motor deficits after stroke. Importantly, these animals had achieved a plateau with low levels of success even after extensive practice and DCS increased performance beyond this plateau level.
Conclusion. Low frequency oscillations are important markers of recovery after stroke, and can be targeted to enhance motor function during rehabilitation. We demonstrate here a novel, easily-translatable stimulation paradigm to modulate ongoing neural dynamics and to improve motor performance.

Title: Functional and neurophysiological outcomes of intensive hand retraining in the acute phase post stroke: a pilot study.

Authors: *M. YAROSSI[1,2], J. PATEL[3], Q. QIU[3], G. FLUET[3], A. MERIANS[3], S. ADAMOVICH[2], E. TUNIK[4];
[1]Grad. Sch. of Biomed. Sci., Rutgers Biomed. and Hlth. Sci., Newark, NJ; [2]Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ; [3]Rehabil. and Movement Sci., Rutgers Biomed. Hlth. Sci., Newark, NJ; [4]Physical Therapy, Movement, and Rehabil. Sci., Northeastern Univ., Boston, MA

Abstract: Upper extremity deficits can profoundly affect independence post stroke. Recovery of dexterous hand function has been found to be particularly recalcitrant to intervention, and the neurophysiological mechanisms underlying functional improvement remain unclear. Evidence from human and animal investigations suggest the first month after stroke is a critical time for synaptic plasticity in peri-infarct zone when impairment focused training may be most effective. The objective of this ongoing pilot study is to investigate the effect of focused intensive hand therapy in the acute stage post-stroke. Following informed consent 11 subjects (4 female, 61.4±15.7 years, 15.3±11.6 days post stroke) received 60 minutes of training 5 days/week for two weeks in addition to their on-going in/out-patient physical, occupational and speech therapy. Subjects were randomized to receive either traditional repetitive task practice training (RTP) or training using virtual reality gaming simulations (VR). To assess the impact of the intervention subjects underwent a battery of clinical, kinematic and neurophysiological testing prior to (PRE), immediately following (POST), and 1 month following training (RET). Both groups improved PRE to POST on the Box and Blocks Test (BBT) and Fugl-Meyer (FM) score, however the VR group showed greater improvement at RET. Transcranial magnetic stimulation was used to measure excitable cortical territory (area) for selected intrinsic (FDI, APB, ADM) and extrinsic (EDC, FDS) hand muscles. Ipsilesional hemisphere excitable area increased for the intrinsic hand muscles across sessions, with little change in extrinsic muscles. Excitable area on the contralesional hemisphere was unchanged with training for all muscles. Changes in cortical motor topography did not differ between groups. Across groups increase in excitable cortical territory from PRE to 1M was significantly correlated with improvement in BBT ($r=0.795$, $p=0.003$) and FM ($r=0.753$, $p=0.007$) for the FDI muscle. These promising preliminary data suggest intensive hand rehabilitation in the acute phase post stroke can promote functional recovery, and training using VR increases retention 1 month following intervention. Across all groups improvement in clinical and kinematic measures was associated with expansion of the lesioned hemisphere excitable cortical territory for the intrinsic hand muscles. Recruitment of a larger patient population will answer questions regarding role of VR in intensive hand rehabilitation in the acute phase post stroke, and identify the utility of excitable cortical area as a biomarker of recovery.

Title: Significance of hyperbaric pressure on ICP drift in porcine models

Authors: ***J. C.-C. WU**[1], K.-Y. CHEN[2], Y.-C. CHAN[2], Y.-H. CHIANG[1];
[1]Dept. of Surgery, Col. of Med., [2]Grad. Inst. of Neural Regenerative Medicine, Col. of Med. Sci. and Technol., Taipei Med. Univ., Taipei, Taiwan

Abstract: Aim:
Intracranial pressure (ICP) monitoring has been a standard of care in neurosurgery for trauma, neoplastic, neurovascular patients. The recent advances in calculation of cerebral perfusion pressure (CPP), pressure reactivity (PRx), optimal CPP (optCPP) has been beneficial for patient care and these indices are built on multiple parameters, including the ICP. The clinical significance of ICP reading remains substantial.
Pressure drift, the deviation of pressure readings over time, is occasionally encountered clinically. One factor to consider in the interpretation of ICP may be the atmospheric pressure fluctuation. The traditional extra-ventricular drainage is exposed to atmosphere and reflects the real-time ICP with the fluid level of the CSF drained. On the other hand, some digital ICP sensors are zeroed upon insertion and absolute value of ICP are measured with respect to the atmospheric pressure upon insertion throughout its duration of implementation without reconsidering the influence of the atmospheric fluctuation. To optimize accuracy of ICP readings and its interpretation using other variables such as CPP, PRx, optCPP, we consider the influence of atmospheric pressure fluctuations and its relevance to digital ICP readings.
Methods:
Range of atmospheric pressure fluctuations is first calculated with data downloaded from public domain. We then analyzed of atmospheric pressure readings for Taipei, New York, London and Berlin. Also, we investigated the relevance of meteorological atmospheric pressure readings to ICU atmospheric readings using data from Taipei and compared to readings within ICU at Taipei Medical University Hospital demonstrated. Lastly, Porcine models were then utilized to demonstrate the correlation between hyperbaric pressure and digital ICP recordings.

Results:
The atmospheric pressure fluctuations revealed that fluctuations at Taipei, New York, London and Berlin were beyond 5mmHg within 5 days were 18%, 75%, 72%, and 69%, respectively. Also, relevance of ICU atmospheric pressure were strongly correlated with ICU atmospheric pressure, and readings revealed a 2.24±0.22 mmHg increase in ICU atmospheric pressure over the meteorological atmospheric pressure reading. Lastly, porcine model using a hyperbaric chamber revealed consistent correlation between atmospheric pressure and ICP fluctuations.
Conclusion:
Atmospheric pressure fluctuation is a significant phenonmenon. Its influence on reading of digital ICP sensors is substantial and its role in clinical decision-making process should be further validated with additional animal studies and clinical trials.

Title: Raise of plasma and brain tissue taurine and other amino acids in a model of intracranial hemorrhage in rats

Authors: *F. C. ESTRELLA[1], L. TRISTAN[1], A. DIAZ-RUIZ[1], S. MEZA-TOLEDO[2], C. RIOS[1];
[1]Neurochemistry, Natl. Inst. of Neurol. and Neurosurg., Mexico city, Mexico; [2]Exptl. chemotherapy, Natl. Politechnic Inst., Mexico city, Mexico

Abstract: Intracranial hemorrhage (ICH) is a cerebrovascular disease with a high mortality rate. Among the main consequences arising from it is the production of edema, that in turn increases cell volume. As a mechanism to preserve its volume, cell activates regulatory mechanisms, such as the eflux of osmolytes like taurine. Previous studies, have related levels of taurine to cerebrovascular diseases, due to their increasing after the establishment of an injury and their reduction after a medical treatment. A relationship between Taurine and edema and their potential use as biomarker to predict a poor outcome in patient who suffered subarachnoid hemorrhage (SHA) has been reported too. However, association between taurine levels and edema in ICH hasn´t been directly characterized yet. In the present study, we quantified the concentration of taurine and other amino acids in plasma and cerebral tissue, in an ICH model in rat. We injected collagenase type VII intrastriatally in male Wistar rat in order to reproduce an

ICH model. After the administration of the enzyme, rats developed neurological deficits (ipsilateral circling behavior, inability to tun to the non injured side and inability for walking along the beam). Animals showing no deficit were discarded. We quantified the concentrations of taurine in plasma and in the whole injured hemisphere at different times after injection: 3, 24, 48, 72 and 96 hours(hrs), while a control group of rats was administrated with saline solution. There were no changes in the plasmatic leves of taurine in any of the groups, having similar levels of concentration as the control group at all times evaluated. Other amino acids related to cerebral injury as glutamate and glutamine, showed no change in plasma when compared with the control group. In tissue, concentration of taurine showed an increased starting at 24 to 96 hrs, when compared to control group. For glutamate, same increasing pattern was observed, being statistically significant at 96 hrs when compared to control group levels. Glutamine also showed increasing levels, with statistically significant at 72 and 96 hrs. After measuring the percentage of water, we observed a slight increase in the content of water up to 48 hrs, decreasing at 72 hrs. Hematoma area was measured by microscopy at the site of collagenase administration, showing the highest levels of hemorrhage at 24 hrs and its partial re-absoption 96 hrs latter. Increase of amino acids such as taurine, glutamate and its precursor glutamine might be considered as potential biomarkers of disease.

Title: JY-515,317, an NMDA receptor modulator with glycine site partial agonist-like properties, shows therapeutic potential for the treatment of neuropathic pain.

Authors: *N. GHOREISHI-HAACK[1], E. M. COLECHIO[1], A. L. GROSS[1], J. L. PRIEBE[1], J. DUNNING[1], J. BURGDORF[2], T. M. MADSEN[1], R. A. KROES[1], M. A. KHAN[1], J. R. MOSKAL[1,2];
[1]Aptinyx Inc., Evanston, IL; [2]Northwestern Univ., Evanston, IL

Abstract: Aim of Investigation: JY-505,317 is an N-Methyl-D-aspartic acid receptor (NMDAR) modulator that acts as a functional glycine-site partial agonist. The present studies examine the

effect of JY-515,317 in multiple rat models of neuropathic pain. Methods: The analgesic effects of JY-515,317 were evaluated in the rat Bennett model (chronic sciatic nerve constriction), the Taxol model of chemotherapy-induced pain, the streptozotocin (STZ) model of diabetic neuropathy, the formalin model of persistent pain, and the tail flick model of acute pain. Potential sedative / ataxic effects were also examined in the rota-rod test. Results: A single oral dose of JY-515,317 produced a rapid-acting (1 hr post-dosing) and long-lasting (24 hrs and 1 week post-dosing) mechanical and thermal analgesia in the Bennett model (mechanical EC_{50} = 0.3 mg/kg PO; thermal EC_{50} = 0.4 mg/kg PO), and mechanical analgesia in the STZ model (EC_{50} = 0.3 mg/kg PO) and Taxol (EC_{50} = 5 mg/kg PO) models. In contrast, the gabapentin (150 mg/kg PO) positive control was not analgesic in the Taxol model, and only produced analgesic effect 1 hr but not 24 hr or 1 week post-dosing in the Bennet and STZ models. JY-515,317 also reduced flinching in the late phase of the formalin test 1 hr post dosing (EC_{50} = 0.2 mg/kg PO) to a similar degree as gabapentin (150 mg/kg PO). JY-515,317 (1 mg/kg PO) was ineffective the tail flick model of acute pain. Lastly, JY-515,317 (1-100 mg/kg PO) did not induce a sedative / ataxic effect in the Rota-rod test when measured up to 2 hr post-dosing, whereas a therapeutic dose of gabapentin (150 mg/kg PO) did produce sedative / ataxic effects at 1 hr and 2 hrs post-dosing. Conclusions: These data show that JY-515,317 has therapeutic potential as a rapid acting and long-lasting therapeutic for the treatment of a variety of neuropathic pain conditions with no sedative or ataxic effects.

Title: Hypothalamic pituitary dysfunction resulting in anxiety and decreased circulating testosterone levels following traumatic brain injury in a male rodent model

Authors: *S. ADAMS[1], C. F. CONOVER[2], S. I. SVETLOV[3], K. WANG[3], P. W. DAVENPORT[3], J. F. YARROW[3];
[1]Hlth. and Exercise Sci., Pfeiffer Univ., Salisbury, NC; [2]North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL; [3]Univ. of Florida, Gainesville, FL

Abstract: Hypothalamic-pituitary dysfunction causes anxiety and lowered circulating testosterone concentrations in soldiers experiencing traumatic brain injury (TBI) from improvised explosive devices. It is unknown if increased anxiety and reduced testosterone occurs in rodents following exposure to multiple (two) dorsal-oriented blasts or a single frontal-oriented overpressurization blast (OB). PURPOSE: Determine anxiety and the circulating testosterone concentrations following a TBI resulting from a closed-head OB to the dorsal or frontal orientations of the skull. METHODS: Male Sprague-Dawley rats aged 2 months were randomized to receive one of three treatments: 1) closed-head dorsal-oriented OB injury to the skull on day 7 (psi=78.70±2.14 SEM) and day 14 (psi=77.83±2.47 SEM) (n=17), 2) closed-head frontal-oriented OB injury to the skull on day 7 (psi=38.60±1.44 SEM) (n=5), or 3) sham OB injury (balloon pop at 90 decibels) on day 7 and day 14 (n=6). Elevated plus maze (EPM) was used to assess exploratory behavior and anxiety-like behavior in open and closed arms for 300 seconds pre and post OB(s). Blood was acquired 14 days after TBI and plasma testosterone measured via ELISA. Open arm EPM times and testosterone concentrations were compared using one-way ANOVA with post-hoc Holm-Sidak measurement. RESULTS: Open arm EPM times were 97% lower after dorsal-oriented OB injury (0.71±0.63 SEM sec, p=0.004) compared to pre-injury (24.33±7.67 SEM sec), 99% lower after frontal-oriented OB injury (0.32±0.32 SEM sec, p=0.027) compared to pre-injury (30.42 ±11.10 SEM sec), while no significance difference was observed for the control group (4.05±3.37 SEM sec, p=0.394) compared to pre-

sham (10.45±5.33 SEM sec). Testosterone was 45% lower after dorsal-oriented OB injury (2.34±0.31 SEM ng/ml, p=0.029) compared to sham OB (4.28±5.33 SEM ng/ml), while no significant difference was observed for the frontal-oriented OB injury (2.71±1.70 SEM ng/ml, p=0.168). CONCLUSION: Increased anxiety seen in the dorsal and frontal oriented OB injuries following the first injury. Lower circulating testosterone observed in male rodents following multiple (two) dorsal oriented OB injuries to the skull. Single frontal oriented OB injury did not appear to reduce circulating testosterone (despite a similar magnitude of reduction), perhaps because the primary blast vector was directed toward occipital region of skull, animals received a single blast injury, or the smaller sample size. Future research evaluating the duration of the testosterone deficit and cortisol concentrations after closed-head OB injury and the functional consequences after TBI is warranted.

Title: Environmental enrichment promotes oligodendrocyte maturation and improves functional recovery in a mouse model of preterm birth

Authors: *T. FORBES[1], B. JABLONSKA[2], V. GALLO[2];
[2]Neurosci., [1]Children's Natl. Hlth. Syst., Washington, DC

Abstract: Hypoxic damage to the developing brain is a major consequence of premature birth and is associated with long-term neurological impairment and permanent neurodevelopmental disabilities. Hypoxia predisposes the developing brain to diffuse white matter injury, a debilitating condition characterized by ventriculomegaly, decreased white matter volume, and disturbances in myelination. Oligodendrocytes, the myelin-forming glia that ensheath axons in the central nervous system, have been found to be highly susceptible to hypoxia-induced oxidative stress in both humans and rodents. Recent clinical studies have demonstrated that social, family, and environmental factors contribute to improve cognitive outcomes in premature children. However, it is unknown if the environment can modulate the outcome of hypoxia-induced white matter brain injury. This study uses environmental enrichment - enhanced stimulation at multiple cognitive, sensory, social, and motor levels to facilitate recovery in the developing brain. Using a rodent model of preterm birth – perinatal chronic hypoxia - we find

that continuous enrichment of the environment implemented within a few days after hypoxic insult promotes cellular, ultrastructural, and functional white matter recovery. By enhancing the endogenous reparative response to hypoxic brain injury, we demonstrate that environmental enrichment attenuates the effects of perinatal hypoxia and is therefore a promising avenue to restore developmental white matter integrity and function after injury.

Title: The effect of focal brain cooling on KCl-induced repetitive cortical spreading depression in rats

Authors: ***Y. HIRAYAMA**[1], T. INOUE[1], H. KIDA[2], K. SUGIMOTO[1], S. SHIRAO[1], H. IMOTO[1], S. NOMURA[1], M. SUZUKI[1];
[1]Dept Neurosurgery, Yamaguchi Univ. Sch. Med., Ube, Japan; [2]Dept Physiology, Yamaguchi Univ. Sch. Med., Ube, Japan

Abstract: Introduction: Cortical spreading depression (CSD) is a reversible depolarization wave that propagates across the brain surface at low velocity. In neurological disorders, CSD may play a key role as a pathophysiological mechanism in brain damage. Focal brain cooling (FBC) reduces neuronal damage and promotes recovery in models of epilepsy, cerebral ischemia, and trauma. Based on the above results, we assume that generation and propagation of CSD can be inhibited by FBC.
Methods: Male Sprague Dawley rats were anesthetized and subjected to craniotomy that was made to establish two operation areas. One area was used to induce CSD by the drop of 1M KCl. Another area was used to observe brain activities. Changes in neuronal and vascular modalities were evaluated using the multimodal recording which can record the simultaneous changes of Brain temperature (BrT), direct-current (DC) to alternating current (AC) range of electrocorticogram (ECoG), and laser speckle imaging of cerebral blood flow (CBF) in the same brain region. Our experiment was designed to identify relative differences between the cooling

(CL) and the non-cooling (NC) group (n = 7 each). We perfused warm or cold saline to control brain temperature at around 37 or 15 °C in each group, respectively. We also measured the effects of FBC on protein levels of endothelial NO synthase (eNOS) using western blot analysis. Results: In the NC group, KCl predominantly exhibited repetitive CSD events (propagation of hyperemia and depolarization and AC suppression of ECoG; mean frequency = 11.57). In the CL group, FBC increased the duration of all CSD events thereby the frequency of CSD was gradually reduced (mean frequency = 0.86). Moreover, eNOS was decreased in the cooled brain region compared with that in the NC group.
Discussion: K+ concentration increase due to the application of KCl to the brain surface causes depolarization and spreading away from a site of KCl application point. When FBC is applied, cooled neurons depolarize the membrane potential to stay of voltage gated Na+ channel inactivation and vasodilation induced by NO is impaired under the cooling condition. The results obtained show that FBC has an impact on the characterization of CSD such as depolarization and eNOS expression.

Title: Water maze strategies used by C57/B16 mice exposed to radiation and pomegranate juice

Authors: *P. V. LORENZO[1], M. DULCICH[2], N. M. BAJWA[2], R. E. HARTMAN[2];
[1]Loma Linda Unversity, Loma Linda, CA; [2]Psychology, Loma Linda Univ., Loma Linda, CA

Abstract: Our laboratory has shown that dietary supplementation with pomegranates, which have a high concentration of bioactive phytochemicals (plant-based compounds such as polyphenols), can improve memory function in humans following open heart surgery, ameliorate neuropathology and spatial learning/memory deficits in tg2576 mice, promote neurogenesis in wildtype mice, and improve rotarod performance in male (but not female) wildtype mice. We have also previously reported that exposure to 2 Gy of proton radiation induced depression-like behaviors in the tail-suspension test that were ameliorated by pomegranate supplementation. In this same study (Dulcich & Hartman, 2013), we showed that irradiation did not impair performance in the water maze, a test of spatial learning and memory. However, a number of other studies (e.g., Janus, 2004; Brody & Holtzman, 2006) have shown that mice can use several

strategies to "solve" the water maze. In the present study, we assessed search strategies from the mice in the Dulcich & Hartman (2013) paper to determine whether irradiation, diet, and/or gender affected the use of strategies to solve the water maze. Swim paths during the water maze trials were digitized and visually categorized into one of seven search strategies (spatial direct, spatial indirect, focal correct, focal incorrect, scanning, random search, and repetitive looping). A discriminate function analysis demonstrated that experimental group predicted search strategy use, correctly identifying 66% by gender, 61% by irradiation status, and 54% by diet. Furthermore, cell counts showed that females had more cells in the subgranular layer of the hippocampus, and that a higher cell count in the dentate gyrus was significantly correlated with increased use of a focal incorrect search strategy. These data demonstrate that the water maze can generate a much richer data set than simple escape latency and/or swim distance, and that different experimental groups can achieve similar performance on this test by the use of a number of different search strategies.

Title: JY-515, 317 is a NMDA receptor modulator with glycine site partial agonist-like properties: *In vitro* and *In vivo* pharmacology

Authors: *A. L. GROSS[1], J. S. BURGDORF[2], X.-L. ZHANG[4], E. M. COLECHIO[1], N. GHOREISHI-HAACK[1], M. E. SCHMIDT[1], S. SAHU[1], P. P. KANSARA[1], E. C. RODRIGUEZ[1], E. A. POLLARD[1], T. M. MADSEN[1], P. K. STANTON[4], M. A. KHAN[1], R. A. KROES[1], J. R. MOSKAL[1,3];
[1]Aptinyx Inc, Evanston, IL; [2]Biomed. Engin., Northwestern Univ., Evanston, IL, IL; [3]Northwestern Univ., Evanston, IL; [4]Cell Biol. & Anat., New York Med. Col., Valhalla, NY, NY

Abstract: Aim of Investigation: JY-515, 317 is an orally bioavailable small molecule NMDA receptor modulator. The present studies detail the in vitro and in vivo characteristics of JY-515, 317. Methods: Functional glycine-site agonist effects were measured using an *in vitro* [^{3}H]MK-801 binding assay in membrane extracts prepared from human NMDAR2A-2D subtype-

expressing HEK cells. NMDA current was measured in pharmacologically isolated NMDA currents in Schaffer collateral-evoked EPSCs in CA1 pyramidal neurons using whole-cell patch clamp recordings. Long-term potentiation (LTP) was measured at Schaffer collateral CA1 synapses in rat hippocampal slices following acute bath application of JY-515, 317 as well as 24 hours post-dosing *in vivo*. Learning and memory as well as behavioral effects were measured in the rat positive emotional learning, Morris water maze, and Porsolt tests. Sedative / ataxic effects were measured in the rat Rota-Rod test. Oral bioavailability was measured in rat plasma by LC-MS/MS. Results: In recombinant human NMDAR2A-2D -expressing HEK cells, partial agonist activity of JY-515, 317 was demonstrated at all 4 receptor subtypes, with greater potency at NMDAR2B (EC_{50} of 55 pM, 28 Fm, 11 pM, 55 pM and % maximal activation relative to glycine of 41%, 47%, 63%, and 58% for NMDAR2A, NMDAR2B, NMDAR2C, NMDAR2D, respectively). JY-515, 317 also increased NMDA current in hippocampal slices at concentrations between 100-500 nM, but not at 5 μM. Similarly, in the hippocampal LTP assay, JY-515, 317 facilitated LTP at concentrations between 100-500 nM, but not at 2 μM. JY-515, 317 (1 mg/kg PO) facilitated *ex vivo* hippocampal LTP 24 hrs post-dosing. JY-515, 317 (1 mg/kg PO) facilitated Morris water maze learning from 1 hr to at least 5 days post-dosing. JY-515, 317 also produced an antidepressant-like effect in the Porsolt test (EC_{50} = 6 μg/kg PO) and facilitated positive emotional learning (EC_{50} = 3 μg/kg PO) 1 hr post-dosing. JY-515, 317 (1-100 mg/kg PO) did not show sedative / ataxic effects in the Rota-Rod test when measured up to 2 hr post-dosing. JY-515, 317 showed ~50% oral bioavailability (IV vs PO plasma AUC). Conclusions: These data demonstrate that JY-515, 317 is an orally bioavailable NMDAR modulator that acts as a functional glycine-site partial agonist. JY-515, 317 facilitates LTP and NMDA current through its interaction with the NMDA receptor where it has affinity for all 4 NR2B subtypes. JY-515, 317 shows efficacy in multiple learning and memory models as well as behavioral models without sedative or ataxic effects.

Title: Development and characterization of a new model of posttraumatic epilepsy

Authors: *J. SZU, D. ORNELAS, S. CHATURVEDI, H. PARK, D. BINDER;
Univ. of California, Riverside, Riverside, CA

Abstract: Traumatic brain injury (TBI) is a major cause of morbidity and mortality in the United States and is a primary public health concern. Injury to the brain may result in serious behavioral and neurological deficits. A consequence of TBI is the development of posttraumatic epilepsy (PTE) where recurrent spontaneous seizures occurs after a brain injury. The pathophysiology in which trauma to the brain leads to spontaneous seizures is unknown and clinically relevant models of PTE are key to understanding the molecular and cellular mechanisms underlying the development of PTE. Current models of PTE have focused on using pentylenetetrazole (PTZ) for testing seizure susceptibility. For example, injured animals injected with a subdose of PTZ were more susceptible to generalized seizures and displayed a decrease in latency to the first spike of an epileptiform discharge as compared to control animals. Diffusion MRI have also associated hippocampal damage to decreased seizure susceptibility in animals that have undergone a TBI, however, a correlation between cortical damage and seizure susceptibility was not observed. In our study, we utilized optical coherence tomography (OCT) to detect changes in tissue dynamics in a controlled cortical impact (CCI) injury mouse model of severe TBI (sTBI). Additionally, animals underwent *in vivo* intrahippocampal electrical stimulation for the assessment of electrographic seizure threshold (EST) and electrographic seizure duration (ESD). OCT imaging revealed structural changes within the cortex after sTBI and injured animals had a lower EST compared to sham controls. Altogether, our data suggest that EST and ESD can be quantitatively determined and OCT can be a potentially powerful imaging tool for optical biomarker detection in our model of PTE.

Title: Lysophosphatidic acid as a key initiating factor in premature infantile post-hemorrhagic hydrocephalus

Authors: *N. C. STODDARD[1,2], Y. C. YUNG[1], M. MERETE[2], J. NHAN[2], J. CHUN[1];
[1]The Scripps Res. Inst., La Jolla, CA; [2]UCSD, La Jolla, CA

Abstract: Post-hemorrhagic hydrocephalus (PHH) is a common neurological disorder associated with intraventricular hemorrhage. It presents with increased intracranial pressure leading to ventriculomegaly, severe cognitive disability, and possible death. Current treatment options are limited to palliative neurosurgical interventions following development of chronic disease. Previous studies have linked the bioactive lipid lysophosphatidic acid (LPA), signaling through cognate G protein-coupled receptors (LPARs), to the initiation of PHH during embryonic life. LPA circulates within the blood, demonstrating elevated concentrations following hemorrhage or trauma. Here, we present a novel mouse model of PHH that implicates LPA signaling at a development period correlated to premature human infants, a group with high risk for hemorrhage and subsequent PHH. Neonatal mice, approximating infants born at 20-32 weeks, were injected intracranially with LPA or vehicle to simulate intraventricular hemorrhage. These injections cause early disruption of ventricular ependymal cells, resulting in dramatic loss of cilia within 24 hours. Allowing 7 days for PHH progression results in severe ventriculomegaly, continued disruption of the ependymal lining, and increased intracranial pressure. These effects can be ameliorated by LPAR knockout. Importantly, this mechanism is distinct from fetal PHH based on affected cell populations and LPAR expression patterns. Ongoing studies include characterization of chronological receptor-mediated events along with efforts to determine the efficacy of LPAR-targeted pharmacological agents as a preventative measure against PHH development.

Title: Gene expression changes in the microglia during fear memory processing

Authors: ***Z. YU**[1], H. FUKUSHIMA[2], C. ONO[3], M. SAKAI[3], Y. KASAHARA[3], T. KIKUCHI[3], Y. TAKAHASHI[4], H. MATSUOKA[4], S. KIDA[2], H. TOMITA[3];
[1]Tohoku Univ., Sendai, Japan; [2]Agr. Chem. and Biosci., Fac. of Applied Bioscience, Tokyo Univ. of Agr., Tokyo, Japan; [3]Disaster Psychiatry, IRIDeS, Tohoku Univ., Sendai, Japan; [4]Psychiatry, Grad. Sch. of Medicine, Tohoku Univ., Sendai, Japan

Abstract: Post-traumatic stress disorder (PTSD) is a complicated central nervous system (CNS) syndrome that characterized by recurrent trauma-related memories. Maintenance of excessive fear states (reconsolidation) or failed to erase fear memories (extinction) could be considered a pathology of PTSD. Animal behavioral study indicates that re-exposure to contextual fear conditioning in a short time influence reconsolidation, and prolonged re-exposure facilitated extinction. Evidence suggested that immunological mechanisms might be involved in the pathophysiology of PTSD. Murine studies showed that microglia, the major CNS immune cells that produced inflammation cytokines could influence contextual fear memory, which suggested microglia as modulator of memory formation. However microglial functions on the fear memory reconsolidation and extinction function remains poorly understood. Herein, we used microarray experiment that base on murine contextual fear extinction model, in order to investigate the activation of microglia on reconsolidation and extinction. Our results show that transmission of nerve impulse relevant genes were significantly over-represented among fear memory consolidation and reconsolidation induced genes, whereas among fear memory extinction reduced genes. M1 microglial production of inflammation cytokines was significantly decreased and anti-inflammation cytokines were significantly increased during extinction compared with fear memory reconsolidation. Our findings indicate that activated microglia may be involved in fear memory consolidation and extinction. Microglia expression neurotransmitter receptors and product inflammation cytokines as a complex interacting network that can effect on fear memory.

Col., Valhalla, NY

Abstract: Background: JY-505,317 is an N-Methyl-D-aspartic acid receptor (NMDAR) modulator that acts as a functional glycine-site partial agonist. In recombinant human NMDAR2A-2D -expressing HEK cells, partial agonist activity of JY-515, 317 was demonstrated at all 4 receptor subtypes, with the greatest potency at NMDAR2B. JY-515, 317 also enhanced whole cell NMDA current in CA1 pyramidal neurons in hippocampal slices at concentrations of 100-500 nM but not at 5 μM. Similarly, JY-515,317 enhanced the magnitude of long term potentiation (LTP) at Schaffer collateral-CA1 synapses in rat hippocampal slices at concentrations of 100- 500 nM but not 2 μM. JY-515, 317 (1 mg/kg p.o.) also facilitated *ex vivo* hippocampal LTP and significantly increased the number of mature dendritic spine morphologies 24 hrs post-dosing. JY-515, 317 is an orally available compound that has also shown efficacy after PO administration in several animal models of learning and memory without demonstrating side effects. JY-515, 317 has approximately 50% oral bioavailability in rats (i.v. vs p.o. plasma AUC). JY-515, 317 (1 mg/kg p.o.) facilitated Morris water maze learning from 1 hr to at least 5 days post-dosing. JY-515, 317 (1-100 mg/kg p.o.) did not show sedative/ataxic effects in the Rota-Rod test.
Methods: Blast-induced brain injury was caused following the protocol of Goldstein modified for use in rats (Goldstein et al., 2012). Briefly, an aluminum shock tube (183 x 61 cm; L-3 Applied Technologies, USA) was positioned 10 cm from the head of the rat. Rats received a single ~45 PSI blast of helium generated by puncturing 0.014 inches of polyester film. Sham controls were placed outside of the blast radius. Animals were dosed with JY-515, 317 (1 mg/kg PO) or 0.5% Na-CMC in 0.9% sterile saline vehicle (1 ml/kg p.o.) 1, 2, 6, or 24 hrs post-blast. Latency to recover from anesthesia was recorded. Recovery was defined as displaying eyeblink and righting reflexes, and normal ambulation. Rats were tested in a learning task 48 hrs post-blast to evaluate potential neuroprotective effects. In addition, changes in tau phosphorylation were assessed immunohistochemically in the hippocampal formation.
Results: A neuroprotective effect was observed in rats treated with JY-515, 317(1 mg/kg, p.o.) up to 24 hours post-blast. In rats dosed 1 hour post-blast, JY-515, 317 produced a neuroprotective effect between 0.1-10 mg/kg with an EC50 = 0.2 mg/kg. Increases in phospho-tau (pSer202 + pThr205) staining were observed in the hippocampal formation in vehicle-treated controls whereas no increase in staining was observed in the JY-515, 317 -treated rats.

Title: Transient disruption of home cage activities and assessment of orexin immunoreactivity following concussive or blast-induced brain injury

Authors: *P. A. VU[1], L. B. TUCKER[2,3], J. LIU[2], E. MCNAMARA[1], A. H. FU[2,3], Y. KIM[2,3], J. T. MCCABE[2,3];

Abstract: Traumatic brain injury (TBI) has become recognized as an invisible wound of modern warfare. The employment of improvised explosive devices by enemy combatants exposes our warfighters to both primary blast wave-induced brain injury as well as secondary concussive

injuries. The majority of reported TBI cases from recent conflicts are mild with sleep-wake disturbances being among the most common clinical complaints. The objective of the current study was to assess the acute effects of concussive brain injury (CBI) and blast wave-induced brain injury, separately. Male C57BL/6J mice (approximately 10 weeks old) were randomly assigned to receive CBI, which was delivered via a Leica ImpactOne controlled cortical impact device; be exposed to blast overpressure of approximately 15 psi in the Advanced Blast Simulator (ABS); or undergo sham procedures for each injury model. Injured animals and their respective shams were further divided into the following subgroups: 24-hour survival in standard housing, 72-hour survival in standard housing, and 72-hour survival in Any-Maze cages (Stoelting, Co.). The Any-Maze cages were used to continuously monitor home cage activity. Mice from each group were tested in an open field, and on the y-maze test for spontaneous alternation behavior (working memory) before brain tissue was collected for analysis of immunoreactive orexin-A neurons. This group of hypothalamic neurons was previously implicated in sleep-wake disorders. Preliminary results showed that both CBI and ABS caused significant, but transient decreases in home cage activities, including wheel running and ingestive behaviors 24 hours postinjury. Furthermore, ABS resulted in general hypoactivity in a 20-minute open field session at both time points for standard-housing animals, but not for Any-Cage-housed animals. This decrease in activity was accompanied by a reduction in orexin-A hypothalamic neurons. In contrast, CBI did not result in hypoactivity in the open field nor did it cause a reduction in orexin-A positive neurons. Instead, mice subjected to CBI spent more time in the center of the open field with no difference in the overall distance travelled during a 20-minute open field session relative to their sham controls. The increase in activity in the center of the open field suggested that CBI mice demonstrated less anxiety than their sham controls. The differential effects of CBI and ABS may speak to the heterogeneous presentation of patients suffering from mild TBI, who often report no or very minor symptoms.

Title: Quantitative and qualitative assessment of glymphatic flux using Evans blue albumin in rats

Authors: M. WOLF[1], Y. CHEN[1], D. SIMON[1], M. MANOLE[1], L. A. NEW[1], H. ALEXANDER[1], P. M. KOCHANEK[1], *R. S. CLARK[2];
[1]Safar Ctr., Pittsburgh, PA; [2]Univ. Pittsburgh, Pittsburgh, PA

Abstract: Introduction: The glymphatic system is a dynamic pathway for clearance of protein and other macromolecules from brain. Normal variation in glymphatic flux occurs under physiologic conditions, e.g. sleep, and recently inefficient or overwhelmed glymphatic flux has been implicated in neurological disease, e.g. amyloid- and tau-opathies. We capitalized on the colorimetric and fluorescent properties of Evans blue labeled albumin in order to evaluate glymphatic flux in rodent models of neurological disease. Methods: 25 µl of 1% Evans blue albumin was injected into the CSF of anesthetized postnatal day (PND) 17 rats via intracisternal (i.c.) injection. This concentration results in complete binding of Evans blue to albumin, thus movement of albumin rather than unbound Evans blue can be traced. Serum was collected and brains harvested at several time points after i.c. injection. Brains were immersed in 3 ml 10% formamide for 3d to extract Evans blue. Evans blue was quantified spectrophotometrically (620nm) against a standard curve. Transit of Evans blue from CSF to blood was monitored qualitatively using intravital multiphoton microscopy and multilabel immunohistochemistry (excitation 530-550nm/emission 590nm). Results: The concentration of Evans blue albumin in serum was 2.1±0.9, 4.3±0.1, 2.0±0.3, and 0.4±0.2 µg/ml; and in brain was 12.2±2.2, 13.3±3.7, 9.2±1.7, and 4.5±1.1 µg/ml at 1, 4, 24, and 72h, respectively (n=4/group). Peri-arteriolar Evans blue albumin was detected using intravital multiphoton imaging at 1h after CSF injection in live PND17 rats. Sagittal sections from rats 2h after i.c. injection showed extravasation of Evans blue albumin from ventricles and leptomeningeal spaces. This extravasation appeared markedly increased when intracranial pressure was increased to 40mmHg in the rats. Conclusion: Injection of Evans blue albumin can be used to dynamically assess protein flux from CSF to brain to blood. This technique may be useful for the study of glymphatic flux in both physiologic and pathophysiologic conditions, including elevated intracranial pressure.

Title: Multiple neonatal anesthetic exposures has more severe effects on adult rodent behavior

Authors: *R. MAKARYUS[1], J. ROBINSON[2], A. JAN[2], T. FLETCHER[2], G. ENIKOLOPOV[1], H. BENVENISTE[1];
[1]Stony Brook Med., Stony Brook, NY; [2]Stony Brook Univ., Stony Brook, NY

Abstract: Background: Anesthesia administration during neuronal development results in an increase in the number of neurons undergoing apoptosis in the mammalian brain. We previously used proton magnetic resonance spectroscopy (^{1}HMRS) to demonstrate that growth of N-acetyl-aspartate (NAA), a marker for neurons, is more severely impaired with multiple anesthesia exposures than with a single exposure, even when total anesthesia duration is the same. Given this, we hypothesized that multiple neonatal exposures would cause a more severe effect on behavior compared to a single neonatal exposure.
Methods: On post-natal day (PND) 5, male rat pups were divided into three groups designated as 'single exposure', 'multiple exposure', and 'unexposed'. For the single exposure group, the pups were exposed to 6 hours of sevoflurane anesthesia on PND 7 only; for the multiple exposure group, the pups were exposed to 2 hours of sevoflurane anesthesia each on PND 5, 7, and 10; while the unexposed group received no anesthesia. The pups were then assessed through a series of behavioral tests after PND 35, specifically by open field and novel object recognition (NOR) testing.
Results: We had 10 rats per group for behavior testing, with a total of 30 rats. Open field testing demonstrated multiple significant differences between the groups, with the multiple exposure group showing the greatest deviation from normal, see Fig. 1. Results of NOR testing is seen in Fig. 2, indicating a trend for exposed animals to spend less time with the novel object, with the multiple exposure group spending the least time with the novel object, however, not statistically significant.
Discussion: ^{1}HMRS data from previous work indicated that brain maturation, as measured by NAA, is more severely impeded, with longer lasting effects, by multiple exposures than by single exposure. Here we have demonstrated that multiple exposures to anesthesia also have a more profound effect on animal behavior than a single anesthesia exposure, even though the total exposure duration was the same for both groups.

Figure 1

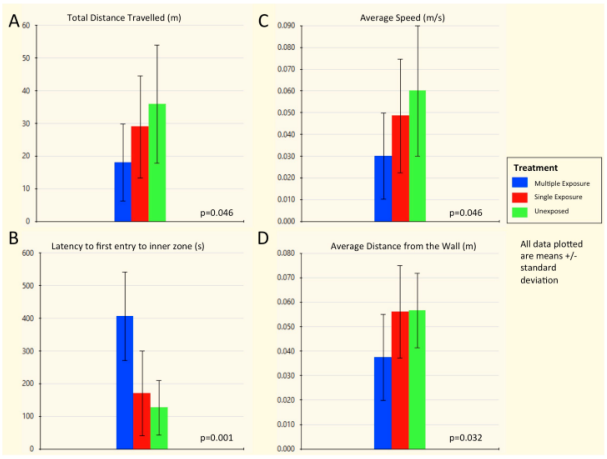

Figure 1: *Results of the open field test demonstrate that animals in the multiple exposure group had a far greater deviation from the unexposed than the single exposure group. This is seen in (A) distance travelled during testing, which also correlates with (B) the average speed of the animals per group. (C) The latency to first entry to the inner zone was highest in the multiple exposure group, possibly indicating a higher level of anxiety. (D) Average distance from the wall, with lower numbers interpreted as an increase in thigmotaxis, was lowest among those who had the multiple anesthesia regimen, again indicating possible*

Figure 2

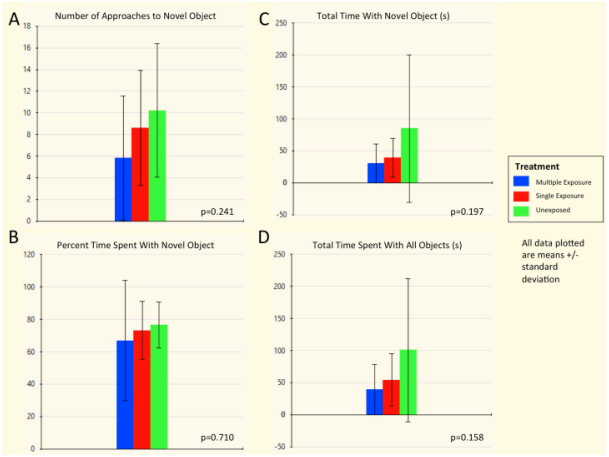

Figure 2: *Results of the NOR test are shown here. Though there are no significant differences among the three groups as determined by ANOVA, there are still important trends to note. First, demonstrated in (A) the number of approaches to the novel object, or interest in the novel object tended to be greater in unexposed group, as well as (B) the total time with the novel object. (C) The amount of time spent with the novel object as a percentage of total time with all objects also had an interesting trend. (D) Total time with both objects is also depicted here, with the multiple exposed group showing the least interest in interacting*

Title: Delayed onset spinal epidural hematoma with development of Brown-Séquard syndrome

Authors: *S. D. ALBANO, B. W. BERMAN;
Neurosurg., Desert Regional Med. Ctr., Palm Springs, CA

Abstract: Background:
Spinal epidural hematoma makes up a minority of spinal injuries. The disease process also represents a challenge in diagnosis when not apparent on initial computerized tomography (CT) scan as the mechanism of injury and force of impact do not directly correlate with incidence of spinal epidural hematomas. Further adding to the diagnostic challenge is the fact that posttraumatic spinal epidural hematomas are rarely associated with fractures[2].
Case Report:
A 74 year old female with a history of transient ischemic attack on Plavix and aspirin 81mg daily, presented for non-radiating upper back pain after a fall from approximately four foot height. No preceding weakness, headache, lightheadedness. Post fall, no loss of consciousness, blurry vision, tinnitus, post nasal drip, otorrhea, loss of bowel or bladder control, nausea, vomiting, motor weakness or paresthesias. However in hospital patient developed episodes of vomiting. Initial physical exam demonstrated 5/5 motor strength and sensation to purposeful touch intact in upper and lower extremities. Initial CT scans showed no intracranial hemorrhage or skull fractures. Cervical spine demonstrated multiple osteophytes from cervical 4-cervical 7. Patient progressed to develop urinary retention and motor deficits. MRI demonstrated spinal epidural hematoma. Patient was taken for emergent decompressive laminectomy. Post operatively patient exhibited Brown-Séquard Syndrome. Motor deficits improved with physical therapy.
Conclusions:
Many options exist for diagnosis of spinal epidural hematoma to include CT scan, myelogram, and MRI. As demonstrated in this case spinal epidural hematoma does not need to be associated with a fracture of the vertebra and can be occult on CT scan. Therefore in the setting of progressive neurologic decline an MRI is indicated and can better elucidate disease process. Treatment options include high dose steroids and observation. However the standard of care in progressive neurologic decline is still emergent decompression.

Title: *In vivo* multi-photon imaging of cerebrovascular changes in chronically stressed brain

Authors: ***S. LEE**[1], J. MIN[2], B.-M. KANG[2], J. KIM[1], M. SUH[1,2];
[1]Inst. for Basic Science, Sungkyunkwan Univ., Suwon, Korea, Republic of; [2]Dept. of Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Repeated stress exposure can increase neurotoxic signals leading to neural dysfunction alongside with alterations of neurotransmitter and neuromodulator release in the synapse. These misregulated environments can cause dysfunction of neurovascular coupling units. We previously reported that 3-week chronic stress decreased hemodynamic response and vascular reactivity and further induced changes in neuronal population and vasomodulatory system in rat restraint stress model. In the present study, we investigated chronic stress effects on the cerebrovascular structure in the mice brain cortex using *in vivo* two-photon imaging method. Two-photon (2p) microscopy provides 3-D vascular structural images in the deep tissue of live animal. Utilizing a chronic cranial window, we could trace the longitudinal vascular structural changes under chronic stress in the same animal. For *in vivo* 2p imaging of the brain, the mice had a cranial window surgery 4-6 weeks prior of imaging session. Before stress protocol, the baseline vascular image was obtained by intravenous injection of texas-red conjugated dextran. After 3-week immobilization stress (6hr/day) session, we found that chronic stressed group showed alterations in cerebral vasculature compared to control group. In stressed group, there was a reduction in both number and volume of larger vessels than capillaries. Also, stressed animal exhibited weakened blood brain barrier integrity, resulting in increased extravasation of fluorescent dye. These results suggest chronic stress may affect cerebrovascular system and their structural solidity. These effects eventually elevate the risk of neurovascular dysfunction.

Title: Effects of chronic stress on neuronal response and connection in the sensorimotor cortex of mice

Authors: *E. BAEG[1], S. BAE[1,2], H. LIM[1,2], J. MIN[1,3], H. KIM[1,3], M. SUH[1,3];
[1]CNIR, Inst. For Basic Sci. (IBS), Suwon, Korea, Republic of; [2]Dept. of Biol. Sci., [3]Dept. of Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: We investigated the effect of chronic stress on neuronal activation in the sensorimotor cortex of mice, an important top-down circuit in attentional and sensory processes. Three weeks of physical immobilization was used to make stress animal model. Membrane voltage changes and blood volume changes from one hemisphere upon the whisker deflection were measured using voltage sensitive dye imaging (VSDI) and optical intrinsic signal (OIS) imaging techniques. Changes of voltage to whisker stimulation started from the barrel cortex and expanded to the motor cortex in normal animals because of the innate connection between sensory and motor cortices. However, the extent of membrane change in stress mouse was smaller, not just in amplitude but in the size of conducted area, suggesting compromised sensorimotor network. Supportive anatomical data for the disruptive connection between the barrel and motor cortices was obtained from immunohistochemical staining using microtubule-associated protein 2 (MAP-2), a neuron-specific cytoskeletal protein. We found the reduction of MAP-2 stained processes in the barrel cortex of stressed animals. In accordance with VSDI results, blood volume changes to whisker deflection were tended to decrease in awake stress mouse. Local field potentials that were recorded in the barrel cortex showed smaller oscillating power in gamma range (30-80hz), compared to control animals. Reduction in the number of parvalbumin (PV) interneurons, which is redeemed as the important neuronal substrate in generating gamma oscillation in the barrel cortex, was observed in stressed animals. Considering the function of gamma oscillation in attention and synchronization between cortices, the reduced gamma power can explain the attentional sensory integrative problem under chronic stress. Our findings reveal the systematic effect of chronic stress on sensorimotor circuit, including cellular death and damaged connectivity between barrel and motor cortices, and explain the neural substrate of stress induced attentional problems.

Title: Chronic stress alters neurovascular coupling in the rodent somatosensory cortex

Authors: *K.-Y. HAN[1,3], J. HAHN[2], D. KIM[2,4], S. LEE[2], J. MIN[2,4], B.-M. KANG[2,4], M. SUH[2,3,4];
[1]CNIR, Inst. For Basic Sci. (IBS), Suwon, Korea, Republic of; [2]CNIR, Inst. For Basic Sci. (IBS), Suwon-City, Korea, Republic of; [3]Samsung Advanced Inst. for Hlth. Sci. and Technol. (SAIHST), Sungkyunkwan Univ., Suwon, Korea, Republic of; [4]Dept. of Biomed. Engineering, Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: The regulation of microcirculation in the brain via neurovascular coupling is crucial for meeting the metabolic demands of neurons and glia. A complex interplay of excitatory and inhibitory neurons, and astrocytes is thought to control neurovascular coupling. Emerging evidence indicates, in pathological conditions, disruptions of this tight interaction leads to the failure of adequate delivery of oxygen and glucose, accelerating disease progression. However, the exact sequence of events that leads to abnormal neurovascular coupling under pathological conditions remains poorly understood. Here, utilizing acute brain slices, which allow better control of complex signaling from neurons and glia, we investigated the interactions of neurons, glia and blood vessels in somatosensory cortex in chronic stress paradigm. To induce chronic stress, 8-weeks-old male C57BL/6 mice were immobilized for 6 hours per day for 3 weeks. The effect of restraint stress on anxiety-related behavior was assessed using the elevated plus maze before all experiments. In our anatomical experiments, we observed an increase in the number of small diameter vessels (< 9 μm in luminal diameter) in chronic stress group compared to control group. In addition, in chronic stress, the number of Parvalbumin(PV)-expressing interneurons as well as Thy1-positive pyramidal neurons decreased, while the number of reactive astrocytes increased. Our functional imaging of arterioles (5 - 10 μm in luminal diameter) with focal electrical stimulation showed both vasodilation and vasoconstriction with a small set of no response in both groups. However, vasoconstriction was more prevalent in chronic stress compared with controls (25% vs 62.5%) and changes in vessel diameter were greater (8.1 ± 0.9% vs 20.6 ± 2.1%). Vasodilation was observed more often in control (62.5% vs 25%), while the degree of dilation was similar in two groups (11.4 ± 1.5% vs 12.7 ± 2.2%). In contrast to focal electrical stimulation, NMDA stimulation induced only vasodilation in arterioles from control and chronically stressed animals with no difference in degree of dilation (14.0 ± 1.2% vs 15.9 ± 4.3%). These results show that the vascular response to neural activity is not uniform, but chronic stress shifts vessel responses toward constriction. Together, our results indicate that

chronic stress remodels the interaction between excitatory and inhibitory neurons accompanying vascular structure, which may be a key step in the development of stress-induced mental disorders and cerebrovascular diseases.

Title: Real time *In vitro* imaging of axonal injury

Authors: *V. LACOVICH, V. POZO DEVOTO, M. ČARNA, G. STOKIN;
Intl. Clin. Res. Ctr. FNUSA-ICRC, Brno, Czech Republic

Abstract: Over the past 30 years, research has linked moderate and severe traumatic brain injury (TBI) to a greater risk of developing Alzheimer`s disease (AD) or other types of dementia years after the original head injury. TBI is a focal injury that results in cerebral contusions at specific location or diffuse axonal injury over a widespread area, probably due to shear forces. Intriguingly, axonal transport, including microtubule tracks, is subject to injury also during aging and in several diseases such as AD, however, mechanisms linking TBI to neurodegeneration, and vice versa, remain to be elucidated. To advance our understanding of the mechanisms underling TBI we have designed an *in vitro* system that allows real-time assessment of axonal response to injury. More specifically, we have developed a system that consists of a specifically designed microfluidic chamber coupled to an electronically controlled syringe pump and a confocal mycroscope. Briefly, human neurons were first differentiated from neural stem cells and seeded in the proximal chamber with their axons elongating through a series of parallel channels ending in the distal chamber. Perpendicularly to the axonal grid an additional channel goes from side to side of the chamber. This channel is connected to a syringe controlled by an electronical device, which sets the pressure of the syringe and ultimately controls the flow through the channel. This setting is mounted on the microscope stage and allows real time visualization of axonal transport by taking advantage of fluorescently labeled surrogate markers of axonal transport. To generate

acute shear stress on the axon we fine-tuned the applied force and duration of the flow. We first examined axonal structural markers for the extent of damage caused by different flow forces. We next evaluated transport dynamics of APP vesicles, mitochondria and lysosomes before, during and after injury. To this end we analysed proportions of anterograde, retrograde stationary movement, mean velocities, direction of reversions and density of all the particles. Changes in the dynamics immediately after the injury were observed and point toward specific mechanisms involved in TBI.

Title: Reversible disruption of neuronal mitochondria by ischemic and traumatic injury revealed by quantitative two-photon imaging in the neocortex of anesthetized mice

Authors: M. KISLIN[1], J. SWORD[2], D. CROOM[2], E. PRYAZHNIKOV[1], E. LIHAVAINEN[3], D. TOPTUNOV[4], H. RAUVALA[1], A. S. RIBEIRO[3], *S. A. KIROV[2], L. KHIROUG[1];
[1]Neurosci. Ctr., Univ. of Helsinki, Helsinki, Finland; [2]Augusta University/Med Coll Georgia, Augusta, GA; [3]Dept. of Signal Processing, Tampere Univ. of Technol., Tampere, Finland; [4]Neurotar LTD, Helsinki, Finland

Abstract: Mitochondria play a variety of functional roles in cortical neurons, from metabolic support and neuroprotection to the release of cytokines that trigger apoptosis. In dendrites, the structure of mitochondria is closely linked to their function, and fragmentation of the normally elongated mitochondria indicates loss of their function under such pathological conditions as stroke and brain trauma. Using in vivo two-photon microscopy in mouse brain, we quantified mitochondrial fragmentation (fission) in a full spectrum of cortical injuries ranging from severe to mild. Severe global ischemic injury was induced by bilateral common carotid artery occlusion, while severe focal stroke injury was induced by Rose Bengal Photosensitization. A moderate and mild traumatic injury was inflicted by focal laser lesion and by mild photo-damage, respectively. Dendritic and mitochondrial structural changes were tracked longitudinally using transgenic

mice expressing fluorescent proteins localized either in cytosol or in mitochondrial matrix. In response to severe injury, mitochondrial fragmentation developed in parallel with dendritic damage signified by dendritic beading. Unlike dendritic beading, mitochondrial fragmentation spread beyond the injury core in focal stroke and focal laser lesion models. In moderate and mild injury, mitochondrial fragmentation was reversible with full recovery of structural integrity after 1-2 weeks. The transient mitochondrial fragmentation observed in the mild photo-damage model was associated with an increase in dendritic spine turnover without any signs of dendritic damage. Our findings indicate that alterations in neuronal mitochondria structure can be reversible in ischemic and traumatic injuries and point to mitochondrial fragmentation as an early sensitive indicator of neuronal damage.

Title: Diminished astrocytic gliosis following focal cerebral ischemia in GPR37 knockout mice

Authors: ***M. Q. JIANG**[1], M. M. GIDDENS[2], X. GU[1], L. WEI[3], R. A. HALL[2], S. P. YU[3]; [1]Neurosci., [2]Pharmacol., [3]Anesthesiol., Emory Univ., Atlanta, GA

Abstract: Ischemic stroke is the third most prevalent cause of death and the leading cause of long term disability with direct and indirect costs amounting to 36.5 billion annually in the United States. Following acute cell death resulting from excitotoxic conditions, secondary damage can occur to surrounding tissues in the peri-infarct region. We have demonstrated that in wild type (WT) mice, ischemia initiates astrocytic gliosis within 6 hours following stroke. Glial fibrillary acidic protein (GFAP) positive astrocytes exhibit pronounced hypertrophy in the peri-infarct region visible within 3 days following injury. Astrocyte mediated gliosis is known to be an acute regulated process that initially aids in the formation of a barrier around brain injury to

limit the spread of noxious chemokines, excitotoxic and inflammatory factors. A mature glial scar comprising of astrocytes can be observed within 7 days following stroke. Since the G protein-coupled receptor GPR37 has recently been reported to mediate neuroprotective and glioprotective effects, we examined the role of GPR37 in ischemic brain damage by evaluating astrocytes and the development of gliosis after cerebral ischemia in WT vs. GPR37 knockout (KO) mice. Adult WT and GPR37KO mice were subjected to a focal cerebral ischemia affecting the right sensorimotor cortex. Mice were sacrificed 3 days following ischemia and histological examinations were performed on frozen 10 μm thick sections. Histological analysis of cell death was quantified using terminal deoxyribonucleotidyl transferase-mediated dUTP nick end labeling (TUNEL). Astrocytes were stained using GFAP and cell nuclei were labeled using a Hoechst dye. Robust reactive astroglia activation and scar formation around the infarct area were observed in WT animals. Reactive astrocytes accumulation was seen at 6 hours following ischemia and the number of astrocyte processes increased significantly by 7 days. A glial scar border marked by GFAP staining appeared by 48 hours following ischemia. In contrast, a glial scar failed to form after the ischemic insult in GPR37KO mice. The number of astrocytes present in the peri-infarct region was significantly reduced by about 50% compared to WT mice (n=3, p=0.0106). Consistently, the mean GFAP fluorescence intensity was significantly weaker in the peri-infarct region of GPR37 KO animals (0.41 ± 0.16 n=5) compared with matched WT mice (2.158 ± 0.3, n=4). These preliminary data suggest that GPR37 protein plays a critical role in astrocyte activation and the formation of glia scar following ischemic insults to the brain.

Title: Self-renewal and differentiation capacity of cerebral cortex reactive astrocytes *In vivo*

Authors: *L. L. CANHOS[1,2], S. FALK[1,2], M. GÖTZ[1,2,3], S. SIRKO[1,2];
[1]Physiological Genomics, Inst. of Physiol., LMU Munich, Munich, Germany; [2]Inst. for Stem Cell Research, Helmholtz Zentrum Munich, Neuherberg, Germany; [3]Munich Cluster for Systems Neurol. (Synergy), Munich, Germany

Abstract: Cells akin to astrocytes act as adult neural stem cells (aNSCs) in specific neurogenic niches of the adult mammalian brain and are characterized by self-renewal and generation of differentiated progeny. While *in vivo* these cells self-renew for a limited number of cell divisions and are bilineage, generating neurons and astrocytes (Calzolari *et al*., 2015; Encinas *et al*., 2011), in the neurosphere assay *in vitro* they self-renew for a long time and are multipotent, giving rise to neurons, astrocytes and oligodendrocytes. Astrocytes outside the neurogenic niches do not proliferate or generate neurons under physiological conditions, but invasive injury triggers both proliferation *in vivo* and activation of NSC potential *in vitro* in a subset of reactive astrocytes (RAs) in the cerebral cortex gray matter (GM) (Buffo *et al*., 2008; Sirko *et al*., 2013). Of note, while *in vivo* RAs undergo only a single cell division, generating two astrocytes (Bardehle *et al.*, 2013), a subset of RAs shows long-term self-renewal and multipotency *in vitro*. The aims of this study were to assess i) whether and to which extent RAs could be stimulated to proliferate several times *in vivo*; and ii) whether cortical RAs could generate different cell types when relocated to a neurogenic environment, such as an aNSC niche. Therefore, we analyzed the proliferative behavior of RAs through their response to repetitive pathological stimuli in the adult murine cerebral cortex GM. To follow cycling cells in the injured GM at different time points after stab wound injury, we used a dual-labeling method by combining two thymidine analogues, 5-bromo-2'-deoxyuridine (BrdU) and 5-ethynyl-2'-deoxyuridine (EdU). Quantitative analysis of *in vivo*-labeled cycling cells showed that repetitive pathological stimuli induced marked changes in the proliferative behavior of RAs and other glial cells (NG2-glia and microglia), and led a subset of RAs to reenter the cell cycle. To analyze the differentiation capacity of RAs *in vivo* we transplanted cortical RAs or aNSCs from the subependymal zone of adult actin-GFP mice cultured as neurospheres heterotopically into the adult dentate gyrus and the embryonic brain. Taken together, RAs can show a larger proliferative potential *in vivo* while their progeny remains more restricted compared to aNSCs.

Title: Short-duration overpressure induces astrocyte reactivity

Authors: ***N. HLAVAC**, S. MILLER, P. VANDEVORD;
Virginia Tech., Blacksburg, VA

Abstract: Blast-induced neurotrauma is a complex, multisymptomatic condition that affects both military personnel and civilians. Exposure to primary blast induces acute cellular changes in the brain that precede chronic deficits in memory and behavior. Glial reactivity, particularly in astrocytes, is a prominent hallmark of acute injury. Astrocyte reactivity is primarily characterized by increased intermediate filament protein expression and hypertrophy. While evidence exists to suggest that glial reactivity is both protective and disruptive in the injured brain environment, definitive mechanistic links between acute cellular responses and chronic deficits remain to be elucidated. Moreover, the secondary injury mechanisms of blast neurotrauma that drive astrocyte reactivity are not well defined. This study aimed to characterize acute cellular response to short-duration overpressure through the use of *in vitro* models. Both astrocyte-rich cultures and mixed cell cultures with neurons and astrocytes were prepared from cortices of Sprague-Dawley rat pups. Cells were exposed to short-duration overpressure using a custom *in vitro* shock wave generator. At 24 hours, viability of astrocytes was assessed using an MTT assay. Furthermore, alterations in expression of structural proteins were analyzed using reverse transcription real-time polymerase chain reaction and Western blotting techniques. Specific targets of interest were cytoskeletal proteins, including actin, vinculin and intermediate filaments, as well as membrane proteins necessary for cell-cell communication. Astrocytes were viable at 24 hours post-exposure to overpressure. Results indicated that astrocytes in the presence of neurons become reactive by the 48 hour time point as assessed by significant upregulation of glial fibrillary acidic protein (GFAP) compared to a sham group (p-value<0.05). Furthermore, astrocyte-rich cultures also displayed significantly higher GFAP protein levels at 48 hours post-exposure compared to sham. These results imply that astrocytes can become activated by mechanical stimulus alone. Transient alterations in gene expression for ezrin and connexin-43 occurred at 24 hours post-exposure, suggesting potential avenues for secondary injury mechanisms that affect cell-cell communication and astrocyte function in the acute stages of injury. The results of this study provide evidence of structural alterations in glia as a result of short-duration overpressure exposure as well as implications for further investigations into secondary injury mechanisms involved in blast neurotrauma.

Abstract: Blast-induced traumatic brain injury (bTBI) is a worldwide health problem. Even those experiencing low-level blast explosions can develop neurocognitive symptoms without evidence of neurotrauma, but the cellular mechanisms of this phenomenon are unknown. We developed a pneumatic device that simulates an explosive blast by producing pressure transients similar to those observed in a free field explosion, using cell cultures of human brain cells in combination with live-cell Ca^{2+} imaging. Here we show that calcium waves induced by a simulated blast propagate primarily through astrocyte-dependent, purinergic signaling pathways that are blocked by P2 receptor antagonists. In addition, we found increased expressions of a reactive astrocyte marker, glial fibrillary acidic protein (GFAP) and a protease, matrix metallopeptidase 9 (MMP-9). Since human astrocytes differ from rodent and other primate astrocytes structurally and physiologically, their response to simulated blast may also differ. By comparing responses to rat astrocytes, we found that human astrocytes had an increased integrated calcium response and prolonged calcium wave propagation kinetics. This differential sensitivity is an important consideration in studies of TBI treatments and countermeasures, suggesting that greater forces may be needed in rodent model systems to replicate comparable damage to human astrocytes.

Title: Triggering receptor expressed on myeloid cells-2 (TREM2) deficiency worsens outcome after experimental traumatic brain injury

Authors: *M. A. YENARI[1], M. KAWABORI[2], J. KIM[2], Z. ZHEN[2], R. KACIMI[2], C. HSIEH[3]; [1]Neurol, Univ. California, San Francisco and San Francisco Veterans Affairs Med. Ctr., San Francisco, CA; [2]Neurol., [3]Med., Univ. of California, San Francisco & San Francisco VAMC, San Francisco, CA

Abstract: Triggering receptor expressed by myeloid cells-2 (TREM2) is a surface receptor present on microglia and macrophages. It was first described as a receptor of the innate immune system which bound pathogens and led to their phagocytosis. TREM2 deficiency leads to dementia, and we recently showed that its deficiency leads to worsened outcome after experimental stroke. Thus, TREM2 may be an important molecule in the clearance of injured cells paving the way towards recovery and repair. Here, we explored whether TREM2 might also play a role in experimental brain trauma TBI. Male TREM2 knockout (TREM Ko) or wildtype (Wt) mice (n=12/group) were subjected to controlled cortical impact (CCI), then assessed for neurological function at 1, 3, 7 & 14 d later. Mice were assessed for neurological deficit (Bederson score), lateralization on an elevated body swing test, and foot faults from a ladder test. Brains were then harvested for histology. TREM Ko mice had worsened neurological recovery compared to Wt on all three functional studies ($p<0.05$) and had markedly increased lesion volumes (2x larger than Wt, $p<0.01$). This was also associated with reduced resorption of injured brain tissue amongst Ko mice. We also studied Neuro2a cells in combination with BV2 microglia. Microglial treatment with IL-4 induced a M2 (anti-inflammatory) phenotype as determined by arginase 1, CD206 & YM1 induction, and also increased TREM2 expression. When TREM2 was silenced using siRNA, arginase1 induction was decreased while iNOS (M1, pro-inflammatory) was increased. TREM2 silencing in BV2 cells also decreased neuronal phagocytosis in response to microglial activators. These results indicate that TREM2 deficiency worsens outcome from experimental TBI, and that TREM2 plays a role in the phagocytosis of injured brain cells, and leads towards a M2 phenotype.

Title: Specific cellular association of liposomes by stem-like cells improves therapeutic efficacy in glioblastoma

Authors: *J. BALÇA-SILVA[1,2], A. DO CARMO[2,3], A. SARMENTO-RIBEIRO[1,2,4], V. MOURA-NETO[5], M. LOPES[2,6], J. MOREIRA[2,6];

Estadual do Cérebro Paulo Niemeyer, Rio de Janeiro, Brazil; [6]Fac. of Pharmacy, Univ. of Coimbra, Coimbra, Portugal

Abstract: Glioblastoma (GBM) is the deadliest astrocytoma. The mean survival time for GBM patients is approximately 14 months under the *gold standard,* temozolomide (TMZ). There are three of the main reasons that make the GBM treatment difficult to surpass: 1) the constitutive activation of important signalling pathways involved in the GBM's proliferative capability, namely the protein kinase C (PKC); 2) the presence of a population of cells with stem-like cell properties (GSCs), which are known to be chemo- and radioresistant; and 3) the existence of the blood-brain-barrier (BBB), that limits the delivery of therapeutic agents.
To overcome these difficulties, we intended to: 1) use a targeted drug delivery liposome that allows BBB passage and reduces the systemic side effects of chemotherapeutics and 2) combine with lower doses of specific drugs, namely tamoxifen (TMX), inhibitor of PKC, and TMZ, that cross the BBB, to potentiate the effect. For that, we used a F3-peptide-targeted sterically stabilized pH-sensitive liposome, which recognizes cell-surface nucleolin (NCL), an overexpressed receptor presented in tumor cells, allowing a drug-specific delivery. These liposomes contained doxorubicin (DXR), an anti-tumor drug with multiple effectiveness, high systemic toxicity and that can not cross the BBB by its own.
Herein, NCL expression and stem-like cell markers were assessed, by flow cytometry, in two GBM cell lines, U87 and GBM11. We also determined the ability of GBM cells to specifically uptake the F3 peptide-targeted liposomes, and further correlated with the expression of stem-like cell markers, by flow cytometry. We assessed the effect of the combined therapy, TMX and

TMZ, with F3 peptide-targeted liposome containing DXR, on PKC expression, by western blot. The cytotoxicity of liposomes combined with TMX and TMZ was further assessed by the MTT assay.
Our results showed that the F3 peptide-targeted liposomes successfully targeted U87 and GBM11 cells, particularly GSCs, but the effect seems to be associated with the NCL overexpression. This approach enabled intracellular delivery of DXR with high specificity, inducing cell cytotoxicity and reducing cell proliferation, when in comparation with non-targeted liposomes. The cell proliferation was further reduced when F3 peptide-targeted liposomes were associated to the TMX and/or TMZ combination.
In this study we showed that liposomes can induce a drug-specific delivery, depending on NCL expression, which emphasized the importance of a personalized therapy. Also, the combination of liposomes with TMX and /or TMZ is a potential strategy to treat GBM.

Title: Effective treatment of traumatic brain injury in rowett nude rats with stromal vascular fraction containing adipose derived stem cells

Authors: *S. BERMAN[1], M. BERMAN[1], E. LANDER[2], R. COHEN[3];
[1]Res., Cell Surgical Network, Beverly Hills, CA; [2]Res., Cell Surgical Network, Rancho Mirage, CA; [3]Biol., California State Univ. Northridge, Northridge, CA

Abstract: Traumatic brain injury (TBI) affects about 1.9 million Americans every year with many more cases going unreported. Blast traumatic brain injury (bTBI) has been labeled the signature injury of the wars in Iraq and Afghanistan, and the physiology is similar to that of a TBI sustained in automobile accidents and recreational activities such as American football. TBI can lead to dizziness, loss of motor skills, rapid mood swings, and memory loss. Current treatments for TBI are lacking with most seeking to ameliorate the symptoms of TBI but doing little to actively repair the neuronal damage near the site of injury. This project investigated the hypothesis that stromal vascular fraction (SVF), a rich source of adipose derived and

hematopoietic stem cells, can assist in functional and histological post-TBI recovery. Human SVF was obtained from patient donors via elective liposuction in accordance with Cell Surgical Network protocols and consent of the patients. After extraction, adipose tissue was incubated in a closed sterile container with collagenase for enzymatic digestion of the extracellular matrix. The sample was washed with sterile saline and centrifuged to isolate the SVF. We utilized the acoustic wave technology of the Storz-D-Actor to induce a closed head TBI in adult Rowett Nude (RNU) immunosuppressed rats. A 5.0 bar acoustic wave was delivered to the left frontal cortex in a closed head procedure. Within one hour post-TBI, the freshly harvested SVF containing approximately 500,000 cells suspended in sterile 0.5 ml lactated Ringers solution was incubated with Qtracker 625 cell labeling solution and was administered into the RNU rats via the tail vein. We utilized a second group of RNU rats that received the same bolus of SVF into the tail vein 72 hours post-TBI. Lactated Ringers solution was also administered via tail vein injection into control RNU rats. Rotarod and water maze assays were used to monitor post-TBI symptoms of declining motor skills and spatial memories, respectively. Rats treated immediately after TBI with SVF showed no signs of diminishing motor skills and memory. SVF treatment 72 hours post-TBI helped the rats return to their motor skills baseline only, while control rats treated with Lactated Ringers solution showed a 25% decrease in their motor skills and memory tests 14 days post-TBI. Histological analysis showed the presence of Qtracker labeled cells within the infarct in both SVF treatment groups. However, Qtracker labeled cells were roughly twice as numerous in the group treated with SVF immediately following TBI. Our study suggests that SVF could serve as a potential therapeutic agent in treating patients recovering from TBI.

Title: The effects of interleukin-1 receptor antagonist treatment in a mouse model of multitrauma

Authors: *M. SUN[1], R. D. BRADY[2], D. K. WRIGHT[3], S. LIU[1], B. D. SEMPLE[1], T. J. O'BRIEN[1], S. J. MCDONALD[2], S. R. SHULTZ[1];
[1]Dept. of Med., The Univ. of Melbourne, Melbourne, Australia; [2]Dept. of Physiology, Anat. and Microbiology, La Trobe Univ., Melbourne, Australia; [3]The Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia

Abstract: BACKGROUND: Multitrauma involves injury to at least two body regions, and is prevalent worldwide. Traumatic brain injury (TBI) and bone fracture are two of the most common components of multitrauma. We have recently demonstrated that this injury combination in mice results in worse TBI-related outcomes than an isolated TBI, and that this occurred in the presence of an exacerbated neuroinflammatory response involving significantly elevated levels of interleukin-1β (IL-1β). Accordingly, here we aimed to determine if treatment with an IL-1 receptor antagonist (IL-1ra) would reduce neuroinflammation and improve outcomes in mice given multitrauma. METHODS: 12 weeks old Male C57Bl/6 male mice were randomly allocated to sham (SHAM) or multitrauma (weight-drop TBI and internally-fixated tibial fracture; MULTI) groups. Mice received subcutaneous injection of either 100 mg/kg of the IL-1ra or vehicle (VEH) at 1-, 6-, 24-hours and then daily for 1 week post-injury. A portion of mice were killed at 48 hours, and the remaining mice were given a 12-week recovery period. Cerebral edema and markers for neuroinflammation were assessed in all mice. Behavioral testing, magnetic resonance imaging (MRI), and pentylenetetrazole (PTZ) challenge tests were also conducted in the 12-week recovery mice. RESULTS: IL-1ra-treated MULTI mice displayed less cerebral edema and cortical neutrophils/monocytes infiltration at 48 hours post-injury compared to their VEH-treated counterparts. Preliminary behavior findings suggest that the VEH-treated MULTI mice had social impairments in the 3-chamber task, while the IL-1ra-treated MULTI mice did not. Additional behavior, MRI and PTZ analyses are ongoing. CONCLUSIONS: These preliminary findings indicate that IL-1ra may be an effective treatment in multitrauma featuring TBI and long bone fracture. Studies are ongoing to determine the influence of IL-1ra treatment at additional acute time points and on long-term behavior, neurodegeneration, epilepsy-related outcomes, and fracture healing following multitrauma.

Title: Transmission from motor cortex to spinal cord neurons and limb muscles in intact and lesioned motor cortex of adult rats

Authors: *H. A. PETROSYAN[1,2], V. ARVANIAN[1,2];
[1]Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY; [2]Northport VA Med. Ctr., Northport, NY

Abstract: Corticospinal tract is a major descending pathway mediating voluntary movements. The loss of cortical input due to injuries or stroke leads to severe deficits with limited recovery. Objective of the current study was to examine transmission from motor cortex to individual neurons in cervical C4-C5 spinal cord and to forelimb muscles in non-injured and in animals after acute lesion of sensorimotor cortex. We performed systematic quantitative evaluation of synaptic transmission to individual spinal neurons bilaterally and its correlation with responses recorded from forelimb muscles. Number of spinal neurons receiving synaptic inputs from the motor cortex and the ratio of excitatory and inhibitory synaptic inputs were determined in intact and in animals immediately after unilateral lesion of SMC. Results demonstrate that in response to electric stimulation of one hemisphere neuronal responses were recorded bilaterally from cervical spinal cord. Motor evoked potentials (MEPs) form both forelimbs were present in response to the same stimulation, although ipsilateral responses required higher stimulation intensity. On the contralateral to stimulation side the majority of responses were EPSPs with 75.9 ± 0.8% out of all responses, 20.7 ± 0.7% of responses were being IPSPs and small number 3.3 ± 0.4% of responses were mixed responses containing both IPSP and EPSP inputs. On the ipsilateral to stimulation side the distribution of recorded responses was different: number of recorded EPSPs was higher and number of IPSPs was lower compared to contralateral side (90.8

± 0.1% for EPSP and 8.4 ± 0.1 % for IPSP). After unilateral acute lesion of SMC, neither MEPs nor the distribution of intracellularly recorded synaptic responses were significantly changed at the contralateral to stimulation (i.e. ipsilateral to injury) side. However, injury significantly affected both synaptic responses and MEPs recorded from the ipsilateral to stimulation (e.g. contralateral to injury) side. MEPs recorded from contralateral to injury forelimbs were diminished. Importantly neurons on the contralateral to the lesion side of the cord were still responsive to ipsilateral SMC stimulation; however number of these neurons was significantly decreased and the ratio of inhibitory vs excitatory inputs was changed. Inhibitory inputs were decreased compared to before injury. Spared ipsilateral projections to individual spinal neurons, which sustain after unilateral cortical lesions, is a novel observation. These projections are promising candidates for future research and strengthening of these projections may be a target for treatment development after TBI and stroke.

Title: NMDA receptor-mediated activity is required for neuronal integration after injury in Xenopus visual system

Authors: *T. J. WISHARD[1,2], A. C. GAMBRILL[2], C. R. MCKEOWN[2], H. T. CLINE[2]; [1]Neurobio., UCLA, Los Angeles, CA; [2]Mol. and Cell. Neurosci., The Scripps Res. Inst., La Jolla, CA

Abstract: More than 5 million Americans suffer from traumatic brain injury (TBI), resulting in an approximate social and medical management cost burden of over $800 million per year, however the cellular and molecular mechanisms that mediate recovery from TBI are poorly understood. We previously developed a penetrative brain injury model with a behavioral output

using the visual system of Xenopus laevis. Focal ablation of part of the optic tectum in Xenopus tadpoles results in increased neurogenesis, however the extent to which newly born neurons are integrated into the tectal circuit, and their role in the circuit's recovery are unclear. NMDA receptors (NMDARs) play an important role in synaptogenesis and network maturation in many systems. To test the requirement of NMDARs in new neuron integration and functional recovery in our injury model, we used pharmacological and molecular techniques to block GluN2B-containing NMDARs. Using electrophysiology, we found that blockade of GluN2B with ifenprodil significantly impairs normal synaptogenesis. Using in vivo time-lapse imaging to evaluate the structural plasticity of individual optic tectal neurons, we found treatment with ifenprodil significantly reduced dendritic arbor elaboration. Injury to the optic tectum results in a quantifiable loss of visually-guided behavior in the Xenopus tadpole. Recovery of behavior takes 5-7 days and is dependent on cell proliferation. We tested the requirement of GluN2B-containing NMDARs for behavioral recovery by using morpholinos to acutely knockdown GluN2B-containing NMDARs. We found that loss of GluN2B significantly slowed the time course of behavioral recovery from injury. Our data indicate that GluN2B-mediated activity is required for normal integration of new neurons into the tectal network and is important for the recovery of circuit function after injury.

Title: Acute administration of endothelial-targeted catalase attenuates neuropathology and cortical microglia activation in traumatic brain injury

Authors: *E. M. LUTTON[1], R. RAZMPOUR[1], M. SEASOCK[1], S. F. MERKEL[1], L. CANNELLA[1], A. M. ANDREWS[1], V. SHUVAEV[2], V. MUZYKANTOV[2], S. H. RAMIREZ[1]; [1]Temple Univ., Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: TBI is a major clinical and social concern that contributes to one third of all injury related deaths in the US. Secondary mechanisms of injury in TBI, such as inflammation, are points at which intervention may improve functional recovery. Current treatment strategies for TBI are supportive, and the pathophysiology is not fully understood; however, evidence suggests that reactive oxygen species (ROS) and oxidative stress propagate blood-brain-barrier (BBB) hyperpermeability and inflammation following TBI. Such inflammation is associated with activated microglia that have been shown to persist for years after injury in the human brain. The novel use of endothelial-targeted catalase in TBI is hypothesized to quench ROS at their source to limit inflammatory activation and protect BBB function. Preliminary data demonstrates a consistent time dependent increase in vascular expression of endothelial ICAM-1 after TBI. To evaluate targeted antioxidant enzyme efficacy in TBI, catalase was conjugated to anti-ICAM-1 antibodies and administered to 6wk old C57BL6 mice 30min after moderate controlled cortical impact injury. Results suggest that administration of catalase targeted to ICAM-1 reduces neuroinflammatory indices and BBB permeability. Specifically, the study of microglia in situ by multiphoton microscopy following TBI revealed that treatment with anti-ICAM-1/catalase attenuates microglia transition to an activated phenotype. These results demonstrate an effective proof-of-concept approach to acute TBI management that may also be applicable to other neuroinflammatory conditions.

Title: Behavioral, neuroanatomical, and dna microarray study after neonatal and adult unilateral brain hemisuction mice

Authors: *A. YOSHIKAWA[1], T. NAKAMACHI[2], H. OHTAKI[3], M. IZUMIZAKI[1]; [1]Dept. of Physiol., Showa University, Sch. of Med., Tokyo, Japan; [2]Lab. of Regulatory Biol., Toyama University, Grad. Sch. of Sci. and Engin., Toyama, Japan; [3]Dept. of Anat., Showa Univ. Sch. of Med., Tokyo, Japan

Abstract: Nervous system is generally hard to regeneration, and the brain subjected to damages such as stroke and trauma results in loss of motor and/or sensory functions. It is also recognized that neonatal brain in infants often exhibits remarkably functional recovery even if they subjected to severe damages. However, it is unclear why the neonatal brain recover the neuronal functions. Here, we compared the differences of forelimb motor function, neuroanatomical recovery and gene expressions between infant and adult brain after left cerebral hemisuction. C57/BL6 strain infant (postnatal day7) and young adult (8-10 weeks) mice were subjected to left cerebral hemisuction under sevoflurane inhalation. Then, the mice were examined ladder walking test, which counted the slipping from ladder on forelimb, 4, 8, and 12 weeks later. After that, Fluoro-gold (FG), a retrograde neural tracer, was injected into the grey matter of right C5 - C6 vertebrae for histological evaluation. Another animals were removed the contralateral hemisphere 1 and 4 weeks after injury to survey their transcriptome with a 8 × 60 K mouse whole genome Agilent DNA chip.
In the behavioral test, the neonatal brain hemisuction mice (NBH) gradually improved the walking in a time-dependent fashion although adult brain hemisuction one (ABH) did not. The percentages of the foot slip in NBH were significantly lesser than those in ABH at all time points. FG signals in the contralateral hemisphere well recognized in the forebrain area of neocortex and were greater in the NBH. The transcriptome analysis was determined that 193 and 61 genes in NBH, and 1703 and 98 genes in ABH increased >1.5-fold at 1 and 4 weeks, respectively. Conversely, 990 and 2161 genes in NBH, and 2595 and 1022 genes in ABH decreased <0.75-fold, respectively. These results suggest that the brain in NBH was higher plasticity than that in ABH, and the compensatory neuronal projection from contralateral hemisphere might be important for the motor functional recovery. Now, we have been analyzing the genes that relate to the neuronal projection.

Title: Angiotensin receptor type 1 deficiency or inhibition improves outcome after experimental traumatic brain injury

Authors: J. KIM[1], N. KIM[1], *Z. ZHENG[3], M. JOHNSON[2], M. A. YENARI[1];
[1]Neurol., [2]Med., Univ. of California, San Francisco & San Francisco VAMC, San Francisco, CA; [3]Neurol, UCSF and VASF, San Francisco, CA

Abstract: Angiotensin II receptor type 1 (ATR1) mediates vasoconstriction, and its inhibition has been widely used to treat hypertension; however, recent work has suggested that it may also modulate apoptosis, and neuroinflammation. Thus, treatment with already available ATR1 blockers may have additional neuroprotective value. We explored the contribution of ATR1 to neuroprotection and brain hemorrhage in a model of TBI. Male, wildtype (Wt) and ATR1 knockout (Ko) mice were subjected to TBI using controlled cortical impact (CCI). Sensorimotor function (adhesive removal & elevated body swing tests), brain hemorrhage and lesion size were assessed out to 14d post insult. Wt mice were also treated with an ATR1 inhibitor (candesartan, 0.1mg/kg IP). ATR1 deficient mice were protected from CCI as evidenced by decreased lesion volumes (decreases of ~40% in lesion size amongst Ko mice, n=6/group, $p<0.05$), improved neurobehavioral outcomes (n=6/group, $p<0.05$) and fewer activated microglia in Ko mice ($p<0.05$). This was also associated with decreased TNF-alpha and IL-6 cytokine expression relative to Wt. Further, the ATR1Ko mice suffered less brain hemorrhage ($p<0.05$) and this was correlated to reduced MMP-9 expression ($p<0.01$). Candesartan similarly protected against brain injury, brain hemorrhage and improved neurological outcome out to 14 days post CCI (n=6/group, $p<0.05$). Candesartan, while often used to treat hypertension in humans, did not reduce blood pressure in mice at the dose studied. These data are consistent with the notion that ATR1 contributes negatively to traumatic brain injury, and its inhibition or deficiency leads to improved outcomes and decreased immune responses. Considering the clinical availability of ATR1 inhibitors, this approach may be a promising novel therapeutic target against TBI and related conditions.

Title: Effects of mild traumatic brain injury on monoamine receptors and anxiety-like behavior in male and female rats: response to post-injury progesterone therapy

Authors: *L. C. FOX[1], G. M. PALMER[1], J. L. SCHOLL[2], M. J. WATT[2], G. L. FORSTER[2]; [2]Basic Biomed. Sci., [1]Univ. of South Dakota, Vermillion, SD

Abstract: Mild traumatic brain injuries (mild TBIs) comprise over seventy-five percent of head traumas in the United States each year, and usually occur in settings of stress (sports, warfare, domestic violence, etc.). Symptoms can persist for weeks, months or even years in some victims, and can include memory difficulties, mood changes, and often generalized anxiety. Both males and females are at risk for mild TBI, but differential outcomes have been observed between males, naturally cycling females, and females taking hormonal contraceptives. Women using pharmacological doses of estradiol and progesterone were found in a 2013 study to experience fewer negative symptoms after injury than women who did not, as well as fewer than males. Our study utilized a rat model to explore the mechanisms behind this sex difference, and any potential benefits ovarian hormones may offer for concussion victims. Male and naturally-cycling female adult rats received a mild TBI via a weight drop mechanism, immediately following an episode of social defeat. This model of paired stress with injury effectively mimics the neurological environment in which most mild TBIs occur. Following assessment of anxiety-like behavior (elevated plus maze, EPM), perfused brains were taken and labeled using immunocytochemistry for serotonin, dopamine and GABA receptors. These neurotransmitters are known to be responsive to changes both in estradiol and progesterone levels. It was found that male rats reliably experience anxiety symptoms following mild TBI, but only females in the diestrus phase of their estrus cycle on the day of testing replicate this. Females in metestrus, estrus and proestrus appear protected, and spend similar times in the EPM open arms to those of uninjured controls. Mechanisms underlying this behavior may involve interactions between ovarian sex hormones and monoamine receptors in the brain. Recognizing this connection and the potential for therapeutic benefit, progesterone (4mg/kg) was administered 3 hours following injury, and then once per day for 5 days afterward. Progesterone treatment did not improve anxiety-like behavior of male rats exposed to mild TBI, suggesting that while progesterone might be protective in females, it may not restore psychosocial symptoms following mild TBI in males. Future work should test different combinations and timings of ovarian sex steroids to determine whether these can prevent psychosocial symptoms from developing following mild TBI in males and females.

Abstract: Traumatic brain injury (TBI) is a common event occurring in civilian and military environments as a result of falls, full contact sports, automobile accidents, acts of violence and shockwaves generated by the detonation of high explosives. Primary brain injury includes brain tissue deformation and/or damage. Secondary brain injury involves neuronal excitotoxicity, oxidative stress and inflammatory processes. Currently there is no FDA approved drug for the management of secondary injury events following TBI. Our prior work described cellular and behavioral benefits and reversals of numerous TBI-induced hippocampal gene expressions by the glucagon-like peptide-1 (GLP-1) receptor agonist exendin-4 in both concussive and blast TBI. Here we describe the actions of a sustained release form of exendin-4 (PT302) on TBI-induced behavioral deficits in a closed head weight drop model of TBI. Concussive mild TBI (mTBI) was induced by dropping a 30 g weight from a height of 80 cm onto the heads of anesthetized male mice. Sub-sets of mice were administered a single subcutaneous administration of PT302 (0.024, 0.12 and 0.6 mg/kg) 1 hr after TBI. Pharmacokinetic studies illustrated sustained plasma Exendin-4 levels, biphasically peaking at 2 hr and then 14 days following PT302 dosing, which matched levels observed in human subjects. Assessment of cognitive and anxiety-like behavior was undertaken 7 days post-injury using the Novel Object Recognition, Y-maze and Elevated Plus Maze paradigms. In mTBI+vehicle animals, cognitive deficits were observed while PT302 treatment 1 hr post-injury ameliorated these TBI-induced impairments. Further studies are evaluating dose-dependence and optimization to support the clinical evaluation of PT302 in human TBI.

Title: Inhibition of eph/ephrin signaling promotes recovery following traumatic brain injury

Authors: S. TENG[1], A. PALMIERI[1], J. PARK[1], R. ZHOU[2], J. ALDER[1], *S. THAKKER-VARIA[1];
[1]Dept Neurosci & Cell Biol, Rutgers University-Robert Wood Johnson Med. Sch., Piscataway, NJ; [2]Rutgers Univ., Piscataway, NJ

Abstract: Revealing the cellular and molecular pathways underlying neuronal cell death and degeneration after traumatic brain injury (TBI) is critical to identifying novel therapeutics. Eph/Ephrin family members are repulsive to process outgrowth and inhibiting Eph function or expression enhances recovery after spinal cord injury. However, whether blocking Eph receptors signaling promotes regeneration after TBI has not been explored. Our data demonstrate that EphA6 receptor is expressed in the adult brain and is upregulated in the hippocampus following the lateral fluid percussion (LFP) model of TBI. In uninjured EphA6 knockout (KO) mice, neurons grow abnormally exuberant processes, suggesting that EphA6 normally restricts growth of axons and dendrites. In the current study, we have used EphA6 KO mice to examine cellular and behavioral recovery following LFP injury in adult male mice. We have demonstrated that EphA6 KO mice have significantly less neuronal cell death and glial scarring following LFP compared to wildtype (WT) animals as indicated by activated caspase-3 and GFAP immunohistochemistry, respectively. Using EphA6 KO mice crossed to transgenic Thy1-YFP mice to visualize axons, we have determined that the absence of EphA6 signaling enhances regeneration in the cortex. For a more clinically relevant treatment paradigm, we have used soluble antagonist EphA6-Fc or control IgG administered to cortex of WT mice via mini-osmotic pumps for 7 d following LFP. EphA6-Fc treated mice exhibited less cell death and degeneration as demonstrated by FluorojadeC staining relative to IgG treated mice. The mice given EphA6-Fc also had a longer latency to fall on the rotarod 21 d after injury indicating improved motor

function compared to control mice. One ligand for the EphA6 receptor is Ephrin-A5 and there is high expression of Ephrin-A5 in the hippocampus and cortex of adult mice. We have shown that clustered Ephrin-A5 is also inhibitory to process outgrowth in vitro. Furthermore our studies indicate that a protein phosphotyrosine phosphatase inhibitor can rescue growth cone collapse induced by clustered Ephrin-A5. This compound is currently being tested in vivo to determine if it can mimic the effects of the EphA6 KO and EphA6-Fc on cell death and motor function. We are also using clustered EphrinA5-Fc, which acts as an agonist to the EphA6 receptor to see if there are exacerbated cellular and behavioral outcomes after LFP. Together these studies will yield insights into the role of Eph/Ephrin pathways in injury and demonstrate the therapeutic potential of intervention of EphA6 signaling via Fc fusion proteins and pharmacological agents for the treatment of TBI.

Title: Distal axotomy induced retrograde signaling enhances presynaptic excitability onto injured pyramidal neurons

Authors: *T. NAGENDRAN[1,2], R. L. BIGLER[3], R. LARSEN[2,4], B. D. PHILPOT[2,4,5], A. M. TAYLOR[1,2,5];

Abstract: Distal injury of long pyramidal tracts remodels cortical circuitry and leads to enhanced neuronal excitability, thus influencing recovery following injury. The neuron-specific contributions to this retrograde injury-induced hyper-excitability remain unclear due to the complex cellular composition and connectivity of the CNS. We developed a novel microfluidics-based *in vitro* model system to examine intrinsic synaptic remodeling following distal axotomy

of long projection pyramidal neurons. We found that distal axotomy of rat pyramidal neurons caused dendritic spine loss at synapses onto the injured neurons followed by a delayed and persistent retrograde trans-synaptic enhancement in presynaptic excitability. Further, this hyper-excitability involved the specific elimination of inhibitory presynaptic terminals formed onto dendritic spines. We found that these changes required differential gene expression and axotomy decreased mRNA expression of the secreted factor netrin-1 coinciding with spine loss. Exogenous netrin-1 applied two days after injury normalized this presynaptic hyper-excitability and restored the fraction of inhibitory inputs onto injured neurons. These findings provide new insights of neuron-specific mechanisms that contribute to synaptic remodeling and demonstrate a novel model system for studying the response of pyramidal circuitry to axotomy.

Title: Adult neural stem cell intracerebroventricular transplantation in experimental traumatic brain injury: analysis of the sonic hedgehog mediated regenerative response and neuroinflammation.

Authors: *G. M. SULLIVAN, R. C. ARMSTRONG;
USUHS, Bethesda, MD

Abstract: Neural stem cells (NSCs) hold promise to promote brain repair by replacing lost cells and/or interacting with host cells to modulate the immune response and stimulate endogenous regenerative capacity. Transplantation strategies are challenging for traumatic brain injury (TBI) due to diffuse rather than focal lesions. Therefore, an intracerebroventricular delivery route may be advantageous in TBI patients, and designed via external ventricular drains implanted to control intracranial pressure. To test this concept, NSCs were isolated from adult mouse subventricular zone (SVZ) and transplanted into the lateral ventricle of adult mice at two weeks post-TBI (subacute stage) followed by analysis at four weeks post-TBI. TBI produced reactive

astrogliosis and microglial activation in the corpus callosum (CC) that was significantly reduced by NSC transplantation. We then examined *in vivo* activation of the Sonic hedgehog (Shh) pathway. Shh has important regenerative roles and *Gli1* transcription is an effective readout for canonical Shh signaling. Mouse reporter lines were generated for induced genetic fluorescent labeling of cells actively transcribing *Shh* or *Gli1 in vivo*. Transplanted NSCs from *ShhCreERT2:RosamTmG* mice showed rare *Shh* expression *in vivo*. In host *ShhCreERT2:RosaTdTomato* mice, *Shh* was primarily expressed in neurons, including CC axons. TBI did not induce *Shh* expression in reactive astrocytes or microglia. *Gli1CreERT2:RosaTdTomato* host mice demonstrated only rare Shh activation in CC cells, even after TBI or NSC transplantation. Additionally, NSC transplantation did not activate Shh signaling in host SVZ cells. Therefore, intracerebroventricular NSC transplantation in subacute stage TBI did not stimulate Shh-mediated regeneration yet did significantly suppress neuroinflammation.

Title: MicroRNA profiling reveals chronically dysregulated NOTCH1 interactome in the dentate gyrus after experimental TBI

Authors: *N. PUHAKKA[1], A. BOT[2], N. VUOKILA[1], K. DEBSKI[2], K. LUKASIUK[2], A. PITKÄNEN[1];
[1]Univ. of Eastern Finland, Kuopio, Finland; [2]The Nencki Inst. of Exptl. Biology, Polish Acad. of Sci., Warsaw, Poland

Abstract: Each year about 1.5 million people in the United States and 2.5 million in Europe suffer traumatic brain injury (TBI). Life-compromising functional impairments develop in about 43% of injured patients. These impairments can result in several dentate gyrus-regulated disabilities, including memory impairment, depression, and epilepsy. The progression of post-TBI secondary pathology and the evolution of impairments can continue for months. Almost nothing, however, is known about the chronic molecular changes after TBI, and their potential as treatment targets. The present study tested the hypothesis that chronic transcriptional alterations after TBI are under micro RNA (miRNA) control. Expression of miRNAs and their target mRNAs in the dentate gyrus was analyzed using microarrays at 3 months after TBI induced by lateral fluid-percussion injury in adult male Sprague-Dawley rats. Altogether 654 genes were upregulated and 212 downregulated ($p<0.05$). Of 305 miRNAs present on the miRNA-array, 12 were downregulated ($p<0.05$). In parallel, 75 of their target genes were upregulated ($p<0.05$). A bioinformatics analysis of miRNA targets highlighted the dysregulation of the transcription factor NOTCH1 and 39 of its target genes (NOTCH1 interactome). Spearman Rank analysis showed a correlation between miRNA downregulation and the upregulation of *Notch1*. Validation assays confirmed dysregulation of the NOTCH1 interactome, including downregulation of miR-139-5p, upregulation of *Notch1* and its activated protein form (NICD), and positive enrichment of NOTCH1 target gene expression in the microarray dataset. These findings demonstrate that miRNA-based interventions targeting the NOTCH1 interactome have therapeutic potential against dentate gyrus pathology-related morbidities, even in the chronic post-TBI period.

Title: Lithium increases synaptic vesicular proteins, improves neurotransmission and promotes recovery of cognitive function after traumatic brain injury

Authors: *S. W. CARLSON, Y. LI, A. FIRDOUS, X. MA, J. HENCHIR, H. YAN, C. DIXON; Neurosurg. and VA Pittsburgh Healthcare Syst., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Experimental models of traumatic brain injury (TBI) reproduce cognitive impairments and secondary injury sequela reported in TBI patients. Our previous work suggests that reductions in the soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex, the machinery facilitating vesicular fusion, contribute to impaired neurotransmitter release. TBI significantly reduces cysteine-string protein α (CSPα), an important chaperone protein that facilitates SNARE complex formation. Lithium treatment in naïve rats reportedly increases expression of CSPα. Lithium-treated TBI-injured rats exhibit improved outcome, but the mechanisms mediating the improvement have not been elucidated. The objective of this study was to evaluate the effect of lithium on SNARE protein abundance, evoked striatal neurotransmission, cortical contusion volume, and neurobehavioral function after controlled cortical impact (CCI). Sprague-Dawley rats received CCI (2.7mm) or sham injury, and injected daily (i.p.) with vehicle or 1.0mmol/kg/ml lithium chloride for up to 14d, beginning 5 minutes post-injury. The brains were dissected at 1, 3, 7, 14d post-injury and processed as whole cell or synaptosomal lysates for immunoblotting (n=6/group). Evoked-dopamine release was evaluated using microdialysis at 7d post-injury (n=6-7/group). Lesion volume was assessed at 14d post-injury (n=6/group). Cognitive function was assessed at 10-14d post-injury (n=14-16/group). Lithium significantly attenuated CCI-induced reductions in CSPα and SNARE complexes at multiple time points. Assessment of contusion volume revealed that lithium did not reduce cortical cell loss. At 7d post-injury, lithium significantly improved striatal high-potassium evoked dopamine release. Lithium significantly improved Morris water Maze acquisition and probe trial performance. Taken together, lithium improves SNARE protein abundance, neurotransmission, and cognitive performance following TBI. These findings highlight that lithium increased the abundance of important synaptic proteins that facilitate neurotransmission and promoted functional recovery after TBI.

Title: Mechanisms of brain edema after injury: Photolysis of a single neuron alters the cytoplasmic Cl^- and cell volume in neighboring neurons.

Authors: *K. EGAWA[1], K. STALERY[2];
[1]Dept. of Pediatrics, Hokkaido Univ. Grad. Sch. of Med., Sapporo, Japan; [2]Dept. of Nerulogoy, Massachusetts Gen. Hosp., Boston, MA

Abstract: Rationale: The mechanisms of cytotoxic edema remain unclear. We investigated the relationship between acute neuronal necrosis and secondary neuronal injury and swelling in neighboring neurons. We studied how acute necrosis of a single neuron affected the chloride concentration in the cytoplasm of surrounding neurons. **Methods:** We used two photon microscopy and the transgenically-expressed chloride fluorophore Clomeleon to explore consequences of death of a neighboring neuron on the intraneuronal chloride ($[Cl^-]_i$) in hippocampal pyramidal cells in organotypic slice cultures. Two photon laser irradiation to the soma of single CA1 pyramidal neuron exclusively lysed the targeted cell. Cell damage was assessed by morphological changes as well as caspase activation using FLICA staining. **Results:** Lysis of the target neuron was followed by an immediate $[Cl^-]$ increase in surrounding neurons; sub-lytic radiation had no effect on neighbors. The time course of $[Cl^-]i$ elevation differed from neuron to neuron, with some neurons exhibiting large increases that persisted over 60 minutes concomitant with caspase activation. The $[Cl^-]i$ increase and subsequent cell damage was exclusively triggered by ionic influx because they were never observed under the perfusion of NaCl free solution. When extracellular NaCl was replaced by Nagluconate, lysis of the target neuron did not cause $[Cl^-]i$ increase or swelling of neighbors, although caspase was activated in cells near the target. In contrast, low Na^+, high Cl^- solutions or NaCl + kynurenic acid had only modest effects on post-lytic $[Cl^-]i$ increase in neighbors. These results highlight the critical role of Cl^- influx for cytotoxic cell swelling and damage after nearby neuronal lysis. The influx pathway of Cl^- is still being elucidated. Pharmacological blockade of $GABA_A$ receptor, cation-chloride co- transporters, and Cl^- channels including sulfate transporters did not reduce the $[Cl^-]i$ increase. The Cl^- channel blockers NPPB and DIDS actually increased neighboring neurons' $[Cl^-]i$ increase and cell volume. **Conclusion:** This novel, readily-studied model demonstrates that cytotoxic edema and injury can occur as purely secondary phenomena in initially uncompromised neurons after acute brain injury. Pharmacological results indicate that swelling

occurs via Cl^- influx pathways that are distinct from known Cl^- channels or transporters. Ion substitution experiments indicate that $[Cl^-]i$ increase is independent of Na^+ influx, suggesting that the counter ion may be potassium. We will continue to utilize this model to explore mechanisms of cytotoxic edema in hopes of developing new therapeutic approaches.

Abstract: Several lines of evidence has shown that the prolonged activation of the classic pro-inflammatory (M1) phenotype of microglia may facilitate brain injury progression, and is critically involved in the secondary injury following traumatic brain injury (TBI). Therefore, therapies targeted to skew the microglia polarization toward an alternative, anti-inflammatory (M2) phenotype could provide a potential new therapeutic opportunity for treatment of the injured brain. In the present study, we demonstrated that NADPH oxidase 2 (NOX2) is elevated at 4- and 7-day post TBI in the murine model of controlled cortical impact. To elucidate the role of NOX2 in the regulation of microglia polarization dynamics after TBI, RT-PCR, immunofluorescence staining and flow cytometry for M1 and M2 markers were performed using brain samples collected from wild-type (WT), NOX2-knock out (NOX2-KO), and NOX inhibitor (apocynin)-treated mice following TBI. Our results revealed that at 4- and 7-day post TBI, the NOX2-KO and apocynin-treated mouse brain showed an increase of the anti-inflammatory M2-like microglia and a corresponding decrease of the pro-inflammatory M1-like microglia in the cortex, as compared to the WT vehicle treated animals. In addition, the NOX2-KO and apocynin-treated mice displayed marked down-regulation of the classical NF-κB pathway in microglia, and reduced production of pro-inflammatory cytokines, TNF-α and IL-1β at 4 and 7-day after TBI. Using an *in-vitro* microglia and primary neuron co-cultures system, we

found that microglia from the brain of adult mice at 7-days after TBI show much higher neurotoxicity than the microglia from control and sham mice. Furthermore, the neurotoxicity of microglia from NOX2-KO and apocynin-treated mice is significantly decreased compared with that from WT vehicle-treated mice. Altogether, our results indicate a key role of NADPH oxidase and the NF-κB pathway in regulating the polarization dynamics of microglia and their neuronal toxicity after TBI, and suggest that targeting NADPH oxidase and the NF-κB pathway may be an effective way to ameliorate inflammation and improve outcome following TBI.

Title: Impaired synaptic long-term potentiation and changes in protein degradation systems in a mouse model of focal traumatic brain injury in somatosensory cortex

Authors: *T. MITTMANN[1], L. K. FELDMANN[2], F. LE PRIEULT[2], V. FELZEN[3], S. THAL[4], K. ENGELHARD[4], C. BEHL[3];

Abstract: Traumatic brain injury (TBI) is a leading cause of death in Europe and the US and a challenge to develop new strategies for therapeutical treatments. Processes of functional reorganization and adaptation of neurons following TBI are still not fully understood. The present study evaluated the effects of an unilateral TBI on long-term synaptic plasticity at the border of the lesion after a survival time of 1-2 days in the ipsilateral and contralateral hemisphere. In parallel, we studied protein homeostasis post-TBI by evaluating changes in protein degradation systems. TBI was induced by a controlled cortical impact (CCI) in somatosensory cortex of anaesthetized mice (P18-P21). Acute brain slices of the somatosensory cortex were prepared after a survival time of 1-2 days. A perforated 32 channel-multielectrode array (pMEA) system was used to stimulate and record extracellular field potentials (FPs) in acute brain slices. Late long-term potentiation (L-LTP) was induced by theta-burst-stimulation

(TBS) and recorded for 3 hours. Immunohistochemistry and Western blots were performed to evaluate alterations in the expression of specific autophagic marker proteins LC3, p62 and BAG3. The autophagic flux was measured by incubating acute brain slices with the lysosomal blocker chloroquine and subsequent detection of accumulated LC3II. We also tested the proteasomal activity as well as the expression of plasticity-related proteins (PRP). The MEA recordings revealed a strongly impaired L-LTP in the ipsilateral cortex at 1-2 days post-lesion compared to sham-operated controls. L-LTP was not affected in the homotopic area of the contralateral hemisphere. Interestingly, the expression of PRPs (CaMKIIα) was significantly reduced in the ipsilateral hemisphere of TBI animals. In parallel we observed an increased autophagic flux and a reduced proteasome activity in the ipsilateral hemisphere. Interestingly, FPs recorded with the pMEA in untreated control mice and in presence of autophagy activators (rapamycin) and/or blockers of protein degradation pathways (MG132) mimicked the missing L-LTP of TBI treated animals. These data indicate that TBI in somatosensory cortex impairs L-LTP after 1-2 days, and it is associated with a dysregulation in the expression of CaMKIIα and an altered activity of protein degradation systems. Our pharmacological experiments indicate that the homeostatic regulation of the somatosensory cortex after TBI by the bilateral change in the activity of autophagy and proteasome pathways could mediate the altered L-LTP following TBI. This could be an important adaptive mechanism for functional recovery of the brain after a focal cortical injury.

Title: High speed and biaxial stretch as *In vitro* models of traumatic brain injury to the blood brain barrier

Authors: *H. ROSAS-HERNANDEZ[1], E. CUEVAS[1], S. M. LANTZ[1], S. Z. IMAM[1], N. STURDIVANT[2], K. BALACHANDRAN[2], W. SLIKKER, Jr[1], M. G. PAULE[1], S. F. ALI[1]; [1]Natl. Ctr. For Toxicological Res., Jefferson, AR; [2]Dept. of Biomed. Engin., Univ. of Arkansas, Fayetteville, AR

Abstract: Traumatic brain injury (TBI) is one of the major causes of disability in the United States. It occurs when external mechanical forces induce brain damage as a result of impact, penetration, and/or rapid acceleration/deceleration that cause deformation of brain tissue. TBI is also associated with alterations of the blood-brain barrier (BBB), a structure that protects brain tissue from substances circulating in the blood. The BBB consists mainly of brain endothelial cells (BECs). Due to the high incidence and drastic consequences of TBI, it is important to understand the critical events that accompany damage in order to develop effective treatment approaches. Using primary rat BECs as an *in vitro* BBB model, the effects of two different types of stretch that mimic aspects of TBI at 0, 5, 10 and 15% perturbation were characterized. Deformation due to biaxial stretch (BS) was achieved by infusing pressurized gas into flexible bottom culture plates using a commercially available system. Deformation due to uniaxial high-speed stretch (HSS) was achieved by moving a linear actuator, coupled to a polydimethylsiloxane chip on top of a silicone membrane at a strain rate of 100 s^{-1}. Live/dead cells, LDH release, caspase 3/7 staining and nitric oxide (NO) production were evaluated 24 hours after a single stretch episode. BS affected the BECs under all conditions tested, inducing a deformation-dependent decrease in NO production, increase in LDH release, cell death and activation of caspase 3/7, suggesting the induction of apoptosis. On the other hand, HSS increased LDH release only at 15% stretch and increased cell death and caspase 3/7 at 10 and 15% stretch. In summary, some of the events that occur in the BBB after TBI were successfully replicated *in vitro* using BS and HSS and the severity of the TBI produced *in vitro* depends on the degree and orientation of cellular deformation. These data support the use of BS and HSS as valuable tools in the study of TBI in vitro by defining stretch intensities. This method may also be useful in evaluating potential drug treatments for this condition.

Title: Selective blockade of the corticorubral tract during intensive forelimb rehabilitation in rats with capsular hemorrhage

Authors: *A. ISHIDA[1], Y. UEDA[1], K. KOBAYASHI[2], T. ISA[3], H. HIDA[1];
[1]Nagoya City Univ. Grad. Sch. of Med. Sci., Nagoya, Aichi, Japan; [2]Div. of Viral Vector Develop., Natl. Inst. of Physiological Sci., Okazaki, Japan; [3]Dept. of Physiol. and Neurobio., Kyoto Univ. Grad. Sch. of Med., Kyoto, Japan

Abstract: Reorganization of the residual neuronal circuits is the key for the poststroke recovery, and it can be promoted by intensive rehabilitation. We reported that forced impaired limb use (FLU) increased the sprouting of the cortico-rubral tract after intracerebral hemorrhage (ICH) that was responsible for the recovered forelimb functions by FLU (Ishida et al., J. Neurosci 2016). However, it is still unclear whether the cortico-rubral tract is involved in the relearning of forelimb functions. In the present study, we investigated the role of the cortico-rubral tract during the period of rehabilitation after ICH in rats.
To block the cortico-rubral pathway during rehabilitation, adult male Wistar rats were injected with two viral vectors: lentivirus vector (NeuRet-TRE-EGFP.eTeNT) was injected into the unilateral red nucleus and adeno-associated virus vector (AAVdj-CaMKII-rtTAV16) was into the ipsilateral motor cortex. Thus, synaptic transmission of the double-infected cortical neurons could be selectively blocked by doxycycline (DOX) administration. Four weeks after the virus injections, ICH was made by collagenase injection into the internal capsule ipsilateral to virus injections.
Half of ICH rats were forced to use their impaired forelimb by one-sleeve cast (FLU) for 7 days from 24 hours after ICH. To block synaptic transmission in the cortico-rubral tract, DOX was orally administered for all rats during FLU. Skilled reaching task was conducted as behavioral assessment for forelimb use at 10-12 and 26-28 days after ICH.
All rats with ICH demonstrated severe impairment of motor function at 24 hours after the lesion. At 10-12 days after the lesion, ICH group without FLU still showed apparent impairment of reaching function. FLU-treated ICH group exhibited substantial recovery of forelimb function. This FLU effect on functional recovery after ICH was not affected by DOX administration during rehabilitation (FLU).
Data indicate that selective blockade of the cortico-rubral tract during FLU did not affect the regain of the forelimb function in an acute phase after ICH, suggesting the compensative recruitment of other descending tract such as cortico-reticulo-spinal pathway rather than the cortico-rubral tract.

Title: An early driver of traumatic brain injury that can be effectively blocked by antibody

Authors: *A. KONDO[1], K. SHAHPASAND[2], O. ALBAYRAM[2], R. MANNIX[3], W. MEEHAN[3], X. ZHOU[2], K. LU[2];
[1]Div. of Translational Therapeut., BIDMC, Harvard Med. Sch., Boston, MA; [2]Div. of Translational Therapeut. Dept. of Med., Beth Israel Deaconess Cancer Ctr. Harvard Med. Sch., Boston, MA; [3]Micheli Ctr. for Sports Injury Prevention, Children's Hosp. Boston Harvard Med. Sch., Boston, MA

Abstract: Traumatic brain injury (TBI) is common in contact sport athletes and blast-exposed veterans. Repetitive mild TBI (rmTBI) or even single moderate/severe TBI (ssTBI) is associated with neuropsychiatric symptoms and cognitive disability, which can cause chronic traumatic encephalopathy (CTE), or increase Alzheimer's (AD) risk, but no treatment is available. Extensive tangles made of phosphorylated tau (p-tau) are identified in CTE brains, similar to tauopathy in AD. Since known tau pathologies are not obvious acutely after closed head TBI, whether tauopathy is an end result or early driver of TBI pathology is unclear. Establishing the early role of tau after TBI could result in new treatments, especially since tauopathy spreads and is reduced by tau immunotherapy. *cis*, but not *trans*, p-tau is an early pathogenic conformation in AD, but its role in TBI is unknown. Here we identify cis p-tau as an early central mediator of brain injury after closed head TBI that is effectively stopped by antibody (Kondo et al., 2015, Nature 523: 431-6). We find robust *cis*, but not *trans*, p-tau in sport- and military-related human CTE brains and their TBI mouse models. Upon stress *in vitro*, neurons robustly produce *cis* p-

tau, which disrupts the microtubule network, interrupts mitochondrial transport in neurites, spreads to other neurons, and leads to massive apoptosis. This process, termed "cistauosis", is effectively blocked by *cis* p-tau antibody (mAb), but amplified by *trans* mAb. In mouse models, ssTBI or rmTBI causes strong and persistent induction of *cis* p-tau induction within 12-24 h post-injury, leading to cistauosis in brains. Treating mice with *cis* mAb after ssTBI effectively prevents induction of *cis* p-tau and cistauosis, and also fully reverses TBI-related anxiety/risk-taking behavior. Thus *cis* p-tau appears to be an early driver of brain injury and tauopathy after TBI, but is effectively blocked by mAb. These insights indicate a novel disease mechanism and a potential new therapy for TBI.

Title: Injury leads to the appearance of cells with molecular characteristics of both astrocytes and microglia in mouse and human brain

Authors: M. PEKNA[1], U. WILHELMSSON[1], D. ANDERSSON[1], Y. DE PABLO[1], R. PEKNY[1], A. STAHLBERG[1], J. MULDER[2], N. MITSIOS[2], T. HORTOBAGYI[3], *M. PEKNY[1]; [1]Univ. of Gothenburg, Gothenburg, Sweden; [2]Karolinska Institutet, Stockholm, Sweden; [3]Univ. of Debrecen, Debrecen, Hungary

Abstract: Microglia perform many functions in healthy and diseased brain, ranging from maintenance of homeostasis and regulation of neural plasticity to trophic support and neuroprotection. Although experimental evidence suggests that microglia are not a homogenous

cell population, the knowledge about their functional diversity and its molecular basis is limited. We used single-cell gene expression profiling of freshly isolated cells from uninjured mouse hippocampus and hippocampus after partial deafferentation to assess the heterogeneity of microglia/monocytes and determine their response to injury. We found that in individual cells, microglial markers *Cx3cr1, Aif1, Itgam* and *Cd68* were co-expressed. In the absence of injury, *Cx3cr1* and the astrocyte marker *Gfap* were expressed in two non-overlapping populations of cells. Injury led to the co-expression of these markers both in the injured and contralesional hippocampus. Exposure to lipopolysaccharide (LPS) increased the fraction of cultured cells co-expressing *Cx3cr1* and *Gfap*. Cells co-expressing astrocyte and microglia markers were also detected in sections from human brain affected by stroke, Alzheimer's disease and Lewy body dementia. Our findings indicate that injury and chronic neurodegeneration lead to the appearance of cells that share molecular characteristics of both microglia and astrocytes, two cell types with different embryologic origin.

Abstract: Traumatic brain injury (TBI) remains one of the major causes of death and disability. Due to the heterogeneity of its causes, the events that occur after TBI can be quite varied and are not well understood. Regardless of the cause, deformation of the brain tissue leads to neuronal and glial cell death as well as other cellular and molecular responses. Understanding the

subsequent events followed by TBI is extremely important for development of therapeutic approaches. The use of *in vitro* systems allows for the study of specific aspects of TBI. The aim of this study was to characterize the effects of TBI on rat astrocytes using two different *in vitro* membrane perturbation systems at 0, 5, 10 and 15% deformation. TBI was simulated by biaxial stretch (BS) of astrocytic cellular matrices *in vitro* by infusing pressurized gas onto flexible bottom culture plates using a commercially available system. Deformation due to uniaxial high-speed stretch (HSS) was achieved by moving a linear actuator, coupled to a polydimethylsiloxane chip on top of a silicone membrane at a strain rate of 100 s^{-1}. Live/dead cells, LDH release, caspase 3/7 staining and nitric oxide (NO) production were evaluated 24 hours after a single stretch injury. BS induced an increase in LDH release, cell death and activation of caspase 3/7 at 10 and 15% stretch, without changes in NO production. HSS increased LDH release, cell death and caspase 3/7 only at 15% stretch, suggesting that the damage induced by BS is achieved at lower percentages of stretch than that induced by HSS. In summary, we have demonstrated that BS and HSS can be used as models to study the effects of TBI on astrocyte viability *in vitro*. Further experiments are underway to evaluate the effects of TBI-like cellular perturbation on astrocyte metabolism and activation and the impact that these events may have on different brain cell types.

Title: The protective effect of glutamate scavenger combining adenosine A2A receptor agonist CGS21680 against severe traumatic brain injury in mice

Authors: Y.-L. NING[1], N. YANG[1], Z.-A. ZHAO[1], W. BAI[1], H.-K. TIAN[2], J.-S. DIAO[1], X.-L. REN[1], R.-P. XIONG[1], X. CHEN[1], P. LI[1], Y. ZHAO[1], *Y. ZHOU[1];
[1]Res. Inst. Surg and Daping Hosp. ,TMMU, Chongqing, China; [2]Dept. of Trauma and Microsurgery, No. 324 Hosp. of PLA, Chongqing, China

Abstract: The adenosine A2A receptor (A2AR) is commonly believed to play an anti-inflammatory role. However, our previous work on moderate traumatic brain injury (TBI) in mice showed that only in the presence of low concentrations of glutamate can the A2AR agonist CGS21680 exert neuroprotective effects, and high concentration of local glutamate switches the effects of A2AR activation from anti-inflammatory and neuroprotective to deleterious. While in a severe traumatic brain injury model, the glutamate levels in the cerebrospinal fluid (CSF) maintained at a high level within 24h. Therefore, there was not a time window to treat the mice with CGS21680 to protect them from brain damage. In the present study we investigated the effects of glutamate scavenger oxaloacetate (OX) combining CGS21680 treatment against severe TBI. Mice were treated with OX intravenously at 1h after severe TBI. The glutamate levels in CSF decreased from 5.707 times to control group to 2.45 times to it at 5h post TBI, and at this time point mice were injected intraperitoneally with CGS21680. At 24h after TBI, nuerological deficit, brain edema and the proinflammatory cytokine TNF-α and IL-1β production were attenuated significantly in OX combining CGS21680 treated mice. Next, to investigate whether the combined treatment is available when CSF glutamate levels were higher and brain insult has been progressed, we treated mice with OX intravenously at 8h after TBI. At 12h after TBI, when the glutamate levels in CSF decreased from 9.377 times to control group to 3.96 times to it, mice were administrated with CGS21680 by i.p. injection. The above brain damages at 24h post TBI were also attenuated in the combined treatment group. Furthermore, the combined treatment exhibited better therapeutic effect than single oxaloacetate treatment did. Taken together, our results demonstrated that A2AR agonist CGS21680 treatment may exert neuroprotective effect against sever TBI when the CSF glutamate level decreased to the range of 2.45 to 3.96 times of that in control group by the impact of OX. Furthermore, no matter the injuries were in early stage or has been progressed, CGS21680 could perform a neuroprotective role, provided the glutamate were maintained at this level by the application of OX, and the protective effects preceded that of oxaloacetate treatment along. The results not only provided a potential therapeutic strategy for the treatment of severe TBI, but also proved the hypothesis that local glutamate levels in the brain dictates the A2AR effects on brain damage outcome.

Title: Evaluation of the effect of THSG on traumatic brain injury

Authors: *Y.-H. CHEN[1], L.-Y. YANG[2];
[1]Taipei Med. Univ., Taipei, Taiwan; [2]China Med. Univ., Taichung 40402, Taiwan

Abstract: Traumatic brain injury (TBI) is one of the leading global health issues and has affected at least 10 million people worldwide every year. TBI has placed a tremendous financial burden on the National Healthcare System, the TBI patients and the caring family members. Although lots of efforts have been devoted to the TBI research, there are still no effective therapeutic treatments for TBI. Previous studies have shown that 2,3,5,4'-tetrahydroxystilbene-2-O-beta-D-glucoside (THSG) exerts a protective effect on rat hippocampal neurons against staurosporine-induced neurotoxicity. It has also been reported that THSG inhibits doxorubicin-induced cardiotoxicity via suppression of the reactive oxygen species (ROS) production and the apoptotic signaling. However, the effect of THSG on TBI remains unclear. In this study, we test the hypothesis that THSG attenuates the degree of TBI. We induced TBI on one side of the brain using the cortical impactor and then administered THSG (30 mg/kg, ip.) or vehicle to mice immediately and 12 hr after TBI. Animals were sacrificed 24 hr following TBI. The injured brain and the intact brain were harvested separately and then protein was extracted and processed for the evaluation of p53 and CRMP-2 using the western blotting technique. Our preliminary results showed that TBI induced the expression of p53 and promoted the cleavage of CRMP2. Application of THSG significantly reduced TBI-induced expression of p53 and the cleavage of CRMP2 ($p < 0.05$). These findings indicate that THSG exerts a beneficial effect on TBI animals and strongly suggest that THSG has a great potential to become a novel and effective treatment for TBI patients.

Title: *In vitro* exosome trafficking across the blood-brain barrier

Authors: *C. CHEN[1,2,3,4], C. WONG[1,2,3,4], L. LIU[1,2,3,4], W. ZHAO[1,2,3,4];
[2]Dept. of Pharmaceut. Sci., [3]Dept. of Biomed. Engin., [4]Sue and Bill Gross Stem Cell Res. Ctr., [1]Univ. of California, Irvine, Irvine, CA

Abstract: Therapeutic delivery to the central nervous system (CNS) remains a major challenge in the treatment of neurological disorders. This is partly due to the presence of the blood-brain barrier (BBB), a dynamic interface that restricts and controls the passage of substances between the peripheral vascular circulation and the CNS. Different nanocarrier strategies have been explored to improve delivery of therapeutic agents across the BBB. Recent studies have shown that cell-derived vesicles, particularly exosomes, are increasingly recognized as an attractive vehicle for targeting drugs to the brain. However, whether or how they cross the BBB remains to be fully elucidated. Here, we investigated exosome trafficking in brain microvascular endothelial cells (BMECs) *in vitro* under conditions that mimic the healthy and inflamed BBB *in vivo*. Exosomes were engineered to carry *Gaussia* luciferase (Gluc) and Transwell assays were employed to study exosome trafficking *in vitro*. Results suggested that luciferase-carrying exosomes can cross a BMEC monolayer under stroke-like, inflamed conditions (TNF-α activated) but not under healthy conditions ($p < 0.05$). Confocal microscopy demonstrated that exosomes are internalized by BMECs through clathrin-mediated and caveolae-dependent endocytosis, co-localize with early and late endosomes, and are partly exocytosed across the BMECs, in effect primarily utilizing the transcellular route of crossing. Furthermore, approximately one third of the total crossing of the BMECs was due to the paracellular route of passive diffusion through intercellular junctions between BMECs treated with TNF-α. Taken together, these results indicate that cell-derived exosomes can cross the BBB model under stroke-like conditions *in vitro*, and this system can be used to examine whether or not exosomes can be utilized to deliver therapeutic agents to specific regions of the injured brain. Our study provides insights for further development of engineered exosomes as drug delivery vehicles or tracking tools for treating or monitoring brain diseases in the near future. Title: C3 transferase gene therapy for neuroprotection and axon regrowth

Authors: *C.-A. N. GUTEKUNST[1], M. E. MACDOUGAL[2], R. E. GROSS[2];
[1]Dept Neurosurg., [2]Neurosurg., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: The bacterial exoenzyme C3 transferase (C3) is a promising therapy for neuroprotection and axon regeneration. However, effects are limited by C3's short duration of action and poor distribution to injured neurons. To address this issue, adeno-associated viral (AAV) vectors tagged with green fluorescent protein (GFP) were engineered to express an endogenous (e) and a secretable/permeable (sp) C3 to allow for long-term and widespread distribution of the C3 protein. C3 gene therapy was delivered via intravitreous injection in the rat optic nerve crush (ONC) injury model. Rats were treated with AAV-eC3GFP or AAV-spC3GFP, or served as controls receiving AAV-eGFP, AAV-spGFP, vehicle alone, or no intervention. At 4 or 8 weeks, RGC survival was quantified following immunostaining of the retina with an RGC-specific Brn3a antibody. The optic nerve was labeled with the anterograde tracer, cholera toxin subunit B, and underwent tissue clearance to allow detailed visualization of the trajectories of regenerating axons through the whole optic nerve. In the control group, only 6% of RGCs survived 8 weeks after injury, whereas treatment with AAV-eC3GFP protected 45% of RGCs from dying, and the widespread distribution by AAV-spC3GFP kept a remarkable 74% of RGCs alive. In addition, robust long-distance axon regeneration was observed at 4 weeks after ONC in both treatment groups compared to controls, with a significant 38- and 24-fold increase in axon regeneration at 1 mm past the crush site for AAV-eC3GFP ($p=0.005$) and AAV-spC3GFP ($p=0.02$), respectively. The neuroprotective studies and three-dimensional analysis of axon regeneration through the transparent optic nerve reveal that this novel C3 gene therapy approach greatly enhances RGC survival and axon regeneration after optic nerve injury. C3 gene therapy could be applied to benefit other neurodegenerative disorders.

Title: Exercise prior to traumatic brain injury increases cerebral blood flow and improves functional outcomes

Authors: *H. V. NGUYEN[1], S. MASHKOURI[1], D. AUM[1], X. KAYA[1], W. QUILLEN[2], N. TAJIRI[1,2], S. ACOSTA[1], J. LEE[1], C. V. BORLONGAN[1];

Abstract: Traumatic brain injury (TBI) affects 1.7 million people in the U.S which results in approximately 52,000 deaths each year. Treatments for TBI are limited to managing symptoms and physical therapies which include exercise. The use of exercise before and after TBI has been shown to reduce functional deficits, but the mechanism of action of exercise remains unclear. TBI causes significant damage to the cerebral vasculature system, hence protecting the vascular system may have beneficial effects. We hypothesize that exercise strengthens and preserves the integrity of the cerebrovasculature as a mechanism of action for ameliorating the TBI-induced functional deficits. To test this hypothesis, we examined the role of exercise prior to TBI in enhancing angiogenesis/ vasculogenesis in cerebrovascular system. Adult Sprague-Dawley rats were exposed to one hour forced running wheel exercise daily for 3 days, then were subjected to moderate control cortical impact (CCI) model of TBI. Laser Doppler readings were recorded at baseline and immediately after TBI. Behavior tests, including neurological exams, elevated body swing test (EBST), and Rotarod test were evaluated at day 1 and day 7 after TBI. Learning and memory function was measured through radial arm water maze (RAWM) at day 7 after TBI for 3 days. The results showed a significant increase in cerebral blood flow of 35% and 105% at baseline and after TBI respectively in exercised animals compared to non-exercised animals (p's <0.05). The neurological scores and Rotarod exams, but not EBST were significantly improved in TBI-exercised group compared to TBI non-exercised group (p's <0.05). Moreover, the TBI-exercised animals performed significantly better in learning and memory assessment compared to TBI non-exercised animals (p's <0.05). Preliminary immunohistochemical analyses revealed no significant differences in CD34 and vWF expression, but trends of increased Ang-1 and Ang-2, while decreased VEGFR2 expression were recognized in the peri-impact area. In conclusion, the findings showed that exercised may improve both motor and cognitive deficits induced by

TBI by enhancing cerebral blood flow, and possibly remodeling of the angiogenic and vasculogenic structures.

Title: Mutant tissue plasminogen activator attenuates white matter injury and improves long term neurological outcomes in a mouse model of traumatic brain injury

Authors: *H. PU[1], X. JIANG[1,2], Y. SHI[1], J. LIU[2], H. MOU[2], S. LUO[2], W. ZHANG[2], W. LI[2], L. ZHANG[1], Y. WANG[2], R. STETLER[1,2], Y. GAO[1,2], X. HU[1,2], J. CHEN[1,2];
[1]Neurol., Univ. of Pittsburgh, Pittsburgh, PA; [2]Neurobio., State Key Lab. of Med. Neurobio. and Inst. of Brain Sci., Shanghai, China

Abstract: Objectives: Traumatic Brain Injury (TBI) is a neurological disorder that leads to long term motor and cognitive dysfunction. Tissue Plasminogen Activator (tPA) has been reported to attenuate motor and cognitive deficits resulting from ischemic injury that shares similar cell death mechanisms with TBI. However, the use of tPA as a neurorestorative agent in clinic may raise concerns, because tPA is also known to cause blood brain barrier damage through its protease actions. In this study, we investigated the long term neuroprotective effects of protease-inactive mutant tPA (tPAm) against TBI.
Methods: TBI was induced in adult male C57BL/6J mice using a controlled cortical impact (CCI) model, and the animals were then randomly assigned to sham, control, 0.9%Nacl and tPAm groups. tPAm was delivered intranasally 1h after CCI and repeated every day for 14 days. For outcome assessments, sensorimotor deficits (rotarod test, cylinder test, foot fault test) were determined at 3-35 days after TBI; cognitive deficits (water maze) was determined at 22-27 days after stroke. The neuronal tracer biotinylated dextran amine (BDA) was injected into the uninjured left motor cortex (M1, 21 day after CCI) to anterogradely label the corticorubral tract and the corticospinal tract. The integrity of myelin sheaths and axons were assessed by expression of myelin basic protein (MBP, Western blots), SMI32 (non-phosphorylated neurofilament), CNPase and NF200. Furthermore, the conductivity of the myelinated nerve

fibers in the corpus callosum surrounding brain regions were evaluated by assessing compound action potentials (CAPs) using electrophysiology.
Results: Our results showed that tPAm attenuated short and long term (up to 35 days after TBI) motor deficits as determined using rotarod test, cylinder and foot fault test. In addition, tPAm significantly improved cognitive performance of TBI mice in the Morris water maze tests at 22-27 days post-TBI. However, tPAm failed to significantly reduce the size of cortical lesion at 35 days after TBI. In contrast to the ineffectiveness in sparing cortical tissue loss, tPAm preserved the integrity of the myelin sheath by preventing the loss of MBP, reducing axonal damage and promoting axonal sprouting. tPAm also promoted functional integrity of white matter, as demonstrated by increased velocity and amplitude of CAP conduction of myelinated nerve fibers in corpus callosum.
Conclusions: In concert, our results suggest that tPAm improves long term neurological outcomes of TBI mice through protection against white matter injury. These observations promote clinical investigations on tPAm as a potential therapeutic agent for TBI patient.

Title: Intrinsic microtubule stabilization by Epothilone B promotes axonal regeneration after spinal root avulsion

Authors: H. LI, *W. WU;
The Univ. Of Hong Kong, Hong Kong SAR, Hong Kong

Abstract: A spinal root avulsion injury disconnects the ventral and dorsal spinal roots with the spinal cord. Due to the limited intrinsic axonal extension speed and the inhibitory environment in the CNS/PNS transitional zone (TZ), the time required for axonal regeneration is prolonged, which consequently leads to muscle atrophy and motor dysfunction. Previously, we demonstrated that blocking the inhibitory chondroitin sulfate proteoglycan (CSPG) receptor protein tyrosine phosphatase-σ (PTP-σ) with a small peptide, namely intracellular sigma peptide (ISP) induced more and faster axonal regrowth and enhanced motor functional restoration. After axotomy, the assembly of a new growth cone and continuous axonal extension requires

reconstruction of cytoskeleton and efficient axonal transportation. Microtubule stabilization has been reported to facilitate axonal regeneration in CNS, probably via favoring polymerization of tubulin dimers.
In the present study, we asked whether intrinsic microtubule stabilization by Epothilone B (EpoB) facilities axons to penetrate the CNS/PNS TZ and eventually promotes motor functional recovery after spinal root avulsion. Adult rats underwent cervical ventral root avulsion followed with re-implantation before being treated with EpoB. Motor functional recovery was remarkably enhanced by the administration of EpoB, reflected by the significantly increased Terzis grooming test score (Mann-Whitney U test, $p<0.05$). This was further confirmed by electromyography. At 6 weeks post surgery, higher electrical responses were recorded in the animals treated by EpoB, while spontaneous potentials, generated by denervated muscle fibers, were reduced. At 4 and 6 weeks post surgery, examination of the regenerated axons in the CNS/PNS TZ leaded to the observation that EpoB facilitated direct axonal elongation, instead of meandering courses found in control animals. In addition, EpoB treatment increased the number of ChAT-positive axons in the TZ. These results provide evidences for that microtubule stabilization by EpoB is able to promote axonal regeneration and functional recovery after spinal root avulsion.

Title: Systemic delivery of a Connexin43 hemichannel blocking mimetic peptide improves functional recovery following spinal cord injury in rats

Authors: *Y. MAO[1], R. TONKIN[2], T. NGUYEN[1], S. O'CARROLL[3], L. NICHOLSON[3], C. GREEN[3], G. MOALEM-TAYLOR[2], C. GORRIE[1];

Abstract: A major challenge in the management of acute spinal cord injury (SCI) is the development of an effective treatment that can be delivered to patients in a timely manner following a traumatic accident. We have shown previously that a mimetic peptide, Peptide5, matching extracellular loop two of the gap junction protein Connexin43 reduces tissue damage and improves functional outcomes when delivered directly to a SCI lesion site. We have now investigated whether systemic (intraperitoneal) delivery results in similar outcomes. Intraperitoneal injections of Peptide5 or control scrambled peptide were given immediately after a mild contusion injury in rats, with injections repeated at 2 and 4 hours post-injury. Rats were then assessed for locomotor recovery and pain hypersensitivity and euthanised at 8 hours (n=8), 2 weeks (n=32) or 6 weeks (n=32) post-injury. The behavioural data of open field and error ladder tests showed an improvement in hindlimb locomotor function in Peptide5 treated rats between 3 and 6 weeks following injury ($p<0.05$). In addition, there was a reduction in at-level mechanical allodynia from 1 week post-injury ($p<0.05$). Immunohistochemistry showed that Peptide5 treatment reduced the expression level of Connexin43 and increased the proportion of phosphorylated Connexin43 protein level at 8 hours after injury compared to the control treatment group ($p<0.05$). At 2 and 6 weeks, lesion size, astrocytic and activated macrophage and microglial responses, as well as neuronal cell loss compared to the controls ($p<0.05$). These results suggest that Peptide5 administered systemically modulates the pathological opening of Connexin43 hemichannels at the lesion site to ameliorate the damage resulting from SCI and has a significant effect on improving functional outcomes.

Title: Matrix metalloproteinase-8 inhibition prevent disruption of Blood-spinal cord barrier and attenuate inflammation in rat model of spinal cord injury

Authors: *H. KUMAR[1], S. SOHN[2], S.-H. LEE[3], I. HAN[2];
[1]CHA Univ., Seongnam-Si, Korea, Republic of; [2]Neurosurg., [3]Biomed. Sci., CHA Univ., Seongnam-si, Korea, Republic of

Abstract: Objective: - After spinal cord injury (SCI), the degradation of tight junction (TJ) proteins causes blood-spinal cord barrier (BSCB) disruption by increasing the BSCB permeability. Neutrophils infiltration is one of the characteristic features of SCI. Matrix Metallopeptidase 8 (MMP-8) or neutrophil collagenase is secreted from neutrophils and mainly acts on ECM macromolecules and is considered as the most important during inflammation, healing, and physiological processes. The role of MMP-8 is not fully established in SCI. Herein, we characterized the role of MMP-8 in the pathology of SCI in rats. **Methods: -** SCI was induced to female Sprague-Dawley rats (200-220 g body weight) after moderate static compression (35 g for 5 min) at T10 spinal cord level. Furthermore, to assess the role of MMP-8 in SCI pathology, we utilized five different approaches, i) (3R)-(+)-[2-(4-Methoxybenzenesulfonyl)-1,2,3,4-tetrahydroisoquinoline-3-hydroxamate] a specific MMP-8 specific inhibitor (MMP-8I) ii) sivelestat, an inhibitor of neutrophil elastase, iii) hydroxycarbamide which bind with zinc ion in MMP-8 complex, iv) zinc chloride which cause oxidative burst and v) N-Acetyl-L-cysteine, to either inhibit MMP-8 activity directly or to modulate neutrophils, a major source of MMP-8. **Results: -** MMP-8 was up-regulated during one and three days after SCI. Moreover, in correlation with increased MMP-8; proinflammatory cytokines (TNF-α, IL-6), microglial markers (Iba-1, Mac-1), heme oxygenase-1 and neutrophil elastase was also increased significantly after SCI. The level of TJ proteins (occludin and zonula occludens-1) were decreased suggesting the disruption of BSCB after SCI. Amusingly, MMP-8 inhibition decreases the proinflammatory cytokines (TNF-α, IL-6) and increases the expression of tight junction proteins after SCI. **Conclusion: -** MMP-8 upregulation during initial phase might be directly linked to inflammatory phase during SCI. Moreover, results suggest that inhibition of MMP-8 prevents disruption of BSCB, provides neuroprotection and can be considered as a therapeutic target in SCI.

Title: Effects of zolmitriptan and NMDA on the firing characteristics of bursting deep dorsal horn neurons following chronic spinal transection

Authors: *T. THAWEERATTANASINP[1], C. J. HECKMAN[2], V. M. TYSSELING[3]; [1]Physiol., Northwestern University, Feinberg Sch. of Medici, Chicago, IL; [2]Physiology, Physical Med. and Rehabilitation, Physical Therapy and Human Movement Sci., [3]Physiology, Physical Therapy and Human Movement Sci., Northwestern University, Feinberg Sch. of Med., Chicago, IL

Abstract: Loss of descending serotonin (5-HT) to the spinal cord contributes to muscle spasms at the chronic stage of spinal cord injury (SCI). At this stage, hyperexcitable motoneurons receive long excitatory postsynaptic potentials (EPSPs) which, in turn, activate their persistent inward currents (PICs) to drive muscle spasms. Deep dorsal horn (DDH) neurons with bursting behavior could be involved in triggering the long EPSPs due to their loss of inhibition in the chronically 5-HT-deprived spinal cord. In the previous study, we found bursting DDH neurons among other types of DDH neurons, i.e. single-spiking and spontaneously tonic-firing neurons, following acute spinal transection at the sacral edge of the lumbar enlargement (i.e. between L6 and S1 spinal segments) in adult mice. Only the bursting DDH neurons showed significant changes in their firing characteristics during administration of the 5-$HT_{1B/1D}$ receptor agonist zolmitriptan and NMDA. Zolmitriptan can suppress the bursting DDH neurons, while NMDA moderately facilitates them. Here in the present study, we further investigate the firing characteristics of the bursting DDH neurons following chronic spinal transection at T10 vertebral level in adult mice during administration of zolmitriptan and NMDA, using the *in vitro* sacral cord preparation and extracellular electrophysiology. Following the 10-week period of transection recovery, zolmitriptan does suppress the bursting DDH neurons by significantly reducing their evoked spikes and burst duration and delaying their first-spike latency. However, NMDA has only a small effect on the bursting DDH neurons by enhancing only their spontaneous firing rate. These results suggest that zolmitriptan may activate 5-$HT_{1B/1D}$ receptors on the bursting DDH neurons to suppress muscle spasms following chronic SCI, as this drug has been previously shown to reduce muscle spasms without affecting the intrinsic properties of spinal motoneurons. On the other hand, activation of NMDA receptors may only raise the spontaneous activity level of the bursting DDH neurons with no significant contribution to the mechanisms of muscle spasms. A future *in vivo* study in decerebrate animals is necessary to see if the bursting DDH neurons exist in the intact spinal cord.

Title: Notch signal inhibition as a promising new therapeutic approach to human ips cell derived transplantation therapy for spinal cord injury

Authors: *T. OKUBO, A. IWANAMI, J. KOHYAMA, N. NAGOSHI, G. ITAKURA, M. MATSUMOTO, M. NAKAMURA, H. OKANO;
Keio Univ., Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: [Introduction] We previously reported that transplantation of certain neural stem/progenitor cells from human iPS cells (hiPSC-NS/PCs) into the injured spinal cord resulted in tumor-like overgrowth and subsequent deterioration of motor function. Remnant immature NS/PCs must be removed or induced into more mature cell types, which may avoid tumor-like overgrowth following transplantation. Meanwhile, Notch signaling controls the neuronal differentiation of NS/PCs, and inhibition of this signaling with gamma-secretase inhibitor (GSI) induces NS/PCs to differentiate into a more mature state with limited proliferation. The purpose of the present study was to elucidate the effects of GSI on tumorigenic hiPSC-NS/PCs.
[Method] hiPSC-NS/PCs, a potentially tumor-like overgrowth cell line, were cultured with GSI. Global analyses of the gene expression profiles were performed by DNA microarray and RT-PCRs. Next, we induced contusive spinal cord injury (SCI) in mice and transplanted hiPSC-NS/PCs with or without GSI pretreatment nine days after SCI. The growth/survival and histological analyses of transplanted cells were examined with bioluminescence imaging (BLI) and immunohistochemistry. Behavioral analyses of motor function were also performed by BMS score, rota-rod test and DigiGait system.
[Result] Compared to the non-treatment (control) group, after following treatment of hiPSC-NS/PCs with GSI (GSI+ group), the gene expression profiles using DNA microarray and RT-PCR showed decreases in pluripotency and self-renewal marker-related genes. After hiPSC-NS/PCs transplantation, the photon counts of transplanted cells increased more than 10-fold from their initial values by BLI, and then showed deteriorated motor function accompanied by tumor-like overgrowth in the control group. However, in the GSI+ group, the photon counts of transplanted cells increased more slowly, but reached a plateau, then showed maintained functional recovery and reduced the tumor-like overgrowth through inhibition of cell proliferation 89 days after transplantation. In the GSI+ group, the proportion of Hu^+ neuron increased significantly, whereas the proportion of $Ki67^+$ and $Nestin^+$ cells significantly decreased compared to the control group.
[Conclusion] We confirm that GSI pretreatment of hiPSC-NS/PCs reduce the proportion of

dividing cells *in vitro*, and prevent tumor-like overgrowth of transplanted cells by inhibiting cell proliferation, resulting in safe and long-lasting functional recovery *in vivo*. Pretreatment of hiPSC-NS/PCs with GSI prior to transplantation can improve their in clinical setting.

Yang-Ming Univ., Taipei, Taiwan; [6]Dept. of Nursing, Central Taiwan Univ. of Sci. and Technol., Taichung, Taiwan; [7]Dept. of Applied Chem., Chaoyang Univ. of Technol., Taichung, Taiwan

Abstract: Spinal cord injury (SCI) often results in neuronal death and demyelination. During the healing process, glial scar formed at the lesion site is one of the major barriers to axonal regeneration. Treatment of chondroitinase ABC (ChABC) has been reported to remove CSPGs glycosaminoglycan (GAG) side chains and enhance axonal regeneration. Cell transplantation therapies for spinal cord injury contributes to restoration of neuronal function by modifying the pathophysiological process after spinal cord injury. We have demonstrated that intrathecal delivery of low-dose ChABC in the acute stage of SCI promotes axonal regrowth and functional recovery. Furthermore, ChABC administrations combining olfactory mucosa progenitor cells (OMPCs) intraspinal transplantation showed better functional recovery and enhance the

consistency of stepping in acute stage of SCI rats. However, in the sub-acute or chronic SCI patients, the dense glial scar has formed and cannot be surgery or digested by intrathecal delivery of ChABC at the injury site. Hence, we have been demonstrated intraparenchymal delivery of high dose ChABC in the sub-acute stage of SCI animal models decreased the level of CSPGs, lesion extension and area, enhanced the axonal outgrowth and improved partial functional recovery. However, previous studies indicated that single ChABC treatment may not be sufficient to enhance neuronal plasticity and the inadequate survival time and rate of OMPCs in the lesion site might limit the regenerative ability. In this study, we will investigate the effects of high dose ChABC delivery combined with repeated transplantation of OMPCs in the acute and sub-acute stage of SCI in the complete spinal cord transection model. Our results showed that there was no functional recovery following a single OMPCs transplantation. Nevertheless, repeated OMPCs transplantation significantly improved functional recovery and enhanced axons outgrowth across the lesion site. In addition, Fluorogold (FG)-positive cells were clearly detected in the red nucleus of midbrain indicated that these axons grew across the lesion site and reached the distal stump of injured spinal cord. Moreover, the degree of fibrotic scarring and macrophages infiltration also decreased after repeated OMPCs transplantation. Furthermore, we evaluated the effects of high dose ChABC combined with repeated OMPCs transplantation in the sub-acute SCI. Although the functional recovery significantly improved via either treatment, but unfortunately no synergistic therapeutic effect can be detected. This study may provide valuable information to form a better therapeutic strategy than ever for SCI in the future.

Title: Mitochondrial biogenesis as a novel therapeutic strategy for spinal cord injury

Authors: *N. E. SCHOLPA, A. NARANG, W. WANG, D. CORUM, S. TOMLINSON, R. G. SCHNELLMANN;
MUSC, Charleston, SC

Abstract: Spinal cord injury (SCI) is characterized by mitochondrial dysfunction and loss of ATP, ultimately leading to excitotoxicity, calcium overload and oxidative stress, and further exacerbating injury in a self-propagating cycle. Therefore, therapeutics targeting reestablishment of mitochondrial function through increased mitochondrial biogenesis (MB) following SCI could potentially alleviate multiple aspects of injury progression. This study examined the effect of formoterol, an FDA-approved β_2-adrenergic receptor agonist, on MB in the spinal cord and functional recovery following SCI. Female C57BL/6 mice were subject to moderate SCI using an 80 Kdyn force-controlled pneumatic impactor-induced contusion model. Formoterol (i.p.) was administered one hour post-SCI and then daily until euthanasia. Treatment with formoterol after injury induced MB in the spinal cord, as evidenced by increased mitochondrial DNA content, and increased expression of PGC-1α, the master regulator of MB, and various mitochondrial- and nuclear-DNA encoded mitochondrial genes. Three days post-SCI, the spinal cord of formoterol-treated mice exhibited less histological damage than that of vehicle-treated mice, namely decreased loss of white matter and structural preservation of the central canal and anterior median fissure. The Basso-Mouse Scale (BMS) was used to assess locomotor capability. A BMS score of 0, observed 24 h following SCI, indicates no movement of the hind limbs, while a score of 9 indicates normal function (sham controls). Seven days post-SCI, mice treated with formoterol demonstrated improved motor function compared to vehicle-treated mice (BMS = 1 vs. 0.3). Fifteen days after injury, formoterol-treated mice exhibited further improvement in motor function (BMS = 4.5 vs. 2), approximately 50% overall functional recovery. Taken together, we suggest formoterol and MB as a therapeutic avenue for the treatment of SCI.

Title: Targeting the thrombin receptor to modulate STAT3-driven inflammatory astrogliosis and improve recovery after spinal cord injury

Authors: *H. YOON[1], M. RODULOVIC[2], I. A. SCARISBRICK[1];
[1]Physical Med. & Rehabilitation, Rehabil. Med. Res. Ctr., [2]Neurobio. of Dis., Mayo Clin., Rochester, MN

Abstract: A significant number of neurological conditions involve deregulation of thrombin activity including hemorrhagic, infectious and traumatic injuries, however little is known regarding mechanisms of action or the utility of therapeutic modulation. Thrombin is well known for its ability to cleave soluble fibrinogen releasing fibrin monomers that support hemostasis. In addition, thrombin is a high affinity agonist for Protease Activated Receptor 1 (PAR1), also referred to as the thrombin receptor. PAR1 is a seven transmembrane G-protein-coupled receptor that is activated by extracellular N-terminal cleavage. Here we critically evaluated the role of PAR1 as a regulator of the spinal cord injury microenvironment by examining cellular, molecular and neurobehavioral outcomes after experimental contusion-compression spinal cord injury (SCI) in wild type and PAR1 knockout mice. Mice with PAR1 loss-of-function displayed improved locomotor recovery after SCI and reduced signatures of inflammation and astrogliosis, including expression of glial fibrillary acidic protein, vimentin, and STAT3 signaling. SCI-associated elevations in pro-inflammatory cytokines such as IL-1β and IL-6 were also reduced in PAR1 knockout mice and co-ordinate improvements in tissue sparing were observed. Moreover, mice with PAR1 loss-of-function showed increased preservation of NeuN-positive ventral horn neurons as well as PKCγ-positive corticospinal axons. Since perilesional astrocytes were positive for both thrombin and PAR1 we investigated the possible significance of this signaling system in primary astrocyte cultures. Introduction of thrombin into astrocyte cultures resulted in increases in the production and secretion of IL-6 and activation of STAT3 signaling in a PAR1-dependent manner. In turn, IL-6-stimulated astrocytes increased expression of both PAR1 and thrombin pointing to a model in which PAR1 activation contributes to increased astrogliosis by feedforward- and feedback-signaling dynamics. These results suggest that PAR1 sits at the interface of the proteolytic microenvironment and cellular responses that contribute to astrogliosis, pro-inflammatory events and neurodegeneration accompanying traumatic SCI. Given the significant improvements in neurobehavioral outcomes observed in mice with PAR1 loss-of-function, these studies suggest that PAR1 may serve as a useful target to modulate astrogliosis, reduce neural injury and promote an environment favorable to repair and recovery of function after spinal cord trauma.

Title: Trimethylene carbonate-caprolactone conduit with poly-p-dioxanone microfilaments to promote regeneration after chronic spinal cord injury

Authors: L. N. NOVIKOVA[1], P. J. KINGHAM[1], A. ULLRICH[2], S. OBERHOFFNER[2], M. RENARDY[3], M. DOSER[2], E. MÜLLER[3], M. WIBERG[1], *L. N. NOVIKOV[1];

Abstract: The majority of patients with chronic spinal cord injury (SCI) have a cystic cavity surrounded by a thick fibrotic and astrocytic scar and complete loss of function below the trauma site. In these patients and in contrast to acute SCI, transplantation of bridging materials to re-connect divided spinal cord segments can be performed without interfering with spontaneous recovery. In this study we evaluated the effects of biodegradable conduits with guidance microfilaments and Schwann cells on axonal regeneration after chronic spinal cord injury in adult rats. The conduits, with an inner diameter of 1100-1200 μm and a wall thickness of 100-200 μm, were fabricated from trimethylene carbonate and ε-caprolactone (TCC) using a wet phase inversion technique. The conduit wall consisted of an inner and an outer "skin" layer with nanoporous structure and small cavities to reduce adverse macrophage infiltration. The microfilaments with longitudinal grooves were produced from poly-p-dioxanone (PDO). Cultured Schwann cells were suspended in diluted fibrin matrix and added to the conduit immediately before transplantation. In vitro studies demonstrated that Schwann cells and adult rat dorsal root ganglia neurons grew on the PDO filaments and that the materials did not induce activation of cultured astrocytes. For in vivo experiments, a spinal cord hemisection was performed at the C3-C4 cervical level. At 2 and 5 months after surgery, the injury site was exposed, the scar tissue was resected and a 2 mm long cavity was created on one side of the cord. The conduits were transplanted into the cavity and animals were allowed to survive for an additional 2 months. Animals with conduits transplanted into acute SCI served as baseline controls. Transplantation of TCC-PDO conduit alone into acute SCI supported ingrowth of numerous sensory CGRP axons and motor 5HT axons, and migration of host Schwann cells and macrophages. Regenerating axons grew along the PDO filaments but were separated from the material surface by migrating cells. When conduits were transplanted into animals with chronic SCI, only sensory CGRP axons were found in the conduit and regenerating fibres were often associated with host Schwann cells. Addition of cultured adult Schwann cells to the conduit stimulated ingrowth of both the sensory CGRP axons and motor 5HT axons into the conduit. Both host Schwann cells and GFP-labelled transplanted Schwann cells were found in close association with regenerating fibres. The conduit had no effect on the reaction of astrocytes and microglia/macrophages in the host tissue. These results suggest that a TCC-PDO conduit with Schwann cells can promote axonal regeneration after chronic SCI.

Title: BET proteins modulate the inflammatory response after spinal cord injury

Authors: ***M. D. TROJANOWSKY**[1], N. G. AYAD[2], J. K. LEE[1];
[1]Neurosurg., [2]Psychiatry and Behavioral Sci., Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Inflammation after spinal cord injury (SCI) is a major source of damage that expands the primary lesion site. Anti-inflammatory therapeutics have shown promise in pre-clinical studies, suggesting that inflammation is an important therapeutic target in acute SCI. Bromodomain and extraterminal domain-containing proteins (BETs) are epigenetic adaptor proteins important for inflammatory transcription. Inhibition of BETs decreases expression of pro-inflammatory signaling molecules *in vitro* and attenuates inflammation in multiple animal models of inflammatory disease. Because BETs are important mediators of inflammation in many diverse mammalian tissues, I hypothesize that BET proteins modulate the inflammatory response after SCI. Using *in vitro* assays, I have demonstrated that BET inhibition attenuates inflammatory signaling by both mouse primary astrocytes and macrophages. Furthermore, BET inhibition in experimental SCI results in decreased expression of pro-inflammatory cytokines, decreased cyclin expression, and mild improvements in locomotor recovery. These results suggest a role for BETs in promoting damaging inflammation after SCI. The study of BETs after SCI is especially timely given the recent development of selective BET bromodomain inhibitors and their use in clinical trials. These studies will contribute to the understanding of epigenetic modulation of inflammation and of BETs as therapeutic targets after SCI.

Title: Gene delivery from injectable, hyaluronic acid-based hydrogels with *In situ*-forming macropores for spinal cord regeneration

Authors: *A. A. EHSANIPOUR, T. ABOUFADEL, P. COX, C. WALTHERS, W. XIAO, S. K. SEIDLITS;
Bioengineering, UCLA, Los Angeles, CA

Abstract: Spinal cord injury (SCI) is the second largest contributor to paralysis worldwide and inflicts up to 80 million people per year. Regeneration is inhibited by the secondary injury cascade, characterized by death or injury of neural and glial cells and the formation of glial scar tissue which may act as a barrier to infiltrating axons. Tissue engineering approaches including delivery of hydrogels, gene vectors, cells, or signals to the injured spinal cord have been investigated to mitigate glial scar formation and loss of function after SCI while providing scaffolds capable of integrating with neural tissue. Injectable treatments are ideal candidates as they prevent excision of potentially spared tissue or overly invasive procedures, however previous injectable therapies have had limited tissue integration, cell infiltration, and transfection by lentivirus encoding for regenerative transgenes. We attempt to improve these processes by incorporating macroporosity into an injectable SCI therapy.
Our unique injectable, macroporous hydrogel platform is based on hyaluronic acid (HA), a common matrix component in the central nervous system (CNS), which may reduce the immune response and glial scar formation after SCI, and fibrin, which can support ingrowth of cells and axons after SCI. By varying polymer concentration, these hydrogels can be tuned to mimic the mechanical properties of brain and spinal cord tissues, ranging from 100Pa to 10kPa. In a preliminary trial, soft HA hydrogels (1kPa) carrying neural progenitor cells (NPCs) were able to successfully form *in situ* in the mouse brain. Treated mice (HA+NPC) survived comparably to

mice treated with NPCs only and showed no adverse reactions to HA gels.
To achieve macroporosity, we encapsulated sacrificial, fibrin microparticles (FMP), which, after degradation within the bulk HA hydrogel, produce macroporous systems that improve nutrient transport, cell infiltration, and viral transduction. Hydrogels with increasing FMP concentrations (0, 33, 50, and 75% of scaffold volume) were delivered to the mammary fat pad of female C57/BL mice. The incorporation of FMPs increased cell infiltration into scaffolds and improved transduction efficiency by firefly-luciferase encoding lentiviral vectors up to 25-fold. This strategy will be translated to an SCI model to deliver lentivirus encoding for regenerative growth factors to evaluate their potential to promote functional recovery. This approach presents an injectable, macroporous, hydrogel platform which is compatible with delivery to the CNS, capable of improving cell infiltration and viral transduction, and holds potential to support recovery after SCI.

Title: Flexible fibers for optoelectronic probing of spinal cord circuits

Authors: ***C. LU**, S. PARK, U. FRORIEP, A. DERRY, J. SELVIDGE, Y. FINK, P. ANIKEEVA;
DMSE, MIT, Cambridge, MA

Abstract: While the majority of the neural engineering efforts of the past decade have focused on interfaces with the brain, fundamental understanding of the spinal cord neural dynamics remains limited by the tools capable of recording and modulation in this organ. Fueled by advances in optogenetics, optoelectronic probes have recently enabled cell-specific neural stimulation compatible with concomitant recording of neural activity. The mechanics of the spinal cord, however, remain difficult to match with hard materials traditionally used in optoelectronics.
Here we address the elastic modulus mismatch by designing flexible multifunctional neural probes capable of conforming to the spinal cord geometry and mechanical properties, while

providing optical stimulation and neural recording.
We mimicked the fibrous and flexible morphology of the spinal cord and fabricated all-polymer fibers that consist of a polycarbonate (PC) and cyclic olefin copolymer (COC) waveguide and carbon-polyethylene (CPE) composite electrodes. The conductive polymer composite electrodes exhibited tip impedance 1-3 MΩ suitable to record local field potentials. To further reduce the impedance, we have fabricated device by dip coating PC/COC waveguides (~100 μm in diameter) with a 1 μm thick layer silver nanowires (AgNWs). The devices were then encapsulated with a layer of poly(dimethylsiloxane) (PDMS) to protect the AgNW mesh from degradation, while maintaining high flexibility. Exposed AgNW mesh ring-electrodes possessed low impedance (~200 kOhm) and were capable of recording isolated action potentials in the mouse spinal cord with high signal-to-noise ratio (SNR 7±1) and low noise level (10 ±3 μV). We also applied the dip coating approach to fibers made of cyclic olefin copolymer elastomers (COCE). COCE is a rubbery material which allows COCE/AgNW fiber electrodes to maintain their conductivity at 100 % extension strain, and could be deformed repeatedly without hysteresis at 20 % strain.
The mechanical properties of the integrated fiber probes matched those of biological tissues, which is difficult to achieve with traditional metallic and semiconducting electrodes. We demonstrated the utility our devices for recording and optical stimulation in the spinal cord of transgenic mice expressing the light sensitive protein channelrhodopsin 2 (ChR2). Furthermore, we found that optical stimulation of the spinal cord with the polymer fiber probes induces on-demand limb movements. Finally, we illustrated that the modest dimensions and high flexibility of our devices permit chronic implantation into mouse spinal cords with minimal damage to the neural tissue.

Title: Changes in the afterhyperpolarizations of rat hindlimb motoneurons following incomplete spinal cord injury and exercise

Authors: *V. V. TURKIN, D. O'NEILL, T. M. HAMM;
Barrow Neurolog Inst., Phoenix, AZ

Abstract: The afterhyperpolarization (AHP) is a critical determinant of motoneuron (MN) discharge properties. We compared the amplitudes and durations of hindlimb MN AHPs in normal rats and rats with incomplete spinal cord injuries (iSCI) to determine whether such injuries alter the distribution of AHP amplitudes and durations. Rats received sham operations (sham group) or moderate contusion injuries (170 kdynes) at T9. Injured animals were randomly assigned to standard caging (SCI-standard group) or cages with exercise wheels (SCI-exercise group) 1 week after injury to determine whether exercise affected AHP properties following iSCI. AHPs were recorded primarily in tibial MNs with ketamine-xylazine anesthesia in terminal experiments 8-10 weeks following sham surgery or injury. AHP amplitudes varied between groups. Mean AHP amplitudes were greater in SCI-exercise than in SCI-standard animals. Half-decay times did not differ between groups. Amplitude and half-decay time were both correlated with input resistance (R_N) in all three groups. The largest AHP amplitudes occurred in SCI-exercise rats throughout the range of R_N, particularly at small and intermediate R_N values, indicating that AHP amplitudes increased with exercise following iSCI in larger MNs. In all groups, AHP amplitude was correlated with half-decay time, but a subset of MNs had small AHP amplitudes (< 1.5 mV) and long half-decay times (> 15 msec). We examined MNs with AHP half-decay times greater than 15 msec, associated with the presence of SK3 channels (Deardorff et al., 2013), and compared those with small (< 1.5 mV) and large (> 1.5 mV) AHP amplitudes. MNs having small AHP amplitudes had smaller input resistance values (2.2 vs. 3.5 MOhms) and larger rheobase currents (8.2 vs. 3.9nA) than those with large AHP amplitudes. MNs from sham, SCI-standard and SCI-exercise rats were not distributed evenly between small- and large-AHP amplitude subsets. SCI-standard rats had more MNs than expected in the small-amplitude subset, while sham and SCI-exercise rats had more than expected in the large-amplitude subset. In the large-amplitude subset, cells are found at all R_N values in the sham and SCI-exercise groups, but only at larger R_N values for SCI-standard rats. In the small-amplitude subset, only small R_N values are found for sham animals and most SCI-exercise rats. R_N values for SCI-standard in this subset are more broadly distributed but smaller than the values in the large-amplitude subset. Thus, long-duration, small-amplitude AHPs occur in some large MNs. The occurrence and distribution of these atypical AHPs change following iSCI but are largely restored by exercise.

Title: Effects of iTBS on motor evoked potentials and H-reflexes in chronic incomplete spinal cord injury: a pilot study

Authors: H. J. FASSETT, C. V. TURCO, T. LULIC, J. EL SAYES, *A. J. NELSON;
Dept Kinesiol, McMaster Univ., Hamilton, ON, Canada

Abstract: Objectives: The use of intermittent theta burst transcranial magnetic stimulation (TBS) induces short-term changes in the excitability of human primary motor cortex (M1). In a placebo-controlled pilot study, we examined the effects of iTBS on motor evoked potentials (MEPs) recorded from the flexor carpi radialis (FCR) muscle in individuals with chronic cervical spinal cord injury (SCI). This pilot study aimed to examine whether the effects of iTBS over either M1 or adjacent primary somatosensory cortex (SI) influences corticospinal excitability in SCI. **Methods**: Participants (N=5) with incomplete cervical spinal cord injury (ASIA B, C or D) with an injury occurring > 1 year were recruited. ITBS involved 600 biphasic pulses at 30 Hz using a stimulator intensity of 80% AMT over the hotspot for FCR. All participants attended 3 separate sessions wherein one of the following was delivered in a pseudo-randomized order 1) iTBS over M1 2) iTBS over SI (~2cm posterior to the FCR hotspot) and 3) sham iTBS over M1. For all sessions, iTBS was delivered to the hemisphere contralateral to the least affected FCR in each participant. Dependent measures were acquired before and immediately following iTBS and included recruitment curves for MEPs and H-reflexes. MEP recruitment curves were recorded from FCR ranging from 10 - 160% RMT. H-reflexes recruitment curves were elicited using a constant current stimulator in steps of 0.5 mA until no further increase was observed. **Results:** There were no significant changes in the amplitude or slope of the recruitment curves for MEPs or H-reflexes for any of the interventions. **Discussion:** In this pilot study demonstrated that iTBS delivered to either M1 or SI do not result in short-term changes in corticospinal excitability in the chronic SCI population studied.

Title: Botulinum toxin injection in the triceps surae muscle causes plastic adaptations in rat spinal cord circuitries.

Authors: *J. B. NIELSEN[1], J. PINGEL[2], N. D. CHRISTIANSEN[2], D. B. JENSEN[2], H. HULTBORN[2];
[2]Dept. of Neurosci. and Pharmacol., [1]Univ. Copenhagen, Kobenhavn N, Denmark

Abstract: Botulinum toxin (Btx) is used in children with cerebral palsy and other neurological patients to diminish spasticity and reduce the risk of development of contractures. Btx prevents release of acethylcholine at the motor end plate and thereby induces muscle paresis. We hypothesized that this may lead to adaptive plastic changes in spinal cord motoneurones and interneuronal circuitries. We consequently investigated changes in spinal cord circuitries 1-8 weeks following Btx injection in the triceps surae muscle in rats.
A total of 58 rats were injected with Botulinum toxin (Btx; 6IU) in the left triceps surae muscle. This resulted in a decrease of muscle weight and maximal muscle force to 20 % of the intact non-injected side, lasting at least 8 weeks. Two weeks after Btx injection, stretch of the injected triceps surae muscle elicited reflex activity with larger amplitude relative to the maximal muscle force than on the non-injected side, and was elicited by lower velocity and amplitude of stretch. Increased central gain of the monosynaptic stretch reflex pathway was confirmed by the demonstration of larger monosynaptic reflexes recorded from the left (injected) than the right (non-injected) L5 ventral root following stimulation of the respective dorsal roots two weeks after Btx injection. Preliminary data suggest that a similar increase in response at the Btx-injected side to stimulation of descending motor tracts may occur, suggesting that increased excitability of spinal motoneurones may at least partly explain the increased reflexes.
The data demonstrate that muscle paresis induced by Btx injection is accompanied by plastic adaptations in the central stretch reflex circuitry, which counteract the intended antispastic effect of Btx.

Title: Functional neurophysiological assessment of volitional motor control following pediatric spinal cord injury

Authors: *D. A. ATKINSON[1,3], S. J. HARKEMA[2,3], S. A. TRIMBLE[3,4], L. X. MENDEZ[3,4,2], A. L. BEHRMAN[2,3,4];
[1]Dept. of Anatom. Sci. and Neurobio., [2]Dept. of Neurosurg., Univ. of Louisville, Louisville, KY; [3]Univ. of Louisville, Kentucky Spinal Cord Injury Res. Ctr., Louisville, KY; [4]Kosair Charities Ctr. for Pediatric Neurorecovery, Louisville, KY

Abstract: Measurement of spinal cord injury (SCI) severity and residual motor capacity in young children presents unique difficulties; the International Society for Neurological Classification of Spinal Cord Injury's American Spinal Injury Association (ASIA) Impairment Scale is not valid for children younger than six years old (Mulcahey et al. , 2011). We adapted the functional neurophysiological assessment (Li et al. , 2012) a standardized, quantitative assessment of volitional motor function, for use in children with SCI. The assessment consists of repeated attempts of standardized single- and multi-joint movements as well as passive cycling and reflex testing, while recording electromyographic activity from 11 trunk and leg muscles bilaterally. We performed this assessment on 13 typically developing children between the ages of 3 and 9 (6.64 ± 2.48) years old, and in 12 children with SCI, ages 2-10 (6.65 ± 2.52) years old. All SCI participants were injured between birth and 6 years of age (2.86 ± 2.11), and the average time since injury was 3.79 ± 2.68 years. All non-injured children were able to perform isolated movement attempts at the knee and ankle. In spinal cord injured children, isolated single joint movement in the knee was observed in one participant, although bilateral knee extensor activity was recorded. We did not observe isolated ankle movement in any spinal cord injured children. Multi-joint and/or bilateral muscle activation was observed during isolated movement attempts in 5 children, while the remaining 7 did not exhibit any muscle activation during lower extremity movement trials. Of those who did not demonstrate the ability to generate muscle activity during lower extremity movement trials, 3 exhibited delayed onset, bilateral activity in all muscles during trunk flexion trials. This pattern of activation has been described in adults (Dimitrijevic et al. , 1984), and is thought to indicate sub-clinical descending influence of supraspinal structures on spinal motor circuitry below the level of lesion. The pediatric functional neurophysiological assessment allows objective measurement and increased sensitivity in the identification and characterization of volitional movement capacity and subclinical descending motor excitation in children as young as 2 years old. Combined with electromyographic assessment of activation during tasks involving the integration of descending and peripheral inputs (such as standing and stepping), this assessment can provide a more comprehensive and objective characterization of motor capacity in children with SCI than currently available measurement tools.

Title: The modulation of disynaptic reciprocal inhibition in people with spinal cord injury

Authors: *Y.-J. CHANG[1], J.-M. CHANG[1], M.-P. LIN[1], M.-D. YU[1], M.-J. HSU[2,3], A. M. WONG[1,4];
[1]Chang Gung Univ., Tao-Yuan, Taiwan; [2]Kaohsiung Med. Univ., Kaohsiung, Taiwan; [3]Kaohsiung Med. Univ. Hosp., Kaohsiung, Taiwan; [4]Chang Gung Mem. Hosp., Taoyuan, Taiwan

Abstract: Spinal circuitry was found to adapt after spinal cord injury. Loss of post activation depression and reciprocal inhibition was related to the spasticity after spinal cord injury (SCI). Studies showed that antagonist muscle contractions could increase the strength of disynaptic reciprocal inhibition in healthy people. The purpose was to evaluate if the electrical stimulation (ES) elicited reciprocal contractions of agonist and antagonist musclescould modulate the disynaptic inhibition in indivicuals with SCI. Five individuals with acute SCI and seven individuals with chronic SCI were recruited. The electrical stimulation were applied on tibia nerve and common peroneal nerve to elicit H reflex and conditioning stimulation. Disynaptic inhibition strength was quantified by the normalized difference between the control and tested H reflexes. The tests were performed before and after 30 minutes of ES elicited reciprocal contractions of dorsiflexor and plantarflexor. The results showed that the disynaptic inhibition was absent in chronic SCI subjects. The disynaptic inhibition strength increased after 30 minutes of contraction in acute SCI but not in chronic SCI subjects. This study concluded that the short term reciprocal types of muscle contraction could modulate spinal circuitry in individuals with acute SCI whose spinal circuitry was not fully adapted. Further studies are needed for individuals whose spinal circuitry has been already adapted.

Title: Viral vector mediated neutralization of NG2 proteoglycan (AAV-NG2Ab) combined with delivery of neurotrophin NT-3 (AAV-NT3) improves transmission, locomotion and urinary tract function after incomplete spinal cord injury in adult rats.

Authors: *V. L. ARVANIAN[1,2], H. PETROSYAN[2], V. ALESSI[2], N. PHAGU[2], J. LEVINE[2], W. F. I. COLLINS[2];
[1]VA Med. Ctr., Northport, NY; [2]Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: We recently demonstrated beneficial effects of neutralization of the NG2 proteoglycan using monoclonal antibodies delivered intrathecally via osmotic mini-pumps after spinal cord injury (SCI). Currently we have developed a novel gene therapy tool for prolonged and clinically-relevant delivery of a recombinant single chain variable fragment (scFv) anti-NG2 antibody: AAV-rh.10 serotype expressing scFv-NG2. Here we examined effects of AAV-NG2Ab alone or in combination with AAV-NT3 in adult rats with thoracic T10 contusion injuries. Immediately after injury, animals received intraspinal injections of either control AAV-GFP, AAV-NG2Ab, AAV-NT3 or AAV-NG2Ab plus AAV-NT3. Two sets of experiments were performed. 1st: Locomotor function was assessed using a battery of behavioral tests (BBB, Ladder, Narrowing beam and Catwalk) for 9 weeks post-injury followed by electrophysiological evaluation of synaptic transmission through spared axons spanning injury epicenter to individual lumbar motoneurons and to hindlimb muscles. 2nd: Lower urinary tract (LUT) function was assessed during the survival period using metabolic chambers to collect and quantify overnight urine production and after 6 weeks during terminal cystometry electrophysiology recordings with simultaneous acquisition of external urethral sphincter (EUS) EMG activity and bladder pressure. Analysis included bladder pressure threshold for and peak bladder pressure during contractions, inter-micturition interval, void volume, residual volume, duration of EUS bursting, and amplitude and duration of EUS activity. BDA tracing was used in both sets of experiments to evaluate any effects of treatment on anatomical plasticity. We found that AAV-NT3 treatment group did not show significant improvements in the first set of experiments and thus was not used in the second set. Both the AAV-NG2Ab and AAV-NG2Ab combined with AAV-NT3

treatment groups demonstrated significant improvements in all behavioral tests compared to other SCI groups. In-vivo intracellular recordings revealed an improved transmission through axons spanning the injury epicenter. Best improvements of both transmission and motor function were seen in animals that received treatment with AAV-NG2Ab combined with AAV-NT3. This combinational treatment improved LUT function as well. Improvements were evident in increased number of voids, smaller mass per void and decreased time between voids. Consistent with these results, cystometry electrophysiology demonstrated the following improvements: reduced number of non-voiding contractions, smaller residual volume, and apparent EUS bursting activity during contractions

Abstract: Spinal cord injury (SCI) is a devastating condition resulting in permanent and irreversible deficits. Despite neurons try to regenerate, their attempts fail due to several dysfunctions. Several studies have already revealed a bidirectional alteration of microRNA following SCI, with some described to be detrimental and some protective. However there is still little evidence of specific axon regrowth microRNA clusters. The challenging goal of this study is focused on evaluating microRNA expression changes in sensorimotor cortex and more specifically in corticospinal motoneurons (CSMN), whose axons are severed by SCI. We intend to select and manipulate microRNAs involved in the regeneration process in order to restore their physiological functions and promote axon regrowth. Complete transection of the spinal cord was induced at the C7 level in 15 postnatal C57BL/6j male mice at 12h after injury (3 WT vs 3 SCI)

and in adult mice at 12h, 3 days and 7 days post injury (3 WT vs 3 SCI per each group). The sensorimotor cortex was dissected, collected for RNA extraction and sequenced for a microRNA profile to evaluate expression changes among the groups. Another set of animals was employed to analyze cortical astrogliosis (GFAP), microglia activation (IBA1) and degenerating neurons (Fluoro-Jade staining). MicroRNAs mainly implicated in neuroplasticity, axon regrowth (miR-19b-3p, miR-381-3p and miR7b-3p) and inflammation (miR-127-5p) resulted dysregulated in the injured groups. The inflammatory microRNA expression seems to follow the glial cells reaction evolving from very low level (12h) to a peak (3 days) and a final decrease at 7 days post injury. Based on these preliminary results, in order to achieve the specific CSMN microRNA profiling, motoneurons will be retrogradely labeled by fluorescent beads and isolated by FACS (Fluorescence-activated cell sorting) or laser capture microdissection. These data will allow us to better select only those small RNAs implicated in the regenerative process and use them as a powerful tool to promote axon regrowth.

Title: Transcranial magnetic stimulation induces somatosensory plasticity and improves behavioral outcome following spinal cord injury in a rat model

Authors: ***V. S. KRISHNAN**[1,2], J. BANERJEE[1,2], P. CELNIK[3], V. BELEGU[1], G. PELLED[1,2]; [1]Kennedy Krieger Inst., Baltimore, MD; [2]Radiology, [3]Dept. of Physical Med. and Rehabil., Johns Hopkins Univ., Baltimore, MD

Abstract: Spinal cord injury (SCI) is the leading cause of disability causing partial or complete damage to sensory and motor pathways, thereby altering neural circuits. Evidence suggests that within minutes after SCI, decreases in spontaneous neuronal activity are observed in cortical areas that correspond to the injured as well as to the non-injured limbs. Moreover, these decreases were correlated with poor recovery. Thus, we hypothesized that an intervention to

attenuate the decreases in neuronal activity applied immediately post-SCI would accelerate neurorehabilitation. Transcranial magnetic stimulation (TMS) is a non-invasive method to induce neuronal excitation and plasticity beyond the stimulation period. We have recently demonstrated that following traumatic brain injury in rats TMS has rescued neuronal activity and led to improvement in behavioral tests (Lu et al., *Scientific Reports*, 2015). Therefore, we have determined if TMS can improve functional outcome post-SCI. SCI was induced at segment T7 in adult rats. We tested sensory and motor functions in three groups: SCI rats that received TMS 10 min after the procedure (immediate-TMS); SCI rats that received TMS starting two weeks after the procedure (delayed-TMS), and SCI rats that received sham TMS (no-TMS). High-frequency (20 Hz) TMS was applied to the sensorimotor cortex via a custom built rodent coil, and was delivered for 10 min, there times a week, for a total of six weeks. Sensory responses to hind limb stimulation were assessed using functional MRI (fMRI) carried out with an 11.7-T scanner which permitted high spatial and temporal resolution. The extent of the fMRI responses to hind limb tactile stimulation were calculated in the corresponding primary somatosensory areas. Preliminary results show that the immediate-TMS group demonstrated the greatest sensory responses with 50.89 ± 8.24 and 51.22 ± 4.92 activated pixels over the right (RHL) and left hind limb (LHL), respectively; the delayed-TMS group showed moderate sensory responses with 35± 2.61 and 32.8 ± 4.04 activated pixels in RHL and LHL; finally, the no-TMS group exhibited low sensory responses with 25± 4.73 and 13 ± 1.53 activated pixels in RHL and LHL, respectively. Motor behavior was assessed by weekly grid walk test, which indicated that the immediate-TMS group had fewer number of footfall errors compared to the delayed-TMS and no-TMS groups. Together, these results reveal the efficacy of TMS in improving outcomes after SCI. We anticipate that application of TMS as a therapeutic strategy could be readily translated into the clinical setting as an alternative or adjuvant to traditional rehabilitation strategies.

Abstract: The main problem of traumatic spinal cord injury TSCI lies in its complexity, as their pathophysiology involves mechanical damage both the primary and secondary mechanical damage. It currently do not have any effective treatment to restore neurological function lost as a result of TSCI. Therefore, our research group has conducted previous studies with polymeric implants of polypyrrole iodine PPyI, which have been shown to have a beneficial effect on some processes of the pathophysiology of TSCI by favoring the nerve tissue preservation and functional recovery in rats. In the present study the implant of PPyI effect was evaluated in Rhesus monkeys. Two females of Macaca mulatta species were used, weighing 5kg to which injury underwent complete spinal cord section CSCIS at the thoracic level 9 under anesthetic effect, and in an operating room. One of these animals received the implant of PPyI CSCIS+PPyI and the other not control. Studies magnetic resonance imaging MRI were performed before and immediately after the surgical procedure, which was repeated 1, 2 and 3 months after CSCIS and fractional anisotropy FA was determined at the times mentioned above. Clinical evaluation was performed daily including Babinski, pulpejo, plantar pressure and patellar reflexes and also measures the diameter of the upper thigh, mid thigh and calf were taken for 4 months. Subsequently, histological evaluation was performed. The results show that the animal receiving the implant of PPyI presented a smaller loss of muscle mass in paralyzed limbs and plantar reflex was more evident when compared to the control animal. In the histological evaluation animal with the implant showed the presence of neurons and better preservation of cytoarchitecture spinal cord compared to the animal that did not received the implant, consistent with that observed in the MRI, while the animal that did not receive the implant presented larger cysts and medullary tissue damage value FA pre CSCIS was 0.9 in the control monkey, which after injury decreased from 0.45 at baseline to 0.15 at the end of the track, while the value of FA in the animal receiving the implant PPYI decreased after injury to 0.3, but increased as time passed until reaching a value of 0.75. The implant of PPYI has neuroprotective effect after a CSCIS to preserve the cytoarchitecture of nerve tissue and maintain FA near baseline after a CSCIS.

Title: Spinal paired associative stimulation with novel parameters induces plasticity at wide range of interstimulus intervals and provides clinically relevant benefits upon long-term use in spinal cord injury patients

Authors: *A. ZUBAREVA[1], P. LIOUMIS[1], E. KIRVESKARI[2], N. BRANDSTACK[3], L. KUUSELA[4], A. YLINEN[5], S. SAVOLAINEN, 00280[6], J. MAKELA[1], A. SHULGA[5]; [1]HUS Med. Hosp., Helsinki, Finland; [6]Natl. Inst. for Hlth. and Welfare, Helsinki, Finland

Abstract: Spinal paired associative stimulation (PAS) is a non-invasive technique where transcranial magnetic brain stimulation (TMS) is synchronized with electrical peripheral nerve stimulation (PNS). The aim of spinal PAS is to synchronize pre-and postsynaptic activation at the level of corticomotoneuronal synapses. It is known that single PAS session can induce transient plasticity in human corticospinal tract. Spinal PAS with commonly used parameters leads to potentiation of motor-evoked potentials (MEPs) at a limited range of interstimulus intervals (the intervals between TMS and PNS). This can limit its value as a technique for long-term treatment in neurological patients, since in these patients measurements required for exact calculation of effective interstimulus intervals might be challenging, and conductivity of the neuronal tracts might change over time. Here we report novel parameters for spinal PAS that lead to potentiation of motor-evoked potentials (MEPs) at a wide range of interstimulus intervals in healthy subjects. We also investigated whether long-term PAS was capable to induce plastic changes in spinal cord injury (SCI) patients. We present several tetraplegic and paraplegic patients in whom long-term use of PAS with these parameters induced clinically relevant improvement in upper or lower limbs, respectively. Our study is a starting point for further development of this technique for the rehabilitation of SCI patients.

Title: Drawing breath after cervical contusion: from functional deficits to recovery

Abstract: Spinal cord injury can cause profound and robust alterations to respiratory function and capacity. However, the inherent plasticity of the respiratory motor system is thought to be a key reason why activity and homeostasis can be maintained after moderate injury, mitigating the functional impact of the anatomical damage. We embarked on a series of experiments to determine if a moderate high cervical contusion injury would cause a measurable deficit in respiratory motor function under 'normal' breathing conditions at acute to chronic stages post trauma. Through plethysmography and electromyography we assessed respiratory output from 4 hours to 12 weeks after a moderate C3 contusion. Through specific analytical procedures, contused animals showed significant decreases in tidal and minute volumes 6 weeks post injury. Further, the degree of change in these variables for contused animals was significantly different from controls, and robust, lasting from 3 days to 12 weeks post injury. In deeper analysis of this data we assessed the degree to which the contusion injury impacted ventilatory pattern variability. Through assessment of original and surrogate data sets, the injury-induced alterations in mutual information and sample entropy show that cervical contusion significantly and robustly decreases the variability of ventilatory pattern again from 3 days to 12 weeks post injury. The enduring deficit to the respiratory motor system caused by contusion was further confirmed through electromyography recordings. When isolated via a lesion, these contused pathways were insufficient to maintain respiratory activity at all time points post injury. Collectively these data illustrate that, counter to the prevailing literature, in our model a profound and lasting functional respiratory deficit may be measured through multiple physiological assessments at all time points

after cervical contusion injury. Further, they demonstrate that the plasticity inherent within the respiratory motor system is not sufficient to induce functional ventilatory recovery as animals progress from acute to chronic time points. However, we provide evidence to suggest that the exogenous induction of plasticity through chondroitinase induced matrix modification can act to robustly evoke recovery of respiratory function at acute and chronic time points post injury. Our continuing research holds considerable promise for a deeper understanding of spinal cord injuries and the development of novel and effectual treatment strategies to combat respiratory motor deficits regardless of the length of time that has passed following trauma.

Title: Unexpected and unexplained accumulation of AAV in the pineal gland after injections into sensorimotor cortex

Authors: *O. STEWARD[1], M. METCALFE[2], K. M. YEE[3], A. COULIBALY[3]; [2]Anat. & Neurobio., [1]Univ. of California, Irvine, Irvine, CA; [3]Anat. & Neurobio., Univ. of California Irvine, Irvine, CA

Abstract: Previous reports establish that regenerative growth of CST axons and recovery of motor function are enhanced by deleting PTEN in cortical motoneurons in the sensorimotor cortex. In rats, PTEN deletion has been achieved by injecting AAV that expresses shRNA against PTEN (Lewandowski & Steward, 2015, J. Neurosci. 34, 9951-9962). The test vectors that we used also express the fluorescent marker ZsGreen (AAV/PTENshRNA-ZsGreen). In follow-up studies, we discovered that the area of expression of AAV/PTENshRNA-ZsGreen can conveniently be revealed by illuminating intact brains before sectioning with a NightSea® flashlight. In doing so, we were surprised to discover that after injections of AAV/PTENshRNA-ZsGreen into the rostral sensorimotor cortex, ZsGreen fluorescence was also prominent in the pineal gland, which is many mm distant from the injection site. The observations reported here were from a study in which adult female Fischer 344 rats received crush injuries to the spinal cord at thoracic level 9. Then, 1-2 weeks post-injury, rats received 4 injections of

AAV/PTENshRNA-ZsGreen into the rostral sensorimotor cortex. Some of the rats also received transplants of neural stem cells (NSCs) into the injury site. Rats were allowed to survive for 4 months after the AAV injections. Illumination of intact brains with a NightSea® flashlight revealed prominent ZsGreen fluorescence in the majority of rats in which the pineal remained attached to the brain. Examination of sections through the pineal gland revealed that ZsGreen fluorescence was primarily in cells near the surface of the gland, suggesting that AAV vector was selectively taken up from the CSF. The test vector used here was constructed from AAV2-9. It will be of interest to determine whether accumulation in the pineal gland is unique to certain AAV subtypes or is a general property of different AAVs. If selective uptake by the pineal gland is a general feature of AAVs, this could be a complication for AAV-based therapies. The mechanisms underlying the selective accumulation of AAV in the pineal remain to be explored.

Title: Functional contexts and roles of fatty acid binding protein 4 and fatty acid binding protein 5 in rats following spinal cord injury

Authors: *J. C. LICERO CAMPBELL;
Loma Linda Univ., Loma Linda, CA

Abstract: The pathophysiology of spinal cord injury (SCI) results from the mechanical insult and secondary phase present during injury onset and resolution respectively. The direct outcomes of mechanical injury involve death of neurons and severance of axonal connections. As a result of neuronal cell death and membrane rupture, there is marked in shift in the spinal cord lipidome which promotes differentiation of resident microglia and infiltration of peripheral inflammatory cells. Our lab and others have demonstrated the onset of a large increase in: pro-inflammatory lipids, and the ω-6: ω-3 polyunsaturated fatty acid (PUFA) ratio in injured rat spinal cord epicenters when compared to controls. Pro-inflammatory fatty acids, including ω-6, have been extensively shown to promote death of neuronal cell populations and diminish axonal

reconnection. Therefore, investigating the proteins involved in binding and shuttling of fatty acids is of great import when in search of improving locomotor and sensory recovery after SCI. Fatty acid binding proteins, particularly fatty acid binding protein 5 (FABP5) and fatty acid binding protein 4 (FABP4), have displayed great therapeutic potential in their ability to bind anti-inflammatory and pro-inflammatory lipids respectively. Our previous publications have documented the presence of FABP5 in neurons, glia, oligodendrocytes, astrocytes, and neural progenitors and its ability to promote neuronal survival and locomotor recovery through modulation of docosahexanoic acid (DHA) and eicosapentanoic acid (EPA) following spinal cord injury. Following an eight-week diet enriched with DHA, levels of mRNA and protein for FABP5 at seven days post injury showed a marked upregulation (mRNA: 556± 168% n= 7-8 rats; $p<.01$; protein: 518±195% n= 6-7 rats; $p<.05$). Furthermore, inhibition of FABP5 was shown to hinder locomotor recovery following SCI. In contrast, unpublished data from our lab has revealed an opposing role for FABP4, whose presence was only prevalent in monocytes and macrophages. Spatiotemporal studies looking at mRNA and protein levels of FABP4 in control diet rats at 1,3,7,14, and 28 days post injury, revealed a marked increase of more than 100 fold mRNA and 15 fold protein differences in injured rats compared to controls at 7 days and 28 days post injury particularly. Of note, inhibition of FABP4 using the BMS 309403 FABP4 inhibitor improved locomotor recovery scored for rats at all time points. Because of these distinct expression profiles and functional contexts we hypothesize that modulation of FABP5 and FABP4 expression after injury is essential in promoting locomotor and sensory recovery following SCI.
