Abstract: Opioids are commonly used to treat pain in the acute phase of spinal cord injury (SCI). We have shown, however, that administration of morphine in this phase of SCI undermines locomotor recovery and increases pain reactivity in a rodent contusion model. These adverse effects appear to depend on kappa opioid receptor (KOR) activation. Activation of the KOR is sufficient to decrease locomotor recovery after SCI, and is necessary for the morphine-induced attenuation of function. Interestingly, we found that KORs are upregulated on microglia following SCI and morphine administration. Using flow cytometry, we showed that SCI significantly increases the number of CD45+ cells expressing KORs at 48 hrs post injury. Morphine also significantly increases the number KOR+ microglia at the lesion site. We hypothesized that morphine activates these microglial-specific KORs to increase inflammation and neurotoxicity, thereby decreasing recovery of function after SCI. To test this, the current study used immunohistochemistry to compare the temporal sequence of cell loss, with and without morphine, in the rodent model. Subjects were given a moderate spinal contusion injury or were sham controls. On the day following surgery, half of the subjects in each injury condition were treated with 10 mg of morphine (i.v.) on days 1-2, 20 mg on days 3-4, and 30 mg on days 5-7. The remaining subjects served as controls, receiving an equivalent volume of 0.9% saline across days. To assess the temporal sequence of cell loss, subjects were humanely euthanized on days 2, 4, or 8, corresponding to 24 hrs after the final dose of morphine. A 1.5 cm section of spinal cord, spanning the injury site, was collected and sectioned (20μm) for immunohistochemistry. Subsets of the tissue were stained with markers for neurons (NeuN, neurofilament), microglia (OX42, IBA1) and astrocytes (GFAP, S-100). All sections were double-labeled with Caspase-3. By Day 2 post injury, SCI significantly decreased the expression of NeuN, and increased the numbers of GFAP+ and OX-42+ cells. There was no effect of morphine on cell expression in this early phase, but by Day 4 locomotor function was reduced in the morphine-treated subjects. After 7 days of morphine administration, both neuron and glial expression were significantly decreased, as was locomotor function relative to vehicle-treated controls. In ongoing experiments, we are using immunohistochemistry to further characterize KOR expression at the site of the lesion. These data will be essential in the development of therapeutic strategies, such as adjuvant medications, that allow for the safe and effective use of opioids for pain management after SCI.

Abstract: Various neurotrophic factors (NTFs), which are secreted from the central and peripheral nervous systems, have crucial roles for the modulation of neural functions and enhancement of neuronal survival and regeneration. Many previous studies have administered various exogenous NTFs to neuronal cells or animal models, however the optimal dose of NTF and the selection of optimal type of NTFs for the regeneration of damaged central or peripheral nerves is still unclear.In this study, we developed a high-throughput microfluidic device which contains 32 microchambers for neuronal cell culture to detect neurite outgrowth and cell survival at 8 different concentrations of applied NTF simultaneously, and also enable the combination use of more than two types of NTFs. Our aim was to reveal which concentration and what combinations of NTFs is optimal for the regeneration of various types of neurons in the central and peripheral nervous systems. Recombinant human nerve growth factor (NGF), neurotrophin-3 (NT-3), and brain-derived neurotrophic factor (BDNF) were produced and separately applied into the microfluidic device, and cortical neurons from the brain and sensory neurons from dorsal root ganglia of rats were cultured within the device for 5 days.We found that all three NTFs were effective to increase neurite outgrowth of cortical and sensory neurons, and the optimal concentration was different according to the type of NTFs and cultured neurons. When NTFs were combined, BDNF and NT-3 was effective for the neurite outgrowth and survival of cortical neurons, and NGF alone showed better results than other combination of NTFs.We concluded that the high-throughput microfluidic device was useful to detect the optimal concentration of various NTFs for neurite outgrowth and neuronal survival, and these results will be applied to animal models of spinal cord injury and peripheral nerve injury.

Title: Genetic absence of the corticospinal tract alters spinal motoneuron regeneration in mice

Authors: *Q. WANG[1], L. SHI[2], L. ZHOU[3];
[1]The GHM Inst. of CNS Regeneration, Jinan Univ., Guangdong, China; [2]The GHM Inst. of CNS Regeneration Jinan Univ., Guangzhou, China; [3]GHM Inst. of CNS Regeneration, Jinan Univ., Guangzhou, China

Abstract: The corticospinal tract (CST)makes direct and indirect connections with spinal motoneurons and controls limb movement, particular skilled movements. By inactivating *Celsr3* in neocortex upon *Emx1-Cre,* we established *Emx1-Cre;Celsr3*$^{f/-}$ mutants, in which corticospinal axons fail to course through the internal capsule and to innervate the spinal cord. Using this model, we tested whether absent cortical inputs affect spinal motoneuorn regeneration and survival. In adult mice, we tore off right C5-C7 motor and sensory roots, and re-implanted right C6 roots back to spinal cord. We found impaired recovery of elbow flexion, a changed motoneuron survival and less axonal regeneration and remylination in *Emx1-Cre;Celsr3*$^{f/-}$ mutants compared to the control. To further study its mechanisms, we used RNAseq to screen gene expression in the local spinal cord of control mutant mice after three days of brachial plexus avulsion, and top 200 changed genes in the mutant are enriched in immune response signaling pathway, such as more polarization of M1 and less polarization of M2 macrophages. The result is identical to the expression levels of M1 and M2 makers using immunofluorescence detection. In conclusion, we propose that the corticospinal inputs may modify the spinal microglia function and subsequently affect motoneuron regeneration and survival after brachial plexus avulsion and replantation.

Title: Sensory transmission to motoneurons is facilitated by cold-sensing C fibres expressing TRPM8 and 5-HT_{1D} receptors: links between management of spasticity and migraines

Authors: Y. LI, A. M. LUCAS-OSMA, S. BLACK, M. J. STEPHENS, K. K. FENRICH, K. FOUAD, *D. J. BENNETT;
Univ. of Alberta, Edmonton, AB, Canada

Abstract: For many years we have known that serotonergic antimigraine drugs (triptans) can be used in treatment of spasticity after spinal cord injury, potently inhibiting the monosynaptic reflex (MSR) from group Ia muscle spindle afferents to motoneurons. However, triptans selectively activate 5-HT_{1D} receptors that are almost exclusively found on unmyelinated C fibres where they inhibit C fibre activity, consistent with their action in migraine treatment, but inconsistent with inhibition of the MSR. This suggests that somehow C fibres modulate MSR transmission. Intriguingly, cold-sensing C fibres (expressing TRPM8) have been implicated in migraines, and thus we specifically explored these fibres. Spinal cords of adult rats were maintained in vitro, while recording the MSR evoked on ventral roots in response to Ia afferent stimulation (1.5xT). Selective C fibre stimulation was obtained by bathing one dorsal root in low dose TTX, to block myelinated axons, but leave TTX-resistant C fibres (with Nav1.8). Electrical stimulation of these C fibres (50xT) led to a long-term facilitation of the MSR (and underlying EPSP) evoked from an adjacent dorsal root (not in TTX), indicating a facilitation of transmission in the Ia afferents. The MSR was likewise increased by cooling or pharmacological activation of cold-sensing C fibres with the TRPM8 agonist icilin. Importantly, following icilin application, electrical C fibre stimulation produced no further facilitation of the MSR, implying that cold sensing C fibres are entirely responsible for the MSR facilitation. Considering that the MSR is involved in tremor and clonus, this finding implies that cold sensing fibres can facilitate clonus. C fibre stimulation or icilin also increased dorsal root reflexes (DRR) evoked by Ia afferent stimulation, though not the primary afferent depolarization (PAD), implying a mechanism not involving PAD. Application of the 5-HT_{1D} agonist zolmitriptan (triptan) potently inhibited the MSR and DRR, and this inhibition was increased or prevented by activation or blocking cold-sensing C fibres, respectively. These results imply that afferent transmission to motoneurons is tonically facilitated by cold-sensing C fibres which in turn are gated by serotonin, and suggest a

spinal mechanism contributing to cold-induced shivering and clonus in normal and pathological states.

Title: Enhancing somatosensory cortical activity alleviates neuropathic pain by suppressing homeostatic hyperexcitability

Authors: ***X. JIN**[1], W. XIONG[2], X. PING[2], M. S. RIPSCH[2], G. SANTA CRUZ CHAVEZ[3], K. JIANG[4], F. WHITE[2];
[1]Iupuistark Neurosci. Res. Inst., Indianapolis, IN; [2]Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Purdue Sch. of Engin. and Technology, IUPUI, Indianapolis, IN; [4]Children's Hospital, Zhejiang Univ. Sch. of Med., Hangzhou, China

Abstract: Central sensitization and hyperexcitability of the nociceptive system is believed to be a basic neurophysiological mechanism in neuropathic pain, while suppressing such hyperexcitability by directly blocking excitation or enhancing inhibition is a major therapeutic strategy for controlling the pain. However, the current pharmacological treatments only partially reduce the pain in less than a half of the patients. Because development of neuropathic pain often involves an initial deafferentation due to a primary lesion of nociceptive pathways while deafferentation is known to cause cortical hyperexcitability through homeostatic activity regulation, we hypothesize that abnormal homeostatic activity regulation of the primary somatosensory cortex (S1) may play a role in pain development and maintenance, and that

neuropathic pain can be controlled by enhancing cortical excitatory activity. Using a transient spinal cord ischemia model of neuropathic pain in GCaMP6-expressing transgenic mice, here we used repeated *in vivo* two-photon imaging to demonstrate that spontaneous firing of layer V pyramidal neurons of the S1 was initially depressed at six hours after injury and subsequently enhanced in one to two weeks, which is consistent with homeostatic activity regulation. Specifically enhancing S1 by optogenetic stimulation both prevented the development and reduced the severity of mechanical hyperalgesia of the hindlimbs. This effect was likely medicated by excitatory drive, because transecting corpus callosum eliminated the ipsilateral, but not contralateral, analgesic effect induced by unilateral optogenetic stimulation of S1. Similar analgesic effect was achieved by pharmacologically enhancing activity by chronically releasing $GABA_A$ receptor antagonist bicuculline in the S1. Furthermore, patch clamp recordings from layer V pyramidal neurons showed that neuronal hyperexcitability in this model could be mainly attributed to increased input resistant and higher frequency of miniature excitatory postsynaptic currents, while S1 optogenetic stimulation reversed these pathological changes and reduced network hyperexcitability. We conclude that abnormal homeostatic activity regulation in the S1 is involved in the mechanism of neuropathic pain, and that stimulating cortical excitatory activity is a novel strategy for the prevention and treatment of neuropathic pain.

Title: Primary somatosensory and anterior cingulate cortex neuronal responses to mechanical stimulation are altered after spared nerve injury.

Authors: *M. A. NOTHEM, A. GRAZIANO, J. BARRETT;
Drexel Univ., Philadelphia, PA

Abstract: Chronic neuropathic pain (CNP) is a prevalent and debilitating condition that causes suffering and current treatments remain inadequate. CNP results in long-term alterations in multiple regions of the CNS that can alter processing of sensory or affective components of pain. The Primary Somatosensory cortex (S1) and Anterior Cingulate cortex (ACC) are two pain-related cortical regions that are involved in pain processing. S1 processes the location and quality of pain, while the ACC processes pain affect and motivated behavior. However, it is currently

unclear if electrophysiological properties of neurons in these cortical regions are altered during the development and maintenance of CNP. In order to identify changes in S1 and ACC neuronal activity during CNP, Sprague Dawley rats were implanted with 2 microwire arrays targeted to S1 and ACC. Neuronal activity and behavioral responses to mechanical stimulation of the hindpaws, using an electronic Von Frey device,were recorded in awake rats prior to and 3,7,14,21 and 28 days after inducing the Spared Nerve Injury (SNI) model of CNP. In ongoing experiments, we have identified parameters of neuronal activity in both S1 and ACC that are altered after SNI. Mean firing rates of ACC neurons increase as early as 3 days and maintain for up to 28 days, while mean firing rates of S1 neurons increases by day 14 and then maintains for up to 28 days. Peak responses to mechanical hindpaws stimulation increase in S1 and ACC cells within the first two weeks after SNI. The increased responses in S1 and ACC coincide with the development of hypersensitivity. Intraperitoneal injection with 30 or 100, but not 10mg/kg of gabapentin reversed mechanical hypersensitivity and mean firing rates and peak responses of ACC neurons. However, gabapentin did not have an effect on S1 neurons, despite reversing mechanical hypersensitivity. These data suggest that S1 and ACC are differentially affected by peripheral nerve injury with increases in neuronal activity occurs first in the ACC during induction and then in S1 during maintenance. Gabapentin preferentially affects ACC neurons suggesting that it may exert an effect in modulating the processing of pain affect.

Ctr., Wonkwang Univ., Iksan, Korea, Republic of

Abstract: Endogenous descending pain modulatory system in the brain is the final arbiter for the emergence of the chronic pain. Typically, however, majority of pain studies have focused on peripheral and spinal mechanisms, so that the mechanisms which lead to the switch of the endogenous modulatory system have not been studied. Here we demonstrate that the metabotropic glutamate receptor 5 (mGluR5) in the periaqueductal gray (PAG) is the molecular executor which determines mode of action of endogenous pain modulatory system. Using brain imaging, electrophysiological recordings and behavioral experiments, we show that the mGluR5 in the PAG (PAG-mGluR5) is persistently active in a normal condition and this activity is necessary to regulate sensory perception in an appropriate range. This mGluR5 activity is declined in chronic neuropathic pain condition, which leads to dysfunction of pain modulation. Notably, we found that the long-lasting mechanical hypersensitivity is produced in the naïve animals by single-time blockade of mGluR5 in the PAG. This suggests that the suspension of the PAG-mGluR5 is able to induce chronic failure of pain modulatory system, not merely transient dysfunction. Our findings provide new insight into how the endogenous pain modulatory system becomes dysfunctional as it contributes to chronic neuropathic pain

Title: Optogenetic dissection of the amygdala-mediated control of the descending pain modulation

Authors: Y. K. SUGIMURA[1], Z. GHASEMI[1,2], Y. TAKAHASHI[1], Y. YANAGAWA[3], R. KANEKO[3], A. M. WATABE[1], *F. KATO[1];

Abstract: The central nucleus of the amygdala (CeA) is well known to play pivotal roles in various aspects of emotional learning. This nucleus is also a key structure in nociception-emotion link as it receives nociceptive information directly from the superficial layer of the dorsal horn via the lateral parabrachial nucleus (LPB). Recently, it has been shown that the CeA not only receives nociceptive information to affect emotional behaviors but also actively modulates nociceptive sensitivity. We have recently demonstrated that direct monosynaptic glutamatergic inputs from the LPB not only excite CeA neurons but also regulate CeA network signaling through robust feed-forward inhibition, suggesting that the activity of CeA network, including its output, is under plastic modulation in pain chronification (Sugimura et al., J Neurophysiol, 2016). As one of the major targets of the CeA output is the periaqueductal gray (PAG), a primary nucleus for descending pain modulation, we sought to examine how outputs from the CeA subsequently affects PAG neurons. To address this issue, we analyzed the CeA-PAG synaptic transmission by using whole-cell patch-clamp technique and optogenetics. We transfected AAV vector for channelrhodopsin-2 (ChR2)-YFP expression to the CeA in 4-5-week-old male Wistar rats or VGAT-Cre rats and prepared brain slices containing the PAG more than 5 weeks after transfection. In the ventrolateral PAG (vlPAG), fibers with YFP fluorescence were observed, and blue light stimulation evoked monosynaptic inhibitory postsynaptic current (IPSC) with very small latency fluctuation in vlPAG neurons. Moreover, IPSC amplitude was decreased by the application of a mu opioid receptor agonist, DAMGO, and this inhibitory effect of DAMGO was stronger in the formalin-induced inflammatory pain model than in the naïve rats. These results suggest that the plastic changes in CeA-PAG synaptic transmission in the sustained pain state might play a role in determining nociceptive sensitivity via the descending pain modulatory system.

Title: Loss of diffuse noxious inhibitory control depends on kappa opioid receptor mediated signaling in a rat model of medication overuse headache

Authors: *K. M. NATION[1], P. I. HERNANDEZ[2], D. W. DODICK[3], F. PORRECA[2]; [1]GIDP in Neurosci., [2]Med. Pharmacol., Univ. of Arizona, Tucson, AZ; [3]Mayo Clin., Scottsdale, AZ

Abstract: Diffuse noxious inhibitory control (DNIC) is an endogenous, bottom-up, pain modulatory system in which one painful stimulus inhibits another painful stimulus. DNIC is tested by the concurrent application of a noxious conditioning stimulus and a noxious test stimulus to remote locations on the body. The application of the conditioning stimulus increases the pain threshold to the test stimulus in subjects with efficient DNIC. A loss of DNIC, also termed conditioned pain modulation (CPM), has been demonstrated in humans with idiopathic pain disorders, including chronic migraine and medication overuse headache (MOH). Stress is commonly reported as a trigger for migraine and dynorphin, an endogenous agonist at kappa opioid receptors (KORs), has been shown to be necessary for aversive behavioral responses to stressors; norbinaltorphimine (nor-BNI), a KOR antagonist, blocks aversive behaviors to stress. The amygdala provides an emotional component to sensory information and is part of the affective pain system. Thus, activity at KORs within the amygdala might cause a lack of resilience to stressors. Drugs used for acute treatment of migraine, including opiates, produce MOH. We have previously demonstrated that priming animals with morphine produces a loss of DNIC that can be reversed by inactivation of the rostral ventromedial medulla revealing enhanced descending facilitation. We hypothesized that the loss of DNIC in morphine-primed rats would be prevented by blockade of KOR signaling following systemic nor-BNI or by microinjection into the central nucleus of the amygdala (CeN). Male S.D. rats were given morphine or vehicle continuously for seven days. Two weeks after the end of drug treatment rats were stressed by exposure to bright lights (BLS) for one hour on two consecutive days. Two hours after the second BLS DNIC was tested by giving rats a forepaw capsaicin injection and applying the Randall-Selitto paw pressure test to the hindpaw. Nor-BNI was given by subcutaneous injection or into the right CeN one hour prior to each BLS session. Rats with previous exposure to morphine showed a loss of DNIC compared to controls. Nor-BNI given

systemically or into the right CeN prevented the loss of DNIC in morphine-treated rats. These results show that signaling at KORs has a critical role in impairment of the DNIC response in MOH. These results also show that the CeN is important in the regulation of the DNIC response in MOH rats. The CeN receives inputs from stress circuits and has outputs to descending pain modulatory centers highlighting the possibility of KOR-mediated enhanced descending facilitation as an amplifier of stress-induced hyperalgesia relevant to migraine pain.

Title: Morphine metabolites and their role in mediating the sexually dimorphic effects of morphine.

Authors: *H. H. DOYLE, A. Z. MURPHY;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Both preclinical and clinical studies utilizing a variety of pain assays report that the effective dose for morphine is approximately 2-fold higher in females than males. Our lab has recently reported that chronic administration of morphine activates microglia and astrocytes within the periaqueductal gray (PAG), a critical site for the pain-relieving effects of morphine. Following administration, ~90% of morphine is converted into two active metabolites: morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G), each with distinct pharmacological profiles. M6G binds exclusively to μ opioid receptors (MOR) and is a potent analgesic; in contrast, M3G binds exclusively to the glial innate immune receptor, toll-like receptor 4 (TLR4). TLR4 activation by M3G initiates a neuroinflammatory response that directly opposes the analgesic effects of both morphine and M6G. In rats, M3G serum concentrations are 2-fold higher, and M3G:morphine ratio is ~5.5-fold higher in females than males. The present studies tested the hypothesis that increased M3G levels, and subsequent TLR4 activation of glia, are a primary mechanism driving the attenuated response to morphine observed in females. We report that intra-PAG administration of M6G resulted in a greater analgesic response in females relative to males, such that sex differences in analgesia were abolished. Similarly, intra-PAG administration of M3G significantly attenuated the analgesic effects of systemic morphine in

males and females. Together, these data implicate 3-glucuronide metabolites as a primary contributing factor in the attenuated response to morphine observed in females.

Title: Characterization of apomorphine-induced antinociception in the periaqueductal gray of the rat

Authors: S. M. SCHOO, *M. M. MORGAN;
Dept Psychology, Washington State Univ., Vancouver, WA

Abstract: The periaqueductal gray (PAG) is part of a descending nociceptive modulatory pathway. Opioid and dopamine neurons and receptors are found in the PAG and both contribute to PAG mediated antinociception. We have previously shown that microinjection of the dopamine receptor agonist apomorphine into the ventrolateral PAG (vlPAG) produces antinociception via a D2 receptor-mediated mechanism. The objectives of the present experiments were to determine whether the antinociceptive effects of apomorphine microinjections into the PAG are comparable in male and female rats (Experiment 1), whether opioid receptors contribute to apomorphine-induced antinociception (Experiment 2), and whether tolerance develops to repeated apomorphine microinjections (Experiment 3). Rats were implanted with a cannula aimed at the vlPAG for microinjection of the dopamine receptor agonist apomorphine (2.2, 4.6, 10, 22, & 46 μg/0.4 μl). Nociception was assessed using the hot plate test before and after microinjection of apomorphine. Experiment 1 showed that microinjection of apomorphine produced greater antinociception in male compared to female rats both in terms of potency and duration of action. Experiment 2 showed that blocking opioid receptors via naloxone (2 mg/kg, s.c.) enhanced apomorphine antinociceptive potency in male, but not female rats. Experiment 3 showed that repeated injections of apomorphine into the PAG enhanced apomorphine-mediated antinociception in both male and female rats. These data show that the antinociceptive effects of apomorphine are similar to morphine following PAG administration in producing a greater effect in male than female rats, but differ from morphine in

that antinociception is enhanced after opioid receptor blockade or following repeated administration.

Title: Immunohistochemical analysis of α2δ-1 subunit of calcium channel in the locus coeruleus (LC) and the periaqueductal gray (PAG) in rats.

Authors: T. NONAKA, K. YOSHIDA, *T. YAMAMOTO;
Kumamoto Univ. Hosp., Kumamoto-shi, Japan

Abstract: Gabapentinoid, such as gabapentin and pregabalin, binds to α2δ subunit of calcium channels. Four α2δ subunit genes have been cloned and α2δ-1 subunit is thought to play an important role in pain transmission. Although gabapentinoids are widely used as an analgesic agent for neuropathic pain, the precise mechanism of gabapentinoids to produce an analgesic effect is not clear. LC, one of the nuclei of descending pain modulation system, has been reported to be the site of action of gabapentinoids. However, the location of α2δ-1 subunit in the LC has not been reported. In the present study, we examined the location of α2δ-1 subunit in nuclei of descending pain modulation system, such as LC and PAG, using immunohistochemistry technique. [Methods] The rats were anesthetized deeply and transcardially perfused with 4% paraformaldehyde. The brain was removed immediately and postfixed overnight at 4℃. Coronal sections were cut with a microtome at 50 μm. The sections were incubated with two antibodies of rabbit anti-α2δ-1 subunit (1:1000; OriGene, MD and ABGENT) for 24 hours at room temperature. The sections were then incubated for 3 hours with Donkey Anti-rabbit IgG (Alexa Fluor 488). The slices were observed and photographed under confocal laser scanning microscopy (FV 1200). [RESULTS] α2δ-1 subunit like immunoreactivity was not found in LC, but in parabrachial nucleus which was located next to LC. Some α2δ-1 subunit like immunoreactivities were found inner and outer circumference of PAG. [DISCUSSION] α2δ-1 subunit was expressed in nuclei of descending pain modulation system and descending pain modulation system may be one of the action site of gabapentinoids.

Title: Stimulation of the secondary somatosensory cortex in neuropathic rats: contribution of the rostral ventromedial medulla to pain attenuation

Authors: ***B. SAGALAJEV**, H. VIISANEN, H. WEI, A. PERTOVAARA;
Dept. of Physiology, Fac. of Med., Univ. of Helsinki, Helsinki, Finland

Abstract: Clinically, transcranial magnetic stimulation of the secondary somatosensory cortex (S2) attenuates neuropathic pain. The mechanisms, however, of pain attenuation by S2 stimulation remain unclear. We therefore electrically stimulated the S2 in neuropathic rats and assessed the contribution to descending pain inhibition of the rostral ventromedial medulla (RVM). The model of neuropathy was spinal nerve ligation. Under light pentobarbital anesthesia, S2 stimulation prolonged the latency for paw withdrawal from heat. Pretreatment of the RVM with an agonist (8-OH-DPAT) of a 5-HT_{1A} autoreceptor, however, prevented antinociceptive action of S2 stimulation. In the RVM, we recorded presumably antinociceptive OFF cells that decrease the discharge rate in response to heat, and presumably pronociceptive ON cells that increase it. In OFF cells, S2 stimulation delayed the onset of heat responses, whereas in ON cells, it shortened the duration. Additionally, in the spinal dorsal horn, we recorded wide-dynamic-range (WDR) cells that increase the discharge rate in response to a light touch and to heat. S2 stimulation suppressed heat responses in WDR cells. Spinal administration of a selective 5-HT_{1A} receptor antagonist (WAY-100635), however, prevented suppression by S2 stimulation of heat responses in WDR cells. We conclude that, in neuropathic rats, S2 stimulation induces spinal antinociception through descending pathways extending throughout the RVM. Particularly, S2 stimulation induces analgesia-promoting discharge changes in OFF- and ON cells and activates spinally projecting serotoninergic cells acting on the spinal 5-HT_{1A} receptor.

Title: Inactivation of neurons in the transitional zone (TZ) in rat sensorimotor cortex reduces responsiveness of nociceptive neurons in the spinal cord to thermonoxious stimulation

Authors: *O. V. FAVOROV[1], V. PELLICIER-MORATA[2], A. DEJONGH CURRY[3], A. BRNA[1], R. S. WATERS[2];

Abstract: Introduction: We previously reported that the transitional zone (TZ) in rat dysgranular cortex, which lies adjacent to the forepaw and hindpaw representations in somatosensory cortex (S1), contains neurons that respond to thermonoxious stimulation. When TZ is inactivated by injection of lidocaine or local cooling, responsivity to noxious stimulation is lowered in the contralateral limb, as measured by foot withdrawal in a heated water bath. In the present study, we examined whether inactivation of TZ alters the responsiveness of nociceptive neurons, recorded in the dorsal horn of the contralateral spinal cord, to thermonoxious skin stimulation. Methods: In rats maintained under isoflurane anesthesia, the skull over sensorimotor cortex was removed, and TZ was localized by microelectrode mapping of the exposed cortex using mechanical and thermonoxious stimulation. Thermonoxious stimulation was applied by lowering the hindlimb in a 50-51 degrees C heated water bath. Control water bath stimulation was set at 41 degrees C. The spinal cord was then opened in the lumbar region (L1-L3) and a microelectrode was inserted into the upper dorsal horn laminae to isolate nociresponsive neurons there and record their responses to thermoneutral and thermonoxious stimulation. TZ was then ablated and the nociceptive dorsal horn neurons were retested with the same thermoneutral and thermonoxious stimuli. Electrolytic lesions were used to mark recording sites in spinal cord. At the end of experiments, rats were perfused, sensorimotor cortex flattened and cut tangentially to reveal the barrel field and the ablated site. Cortical and spinal cord sections were stained with cytochrome oxidase. Results: (1) Thermonoxious stimulation applied to the hindlimb activated neurons in the ipsilateral dorsal spinal cord and contralateral TZ. (2) Inactivation of TZ reduced the responsiveness of nociceptive spinal cord neurons to thermonoxious stimulation. (3) Following TZ inactivation, response of nociceptive dorsal horn neurons to thermonoxious stimulation became similar to their response to thermoneutral stimulation. Conclusion: These

results strongly suggest that TZ plays an important role in pain perception through facilitatory modulation of nociceptive neurons in the spinal cord dorsal horn.

Title: Divergent periaqueductal gray neuronal populations drive pruritus processing

Authors: *V. K. SAMINENI[1], J. G. GRAJALES-REYES[2], B. A. COPITS[2], R. W. GEREAU IV[2];
[1]Washington Univ. Pain Ctr. and Dept. of Anesthesiol., Washington Univ., St Louis, MO;
[2]Washington Univ. in St Louis, St Louis, MO

Abstract: Chronic itch, like chronic pain, is a major clinical problem. Despite the similarities between itch and pain, the underlying neural circuitry for itch is poorly understood, as is the mechanism by which itch is suppressed by pain. Profound analgesia occurs with stimulation of the periaqueductal gray, however the precise role of the PAG in itch is unknown. We hypothesized that specific subsets of neurons within the PAG could suppress itch and provide a neural substrate for the inverse interaction between itch and pain. To determine the role of PAG in mediating itch, we activated or inhibited PAG neurons using engineered G-protein coupled receptors (GPCRs) activated exclusively by synthetic, systemically administered small molecules (i.e., DREADD technology). Engineered excitatory (Gq) or inhibitory (Gi) GPCRs were expressed in PAG neurons via adeno-associated viral vectors. We found that chemogenetic activation of non-specific PAG neurons produced a reduction of itch, whereas inhibition of non-specific PAG neurons resulted in enhanced itch. In contrast, when only the GABAergic neurons in the PAG were targeted, activation resulted in decreased itch, conversely inhibition of PAG GABAergic neurons resulted in increased itch. When glutamatergic neurons in the PAG were selectively targeted we found that activation led to enhanced itch, while inhibition neurons

produced decreased itch. We conclude that the PAG is an essential neuronal substrate in mediating itch behaviors and is a neural control center for pruritus.

Title: The analgesic effect of dopamine in male and female mice

Authors: *J. PEI[1], N. E. TAYLOR[4], K. Y. VLASOV[2], J. A. GUIDERA[4], K. SOLT[4], E. N. BROWN[3];
[2]Brain and Cognitive Sci., [3]Anesthesia, [1]MIT, Cambridge, MA; [4]Anesthesia, Massachusetts Gen. Hosp., Boston, MA

Abstract: Women are at substantially greater risk than men for many clinical pain conditions [1]. In addition, drugs which modulate neural dopamine (DA) represent an important novel analgesic, and yet their effects have never been studied in females. We hypothesized that female mice would be more sensitive to carrageenan-induced inflammation than males, that d-amphetamine would be as effective as morphine in treating this pain, and DA neurons in the ventral lateral periaqueductal grey (vlPAG) mediate the analgesic effect. To test this hypothesis, we used DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) to see if selective stimulation of DA neurons in the vlPAG could produce analgesia. Adult C57BL6 male and female mice received injections of carrageenan into the left hind paw to induce inflammatory pain, and thermal hyperalgesic responses were measured using the Hargreaves method. Afterwards, separate groups of mice were treated using intraperitoneal (i.p.) injections of morphine and D-amphetamine, and paw withdrawal latencies to a thermal stimulus were recorded. Adult DAT-cre mice then received bilateral injections of adeno-associated virus (AAV) carrying an excitatory DREADD (HM3Dq) in vlPAG. Mice receiving injections of AAV lacking the DREADD served as controls. After at least 4 weeks to allow for viral transfection, thermal hyperalgesia was tested in mice with carrageenan-induced inflammatory pain.

Immunohistochemistry was used to confirm viral expression and co-localization. We found that the onset of inflammatory pain was significantly faster in female BL6 mice (n=6) as they were more sensitive to the thermal stimulus in the first 3 hours following carrageenan injection than the males (3.2±0.9s vs 6.0±2.1s, $p<0.005$). However, there was no difference in paw withdrawal latencies after 6hrs (2.0±0.3s vs 2.5±0.4s). Both males and females showed significant analgesic responses with 3 mg/kg morphine (n=6) and 3 mg/kg D-Amphetamine (n=6). Analgesia was also achieved in animals with DREADD activation of vlPAG DA neurons by CNO (n=9), as they showed no significant difference in paw withdrawal latencies between treated (8.2±1.7s) and untreated paws (9.3±1.6s). DREADD viral expression and co-localization in vlPAG DA neurons was confirmed. In summary, females exhibited faster onset of inflammatory pain and greater sensitivity to analgesic medications, but were effectively treated using both systemic administration of D-amphetamine as well as selective activation of DA neurons in the vlPAG. DA modulating agents may represent a novel new treatment for pain in both males and females.

Title: The parabrachial complex links pain transmission to pain modulation

Authors: Q. CHEN[1], Z. ROEDER[1], Y. ZHANG[1], M. LI[1], S. L. INGRAM[1], *M. M. HEINRICHER[2];

Abstract: An important factor in both normal and clinically significant pain is the intrinsic pain-modulating system, which regulates nociceptive processing via projections from the brainstem to the dorsal horn. The output of this modulating system, the rostral ventromedial medulla (RVM), can facilitate or suppress nociceptive transmission at the dorsal horn by the respective action of

two distinct classes of neurons, “ON-cells” and “OFF-cells”. Both classes respond to noxious inputs: ON-cells are activated, leading to a “burst” of activity associated with behavioral responses to noxious stimulation, whilst OFF-cell firing is suppressed, producing a “pause” in any ongoing activity. However, the pathway through which noxious inputs drive changes in RVM activity is only now being defined. Anatomically, the RVM receives direct spinoreticular and trigeminal reticular inputs, as well as afferents from the parabrachial complex (PB), which is the major target of supraspinal projections from the superficial dorsal horn. The aim of this study was to test the hypothesis that noxious information is relayed to the pain-modulating neurons of the RVM via the PB, under basal conditions and in persistent inflammation. ON-cells and OFF-cells were recorded in the RVM in lightly anesthetized rats. The reflex-related ON-cell burst and OFF-cell pause were attenuated or blocked by pharmacological inactivation of the lateral PB *contralateral*, but not ipsilateral, to the noxious stimulus. By contrast, in animals subjected to chronic inflammation (CFA in one hindpaw), block of PB *ipsilateral* to the inflamed paw interfered with the ON-cell burst and OFF-cell pause elicited by normally innocuous stimulation of that paw. This implies recruitment of a normally inactive pathway during inflammation. A direct PB input to RVM was demonstrated using optogenetic methods. Inactivation of archaerhodopsin-expressing PB terminals in RVM in normal animals interfered with both the ON-cell burst and OFF-cell pause. Activation of channelrhodopsin2-expressing PB terminals in RVM was able to drive RVM neurons *in vivo*, and in an RVM adult slice preparation, evoked synaptic currents. These data show that a substantial component of the relevant nociceptive drive to RVM pain-modulating neurons is relayed through the parabrachial complex, and that RVM neurons receive direct input from PB. While the contralateral PB relays noxious input under basal conditions, the ipsilateral PB is recruited in persistent inflammation. Thus, the parabrachial nucleus, well known as an important relay for ascending nociceptive information, also accesses descending control systems through a connection with the RVM.

Title: Posterior-hypothalamic modulation of nociception for male and female rats in a neuropathic pain model

Authors: *M. A. WAGNER, J. E. HOLDEN;
Univ. of Michigan, Ann Arbor, MI

Abstract: The aim of this study was to examine the effect of PH stimulation on nociception in female and male rats in a model of neuropathic pain. Female and male Sprague-Dawley rats received left sciatic nerve ligation to induce the thermal hyperalgesia of neuropathic pain (n = 4 - 8). Fourteen days later, either carbamoylcholine (carbachol; 500nmol in 0.5 µl normal saline) or normal saline for control was microinjected into the left PH of each rat. Left paw withdrawal latency (PWL) from a thermal stimulus was measured at baseline and every 5 minutes for 45 minutes. Two-way repeated measures ANOVA was conducted for statistical analysis using Sigma Stat. Data were excluded if microinjector placement was located outside of the PH. Left PH stimulation with 500 nmol of carbachol produced significant antinociception in left PWL in female neuropathic rats (10.33 ± 0.99 Vs 5.79 ± 0.92 sec for saline control; $p = 0.005$), but not male neuropathic rats (9.50 ± 1.58 Vs 7.36 ± 1.29 sec for saline control; $p = 0.33$). These preclinical findings are suggestive that the effectiveness of PH stimulation may be dependent on sex.

Title: Deep brain stimulation of the nucleus accumbens alleviates acute inflammatory pain

Authors: *H. HARRIS, J. N. STRAND, A. S. PARCHURE, Y. B. PENG;
Psychology, Univ. of Texas At Arlington, Arlington, TX

Abstract: The assertion of involvement of the nucleus accumbens in pain processing has been supported by findings of projections to and from the thalamus, somatosensory cortex, and anterior cingulate cortex, which send and receive signals along dopaminergic and glutamatergic pathways (Salgado et al., 2015). One specific affective network through the nucleus accumbens is an indirect pathway known to be associated with negative affect and acute aversive events (Ren et al., 2016). Because of suggested associations between the nucleus accumbens and pain

processing, researchers have begun to examine analgesic effects of treatments such as deep brain stimulation targeted toward the nucleus accumbens and other striatal regions (Mallory et al., 2012). It has previously been shown to be effective for treating Parkinson's symptoms, OCD, depression, and chronic pain (Flora et al., 2010; Nauczyciel et al., 2013; Sturm et al., 2003). Furthermore, research from our laboratory has successfully produced an analgesic effect with deep brain stimulation of the VTA (Li et al., 2016), a structure known to project to the nucleus accumbens. The purpose of this study is to provide evidence of analgesia via stimulation in the nucleus accumbens. The hypothesis of the current study is that deep brain stimulation of the nucleus accumbens will alleviate acute inflammatory pain. To test this hypothesis, electrodes were implanted into the core of the left nucleus accumbens in male Sprague-Dawley rats. After seven days, the rats were tested for noxious heat by thermal paw withdrawal threshold test (TPWT) in order to demonstrate that implantation alone did not affect pain response, and to establish a baseline. Rats were given subcutaneous injections of .05mL of 3% formalin in the right hindpaw. A wireless stimulation module was attached to the implanted electrode. The TPWT was measured again before and after turning on the electrical stimulation at 1 ms pulse width, 100 Hz, and 5 V. Results show paw withdrawal latency significantly increased after stimulation of the nucleus accumbens ($p < .001$), indicating analgesia. However, there was still a significant difference between the latency of the right hindpaw post-stimulation and the left control hindpaw post-stimulation ($p = .003$), indicating that pain was alleviated by deep brain stimulation, but not totally reversed. In conclusion, intracranial stimulation of the nucleus accumbens appears to reduce acute pain response.

Abstract: Itch (or pruritus) is a skin sensation that provokes desire to scratch. The underlying mechanisms for the induction of itch are still unclear. ATP is an energy source and plays an important role in the cell signaling. ATP produces several physiological actions through purinoceptors. P2X3 receptors (P2X3Rs), a member of ATP-gated cation channels as a purinoceptor, are predominantly expressed in small-diameter primary afferent sensory neurons. A growing body of literature has indicated the participation of this channel in nociception. However, the role of P2X3Rs in itch remains unclear. In the present study, we investigated the function of P2X3Rs as itch-related receptors in primary sensory neurons. Intradermal injection of either αβ meATP (a P2X3R agonist) or ATP (an endogenous agonist of P2X3Rs) into the cheek of mice induced scratching, an itch-related response. A317491, a specific antagonist of P2X3Rs, inhibited αβ meATP-evoked scratching. Immunohistochemical analyses using *Mrgpra3*$^{GFP\text{-}Cre}$ transgenic mice revealed that some P2X3Rs were expressed in MrgprA3-positive neurons which are itch specific sensory neurons. Inactivation or deletion of MrgprA3-positive sensory neurons resulted in reduction of P2X3R-mediated scratching. Furthermore, scratching induced by P2X3R agonists was attenuated in mice lacking receptors for gastrin-releasing peptide (GRP), an itch-inducing neuropeptide in the spinal dorsal horn. These findings indicate that activation of P2X3Rs in MrgprA3-positive primary afferent sensory neurons elicits the itch sensation through a pathway involving GRP receptors in dorsal horn neurons.

Title: Eosinophils increase thymic stromal lymphopoietin receptor expression in sensory nerves: a potential mediator of itch

Authors: *Q. ROTH-CARTER[1], J. J. LEE[4], A. D. FRYER[2], D. B. JACOBY[3];
[1]Cell and Developmental Biol., [2]Physiol. and Pharmacol., [3]Pulmonary and Critical Care Medicin, Oregon Hlth. & Sci. Univ., Portland, OR; [4]Mayo Clin., Scottsdale, AZ

Abstract: Atopic dermatitis is an inflammatory disease of the skin primarily characterized by chronic itch. Our ability to develop effective therapies has been seriously limited by our lack of understanding of the neurobiology of itch in this disease. Itch is mediated by cutaneous sensory nerves, and interactions between sensory nerves and the immune system are key for the development of chronic itch in atopic dermatitis. Using a mouse model of atopic dermatitis we have found that the eosinophil (an immune cell), and specifically the eosinophil granule protein eosinophil peroxidase (EPX), are required for itch in atopic dermatitis. Supporting this finding, eosinophils are elevated and localize to sensory nerves in the skin of patients with atopic dermatitis. However, the mechanism by which eosinophils activate sensory nerves to induce is unknown. A recent finding that cytokine thymic stromal lymphopoietin (TSLP) activates sensory nerves to induce itch led to our hypothesis that eosinophils induce itch in atopic dermatitis by increasing TSLP expression and enhancing TSLP signaling in nerves supplying skin. To address this hypothesis primary cultures of keratinocytes from skin were treated with EPX and its substrates hydrogen peroxide and bromide, and 12 hours later TSLP was measured. EPX and its substrates hydrogen peroxide and bromide significantly increased TSLP gene expression in keratinocytes, and significantly increased TSLP in media. Neither EPX alone, nor hydrogen peroxide and bromide had any effect on TSLP. In separate experiments, co-culture of eosinophils with sensory nerves from dorsal root ganglia significantly increased gene expression for TSLP receptors in sensory nerves. These data show that eosinophils and eosinophil proteins are sufficient to induce expression of TSLP in keratinocytes and TSLP receptors in sensory nerves. These data suggest that eosinophils may mediate itch in atopic dermatitis by increasing TSLP in skin and TSLP receptors on sensory nerves, and that eosinophils and TSLP receptors may be therapeutic targets to treat itch in atopic dermatitis.

Title: Role for NRTN in spontaneous itch and density of nonpeptidergic intraepidermal fibers in a mouse model of psoriasis

Authors: K. SAKAI[1], K. SANDERS[1], M. YOUSSEF[1], L. JENSEN[2], G. YOSIPOVITCH[1], *T. AKIYAMA[3];
[1]Dermatol., [2]Microbiology and Immunol., [3]Dermatol. & Anat. and Cell Biol., Temple Univ., Philadelphia, PA

Abstract: Chronic itch is the most troublesome symptom of psoriasis, a chronic autoimmune skin disease of scaling and inflammation. The imiquimod-induced psoriasis mouse model has been reported as a useful model to investigate chronic itch in psoriasis. Neurotrophins are thought to be involved in chronic itch through increasing the density of epidermal nerve fibers. We presently investigated if neurotrophins affect the density of intraepidermal fibers and are involved in chronic itch in the imiquimod-induced mouse model of psoriasis. Psoriasis-like skin lesions were produced by daily topical application of imiquimod on the back skin of adult C57BL/6 mouse. Over the time course of imiquimod treatment, the density of epidermal nonpeptidergic nerves significantly increased, while the density of peptidergic nerves significantly decreased. Epidermal nonpeptidergic nerves expressed GDNF family receptor alpha-2, neurturin (NRTN) receptor. NRTN immunoreactivity increased in the skin of imiquimod-treated mice. To block the biological effects of NRTN, a NRTN-neutralizing antibody was intradermally injected into the imiquimod treatment area before each topical application. The NRTN-neutralizing antibody significantly inhibited the increase in nonpeptidergic nerve density as well as spontaneous scratching, a behavior associated with chronic itch. These results indicate that NRTN contributes to an elongation of nonpeptidergic nerves in the skin of imiquimod-treated mice that is likely involved in chronic itch. Therefore, inhibition of NRTN could be a potential treatment for chronic itch in psoriasis.

Abstract: Itch is a unique sensory experience that elicits a desire to scratch. However, pathological itch can arise from a wide variety of neurological disorders and become debilitating. Itch can be classified as either histaminergic or nonhistaminergic based on the involvement of histamine, a pro-inflammatory compound released from immune cells. While most existing research has focused on investigating histaminergic itch, the molecular and circuit mechanisms governing nonhistaminergic itch are still poorly understood. Recent work has identified the MRGPR family of G protein coupled receptors (GPCRs) as the main receptors for detecting nonhistaminergic itch inducing compounds. Many of these GPCRs are expressed by the primary sensory neurons that convey itch, which include small diameter C-fiber dorsal root ganglion (DRG) and trigeminal ganglion (TG) neurons that carry information into the spinal cord and medulla. A subset of these neurons express MRGPRD and are polymodal nociceptors in that they mediate various modalities of both pain and itch at the behavioral level. However, how such a task is accomplished is unclear.
Here, we generated a new mouse line in which an inducible Cre-recombinase is knocked into the *Mrgprd* locus. We were then able to specifically express channelrhodopsin (ChR2) in MRGPRD$^+$ neurons and use blue light to activate their peripheral terminals in the ear skin of awake and behaving mice, showing that these mice preferentially scratched the area of stimulation after light exposure. To our knowledge, our experiments are the first example of optogenetically induced itch, and provide evidence that a subset of neurons are preferably tuned to mediate itch within the MRGPRD$^+$ neuron population. In addition, we demonstrate that optogenetically activated itch lasts for at least an hour after stimulation, suggesting the existence of mechanisms for generating the persistence of itch sensation. Furthermore, compared with the use of direct chemical injections for inducing itch, our optogenetic method is less invasive, temporally precise, and the population of activated neurons is unambiguous. Thus, our work lays a foundation for further study of the mechanisms underlying nonhistaminergic itch.

Title: A TRPV1 blocker riboflavin (vitamin B2) for histamine itch relief

Authors: *S. JUNG;
Hanyang Univ. Med. Sch., Seoul, Korea, Republic of

Abstract: Riboflavin has various therapeutic effects, such as anti-cancer, anti-oxidant, and anti-inflammatory activities. Riboflavin is considered to be important for blockage of transient receptor potential vanilloid 1 (TRPV1), which plays an important role in itch and pain. While riboflavin is known to have therapeutic effects, histamine, a major agitator in various skin diseases, provokes itching by exciting a subset of sensory neurons, predominantly C-fibers. In the recent study, we investigated the effects of riboflavin on itch behaviors in histamine-itching mouse model, and as an attempt to explain its mechanism, we characterized inhibitory effects of riboflavin on TRPV1 in dorsal root ganglion (DRG) neurons. DRG neurons were classified into two types on the basis of their neurochemical and electrophysiological properties such as cell size, and inward current of capsaicin and histamine by using whole-cell patch clamp. Riboflavin reversibly inhibited TRPV1 current by capsaicin and histamine in TRPV1+/Capsaicin+/Histamine+ and TRPV1 transfected HEK293 cells. Effects of riboflavin were also observed in vivo, where itching behavior was reduced in riboflavin-fed mice. However, riboflavin failed to diminish Hargreaves test, which was attributable to the blockade of other TRPV1 pathways. Taken together, these results suggest that riboflavin may serve as an anesthetic agent for other itching conditions. Key word. Riboflavin, TRPV1, Itch, Histamine, Capsaicin, channel blocker

Title: Thromboxane A_2 increased in atopic dermatitis-like skin lesions induces itch-associated responses through TP receptors on primary afferents in mice

Authors: *T. ANDOH[1], A. YAMAMOTO[1], Y. KURAISHI[2];
[1]Univ. Toyama, Toyama, Japan; [2]Tokyo Med. Dent. Univ., Tokyo, Japan

Abstract: Atopic dermatitis (AD) is a severe and chronic inflammatory skin disease. The itching is its major symptom in AD patients. The scratching induced by the itch sensation aggravates dermatitis and furthermore increases the frequency of itching. Therefore, itch control is very important to improve quality of life and to treat AD. However, the underlying mechanisms of itching in AD patients are still unknown completely. Thromboxane (TX) A_2 is an arachidonic acid metabolite produced by catalysis with COX and TX synthase (TXSyn). Our previous report has shown that an intradermal injection of TXA_2 analogue U-46619 elicits itch-related responses in mice, suggesting that TXA_2 is an itch mediator. In this study, to investigate the mechanisms underlying itch in AD, we examined whether TXA_2 was involved in spontaneous scratching, an itch-related response, in NC mice with AD-like skin lesions (dermatitis mice). The spontaneous scratching in dermatitis mice was inhibited by TP TXA_2 receptor antagonist ONO-3708. The mRNA expression of TXSyn and the concentration of TXB_2, a metabolite of TXA_2, were increased in lesional skin. The immunoreactivity of TXSyn was detected in epidermis, especially stratum spinosum and granular layer. In addition, the primary afferents were elongated into epidermis in dermatitis mice. TP receptor was expressed in primary cultures of dorsal root ganglion (DRG) neurons. U-46619 activated primary cultures DRG neurons. These result suggest that TXA_2 produced in keratinocytes elicits itch-related responses through the activation of TP receptor on primary afferents in dermatitis mice.

Title: MCP-1/CCR2 signaling elicits itch- and pain-like behavior in a murine model of allergic contact dermatitis

Authors: H. JIANG[1,2], C. CHEN[2], S. G. SHIMADA[2], P. ZHANG[2], *C. MA[1], R. H. LAMOTTE[2];
[1]Inst. of Basic Med. Sciences, CAMS&PUMC, Beijing, China; [2]Anesthesiol., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Spontaneous itch and pain are the most common symptoms in various skin diseases, including allergic contact dermatitis (ACD). Monocyte chemoattractant Protein-1 (MCP-1) is a chemokine produced by a variety of non-neuronal cell types during the elicitation phase. The chemokine MCP-1 (CCL2) and its receptor CCR2 are involved in the pathophysiology of ACD; but little is known of the role of MCP-1/CCR2 for the itch and pain accompanying this disorder. C57BL/6 mice previously sensitized to the hapten, squaric acid dibutyl ester, applied to the abdomen were subsequently challenged twice with the hapten delivered to either the cheek or to the hairy skin of the hind paw resulting in contact hypersensitivity (CHS, the murine model of ACD) at that site. By 24 h after the 2nd challenge to the hind paw MCP-1 and CCR2 mRNA, protein, and signaling activity were upregulated in the dorsal root ganglion (DRG). Calcium imaging and whole-cell current-clamp recordings revealed that MCP-1 directly acted on its neuronal receptor, CCR2 to directly activate a subset of small-diameter, nociceptive-like DRG neurons retrogradely labeled from the CHS site. Intradermal injection of MCP-1 into the site of CHS on the cheek evoked site-directed itch- and pain-like behaviors which could be attenuated by prior delivery of an antagonist of CCR2. In contrast, MCP-1 failed to elicit either type of behavior in control mice. Results are consistent with the hypothesis that CHS upregulates MCP-1/CCR2 signaling in a subpopulation of cutaneous small diameter DRG neurons and that MCP-1 can activate these neurons through neuronal CCR2 to elicit itch and pain. Targeting the MCP-1/CCR2 signaling might be beneficial for the treatment of allergic itch and pain in humans.

Title: Investigating the role of Piezo2 in neuropathic pain

Authors: *S. MURTHY, A. FRANCISCO, M. LOUD, A. PATAPOUTIAN;
Neurosci., The Scripps Res. Inst., LA Jolla, CA

Abstract: Neuropathic injury has been known to cause behavioral sensitivity to mechanical stimuli through a combination of central and peripheral sensitization mediated by sensory neurons. However, the molecular mechanism underlying the role of a mechanosensitive ion channel at the periphery remains unknown. We have previously shown that Piezo2, a mechanically activated ion channel, is expressed in a subpopulation of sensory neurons, and is essential for touch sensation and proprioception in mice. In the current study, we investigated the role of Piezo2 in touch-evoked pain after nerve injury. We find that, after subjecting mice to the chronic constriction injury (CCI) neuropathic pain model, mice lacking Piezo2 continue to display mechanical allodynia, a heightened response to low mechanical forces. These results suggest that injury-mediated peripheral sensitization occurs via a pathway independent of Piezo2, or that in the absence of Piezo2 a compensatory mechanism contributes to mechanical hypersensitivity.

Title: Mrgb2 contributes to mechanical and thermal allodynia in animal models of inflammatory and neuropathic pain

Authors: *D. GREEN[1], V. TIWARI[2], X. DONG[2];
[1]Neurosci., [2]Johns Hopkins, Baltimore, MD

Abstract: Aim of Investigation: As one of the key effector cells in the inflammatory process, mast cells are an important contributor to pain pathophysiology. The role of mast cells in

mediating postoperative pain is incompletely understood, although studies using mast cell stabilizers demonstrate that this immune cell is involved in contributing to nociception in animal models of postoperative pain. Thus, there is a compelling need for fundamental research aimed at understanding the mechanisms of mast cells in postoperative pain. **Methods:** Towards this objective, our lab has previously published data identifying a novel mast cell specific receptor, Mas-related G-protein-coupled receptor B2 (MRGB2) and its human orthologue, MRGX2, in non-allergenic activation of mast cells. To evaluate the role of MRGB2 in postoperative pain we utilized a hindpaw incision model. After baselines were measured, mice were anesthetized and a 5-mm incision beginning 2 mm from the proximal edge of the right heel was made. Curved forceps elevated the underlying muscle. A mattress suture of 8-0 nylon on a TG175-8 needle were then used to close the incision. Antibiotic ointment (Bacitracin Zinc Ointment) was then applied. As neuropathic pain has also been reported in patients post-surgery we evaluated the role of MRGB2 in nerve injury utilizing a chronic constriction model (CCI). After baselines were measured, mice were anesthetized and the sciatic nerve was exposed at the level of the middle of the thigh by blunt dissection. Three ligatures (silk 6-0) were tied loosely around the nerve with about 1 mm spacing and the incision was closed in layers. **Results:** Male C57bl/6 wild-type (WT) or MRGB2KO (n=6/group) were tested 24 h after incision surgery. Behavioral testing was done utilizing the radiant heat test and Von Frey filaments. At 24 hours post-surgery we saw significant reduction in both mechanical and thermal allodynia in MRGB2 KO mice but not WT. In the CCI model of neuropathic pain, similar results were observed. Behavioral testing was done 14 days after surgery, and we saw significant reduction in both mechanical and thermal allodynia in MRGB2 KO mice but not WT. **Conclusion:** Results indicate that mast cells contribute to postoperative allodynia via MRGB2 and contribute to the thermal and mechanical allodynia seen in a neuropathic pain model. Further study of the mechanisms underlying the role of this receptor in mediating incision induced pain may provide potential strategies for the development of novel analgesics to treat debilitating postoperative and neuropathic pain.

Title: Slack channel regulate mechanical pain though both dorsal root ganglia and spinal cord mechanism

Authors: ***Z. ZHANG**, F.-F. ZHANG, Y. SONG, R. WANG, J. CHEN, S.-H. GAO, M.-H. SUN, M.-J. TAN, Q.-Y. TANG;
Xuzhou Med. Col., Xuzhou, China

Abstract: Slack (Slo2.2, KCNT1) channels are sodium activated potassium channels that are widely expressed in nervous system, such as dorsal root ganglia, spinal cord and brain. The role of Slack channels in pain sensing is still in debating (Lu R, et al 2015;Huang F, et al 2013). In this abstract, we reported that Slack channels regulate mechanical pain sensing but do not alter thermal or cold pain sensing by examining Slack channel knockout mice. In addition, we found that Slack channels are richly expressed in IB4 positive Drg neurons but are relative lower expressed in CGRP and NF200 positive Drg neurons. Electrophysiological data showed that mediate and small Drg neurons of Slack KO mice have increased firing rate and higher resting potentials than mediate and small Drg neurons of WT mice. But the large Drg neurons of Slack KO mice did not show different excitability with large Drg neurons of WT mice. However, the Slack channels also are richly expressed in Spinal cord, especially in dorsal horn. Immunostaining, in situ hybridization and electrophysiological study showed that spinal cord mechanism is also important for Slack channel's role in pain sensing.

Title: The contribution of transient receptor potential channels to axonal mechanical sensitivity and radiating pain

Authors: *G. GOODWIN, A. DILLEY;
Brighton and Sussex Med. Sch., Brighton, United Kingdom

Abstract: Work from our laboratory has shown that inflammation (neuritis) can cause intact nociceptive axons to become mechanically sensitive (1). Such axonal mechanical sensitivity (AMS) may underlie movement-evoked radiating pain. Axonal transport is disrupted at the neuritis site (2), and we have hypothesised that transported mechanically sensitive ion channels may be accumulating at this site, leading to AMS. In this study, we have examined the physiological properties of mechanically sensitive axons and have begun to identify a potential role for TRP channels. In anaesthetised adult male Sprague Dawley rats, a strip of absorbable gelatin sponge saturated in either 0.1mM vinblastine (n=5) or complete Freund's adjuvant (n=3) was wrapped around the sciatic nerve as previously described (2). Vinblastine disrupts axonal transport in the absence of inflammation or degeneration and causes intact C-fibre axons to develop AMS (2). Three to 5 days post-surgery, the sciatic nerve was extracted and maintained at 32 °C in a recording bath that was perfused with oxygenated synthetic interstitial fluid. Single unit extracellular recordings from teased C-fiber axons were performed. The nerve was mechanically stimulated using a silicone tipped probe. Once a mechanically sensitive 'hotspot' had been located, a feedback-controlled mechanical stimulator (Aurora Scientific) was used to apply increasing forces to the nerve (20-250mN; duration of each stimulus: 2 sec). A ring was positioned over the nerve at each 'hotspot' to allow 10-50μM ruthenium red, a TRP channel blocker, to be applied. Force-discharge relationships were reassessed following the application of these agents. TRPV1 channel expression at the treatment site was also examined using immunohistochemistry. AMS 'hot spots' were identified at the treatment site in vinblastine-treated and neuritis nerves. There was a positive relationship between force applied and firing rate (vinblastine, $r^2 = 0.66$, n=10; neuritis $r^2 = 0.35$, n=7). The mean thresholds for AMS were 79mN (SEM +/- 16) in vinblastine-treated and 47mN (SEM +/- 6) in neuritis nerves. 50uM ruthenium red increased the threshold of mechanical sensitivity by 38.5% (SEM +/- 10) and 31% (SEM +/- 37) respectively. Preliminary immunohistochemical data revealed TRPV1 labelling at the treatment site. In summary, our data has revealed a role for TRP channels in the development of AMS. Therefore, drugs that target TRP channels may be effective in the treatment of radiating pain.

Title: Role of voltage-gated sodium channels and calcium channel subunit alpha-2/delta-1 in the lumbar dorsal root ganglions of persistent peripheral neuropathic pain model mice.

Authors: *H. KABURAGI, A. SUMI, T. HIRAI, Y. WAKABAYASHI, T. YOKOTA, A. OKAWA, M. ENOMOTO;
Tokyo Med. and Dent. Univ., Tokyo, Japan

Abstract: Voltage-gated ion channels are implicated in the development and maintenance of chronic pain. However, their exact roles in chronic pain, particularly in neuropathic pain, have yet to be elaborated as their roles could vary depending on the nature of the pathology and over time. Thus, formulating an ion channel-based treatment strategy will depend on understand the role of ion channels across a number of painful neuropathies and their chronological expression. The current study quantified changes over time of voltage-gated sodium channels (Nav) and the Ca2+ channel α2δ-1 subunit in lumbar dorsal root ganglia (DRG) in mice with either a spared nerve injury (SNI) or a partial sciatic nerve ligation (PSNL). Following nerve injury surgery, hind paw responsiveness to mechanical, cold and heat stimulation were assessed weekly. Following behavioral testing, total RNA was extracted from L3-L5 DRG and expression of Nav. 1.7, 1.8, 1.9 and calcium channel α2δ-1 subunit was quantified with real-time PCR. Following SNI, mice exhibited significantly increased sensitivity to tactile and cold stimuli (hyperalgesia) within 3 days of surgery, which lasted 6 weeks after surgery. PSNL mice gradually increased cold hyperalgesia after surgery. Heat hyperalgesia was observed in both models for the duration of the observational period. Expression of Nav1.7 mRNA in either model did not change over the course of the observational period. Expression of Nav1.8 and Nav1.9 mRNA in the PSNL was decreased three days after surgery. Compared to control (non-injured) mice, Nav1.8 and Nav1.9 in both models were decreased 25% and 27% respectively three weeks after injury. Six weeks after injury, expression of Nav1.8 and Nav1.9 in both models did not significantly differ from that of control mice. Compared to control mice, expression of α2δ-1 mRNA in both models was immediately increased three days and about 3-fold beginning 1 week after surgery. Six weeks after injury, SNI mice showed higher expression of α2δ-1 compared to PSNL mice. The current findings suggest that Nav1.8 and α2δ-1 contribute to the transition from an acute to chronic pain state since their expression in both neuropathic pain models changed over time. However, 6 weeks after surgery, α2δ-1 expression was still significantly altered, whereas Nav expression returned to control levels. The findings suggest that targeting α2δ-1 expression, rather than Nav, during the chronic phase could be crucial in alleviating persistent neuropathic pain.

Title: Functional and transcriptional changes in somatosensory neurons after peripheral nerve injury.

Authors: *I. TOCHITSKY[1,3], S. LEE[3], I. CHIU[2], C. WOOLF[3];
[1]Harvard Med. Sch., Brookline, MA; [2]Microbiology and Immunol., Harvard Med. Sch., Boston, MA; [3]Neurobio., Boston Children's Hosp., Boston, MA

Abstract: Neuropathic pain is a common disorder typically caused by disease of or damage to the peripheral nervous system. Spontaneous pain is a major feature of neuropathic pain disorders. This ongoing pain is thought to be generated by the ectopic activity of peripheral somatosensory neurons which is caused not by any external stimulus but rather the intrinsic hyperexcitability of injured neurons. Unfortunately, our current understanding of this ectopic activity is incomplete. In particular, it is not known which subtypes of peripheral sensory neurons become spontaneously active after nerve injury or what changes in gene expression cause their hyperexcitability. Here, we present functional and transcriptional data exploring the changes that take place in injured somatosensory neurons and drive their hyperexcitability. We used the spared nerve injury in mice as an animal model of neuropathic pain. Spared nerve injury leads to pain behaviors such as heat and mechanical hyperalgesia, and mechanical allodynia, which are also present in patients with neuropathic pain. One week after injury, we dissected and cultured the ipsilateral injured and contralateral uninjured lumbar L3 and L4 dorsal root ganglia (DRG) neurons *in vitro* and then performed a range of functional and transcriptional analyses on these cultured neurons. We observed a higher incidence of spontaneous activity in the ipsilateral DRG neurons as compared to the contralateral DRG neurons using both patch clamp electrophysiology and calcium imaging methods. Additionally, the injured DRGs were less excitable to a variety of electrical stimuli. We also observed a lower current density of voltage gated potassium currents in the ipsilateral DRG neurons, which would be consistent with their hyperexcitability. We confirmed the deficit in potassium channel function using the thallium assay, which involves imaging potassium flux into DRG neurons. Finally, we performed a transcriptional analysis on the injured vs uninjured DRG neurons and found a number of differences in ion channel expression that are associated with injury-induced hyperexcitability. We believe that our combined functional and transcriptional analysis may help identify new drug targets for the treatment of neuropathic pain and may lead to the development of improved therapeutics.

Title: Optogenetic control of Aβ-fibers in acute and chronic pain conditions

Authors: ***A. CHAMESSIAN**[1], M. W. WANG[2], Y.-H. KIM[1], T. VAN DE VEN[1], R.-R. JI[1]; [1]Anesthesiol., [2]Duke Univ., Durham, NC

Abstract: The ability to gain genetic access to light touch-sensing Aβ primary sensory neurons would be broadly enabling to the study of normal and pathological sensory processing. To that end, we have characterized a new knockin-in Cre-driver line that expresses under the control of the Vesicular Glutamate Transporter 1 (VGLUT1) gene locus. To examine whether VGLUT1-Cre shows faithful expression in VGLUT1-expressing (dorsal root ganglia) DRG neurons, we crossed VGLUT1-Cre with a floxed Channelrhodopsin-EYFP (ChR2) reporter line (Ai32). The resulting cross, VGLUT1-ChR2, both marks VGLUT1-positive neurons and also allows for optogenetic control of this neuronal population. Extensive characterization of the VGLUT1-ChR2 line by immunofluorescence microscopy demonstrated that VGLUT1-ChR2 is expressed in medium- and large-sized DRG neurons and colocalizes with Parvalbumin, Ret, Piezo2, and Neurofilament 200 (NF200). Moreover, the ChR2-EYFP neurons showed virtually no colocalization with the nociceptive markers IB4, Peripherin, and CGRP, demonstrating that ChR2-EYFP expression is not present in nociceptors. In the spinal cord, VGLUT1-ChR2 fibers were observed specifically in the deep dorsal horn (lamina III-V), dorsal column, and to a lesser extent, the ventral horn, consistent with the features of myelinated A-fibers. In the skin, ChR2-EYFP is present in Meisnner Corpuscles, Hair Follicles and Merkel Cell-Neurite complexes, indicating that the VGLUT1-ChR2 population encompasses both rapidly adapting and slowly adapting subtypes of Aβ fiber. Optogenetic photostimulation of the plantar hindpaw in awake, behaving animals showed clear innocuous responses to photostimulation, namely paw lifting and ambulation, but never any nocifensive responses such as licking, biting, flinching or jumping.

Taken together, these results strongly suggest that the VGLUT1-ChR2 line is a specific tool for the manipulation of low-threshold A-fibers. With this tool in hand, we are now using the VGLUT1-ChR2 mouse to interrogate the specific contributions of Aβ fibers to pain in models of inflammatory and neuropathic conditions.

Title: Expression of bestrophin-1 in dorsal root ganglion neurons after nerve injury in the rat.

Authors: *J. MURBARTIAN, G. GARCÍA;
Cinvestav, Sede Sur, Mexico, DF, Mexico

Abstract: The calcium-activated chloride channels (CaCC) are involved in several physiological processes including neuronal regeneration and sensory transduction. Four genes encoding for bestrophins (Best) have been reported, the first channels to settle within CaCC family. Although Best-1 has been involved in neuropathic pain, the expression profile in individual dorsal root ganglia (DRGs) of this channel is lacking. The purpose of this study was to determine the expression of Best-1 in individual L4, L5 and L6 DRGs in rats subjected to the spinal nerve ligation (SNL). Best-1 was expressed in L4, L5 and L6 DRGs of naïve and sham-operated rats. SNL increased Best-1 protein expression in L5 and L6, but not in L4, DRGs. Of note, SNL enhanced Best-1 protein expression in L5 DRG at 1 day after nerve injury, while it increased Best-1 protein expression in L6 DRG at 14 and 21 days after injury. Likewise, SNL rose protein expression of the nerve injury marker activating transcription factor 3 (ATF3) in L5 and L6, but not L4, DRGs. Since Best-1 has been involved in nerve regeneration and pain, our results suggest that Best-1 channels could contribute to axonal regeneration and nociceptive processing after nerve injury.

Title: Participation of TRPC in pronociceptive effect induced by hydrogen sulfide in hyperglycemic rats

Authors: *J. E. ROA-CORIA[1], F. J. FLORES-MURRIETA[1], V. GRANADOS-SOTO[2], H. I. ROCHA-GONZALEZ[1];
[1]Superior Sch. of Med. IPN, México, D.F., Mexico; [2]CINVESTAV-SUR, Ciudad de México, Mexico

Abstract: Hydrogen sulfide (H_2S) is a gasotransmitter that produces a pronociceptive effect in many nociceptive models, but little is known about the molecular targets involved in such effect. The aim of this work was to establish the participation of TRPC receptor in the nociception induced by H_2S in peripheral neuropathy associated with diabetes. Hyperglycemia was induced by streptozotocin (60 mg/kg, ip) in Wistar rats, which had values of glucose >350 mg/dL within 2 weeks. Nociception was evaluated by injection of 0.5 % formalin into the right hind paw of the rat. Local peripheral ipsilateral, but not contralateral, injection of H_2S (100 µg/paw) increased nociceptive behavior. Moreover, pronociceptive effect of H_2S was prevented by local administration of SKF96365 (TRPC receptor antagonist; 30, 100 µg/pata) and GsMTx4 (TRPC1 and TRPC6 receptor selective antagonist; 1, 5.6 µg/paw). These data suggest that the local pronociceptive effect induced by H_2S in rats with peripheral neuropathy could be mediated by activation of TRPC receptors, so the use of blockers of these channels may be a useful strategy to treat painful peripheral neuropathy associated with diabetes.

Abstract: We have recently demonstrated that the sigma-1 receptor (σ1R) is present in dorsal root ganglions (DRG) and that the activation of the σ1R in DRG diminishes I_{Ca} and intracellular Ca^{2+} store which are known features of painful injury in primary sensory neurons. The present study explored the role of σ1R in the DRG as it relates to neuropathic pain at the pharmacological, electrophysiological, and molecular biological level. (A) The σ1R agonist (+)-pentazocine or antagonist BD1047 (4μg/2μl) was injected directly into the 4th and 5th lumbar (L4, L5) DRGs. (+)-Pentazocine produced a hypersensitivity to threshold mechanical stimulation and also a trend toward hypersensitivity to noxious mechanical, brush or cold stimulation. In spinal nerve ligation (L5 & L6) rats, BD1047 diminished neuropathic hypersensitivity. (B) To explore the σ1R agonistic effect on the neuronal excitability, (+)-pentazocine was tested in a system using intact DRG recording and dissociated sensory neurons. (+)-Pentazocine (10 μM) decreased both the AHP amplitude and duration which allowed for more APs following high frequency depolarizing stimuli. Those findings indicate that the σ1R controls the DRG excitability in that the σ1R agonist increases the neuronal excitability in DRG. (C) (+)Pentazocine (100 μM) caused an inhibition of activity-induced (50 mM K^+, 3s) Ca^{2+} transients in DRG neurons; the reduction of the Ca^{2+} transient is known to relate to neuropathic pain. Interestingly, this inhibition caused by (+)pentazocine was not seen in DRG neurons transfected by AAV6-σ1R shRNA. When taken together, the above results suggest that the σ1R participates in the DRG-generated neuropathic pain by regulating the excitability of DRG. (Supported in part by the IRP, NIDA, NIH/DHHS)

Title: Deciphering the molecular complexity of DRG neurons using single cell molecular profiling technology

Authors: *N. ALESSANDRI-HABER, R. BREESE, Y. BAI, W. FURY, M. SIVULA, Y. WEI, M. NI, C. ADLER, C. LIN, A. MURPHY, L. MACDONALD;

Abstract: Chronic painful conditions affect millions of people worldwide. Patients suffering from chronic pain often experience hypersensitivity to mechanical, thermal and/or chemical stimulation in the form of hyperalgesia and/or allodynia. This hypersensitivity is mediated, at least in part, by sensitization of signaling processes in different subpopulations of primary sensory neurons known as nociceptors. The cell bodies of these neurons are clustered in nodules on dorsal roots of the spine known as dorsal root ganglia (DRG). The axons of these neurons split into two branches; one branch innervates the peripheral tissues (skin, muscles, joints and organs) and the other connects to the spinal cord to carry signals to the appropriate integration center in the brain. Nociceptors fall into different subpopulations based on their conduction properties, molecular profile and whether they respond to a single type of physical stimulus or integrate and generate a response to different types of stimuli. Although the development of chronic pain has been associated with increased excitability of nociceptors, their molecular complexity has made it difficult to fully elucidate the critical mechanisms underlying persistent pain. To get a better understanding of the molecular complexity within the different subpopulations of DRG neurons, we utilized the Fluidigm C1™ single-cell RNA sequencing system. We show here that we can reproducibly discriminate different subpopulations of DRG neurons and correlate them to known functional subclasses of sensory neurons. These distinct subpopulations of neurons are still reproducibly detected following peripheral injections of the inflammagen carrageenan or i.p. injection of the chemotherapy drug, Paclitaxel. Moreover, we show that distinct subpopulation of neurons display different gene signatures in an animal model of Paclitaxel-induced neuropathy. Our results suggest that single cell molecular profiling technology could help unravel the molecular mechanisms occurring in distinct subpopulations of DRG in the setting of neuropathic pain.

Abstract: The introduction of nucleic acids in to living cells has become a groundbreaking toolbox for exploring gene function. In example RNA interference (RNAi), a form of post-transcriptional gene silencing provides a powerful tool to explore pathway, gene and protein function in cell cultures. However, the key for successful RNAi experiments is efficient delivery of the siRNA into the cell type of interest, and in biologically relevant cells models, which are typically primary and/or non-dividing, transfection can be highly challenging.
Electroporation is an efficient method for nucleic acid delivery that may be applied for a variety of cell types. Transfection of primary cells is however generally challenging. Using Cellaxess® Elektra platform, we can efficiently transfect adherent primary cells in vitro in high density microplates. In this particular case, our aim was to develop a plate-based assay in 384-well format for screening of RNAi knockdown in cultured rat dorsal root ganglia (DRG) neurons, targeting genes in the pain pathway.
For this purpose, we used the multiple capabilities of the Cellaxess® Elektra platform. siRNA was delivered to cultured rat dorsal root ganglia (DRG) neurons followed by electric field stimulation (EFS) and detection/imaging of the excitability response using a calcium indicator. Following this, cultures were immunolabeled for nociceptive neuron identity (RIIb) and read on a high content imaging platform. These images were then aligned with the EFS data which enabled analysis of neuronal excitability of the nociceptive neurons only. siRNAs were selected to target pain relevant genes, including the voltage gated sodium channel NaV1.7, the nerve growth factor (NGF) receptor tyrosine receptor kinase A (TrkA), and growth-associated protein 43 (GAP43). A non-targeting control and technical control siRNA was used for reference purposes.
Taken together, this study demonstrates the multiple applicability of the Cellaxess® Elektra® platform for efficient identification of novel pain targets in a physiologically relevant context.

Title: Deletion of novel peptide TMEM35 alters pain signaling in mice

Authors: *P. V. TRAN[1], B. C. KENNEDY[2], W. V. HOHENBERG[3], J. C. GEWIRTZ[3]; [1]Dept. of Pediatrics, [2]Program in Neurosci., [3]Dept. of Psychology, Univ. of Minnesota, Minneapolis, MN

Abstract: Chronic pain affects over 100 million adults in the USA, with considerable economic costs in healthcare and loss of productivity. Notable progress has been made in elucidating neural mechanisms underlying pain perception, leading to important insights into the maladaptive changes that produce persistent or chronic pain. Nevertheless, there is still potential benefit for medical discovery to generating additional molecular targets for alternative treatment strategies. We investigated a novel and evolutionarily conserved polypeptide (TMEM35) that is strongly expressed in developing and adult pain networks (i.e., dorsal root ganglia (DRG) and spinal cord). Given the persistently reduced TMEM35 expression in the spinal cord following spinal cord injury, the potential role for TMEM35 in neuropathic pain was probed by assessing whether TMEM35 protein levels in the spinal cord are altered by spared nerve injury, a model of chronic pain. Additionally, we generated a *tmem35* knockout (KO) mouse and measured pain sensitivity utilizing various stimuli, including Hargreaves, von Frey, tail flick, and temperature preference. Relative to wild type (WT) mice, KO mice exhibited heightened pain sensitivity across all behavioral measures, indicating a role for TMEM35 in pain signaling. Finally, we quantified expression of peptidergic and non-peptidergic nociceptors in the DRG and projections to the spinal cord, and found that deletion of TMEM35 alters characteristics of the peripheral pain networks. Collectively, our findings suggest that TMEM35 may function to protect against

hyperalgesia in normal animals. Further investigation is needed to determine the molecular role of TMEM35 in pain networks.

Title: Functional characterization of two overlapping populations of cutaneous afferent fibers by optogenetic activation

Authors: ***M. WRIGHT**, K.-H. LEE, P. C. ADELMAN, H. KOERBER;
Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Sensory neurons in mammalian dorsal root ganglia (DRGs) can be organized and characterized based on many criteria, including their end organ innervation patterns, physiological response characteristics, and gene expression profiles. Here, we characterized the response properties following optogenetic activation of two partially overlapping subpopulations of small diameter sensory neurons. *Trpv1*^{Cre} and *Mrgd*^{Cre} mice were each crossed to the channelrhodopsin-YFP reporter (*Ai32*), enabling their histological examination and selective activation by exposure to blue light. The *Trpv1*^{Cre} line labels all *Trpv1*-lineal afferents, encompassing both peptidergic and nonpeptidergic small diameter fiber subpopulations, including many Mrgd-expressing neurons. *Mrgd*^{Cre} mice similarly label all *Mrgd*-lineal afferents, including those that express Mrga3, though labeling is limited to putative nociceptors. Using an *ex vivo* DRG-saphenous nerve-skin preparation, we evaluated the impact of blue light on ChR2-expressing cells and determined both that light activation elicits indistinguishable activity in each Cre line and that this activation is comparable to responses seen following mechanical and thermal stimulation. Surprisingly, our initial behavioral assays show that *Trpv1*^{Cre}*;Ai32* mice had a strong withdrawal response to blue light, while *Mrgd*^{Cre}*;Ai32* mice had a much more attenuated response. This led us to investigate how aversive the activation of these two afferent subpopulations is during normal animal behavior. Mice were tested in a novel place-preference

behavioral assay in which a testing chamber was floor-lit with blue light on one side and matched-intensity yellow control lights on the other. Lights were either left on (sustained) or flashed at 2Hz for 15 minutes. On average, *Trpv1^{Cre};Ai32* mice spent < 5% of the entire testing period on the blue lit side of the testing chamber during both light exposure paradigms, indicating a strong aversion to *Trpv1^{Cre}* afferent activation (n=4 mice). In contrast, *Mrgd^{Cre};Ai32* mice showed neither a preference for or aversion to either side of the testing chamber, spending an equal amount of time on both sides (n=10 mice), suggesting that activation of *Mrgd^{Cre}* afferents may not be aversive. Interestingly, preliminary data suggests that spinal nerve ligation (SNL) injury causes activation of *Mrgd^{Cre};Ai32* afferents to become aversive, with *Mrgd^{Cre};Ai32* mice spending significantly less time on the blue lit side of the chamber post-injury (n=6 mice). These results suggest that *Mrgd^{Cre}* afferents may not normally function as true nociceptors, though this may change in the context of nerve injury.

Title: Long-term effects of chronic inflammation on sodium channel gene expression in dorsal root ganglion neurons

Authors: *M. E. O'LEARY, A. BOTTARO, I. KUZIN, C. HO, B. FISCHER;
Rowan Univ. Cooper Med. Sch., Camden, NJ

Abstract: The goal of these studies was to investigate the effects of chronic inflammation on the expression of voltage-gated sodium channels in dorsal root ganglion (DRG) neurons. We employed a transgenic mouse model (TNFtg) that over expresses tumor necrosis factor-alpha (TNFα) resulting in chronic systemic inflammation. After 20 weeks the mechanical sensitivity of the hindpaws of TNFtg animals determined using von Frey filaments increased 3-fold by comparison to control littermates. This is consistent with ambulatory behavior measured in open arena testing which was reduced 3.8-fold in the TNFtg animals. Hargraves testing revealed that the TNFtg mice displayed a significant 31% decrease in hindpaw withdrawal time in response to noxious thermal stimulation. The observed mechanical allodynia and thermal hyperalgesia are hallmarks of plantar nociceptor sensitization. The underlying mechanism was further investigated using single-cell RT-PCR to quantitatively compare the expression of sodium channel transcripts in small-diameter (<25 μm) nociceptors isolated from acutely-dissociated

DRGs of control and TNFtg mice. While the transcripts of many of sodium channels were not altered (Nav1.1, Nav1.6, Nav1.7), a broadly expressed neuronal sodium channel (Nav1.2) and two nociceptor-specific sodium channels (Nav1.8, Nav1.9) were significantly upregulated in the nociceptors of TNFtg animals. Nav1.8 is a high threshold, tetrodotoxin-resistant (TTX-R) sodium channel that drives the rapid upstroke of the nociceptor action potential. Nav1.9 is a low threshold TTX-R sodium channel characterized by slow gating kinetics and substantial overlap of the activation and inactivation relationships that produce persistent inward sodium current at voltages near the resting membrane potential. The combination of a 2-fold increase Nav1.8 and 4-fold increase in Nav1.9 in nociceptors of TNFtg mice is predicted to lower the threshold and potentiate the repetitive firing of action potentials. These data indicate that an increase sodium channel gene expression produced by over-expression of TNFα contributes to the development of chronic inflammatory pain.

Title: Inflammatory and neuropathic cold allodynia are selectively mediated by the neurotrophic factor receptor GFRα3

Authors: ***S. ONGUN**[1], E. K. LIPPOLDT[2], G. K. KUSAKA[2], D. D. MCKEMY[2];

Abstract: Tissue injury prompts the release of a number of proalgesic molecules that induce acute and chronic pain by sensitizing pain-sensing neurons (nociceptors) to heat and mechanical stimuli. In contrast, many proalgesics have no effect on cold sensitivity or can inhibit cold-sensitive neurons and diminish cooling-mediated pain relief (analgesia). Nonetheless, cold pain (allodynia) is prevalent in many inflammatory and neuropathic pain settings, with little known of the mechanisms promoting pain vs. those dampening analgesia. Here, we show that cold allodynia induced by inflammation, nerve injury, and chemotherapeutics is abolished in mice lacking the neurotrophic factor receptor glial cell line-derived neurotrophic factor family of

receptors-α3 (GFRα3). Furthermore, established cold allodynia is blocked in animals treated with neutralizing antibodies against the GFRα3 ligand, artemin. In contrast, heat and mechanical pain are unchanged, and results show that, in striking contrast to the redundant mechanisms sensitizing other modalities after an insult, cold allodynia is mediated exclusively by a single molecular pathway, suggesting that artemin-GFRα3 signaling can be targeted to selectively treat cold pain.

Title: Protease activated receptor type 2 (PAR2) mediates nociception in a mouse behavioral model of migraine

Authors: *S. N. HASSLER[1], F. B. AHMED[1], J. VAGNER[2], S. BOITANO[3], T. J. PRICE[1], G. O. DUSSOR[1];
[1]UT Dallas, Dallas, TX; [2]Bio5 Inst., [3]Physiol., Univ. of Arizona, Tucson, AZ

Abstract: Migraine pain adversely affects millions of people each year in the U.S. and is a significant public health concern. The etiology that causes migraine pain is not well understood but is generally thought to occur as a result of sensitization of afferents that innervate the cranial meninges. Protease activated receptors (PARs) are expressed in trigeminal neurons and dural fibroblasts and have been implicated in other types of pain disorders. PAR2 is endogenously activated by trypsin and tryptase, the latter of which is released by mast cells. Since mast cell degranulation has been proposed to contribute to migraine pain, PAR2 may be a link between immune cell activation and neuronal activity. The current project investigated the role of meningeal PAR2 in migraine using a novel mouse behavioral model and calcium imaging of

trigeminal ganglia cultures. We found that 2-aminothiazol-4-yl-LIGRL-NH_2 (2AT), a PAR2 peptidomimetic agonist increases tactile sensitivity and grimacing, and C391, a PAR2 peptidomimetic antagonist is able to attenuate 2AT mediated nociceptive behaviors when applied onto mouse dura. Further, 2AT activates calcium signaling in primary trigeminal and dural cell cultures (fibroblasts), with C391 attenuating the calcium signaling response to 2AT. When given intravenously, C391 is able to attenuate nociceptive behaviors produced after dural application of compound 48/80, a mast cell degranulator, demonstrating efficacy against an endogenous mechanism thought to contribute to migraine pain. Together, these data show that trigeminal neuron PAR2 signaling contributes to nociceptive behaviors observed in a mouse migraine behavioral model and also show a possible contribution of PAR2 on dural fibroblasts to this process. The study suggests that PAR2-dependent activity in the meninges involves the interaction between neuronal and non-neuronal cells and that these PAR2 effects are a potential therapeutic target for treating migraine pain.

Title: DNMT1-mediated epigenetic repression of Kcna2 channel in primary sensory neurons contributes to neuropathic pain genesis

Authors: ***L. SUN**[1], X. GU[2], S. WU[2], L. LIANG[2], B. LUTZ[2], A. BEKKER[2], Y. TAO[2]; [1]Anesthesiol. Department, Rutgers Univ., Newark, NJ; [2]Anestheisology Department, Rutgers Univ., Newark, NJ

Abstract: Peripheral nerve injury-induced downregulation of the voltage-gated potassium channel Kcna2 in dorsal root ganglion (DRG) neurons contributes to neuropathic pain genesis. However, the mechanism of how this occurs is still elusive. DNA methylation that gates gene expression is caused by DNA methyltransferases (DNMTs) including DNMT1, DNMT3a, and

DNMT3b. It is generally believed that DNMT3a and DNMT3b function as *de novo* methyltransferases, while DNMT1 is the primary maintenance enzyme. Recent evidence suggests that DNMT1 might also have *de novo* methylation activity. In the present study, we aimed to investigate the potential epigenetic modulation of DNMT1 on *Kcna2* gene in DRG under neuropathic pain conditions. DNMT1 is expressed exclusively in DRG neurons. Unilateral fifth spinal nerve ligation (SNL) increased the levels of DNMT1 mRNA and protein in the injured DRG. This increase was triggered by the activation of the transcription factor CREB. Blocking this increase via microinjection of adeno-associated virus expressing Cre into the injured DRG of DNMT1 floxed mice or via crossing these mice with a primary sensory neurons-specific line restored DRG *Kcna2* gene expression and function, reduced DRG neuronal excitability, and impaired SNL-induced neuropathic pain development. Moreover, DNMT1 bond to Kcna2 promotor regions and co-expressed with Kcna2 in individual DRG neurons. Given that Kcan2 is a key player in neuropathic pain genesis, DNMT1 is likely a new target for the treatment of neuropathic pain.

Title: Epigenetic silencing of opioid receptors by G9a in in dorsal root ganglia after nerve injury

Authors: ***S. WU**[1], L. LIANG[1], X. GU[1], B. M. LUTZ[2], L. SUN[1], A. BEKKER[1], Y.-X. TAO[1]; [1]Anesthesiol., Rutgers, The State Univ. of New Jersey, Newark, NJ; [2]Anesthesiol., Rutgers Grad. Sch. of Biomed. Sci., Newark, NJ

Abstract: Downregulation of opioid receptors in the first-order sensory neurons of dorsal root ganglion (DRG) contributes to neuropathic pain genesis after nerve injury. Recent studies

suggested that epigenetic regulations such as DNA methylation and histone methylation may play roles in the downregulation of opoid receptors. We found that nerve injury induced the expression of histone methyltransferase G9a and its catalyzed repressive mark H3K9me2, which correlated with mu (MOR), kappa, and delta opioid receptor genes downregulation in the injured DRG neurons. Nerve injury-induced opioid receptors downregulation could be reversed by G9a knockdown and mimicked by G9a overexpression in the DRG. Chromatin immunoprecipitation assays demonstrated that nerve injury increased binding activitis of G9a and H3K9me2 to the promoter and 5'-untranslational regions of MOR gene. These data suggest that G9a is required for nerve injury-induced epigenetic silencing of opioid receptors. G9a inhibitors may serve as promising medications for the use as adjuvants with opioid in neuropathic pain management.

Abstract: Neuropathic pain is a complex disorder in which current treatment options are often ineffective due in part to unexplained changes in gene transcription and translation in the first-order sensory neurons of dorsal root ganglion (DRG). Gene expression can be modified by DNA methylation. In this study, we reported that DNMT3a expresses exclusively in DRG neurons and

distributes predominantly in medium and large DRG neurons. *In vivo* studies revealed that the *de novo* methyltransferase DNMT3a (but not DNMT3b) expression increases at the levels of mRNA and protein in the neurons of the injured DRG at 3 and 7 days after spinal nerve ligation (SNL) in mice. No changes are seen after injection of complete Freund's adjuvant. Blocking the increase in DRG DNMT3a after SNL alleviates mechanical allodynia and thermal/cold hyperalgesia on days 3, 5, and 7 post-SNL. Additionally, overexpression of DNMT3a in DRG leads to the development of mechanical, thermal, and cold pain hypersensitivities. DNMT3a may participate in neuropathic pain development and be a novel target for advanced therapeutics.

Title: DNMT3a-mediated Kcna2 downregulation in DRG after peripheral nerve injury

Authors: ***X. GU**, J.-Y. ZHAO, L. LIANG, L. SUN, S. WU, J. FENG, K. MO, B. LUTZ, A. BEKKER, E. J. NESTLER, Y.-X. TAO;
Anesthesiol., NJMS, Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: The mechanisms of neuropathic pain development remain elusive; however it is known that changes in gene expression are associated with this disorder. DNA methylation regulates gene expression. Our pilot data indicate that nerve injury-induced increase in the expression of the *de novo* methyltransferase (DNMT3a) in the injured dorsal root ganglia (DRG) contributes to neuropathic pain development. However, the mechanism underlying this phenomenon is still unclear. We showed that the increase in DNMT3a is accompanied by a decrease in the expression of the voltage-gated potassium channel (Kcna2) in the injured DRG. *In vivo* studies show that overexpression of DNMT3a in mouse DRG leads to a decrease in Kcna2 mRNA and protein. Knockdown of DRG DNMT3a using a Cre-lox approach restored the expression of Kcna2 mRNA and protein on day 7 after spinal nerve ligation (SNL). Chromatin immunoprecipitation assays showed that the binding of DNMT3a to the Kcna2 promoter region

increases in the injured DRG on day 7 after SNL. This increase in binding is also accompanied by an increase in DNA methylation at the Kcna2 promoter. shRNA-mediated knockdown of DNMT3a abolished the increase in DNA methylation at the Kcna2 promoter. Electrophysiology studies showed an increase in DRG neuron excitability and a decrease in Kv current after DNMT3a overexpression in mouse DRG. These findings reveal that DNMT3a likely acts as an endogenous instigator of neuropathic pain genesis by epigenetically silencing DRG Kcna2.

Title: Contribution of the histone methyltransferase G9a in dorsal root ganglia to neuropathic pain

Authors: *L. LIANG[1], X. MIAO, 07103[2], X. GU, 07103[2], S. WU, 07103[2], H. SUN[3], B. LUTZ[2], A. BEKKER, 07103[2], E. J. NESTLER[3], Y. TAO, 07103[2];

Abstract: The histone methyltransferase, G9a, methylates histone H3 on lysine residue 9 (H3K9) to predominantly produce dimethylation (H3K9me2), a dynamic histone methylation mark. This modification results in condensed chromatin and gene transcriptional repression. G9a is implicated in several biological processes including cell survival, cell death, drug addiction, stress responses, and other forms of behavioral plasticity through silencing specific gene expression. Whether G9a participates in neuropathic pain is unknown. Our immunohistochemistry staining showed that G9a co-expressed with NeuN in cellular nuclei but was not detected in GS-labeled cells. G9a was detected in all these three types of neurons including calcitonin gene-related peptide (CGRP, a marker for small DRG peptidergic neurons), isolectin B4 (IB4, a marker for small non-peptidergic neurons), and neurofilament-200 (NF200,

a marker for medium/large cells and myelinated A-fibers). Peripheral nerve injury increased the mRNA and protein expression of G9a and H3K9me2 in the injured DRG neurons. The fifth spinal nerve ligation (SNL)-induced pain hypersensitivities could be blocked by intrathecally administration of the G9a inhibitor BIX01294, by microinjection of adeno-associated virus (AAV)-Cre into the injured DRG of G9a flox mice, or in DRG G9a conditional knockout mice. Overexpression of G9a in DRG by microinjection of herpes simplex virus (HSV) expressing full-length G9a led to neuropathic pain symptoms. These data suggest that G9a is essential for SNL induced neuropathic pain and that G9a inhibitors may serve as promising adjuvants for neuropathic pain management.

Title: Contribution of the histone methyltransferase SUV39H1 in dorsal root ganglia and spinal cord dorsal horn to neuropathic pain

Authors: *Y. TAO[1], J. ZHANG[2], L. LIANG[2], S. WU[2], Q. MAO[2], M. XIONG[2], A. BEKKER[2]; [2]Anesthesiol., [1]New Jersey Med. School, Rutgers, Newark, NJ

Abstract: Peripheral nerve injury-induced alterations in the genes encoding receptors, ion channels, and enzymes in the dorsal root ganglion (DRG) and spinal cord dorsal horn are believed to participate in neuropathic pain genesis. Histone methylation gates gene expression. Whether the histone methyltransferase SUV39H1 contributes to neuropathic pain is unknown. We reported that SUV39H1 was detected in the neuronal nuclei of the DRG and dorsal horn. In the DRG, it was expressed predominantly in the small DRG neurons, in which it co-expressed with mu opioid receptor (MOR). The level of SUV39H1protein in both injured DRG and ipsilateral L_5 dorsal horn was time-dependently increased after the fifth lumbar spinal nerve ligation (SNL). SNL also produced an increase in the amount of SUV39H1 mRNA in the injured DRG. Intrathecal injection of chaetocin (a SUV39H1 inhibitor) as well as DRG or intraspinal

microinjection of SUV39H1 siRNA impaired SNL-induced pain hypersensitivity. DRG microinjection of SUV39H1 siRNA also restored MOR expression in the injured DRG. Our findings suggest that SUV39H1 contributes to nerve injury-induced pain hypersensitivity through gating MOR expression in the injured DRG. SUV39H1 inhibitors may be used with opioids in neuropathic pain management.

Title: Ghrelin agonist HM01 attenuates oxaliplatin and cisplatin-induced neuropathy in murine models

Authors: ***B. S. SLUSHER**[1], K. M. WOZNIAK[1], Y. WU[1], E. POMMIER[1], Y. LIU[2], M. POLYDEFKIS[2], M. FARAH[3], R. RAIS[4], C. PIETRA[5];

Abstract: Use of chemotherapeutic agents is associated with neuropathic toxicities which are often dose-limiting and have an impact on the life quality and survival of cancer patients. Ghrelin and ghrelin agonists, such as Anamorelin, have been found to be effective in preclinical and clinical studies of cancer-related cachexia. Ghrelin has also been shown to possess neuroprotective and neuropathic pain attenuating properties. In this study we evaluated the new PNS/CNS-penetrating ghrelin agonist HM01 in two experimental models of chemotherapy-induced neuropathy following nerve conduction velocity/amplitude, hyperalgesia, and footpad intra-epidermal nerve fiber density (IEFD). Oxaliplatin administered at its maximum tolerated dose in BALBc mice (6 mg/kg ip Q4Dx8), produced significant decreases in nerve conduction which were ameliorated by concomitant HM01 dosing (10 and 30 mg/kg PO daily). Specifically, oxaliplatin induced a significant decline in digital nerve conduction velocity (-10% $\pm$ 2.3%; $p < 0.05$) which was completely and significantly normalized by HM01 treatment. The oxaliplatin-induced digital amplitude deficit (-15% $\pm$ 7%; $p < 0.01$), although not statistically significant,

tended to also be improved by 10 and 30 mg/kg HM01 (19.8± 7.4% and 38.7± 10.9%, respectively; $p<0.05$ for 30 mg/kg dose). While there was no effect on sciatic nerve and dorsal root ganglia (DRG) morphology with this oxaliplatin regimen, a trend for reduction of IEFD in the footpads was observed (-15.1 ± 9.2%), which tended to be normalized by concurrent HM01 treatment. Interestingly, pharmacokinetic studies showed large accumulation of HM01 in DRG and sciatic nerve tissue (tissue penetration index of 18-19 and 9-12 fold versus plasma, respectively). In a separate cisplatin-induced neuropathy study, rats were dosed with cisplatin (0.5 mg/kg IP) and HM01 (3, 10 and 30 mg/kg PO) for several days. Cisplatin resulted in a significant decrease in food intake and weight gain, both of which were significantly prevented by concurrent HM01 treatment. Cisplatin also decreased the paw withdrawal threshold response to Von Frey filaments indicating development of mechanical hypersensitivity. Pretreatment with HM01 at doses of 10 and 30 mg/kg significantly reduced this hyperalgesia on multiple test days. Together these findings suggest a potential therapeutic use of the ghrelin agonist HM01 for treatment of both the nerve conduction impairments and painful hypersensitivity associated with chemotherapy-induced neuropathy.

Title: Sex differences in pain and disease related outcomes in a mouse model of MS

Authors: ***K. A. MIFFLIN**[1], E. FRIESER[1], G. TENORIO[1], G. RAUW[2], G. BAKER[3], C. A. BENSON[1], B. J. KERR[4];

Abstract: Multiple Sclerosis (MS) is an inflammatory autoimmune and neurodegenerative disease. Although the primary symptoms of MS include the loss of sensory and motor function, many patients experience secondary symptoms such as chronic neuropathic pain. Recent work from our laboratory has explored voluntary exercise as a possible treatment for chronic pain in the mouse model commonly used to study MS: experimental autoimmune encephalomyelitis (EAE). These initial studies were carried out in female mice. We found that daily voluntary wheel running reduced pain at disease onset and also diminished dorsal horn microglial activation and T-cell infiltration. Voluntary wheel running was also shown to reduce oxidative stress in the spinal cord of female mice with EAE. Although exercise could delay the onset of clinical signs, there was no significant difference in the severity or progression of clinical signs once the disease was established. In the present study, we explored whether daily voluntary wheel running would also be effective at reducing nociceptive behaviour in male mice with EAE. Male mice were given access to a running wheel for 1 hour a day for 40 days. Surprisingly, voluntary wheel running did not reduce mechanical allodynia (tested with von Frey hairs) in males with the disease. We did find however, that unlike in females, daily wheel running significantly improved clinical scores in male mice with EAE. Direct comparison of inflammation, axonal injury, and oxidative stress in male and female mice with EAE revealed significant differences in the amount of T-cell infiltration, microglia and astrocyte reactivity, demyelination, and axon integrity in males and females with EAE. Male mice with EAE given daily access to running wheels had significantly less ongoing oxidative stress compared to all other groups. Taken together our results indicate that the inflammatory response generated in EAE is distinct between the sexes and its modulation by daily exercise can have sex specific effects on disease related outcomes.

Title: Aging alters inhibitory and excitatory synaptic input in the spinal cord superficial dorsal horn

Authors: *J. MAYHEW, R. J. CALLISTER, D. W. SMITH, B. A. GRAHAM;
Sch. of Biomed. Sci. and Pharm., Univ. of Newcastle, Callaghan, Australia

Abstract: The superficial dorsal horn (SDH) of the spinal cord is the first site in the central nervous system to process sensory processing from the body, and is essential for the segregation of sensory modalities, including touch, temperature, itch, and nociception. Disruption of this process can result in the emergence of aberrant sensory experiences such as allodynia and hyperalgesia. Importantly, altered pain states are more prevalent among the elderly, however the majority of preclinical studies on the underlying mechanisms of aberrant sensory processing are conducted in juvenile or young adult animals. Here we compare the spontaneous inhibitory and excitatory synaptic input to neurons in the SDH of young adult (3-4 months) and aged (28-32 months) mice. Briefly, male mice were deeply anaesthetized with ketamine (100mg/kg, i.p.) and decapitated. Sagittal spinal slices (300 um thick) were prepared from the lumbar cord. Patch clamp recordings were made with a CsCl-based (for inhibitory currents) or K-gluconate-based internal (for excitatory currents) from a holding potential of -70 mV. Because both GABA and glycine can mediate inhibition in the SDH recordings of mixed inhibition were first obtained (aged n =19, young n =9), before glycinergic inhibition was isolated by bath administration of bicuculline. Mixed sIPSCs from aged animals had similar amplitudes (-41.2 ± 5.5 pA vs -33.9 ± 4.5 pA), frequencies (0.4 ± 0.1 Hz vs 0.5 ± 0.2 Hz), and rise times (2.5 ± 0.2 ms v 2.5 ± 0.3 ms), but slower decay time constants (30.5 ± 2.4 ms vs 22.3 ± 3.6 ms). Subsequent application of bicuculline in a subset of recording (aged n = 8, young n = 8) dramatically reduced the frequency of glycinergic sIPSCs (0.07 Hz ± 0.02 vs 0.17 ± 0.4 Hz). In contrast, glycinergic sIPSC amplitude (-37.0 ± 10.8 vs -24.0 ± 3.8), rise time (2.3 ± 0.3 ms vs 2.5 ± 0.2 ms) and decay times (22.8 ± 5.0 vs v 21.9 ± 3.7) were similar in young and aged animals. Together, the slower decay of mixed sIPSCs and reduced frequency of glycinergic sIPSCs in aged recordings suggest a reduced role for glycinerigc inhibition in the aged SDH. For excitatory input (aged n = 38, young n = 21), sEPSCs from aged animals displayed reduced amplitudes (-15.3 ± 0.7 pA vs -25.0 ± 3.5 pA), but had similar frequencies (3.6 ± 1.0 vs 2.0 ± 0.6), rise times (1.24 ± 0.1 ms vs 1.23 ± 0.1 ms), and decay time constants (5.0 ± 0.3 vs 4.8 ± 0.5). Thus, the strength of excitatory input in the SDH diminishes with age. Together these age-related perturbations to excitatory and inhibitory synaptic transmission will impact baseline excitability of this region, upon which pathological disturbances such as allodynia and hyperalgesia are superimposed.

Title: Epigenetic regulation of chronic pain after mild traumatic brain injury

Authors: *D.-Y. LIANG, P. SAHBAIE, Y. SUN, X. SHI, A. MEIDAHL, T.-Z. GUO, P. LIU, D. C. YEOMANS, D. J. CLARK;
Anesthesiol., Stanford Univ., Palo Alto, CA

Abstract: Chronic pain after traumatic brain injury (TBI) is very common, but the mechanisms linking TBI to pain and the pain-related interactions of TBI with peripheral injuries are poorly understood. In the current work we pursue the hypothesis that epigenetic changes induced by TBI support chronic pain sensitization. We used the rat lateral fluid percussion model to induce mild and moderate TBI. Some animals received hindpaw incisions as well. Mechanical allodynia was measured for up to eight weeks post-injury. Inhibitors of histone acetyltransferase (HAT) and histone deacetylase (HDAC) were used to probe epigenetic mechanisms. We followed serum markers including glial fibrillary acidic protein (GFAP), neuron-specific enolase 2 (ENO2) myelin basic protein (MBP) and S100β to gauge TBI injury severity. Our results showed that both mild and moderate TBI caused mechanical allodynia in the hindpaws of the rats lasting 3 or more weeks. Hindpaws contralateral to TBI showed more rapid and profound changes. The inhibition of HAT using curcumin 50 mg/kg s.c reduced mechanical sensitization while the HDAC inhibitor suberoylanilide hydroxamic acid 50mg/kg i.p. prolonged sensitization in the mild injury model rats. These agents did not systematically change serum markers in ways suggesting regulation of the degree of brain injury constituted a complete explanation for the observations. Immunohistochemical analyses of spinal cord tissue localized changes in the level of acetylation of the H3K9 histone mark to dorsal horn neurons. Taken together, these findings demonstrate that TBI induces persistent pain sensitization, and changes in spinal neuronal histone proteins may play an important role.

Title: Ryr plays an important role through mitochondrial ros in hiv gp120-induced neuropathic pain in rats.

Authors: *K. GODAI[1,2], H. YI[2], S. LIU[2], K. TAKAHASHI[2], C.-H. LIU[2], Y. KANMURA[1], D. A. LUBARSKY[2], S. HAO[2];

Abstract: The exact molecular mechanisms of human immunodeficiency virus (HIV) neuropathic pain are elusive. Ryanodine receptors (RyRs) are located in the endoplasmic reticulum (ER) membrane. ER stress and ROS are involved in neuropathic pain. In the present study, we investigated the relationship of RyRs and ROS in HIV coat glycoprotein gp120-induced neuropathic pain state in rats. HIV-related neuropathic pain was induced by repeated administration of intrathecal recombinant HIV gp120 in rats. Mechanical allodynia was assessed by measuring the threshold of paw-withdrawal response to graded mechanical stimuli using von Frey filaments and the up-and-down method. RyR expression was measured using western blots. Mitochondrial superoxide in the spinal dorsal horn was measured using MitoSox (a mitochondrial superoxide indicator) profile cells. Repeated administration of intrathecal recombinant HIV gp120 induced mechanical allodynia lasting for 4 weeks. Intrathecal gp120 increased the expression of RyR and upregulated the mitochondrial superoxide. Intrathecal administration of either RyR antagonist (dantrolene) or mitochondrial ROS scavenger Mito-Tempol increased mechanical threshold. Intrathecal dantrolene suppressed the upregulation of mitochondrial MitoSox profile cell number. These results demonstrated a substantial role of RyR through mitochondrial ROS in the HIV gp120-related neuropathic pain state, which provides a novel approach to treating HIV-related neuropathic pain.

Title: Involvement of glial EphA4 receptor in development of trigeminal neuropathic pain in rats

Authors: ***M. KIM**[1], H. KIM[1], J. JU[1], J. SON[1], M. LEE[2], M. PARK[3], D. AHN[1];
[1]Sch. of Dent. Kyungpook Natl. Univ., Daegu, Korea, Republic of; [2]Dong-Eui Univ., Busan, Korea, Republic of; [3]Kyung-Woon Univ., Gumi, Korea, Republic of

Abstract: Glial-neuronal cross-talk plays a critical role in pain facilitation following peripheral nerve injury or in central sensitization that is characteristic of neuropathic pain. Ephrins and Eph receptors participate in the regulation of synapse formation through neuron-neuron and/or neuron-astrocyte interaction. However, it is still unknown whether Ephrin and Eph receptor-mediated cross talks at sites of glial-neuronal contact are involved in the central nociceptive processing associated with sensory abnormalities in persistent pain states. We hypothesized that changes in EphA4 receptor may play an important role in the development of neuropathic pain. For this purpose, the present study examined changes in EphA4 expression in the medullary dorsal horn and evaluated anti-nociceptive effects after blocking EphA4 pathway in rats with inferior alveolar nerve injury. Under anesthesia, the left lower second molar of male SD rats was extracted, followed by the placement of a mini dental implant to injure the inferior alveolar nerve. This injury produced mechanical allodynia along with the up-regulation of EphA4 and D-serine expression in the astrocytes and NR2 expression in the neurons of the medullary dorsal horn. The early treatment with EphA4-Fc, an EphA4 inhibitor, beginning on POD 0 for 3 days significantly attenuated mechanical allodynia and reduced up-regulated EphA4, D-serine and NR2 expression. Knockdown of EphA4 expression by intracisternal injection with EphA4 small interfering RNA also reduced mechanical allodynia produced by the inferior alveolar nerve injury. These results suggest that blocking EphA4 pathways in astrocytes produces attenuation of trigeminal neuropathic mechanical allodynia through a regulation of D-serine and NR2

expression in the medullary dorsal horn. These results provide that a modulation of the glial EphA4 signaling is a potentially important treatment strategy for trigeminal neuropathic pain.

Title: Dissociated nociceptors generate irregular subthreshold fluctuations in resting membrane potential that are enhanced after spinal cord injury and contribute to spontaneous activity

Authors: ***M. A. ODEM**[1], R. M. CASSIDY[2], A. G. BAVENCOFFE[1], E. T. WALTERS[1]; [1]Integrative Biol. and Pharmacol., McGovern Med. Sch. At UTHealth, Houston, TX; [2]McGovern Med. Sch. at UTHealth, Houston, TX

Abstract: After thoracic (T10) spinal cord injury (SCI) in rats, primary nociceptors become hyperexcitable and generate spontaneous activity (SA) in their somata *in vivo* and after dissociation (Bedi et al., *J Neurosci*, 30:14870, 2010; Wu et al., *Pain*, 154:2130, 2013; Yang et al., *J Neurosci*, 34:10765, 2014). The increased incidence of SCI-induced SA correlates with behavioral hyperreflexia, and nociceptor hyperactivity is required for spontaneous pain. Wu et al. noted prominent depolarizing subthreshold fluctuations (SFs) of resting membrane potential (RMP) in nociceptors and suggested that these promote SA in C-fiber nociceptors after SCI. In A-fiber sensory neurons, sinusoidal subthreshold oscillations (SOs) were shown to be necessary for SA and to be enhanced by nerve injury (Amir et al., *J Neurosci*, 19:8589, 1999). We are using a novel quantitative method to characterize spontaneous SFs of RMP in nociceptors and their contributions to SCI-induced SA. Presumptive nociceptors are identified under whole cell current clamp 18-24 h after dissociation by an electrophysiological signature that reliably predicts capsaicin sensitivity in small DRG neurons. We have found that nociceptor SFs are irregular (non-sinusoidal) within the normal range of RMP in naïve and SCI conditions, confirming previous observations of their random nature (Study and Kral, *Pain*, 65:235, 1996). Whereas the incidence of irregular SFs reported in A-fibers is very low (3%; Amir et al., J

Neurosci, 22:1187, 2002), we have observed SFs in nearly all recorded nociceptors. SCI significantly increased the amplitude of the SFs in nociceptors exhibiting SA compared to silent nociceptors within the same range of RMP. The SCI-induced increase in amplitude of depolarizing SFs increases the likelihood that SFs reach firing threshold and thereby contribute to SA. Results thus far indicate that the basic mechanisms that generate irregular SFs in C-fibers differ substantially from those described for the sinusoidal SOs in A-fibers (Amir et al., Brain, 125:421, 2002). Interestingly, sinusoidal SOs can sometimes occur together with irregular SFs in the same C-fibers, especially when RMP is abnormally depolarized. Ongoing experiments are identifying ion channels important for generating SFs, as well as the cell signaling pathways that enhance SFs, SOs, and SA (see poster abstract by Bavencoffe, Odem, Dessauer, and Walters). Conditions that enhance nociceptor SFs and consequent SA may promote many forms of persistent pain.

Title: Demethylated CXCR3 contributes to central sensitization and neuropathic pain

Authors: *B.-C. JIANG[1], L.-N. HE[1], X.-B. WU[1], H. SHI[1], W.-W. ZHANG[1], W.-W. ZHANG[1], J. GU[1], Y. LU[1], Y.-F. ZHANG[2], Y.-J. GAO[1];

Abstract: DNA methylation was recently implicated to be involved in the pathogenesis of chronic pain. Here we investigated how chemokine receptor CXCR3 is regulated by DNA methylation and its contribution to neuropathic pain induced by spinal nerve ligation (SNL) in mice. All animals used in this study were adult male ICR or C57BL/6 mice. Quantitative RT-PCR and ELISA showed that SNL increased *Cxcr3* mRNA and protein expression in the spinal cord. In situ hybridization combined with immunofluorescence staining further showed that

Cxcr3 was mainly expressed in spinal neurons. Meanwhile, the CpG (cytosine guanine dinucleotide) island in the *Cxcr3* gene promoter region was demethylated, and the expression of DNA methyltransferase 3b (DNMT3b) and its binding with *Cxcr3* promoter were downregulated in mice with neuropathic pain. Furthermore, SNL increased the binding ability of CCAAT/enhancer binding protein α (C/EBPα) with *Cxcr3* promoter and upregulated the expression of C/EBPα in dorsal horn neurons. Inhibition of C/EBPα by intrathecal siRNA attenuated SNL-induced pain hypersensitivity and reduced *Cxcr3* expression. Additionally, SNL-induced pain hypersensitivity was markedly reduced in *Cxcr3*$^{-/-}$ mice. Consistently, spinal inhibition of *Cxcr3* by shRNA or CXCR3 antagonist attenuated established neuropathic pain. On the other hand, CXCL10, the ligand of CXCR3 was increased in the spinal neurons and astrocytes after SNL. Intrathecal injection of CXCL10 induced CXCR3-dependent pain hypersensitivity. Finally, superfusion spinal cord slices with CXCL10 enhanced spontaneous EPSCs and potentiated NMDA- and AMPA-induced currents of lamina II neurons in a CXCR3-dependent manner. Collectively, our results demonstrated that CXCR3, increased by DNA demethylation and enhanced interaction with C/EBPα, can be activated by CXCL10 and facilitate excitatory synaptic transmission in neuropathic pain condition. Inhibition of CXCR3 signaling may provide a new therapy for neuropathic pain management.

Title: Spinal injury transforms how BDNF affects nociceptive sensitization and GABA function

Authors: *Y.-J. HUANG[1], K. H. LEE[2], J. W. GRAU[1];
[1]Neurosci., Texas A&M Univ., College Station, TX; [2]Neurobio., Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: In spinally transected rats, prior work has shown that both intrathecal (i.t.) BDNF and bicuculline (a $GABA_A$ receptor antagonist) administration exert a protective effect that counters

the learning impairment and enhanced mechanical reactivity (EMR) elicited by a peripheral irritant (capsaicin). In contrast, in intact rats, BDNF and bicuculline are thought to enhance capsaicin-induced nociceptive sensitization. We compared the effects of BDNF and bicuculline (i.t.) treatment in intact and spinally transected rats on capsaicin-induced EMR. Subjects received a complete spinal transection at T2 or sham operation. Twenty-four hours later, subjects received drugs (BDNF or bicuculline) or vehicle (i.t.) administration followed by peripheral treatment with capsaicin. We found both BDNF and bicuculline show opposite effects with or without SCI. BDNF and bicuculline both enhanced capsaicin-induced EMR in intact rats, but blocked it in transected rats. A cellular marker (ERK phosphorylation) of central sensitization exhibited the same pattern of results. These findings show that SCI alters how BDNF and GABA affect nociceptive processing within the spinal cord. BDNF is known to affect KCC2 expression, which determines GABAergic tone, and this effect may be modulated by SCI. To examine this possibility, we assessed KCC2 expression in BDNF treated intact and spinally transected rats. BDNF up-regulated KCC2 expression in transected rats, but down-regulated it in intact rats. Next, we tested whether BDNF also alters how a GABA agonist affects capsaicin-induced EMR. To test this, transected or sham-operated rats received BDNF or vehicle (i.t.) 24hrs after surgery. After BDNF treatment, subjects received either muscimol (a $GABA_A$ receptor agonist) or vehicle (i.t.) followed by capsaicin treatment. We found that BDNF treatment attenuated the muscimol-induced inhibition of EMR in intact rats. In transected rats, it had the opposite effect. These findings suggest that spinal injury transforms how BDNF affects GABA function and that this impacts the development of central sensitization.

Title: Electrophysiological evidence for the establishment of central sensitization in neuropathic mice.

Authors: *A. BITTAR[1], J. WANG[2], C. BAE[2], J.-H. LA[2], H. SHIM[2], J. CHUNG[2];

Abstract: Following nerve injury, aberrant afferent inputs lead to neuropathic pain. It is believed that long-term synaptic plasticity in the spinal dorsal horn underlie a state of increased excitatory but decreased inhibitory tones, leading to central sensitization and pain. However, long-term synaptic plasticity is seldom assessed in neuropathic animals. Rather, it is often induced in naïve intact spinal cords via a conditioning stimulus mimicking neuropathic conditions. Therefore, this study investigated whether long-term changes in the synaptic strength on two types of pain-relaying neurons were actually established in the spinal nerve ligation model (SNL). We hypothesized that long-term potentiation (LTP) would already be established in spinothalamic tract neurons (STTn), whereas long-term depression (LTD) would be established in GABAergic interneurons (GABAn) in the dorsal horn of SNL mice, leading to central sensitization. Long-term changes were assessed by comparing the following between naïve and SNL mice: 1) The frequency and amplitude of miniature-EPSCs (mEPSC) in STTn and GABAn, 2) The induction of synaptic plasticity following conditioning stimulus. Results showed that the frequency of mEPSCs is higher in SNL-STTn than in their naïve counterparts. However, the frequency of mEPSCs in SNL-GABAn is lower than that of naïve-GABAn. Furthermore, following low frequency stimulation, LTP was induced in the STTn of naïve mice but was occluded in the STTn of SNL mice. Similarly, LTD was induced in naïve-GABAn but occluded in SNL-GABAn. These results suggest that, in SNL mice, STTn are sensitized with increased excitatory synaptic activities, whereas GABAn are desensitized with decreased excitatory synaptic activities, leading to central sensitization and neuropathic pain.

Title: Capsaicin-induced secondary mechanical allodynia and hyperalgesia are mediated by different central sensitization mechanisms involving reactive oxygen species

Authors: *J.-H. LA, J. WANG, A. BITTAR, H. SHIM, C. BAE, J. CHUNG;
Dept. of Neurosci. and Cell Biol., Univ. of Texas Med. Br., Galveston, TX

Abstract: Intradermally injected capsaicin induces mechanical allodynia and hyperalgesia outside the injection site. Thus termed 'secondary', the two phenomena are attributed to 'central sensitization'. In humans, capsaicin-induced secondary mechanical allodynia (CSMA) and hyperalgesia (CSMH) are distinct in terms of their duration as well as their dependency on aberrant afferent discharges arising from the capsaicin injection site. This suggests that CSMA and CSMH are mediated by different central sensitization mechanisms. We tested this possibility in mice, focusing on the action of reactive oxygen species (ROS) that are shown to play a key role in central sensitization. Mice developed CSMA and CSMH to punctate stimuli after intradermal injection of capsaicin. As in humans, CSMA in mice lasted for a shorter time period than CSMH. In addition, unlike CSMH, CSMA was resolved by an anesthetic given at the capsaicin injection site. The ROS scavenger phenyl-*N*-tert-butylnitrone (PBN), administered prior to capsaicin injection, prevented the induction of CSMA, whereas it significantly shortened the duration of CSMH without preventing its induction. PBN treatment after capsaicin nearly abolished CSMA but only slightly attenuated CSMH. An intrathecal injection of the ROS donor, KO_2, induced both mechanical allodynia and hyperalgesia with the mechanical hyperalgesia outlasting the allodynia. These results suggest that the full activation of central sensitization mechanisms for CSMA and CSMH requires ROS. Once activated, the mechanism for CSMH is long-lasting and neither critically dependent on ongoing afferent inputs from the capsaicin injection site nor on the continuous presence of ROS. On the contrary, the presence of ROS and ongoing afferent inputs are indispensable for the development and maintenance mechanism for CSMA.

Title: Iron chelation restores the GABAergic inhibitory function depressed in neuropathic pain

Authors: *H. SHIM, J.-H. LA, C. BAE, A. BITTAR, J. WANG, J. CHUNG;
Dept. of Neurosci. & Cell Biol., UTMB, Galveston, TX

Abstract: *Background:* One feature of neuropathic pain is a reduced gamma-aminobutyric acid (GABA)-ergic inhibitory function in the spinal cord. We previously demonstrated that oxidative stress induced both loss and dysfunction of GABAergic neurons (GABAn). Iron chelators have been known to reduce oxidative stress. However, the effect of iron chelation on neuropathic pain in relation to GABAn remains to be elucidated.
Objective: In this study, we investigated the effect of deferoxamine (DFO), an iron chelator, on spinal nerve ligation (SNL)-induced neuropathic pain in mice.
Methods: We examined the effects of intrathecally administered DFO, with and without the $GABA_A$ receptor antagonist bicuculline, on pain behaviors evoked by punctate mechanical stimulation in SNL mice. In electrophysiological studies, the effect of DFO on excitatory postsynaptic currents (EPSCs) was examined in GABAn using whole cell patch-clamp recordings in the mouse spinal cord slice.
Results: A single intrathecal injection of DFO significantly ameliorated SNL-induced mechanical allodynia. This analgesic effect of DFO was blocked by bicuculline. In electrophysiological recordings, tetanic afferent stimulation induced long-term depression (LTD) of EPSCs in GABAn. DFO prevented the induction of this LTD.
Conclusions: Taken together, these results suggest that iron chelation reduces neuropathic mechanical allodynia by restoration of GABAergic inhibitory function in the spinal cord.

Title: Inhibition of EPAC signaling suppresses persistent spontaneous activity in primary nociceptors after spinal cord injury

Authors: *A. G. BAVENCOFFE, M. A. ODEM, C. W. DESSAUER, E. T. WALTERS; Integrative Biol. and Pharmacol., McGovern Med. Sch. At UTHealth, Houston, TX

Abstract: A majority of people with spinal cord injury (SCI) suffer from chronic neuropathic pain. In a rat T10 contusion model, nociceptors at and below the injury level exhibit chronic spontaneous activity (SA) generated in their somata in vivo and in vitro that persists for months

after SCI (Bedi et al., J Neurosci 30:14870, 2010). The nociceptor hyperactivity is correlated with chronic pain-related behaviors and is necessary for the maintenance of both reflex hypersensitivity and an operant measure of spontaneous pain (Yang et al., J Neurosci 34:10765, 2014). Recently we found that SCI-induced SA in dissociated nociceptors requires ongoing cAMP signaling in a macromolecular complex composed of A-kinase anchoring protein (AKAP150), adenylyl cyclase (AC5/6) and PKA (Bavencoffe, Li et al., J Neurosci. 36:1660, 2016). The importance of cAMP signaling raises the possibility that multiple downstream cAMP effectors might contribute to SCI-induced SA in nociceptors. We have begun to investigate the contribution of EPAC (Rap1 exchange protein activated by cAMP) to the maintenance of SA after SCI by examining the effects of an EPAC inhibitor, ESI-09. Neurons were isolated from DRGs L3 to L5 1-2 months after SCI and recorded 18-24 h after dissociation. Presumptive nociceptors were identified by characteristic electrophysiological properties we found to be a reliable signature for capsaicin sensitivity in small DRG neurons. As reported previously, SA incidence recorded in current clamp (I=0) was significantly higher in nociceptors from SCI rats (21 of 29 neurons) compared to nociceptors from naïve, uninjured rats (1 of 11 neurons). In the SCI group, incubation of sensory neurons with ESI-09 (5 μM) significantly reduced SA incidence. It also hyperpolarized resting membrane potential (RMP) and decreased the amplitude of subthreshold fluctuations of RMP (see poster abstract by Odem, Cassidy, Bavencoffe and Walters). Co-incubation with EPAC activator 8-pCPT-2-O-Me-cAMP-AM (10 μM) reversed the effects. In the naïve group, incubation of nociceptors with ESI-09 did not significantly change the low incidence of SA. However, ESI-09 produced a similarly large hyperpolarization of RMP in sensory neurons from the naïve and SCI groups. These observations indicate that ongoing EPAC signaling contributes to normal nociceptor excitability under our culture conditions and might also contribute to resting excitability of nociceptors in uninjured animals in vivo. An important question is whether SCI further enhances cAMP-EPAC signaling to produce nociceptor SA. Our results encourage the study of cAMP-EPAC signaling as a potential therapeutic target for chronic pain.

Title: GPR151 in the spinal cord contributes to the pathogenesis of neuropathic pain

Authors: *Y. LU, T. YANG, B.-C. JIANG, W.-W. ZHANG, Y.-J. GAO;
Nantong Univ., Jiangsu, China

Abstract: G protein-coupled receptors (GPCRs), which consist of approximately 850 members, are the largest family of signaling proteins. Many of them are demonstrated to be involved in the development and maintenance of chronic pain. Using Gene array and Real-time PCR, we found that the expression of orphan G-protein coupled receptor 151 (GPR151) was dramatically increased in the spinal cord of adult male ICR mice after spinal nerve ligation (SNL). In this study, we investigated the role of GPR151 in SNL-induced neuropathic pain. Real-Time PCR showed that SNL induced persistent GPR151 upregulation in the spinal cord, which started 3 days after SNL and lasted for more than 21 days. Intrathecal injection of GPR151 siRNA or intraspinal injection of GPR151 shRNA lentivirus relieved SNL-induced neuropathic pain. GPR151 was mainly expressed in spinal astrocytes. Overexpression of GPR151 in primary cultured astrocytes increased the expression of phosphorylated extracellular signal-regulated kinase (pERK) and glial fibrillary acidic protein (GFAP, astrocytic marker). Intrathecal injection of GPR151 siRNA significantly reduced pERK expression in the spinal cord after SNL. Interestingly, SNL increased the binding ability of STAT3 (signal transducer and activator of transcription-3) with GPR151 promoter and the phosphorylation of STAT3. Inhibition of STAT3 by intrathecal injection of AG490 attenuated SNL-induced pain hypersensitivity and reduced GPR151 expression. Collectively, our results suggest that GPR151, upregulated in spinal astrocytes via the binding of STAT3 with its promoter, plays a crucial role in neuropathic pain through the activation of ERK signaling. Targeting GPR151 might provide a novel and promising approach to the treatment of neuropathic pain.

Abstract: Reactive oxygen species (ROS) in the spinal cord, which plays a crucial role in sensitization of dorsal horn neurons, has been implicated in neuropathic pain. ROS is an important mediator for regulating spinal AMPA receptor (AMPAR) phosphorylation to induce persistent pain. Phosphatidylinositol 3-kinase (PI3K) is involved in mediating inflammatory pain. In this work, we investigate a possible connection between PI-mediated signaling and AMPAR phosphorylation using nerve injury-induced and ROS donor-treated hyperalgesic rats. Mechanical hyperalgesia, induced by L5 spinal nerve ligation (SNL) or an intrathecal (i.t.) administration of a ROS donor (t-BOOH) and evaluated by measuring paw withdrawal threshold upon the application of von Frey hairs, was attenuated by pretreatment with either ROS scavenger alpha-phenyl-N-tert-butyl nitron (PBN) or PI3K inhibitor (wortmannin or LY294002). PIP3 levels, PI3K activity, and levels of oxidized inactive PI3-phosphatase (PTEN) were increased in the lumbar spinal dorsal horn of both SNL and ROS-treated rats. Such increases were attenuated by pretreatment with PBN or LY294002. An i.t. t-BOOH injection increased significantly phosphorylation levels of GluR1 at Serine-831 (GluR1-pS831) and at Serine-845 (GluR1-pS845) and GluR2 at Serine-880 (GluR2-pS880) compared to vehicle injection. All these elevated phosphorylation levels were attenuated by pretreatment with LY294002 or PIP3-dependent kinase (PDK) inhibitor (DCA), but not AKT inhibitor (MK-2206) or GSK3 inhibitor (AR-A014418). This increased phosphorylation was also attenuated for GluR1-pS831 by CaMKII inhibitor (KN-93), for GluR1-pS845 by PKA inhibitor (H-89), and for GluR2-pS880 by PKC inhibitor (GF109203X). GluR1 level in the membrane fraction and GluR2 level in the cytosolic fraction, sampled from lumbar spinal cord, were elevated in both SNL and i.t. t-BOOH-treated rats. The results suggest that ROS induce AMPAR phosphorylation through activation of PDK, but not of AKT/GSK3 signaling pathway. This PDK-mediated process may include phosphorylation of GluR1-S831 and GluR1-S845 by CaMKII and PKA, respectively, for the insertion of GluR1-containing AMPARs whereas phosphorylation of GluR2-S880 by PKC for endocytosis of GluR2-containing AMPARs at the postsynaptic zone, leading to central sensitization and thus neuropathic pain.

Title: β-arrestin-2 regulates NMDA receptor function in spinal lamina II neurons and controls the duration of persistent pain and resolution of chronic pain

Authors: *G. CHEN[1], R.-G. XIE[1], Y.-J. GAO[2], Z.-Z. XU[1], L.-X. ZHAO[2], S. BANG[1], T. BERTA[1], C.-K. PARK[1], M. LAY[1], W. CHEN[3], R.-R. JI[1];
[1]Dept. of Anesthesiol. and Neurobio., Duke Univ. Med. Ctr., Durham, NC; [2]Inst. of Nautical Medicine, Co-Innovation Ctr. of Neuroregeneration, Nantong Univ., Nantong, China; [3]Dept. of Med., Duke Med. Ctr., Durham, NC

Abstract: β-arrestins are multifunctional scaffold proteins that regulate the desensitization of GPCRs including the mu opioid receptors. However, the unique role of β-arrestin in inflammatory and neuropathic pain has not been clearly investigated. Here we demonstrate an active role of β-arrestin 2 (Arrb2) in regulating spinal cord NMDA receptors (NMDAR) function and the duration of pain.
Intrathecal injection of the mu-opioid receptor agonist [D-Ala2, NMe-Phe4, Gly-ol5]-enkephalin (DAMGO) produces paradoxical behavioral responses: early-phase analgesia and late-phase mechanical allodynia; and notably, both phases are prolonged in Arrb2 knockout (KO) mice. Unlike the early-phase analgesia, the late-phase allodynia requires spinal cord activation of NMDAR. As expected, spinal administration of the NMDAR antagonist MK-801 reversed DAMGO-induced mechanical allodynia in WT and KO mice. Also, NMDA-induced currents in lamina IIo neurons of spinal cord slices were enhanced in DAMGO-treated WT mice at 24 h. Interestingly, spinal administration of NMDA induces GluN2B-dependent mechanical allodynia, which is prolonged in Arrb2-KO mice and conditional KO mice lacking Arrb2 in presynaptic terminals expressing Nav1.8. Loss of Arrb2 also increases the expression of synaptic GluN2B in lamina IIo neurons of spinal cord slices. Biotinylation experiment showed that the surface expression of Arrb2 was inversely correlated with that of GluN2B but not GluN2A in Hela cells, suggesting a specific interaction between Arrb2 and GluN2B. Loss of Arrb2 also results in prolongation of inflammatory pain and neuropathic pain and enhancement of GluN2B-mediated NMDA currents in spinal lamina IIo neurons. Finally, spinal over-expression of Arrb2 reverses

chronic neuropathic pain for several months.
In summary, using both loss-of-function (Arrb2-KO mice) and gain-of-function (Arrb2 over-expression) strategies, we demonstrate that Arrb2 controls the transition from acute to chronic pain via suppressing the activity of NMDAR/GluN2B in spinal lamina IIo neurons. Targeting spinal Arrb2 signaling may shed light on the development of new therapeutics for the prevention and treatment of chronic pain.

Title: Analgesic effect of intrathecal MSCs in nerve-injured rats is associated with changes in levels of multiple cytokines in CSF

Authors: ***G. FISCHER**[1,2], F. WANG[2], Z. LIU[2], X. BAI[2], H. YU[2], Q. HOGAN[2];
[1]Anesthesiol., VAMC, Milwaukee, WI; [2]Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Neuropathic pain secondary to damage to peripheral nerves remains a serious, and unsolved, problem for a large number of patients. Recent studies have indicated that stem cells, particularly mesenchymal stem cells (MSCs) may have a constitutive effect on the evolution and maintenance of these phenomena. In the present study, we examined the effect of intrathecal administration of MSCs on established pain in animals which had undergone the tibial nerve injury (TNI) model. Specifically, MSCs were harvested from the femurs of young (4 to 5 weeks old) animals. Cells were cultured for the minimum time necessary to produce a culture of sufficient quality and quantity for injection. Animals showed a significant reduction in painful behavior to noxious stimulation after MSC administration, which was not reflected in animals receiving a control injection. This effect was long lasting, showing no sign of diminution for the duration of the study. Histological examination revealed that undifferentiated MSCs integrated into the white matter of the spinal cord and remained for the duration of the study. To illuminate the potential mechanisms mediating this analgesic effect, cerebrospinal fluid (CSF) was collected from animals and subjected to an antibody array to examine the effect of MSC administration on the expression levels of 67 cytokines in the CSF. Analysis showed that injury had a significant

effect on six cytokines: ICAM-1, IL-1β, IL-10, HGF, Idgcc4 (Nope), and Notch-1. Stem cell injection caused a significant change in five of these cytokines, ICAM-1, IL-1β, IL-10, HGF, and Idgcc4.

Title: Role of LIM motif-containing protein kinases in chronic pain

Authors: ***X. YANG**[1], G. HE[1], L. CHEN[2], L. CHIANG[1], Z. JIA[3], W. LIU[2], Z. ZHOU[1]; [1]Inst. of Life Sciences, Southeast Univ., Jiangsu, China; [2]Jiangsu Key Lab. of Neurodegeneration, Nanjing Med. Univ., Nanjing, China; [3]The Hosp. for Sick Children, Univ. of Toronto, Toronto, ON, Canada

Abstract: LIM motif-containing protein kinases (LIMKs), a kind of serine/threonine kinase, are widely expressed in the central nervous system and are the regulator of Actin Depolymerizing Factor (ADF)/Cofilin. LIMK1/2 play important roles in the actin remodeling, which are critical to synaptic plasticity in the brain. To investigate the roles of LIMK1/2 in pain transmission and chronic pain formation in the spinal cord, we evaluated the behavioral changes and spinal cord synaptic transmission using LIMK1/2 double knock out (DKO) mice. Behavioral tests revealed that DKO mice have normal nociception properties, while compared to wild type (WT) mice, the hyperalgesia and alloydnia is significantly resisted in DKO mice in a battery of chronic pain models. Moreover, electrophysiological recordings showed altered excitatory synaptic transmission. Pharmacological inhibition of LIMK1/2 in WT mice significantly alleviated chronic pain phenotypes. These findings demonstrate that LIMKs are important in chronic pain in spinal cord via synaptic remodeling.

Title: Chemokine pair CCL2/CCR2 regulates nerve injury-induced neuropathic pain and depression via increase of NR2B current in the nucleus accumbens of mice

Authors: *X.-B. WU, B. LIANG, P.-B. JING, Z.-J. ZHANG, Y.-J. GAO;
Nantong Univ., Jiangsu, China

Abstract: Symptoms including anhedonia, decreased motivation and depression are common affective features in patients with chronic pain. CC-chemokine receptor 2 (CCR2), a dominant receptor for monocyte chemoattractant protein-1 (MCP-1) has been the focus of attention because of its facilitative effects on nociceptive signal processing in chronic pain at peripheral nerve and dorsal horn. The nucleus accumbens (NAc) is an important area in mediating pain sensation and pain-related anxiety and depression. Whether MCP-1/CCR2 contribute to pain sensation and/or pain affect in the NAc remain unclear. In this study, we found that chemokine MCP-1 was increased in the neurons of NAc after spinal nerve ligation (SNL). CCR2 was also increased in NAc neurons after SNL. Inhibition of CCR2 by shRNA lentivirus in NAc shell attenuated SNL-induced pain hypersensitivity and depression-like behavior. Furthermore, whole-cell patch clamp recording of medium spiny neurons (MSNs) in NAc shell showed a significant increase in the function of NR2B-mediated currents after SNL, which was reduced by a selective CCR2 antagonist RS504393. Additionally, SNL increased the expression of phosphorylated NR2B (pNR2B), which was colocalized with CCR2 in the NAc. pNR2B upregulation by SNL was inhibited by intra-NAc injection of CCR2 shRNA lentivirus. Finally, Perfusing MCP-1 increased the NMDAR current. Intra-NAc MCP-1-expressing lentivirus increased pNR2B expression and induced pain hypersensitivity and pain-like behaviors. These results suggest that MCP-1/CCR2 signaling in the NAc is important in mediating the pain hypersensitivity and depression via NR2B following peripheral nerve injury.

Title: Functional regeneration and reinnervation of the ligated spinal nerve in the rat spinal nerve ligation neuropathic pain model

Authors: *W. XIE, J. A. STRONG, J.-M. ZHANG;
Anesthesiol., Univ. Cincinnati Coll Med., Cincinnati, OH

Abstract: The spinal nerve ligation model (SNL; "Chung model"), in which the L5 (and sometimes L6) spinal nerves on one side are ligated, is a widely used rodent model of neuropathic pain. The model causes long-lasting thermal and mechanical hypersensitivity and allodynia of the hindpaw, and signs of spontaneous pain. Conceptually, the model was designed to allow separation of the roles of injured vs. uninjured sensory afferents in mediating pain; studies using this model almost always assume that the ligated spinal nerve does not regenerate and that any observed pain behaviors are mediated by neurons in the intact L4 DRG. While using this model, our dye tracing experiments showed apparent connections between the hindpaw and the ipsilateral L5 DRG neurons, leading us to conduct further experiments confirming that functional regeneration and target reinnervation of the L5 spinal nerve was occurring. The SNL model was implemented as in our previous studies: in Sprague Dawley rats of both sexes, the ventral ramus of the L5 spinal nerve on one side was ligated with 6-0 silk 2-3 mm distal to the DRG, then cut distal to the suture. In vivo, by day 14, a thin, clear, regenerated nerve could be observed emerging from the nerve stump proximal to the ligature, rejoining the distal segment of the ligated spinal nerve. By day 70 this regenerated nerve was thicker and whiter, more similar to the original structure. The neuronal tracer DiI injected into the paw labeled neuronal cell bodies (both NF200-positive and unmyelinated) in the L5 DRG (examined 5 -6 weeks after SNL). The long-lasting Dextran label injected into the proximal spinal nerve stump at the time of ligation could be observed in regenerated fibers in the paw skin as early as 21 days later. In vivo fiber recording from filaments teased from the L5 dorsal root and disconnected centrally verified that electrically stimulated axon potentials could conduct through the newly regenerated segment (observed in ~18% of filaments on day 14 and 80 - 100% from day 28 on). Signals from receptive fields stimulated in the periphery could also be detected conducting through the regenerated nerve; initially (day 14) most receptive fields detected were in the thigh and upper leg; by day 28 receptive fields in the knee, lower leg and paw began to be observed. We

conclude that functional regeneration and target reinnervation of the ligated spinal nerve is faster and more robust than has been assumed in this model, confounding some previous interpretations of studies with this model that assumed that ligation and suture would prevent reconnection of the L5 sensory neurons to the periphery.

Title: Regeneration and target reinnervation of the injured nerve are associated with the persistence of neuropathic pain and spontaneous activity in rats

Authors: ***J.-M. ZHANG**, W. XIE, J. A. STRONG;
Dept Anesthesiol, Univ. of Cincinnati Col. of Med., Cincinnati, OH

Abstract: Abnormal spontaneous activity in sensory neurons is a common early feature of preclinical pain models, and blocking this activity blocks development of pain behaviors. Neuronal outgrowth during development also requires a period of spontaneous activity. The spinal nerve ligation model (SNL), in which the L5 spinal nerve on one side is ligated and cut, is a widely used rodent model of neuropathic pain. Recently (see related abstract) we have found that the spinal nerve undergoes functional regeneration and target reinnervation in this model. We hypothesize that regeneration is closely associated with spontaneous activity and pain. After implementing the SNL model in rats of both sexes, *in vivo* fiber recording (from filaments teased from the L5 dorsal root and disconnected centrally) showed a high incidence of spontaneous activity at day 14 or 28 (not including normal muscle spindle activity), and resection experiments showed the newly regenerated nerve was the primary source. The incidence declined gradually from day 28 to 70 (later times not examined). To inhibit nerve regeneration, we used local perfusion of the injury site via 14 day osmotic pump with semaphorin 3a (Sema 3a), an inhibitory axonal guidance molecule that collapses growth cones. In the SNL model, perfusion of the ligated spinal nerve starting immediately after injury reduced mechanical pain behaviors for the duration of the experiment (60 days) except for on day 1; and greatly reduced spontaneous

activity in fiber recording. Functional regeneration and target reinnervation were also impaired: receptive field responses conducting through regenerated nerve could only be detected in the thigh and upper leg, whereas without Sema-3a perfusion, receptive fields in the knee, lower leg, and paw could also be detected starting from day 28. Blocking activity at the injury site with 14 day local TTX perfusion also blocked mechanical pain behaviors at all time points (thru day 60, i.e., outlasting the drug perfusion time), and blocked reinnervation of more distal receptive fields. Our data suggest an association between nerve regeneration and its accompanying spontaneous activity, and pain behaviors.

Title: TNF and IFNβ comodulate tactile allodynia in a murine model of arthritis

Authors: *S. A. WOLLER[1], T. YAKSH[2], M. CORR[2];
[1]UCSD, LA Jolla, CA; [2]UCSD, La Jolla, CA

Abstract: Male C57Bl/6 (WT) mice develop transient inflammation in response to transfer of K/BxN serum and show a corresponding tactile allodynia (TA), which persists beyond the resolution of inflammation. Here, we examined the role of spinal cytokines, specifically TNF and IFNβ in the transition to a persistent pain state in males, which is mediated through Toll-like receptor (TLR) 4 signaling. Importantly, the contribution of TLR4 to pain states has been found to differ between male and female animals. Thus, our second aim was to examine whether female WT mice respond similarly to K/BxN serum transfer, and to examine whether TLR4 signaling associated spinal cytokines were involved in the development of TA in female animals.

In examining spinal cord TNF and IFNβ gene transcripts on d10 post K/BxN serum transfer, we found IFNβ transcripts decreased in WT mice (average fold change (AFC): 0.41) and were increased in *Tlr4*$^{-/-}$ mice (AFC: 18.84). In contrast, TNF transcripts increased in WT mice (AFC 1.33), and remained unchanged in *Tlr4*$^{-/-}$ mice (AFC 0.96). Next, we assessed the development of TA in male *Ifnar1*$^{-/-}$ and *Tnf*$^{-/-}$ mice. The inflammatory phase TA was attenuated in *Ifnar1*$^{-/-}$ mice (1.18g relative to 0.5g in WT males, $p < .05$); however these mice develop persistent TA while the late phase TA is reduced in *Tnf*$^{-/-}$ mice (1.29g relative to 0.74g in WT males, $p < .05$). Next, we examined female WT mice, and found they developed TA that was indistinguishable from males (0.72g), but, surprisingly, did *not* develop a persistent TA (1.36g, $p < .05$). The behavioral phenotype of female WT mice resembled that of *Tlr4*$^{-/-}$ males, and we assessed whether similar cytokine signaling contributed to the K/BxN TA phenotype. Both female *Ifnar1*$^{-/-}$ and *Tnf*$^{-/-}$ mice were indistinguishable from their male counterparts in terms of both ankle inflammation and TA. We then determined whether TNF and IFNβ transcripts change over time male and female WT mice. Males showed a general increase in spinal TNF mRNA expression relative to IFNβ, while females showed a higher ratio of IFNβ to TNF over time.
In another study, male WT mice were given IT anti-TNF antibody or IT IFNβ with no effect on TA. However, when *Tnf*$^{-/-}$ male mice were given IT IFNβ, we saw a persistent reversal in TA. *Ifnar1*$^{-/-}$ mice given IT anti-TNF antibody showed transient reversals in TA. Together, these results show persistent TA in WT male animals is associated with differential modulation of TNF and IFNβ. Female WT animals, however, fail to develop persistent TA, and show a recovery of spinal IFNβ transcription. The combination of genetic and pharmacological manipulations suggest that co-modulation of TNF and IFNβ may be necessary to prevent or reverse persistent TA.

Title: Plasticity changes of forebrain activity during neuropathic pain development in sciatic nerve injured rat

Authors: *T.-H. H. CHAO, J.-H. CHEN, R.-F. CHEN, C.-T. YEN;
Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Peripheral nerve damage frequently induces ectopic discharge in injured nerve fibers, which causes central sensitization and the development of neuropathic pain. Although there are many brain imaging studies of well-established chronic neuropathy, the involvement of the forebrain areas in the chronification process in the initiation phase is less studied. We hypothesize that ectopic barrage from the peripheral may cause sustained activation in the forebrain to initiate the plasticity involved in chronic neuropathic pain development.
In this study, we combined the advantages of different MRI methods, and demonstrated the transition of the brain activation changes during the neuropathic pain development in the spared nerve injury (SNI) model of the rat. We compared the brain activity during three different neuropathic pain development stage, including the moment of nerve injury using fMRI, and the 1st day and the 8th day after the neuropathic pain onset using manganese-enhanced magnetic resonance imaging (MEMRI).
Our main findings were: (1) Insular cortex (IC) and cingulate cortex (CC) showed sustained activation immediately after the SNI surgery. These sustained activations maintained at least 5 minutes throughout the whole fMRI scanning. (2) During the following days after the SNI surgery, we found consistently increased activation in ipsilateral IC. (3) Plasticity change of functional connectivity between ipsilateral IC, contralateral S1 and bilateral rostral anterior IC (RAIC) was established under the neuropathic pain condition. These results imply that IC may play an important role in neuropathic pain chronification.

Title: Effects of analgesic substances on sensory and emotional pain-related behavior in neuropathic rats

Authors: *E. LEE, D.-W. KIM, J. LEEM, S. JUNG;
Dept. of physiology, college of medicine, Yonsei Univ., Seoul, Korea, Republic of

Abstract: The place-conditioning paradigm, which measures conditioned place avoidance, has been successfully used to analyze the affective component of pain. Although this behavioral test for analysis of emotional pain component is reliable for cases of acute pain, it is not applicable to chronic pain state including neuropathic pain.
The aims of the present study were 1) to establish the place avoidance paradigm applicable to emotional component of chronic pain, 2) to ensure the presence of emotional component of chronic neuropathic pain using the established behavioral testing protocol, and 3) to investigate the effects of several analgesic substances often used for pain management on the emotional component of neuropathic pain.
The place avoidance test, in which rats were able to avoid the compartment with a strong vinegar odor-producing 1% acetic acid and stay in the other compartment with cinnamon odor that provided masking effect, revealed that animals with an acute inflammatory pain induced by formalin injection into the hind-paw showed avoidance from the acetic acid odor compartment. This place avoidance behavior was prevented by bilateral lesions of the rostral anterior cingulate cortex (r-ACC) known to process emotional aspect of pain. From these data, we considered the place avoidance behavior as an expression of emotional pain component. For a rat model of neuropathic pain, sensory pain-related nociceptive behavior that was measured by hind-paw withdrawal test was significantly increased compared to sham-operated controls. The place avoidance test revealed that as compared to sham-operated rats, neuropathic animals stayed longer in a compartment with cinnamon odor than acetic acid odor. Bilateral lesions of r-ACC in neuropathic rats reversed the place avoidance behavior but not nociceptive behavior. However, bilateral lesions of the ventroposterior lateral nuclei of the thalamus that processes sensory component of pain reduced nociceptive behavior. In neuropathic rats, an intraperitoneal (i.p.) injection of amitriptyline (1.5 mg/kg) partly reversed nociceptive behavior whereas it completely blocked the place avoidance behavior. An i.p. gabapentin (50mg/kg) showed a significant decrease in both nociceptive and place avoidance behavior in neuropathic rats. On the other hand, i.p. memantine (20mg/kg) had a significant effect only on nociceptive behavior in neuropathic rats.
The results imply that the place avoidance paradigm used in the present study is proper for measuring emotional component of neuropathic pain and that the degree to which analgesic drugs contribute to alleviating each pain component is different.

Title: Spinal nerve injury-induced aberrant tenascin-C upregulation contributes to pain hypersensitivity

Authors: *N. GONG[1], K.-W. LI[1], T. KWEON[1], B. VO[1], M. LI[1], N. ABDO[1], G. OREND[2], K. MIDWOOD[3], Z. LUO[1];

Abstract: Neuropathic pain is a common disorder derived from nerve injuries and its mechanisms remain largely unknown. Our gene chip microarray analysis in dorsal root ganglion (DRG) neurons from a neuropathic pain model of unilateral spinal nerve ligation injury indicates that mRNA of tenascin-C, a large hexameric extracellular matrix glycoprotein, is increased in the injury side that correlates temporally with neuropathic pain state development. In this study, we examined the potential role of tenascin-C in promoting neuropathic pain development in the same neuropathic pain model of spinal nerve ligation injury. Our data indicated that tenascin-C protein levels were significantly upregulated in the injury side of DRG and dorsal spinal cord that temporally correlated with the development of neuropathic pain states. Blockade of injury-induced tenascin-C activity by intrathecal anti-tenascin-C antibodies or tenascin-C upregulation by siRNA oligonucleotides reversed established neuropathic pain states in rats post injury, although general knockout of the tenascin-C gene in mice could not prevent the development of neuropathic pain post injury. Intrathecal injection of recombinant tenascin-C proteins into naïve rats dose-dependently induced behavioral hypersensitivities, which could be reversed by intrathecal anti-tenascin-C antibodies. Thus, elevated spinal tenascin-C alone can lead to pain state development without the influence from other injury-induced factors. Since tenascin-C binds to different receptors, including toll-like receptor 4, epidermal growth factor receptors, integrin receptors, and annexin II receptors, we examined the potential receptor system(s) involved in tenascin-C mediated pain states. Antagonists or neutralizing antibodies against these potential tenascin-C receptors were injected intrathecally into tenascin-C injected rats with behavioral hypersensitivity, which was followed by behavioral testing. Our data indicated that only anti-annexin II receptor antibodies could reverse tenascin-C-induced pain states. Together,

these results support that injury-induced tenascin-C contributes to the development of neuropathic pain states through the annexin II receptors, and illustrate a pathological role of tenascin-C as an endogenous pain mediator.

Title: Using two-photon calcium imaging to detect antidromic spikes evoked by presynaptic $GABA_A$ receptor activation in primary afferent neurons

Authors: ***P. TAKKALA**[1], S. A. PRESCOTT[2];
[2]Physiol., [1]Univ. of Toronto, Toronto, ON, Canada

Abstract: Presynaptic GABAergic input on primary afferent neurons is generally inhibitory but can evoke spikes under certain pathological conditions. Antidromic conduction of those spikes can lead to peripheral release of inflammatory mediators, resulting in neurogenic inflammation. Due to the high intracellular chloride concentration in primary afferent neurons, activation of $GABA_A$ receptors on their central terminals causes primary afferent depolarization (PAD). PAD normally inhibits spike propagation and synaptic release via shunting effects and sodium channel inactivation but its alteration can lead to PAD-induced spiking. We have previously described the conditions under which PAD can evoke spikes, in particular, simultaneous intracellular chloride accumulation and altered spike initiation properties (i.e. enhanced excitability). This combination of changes can arise in damaged peripheral nerves via enhanced function of the Na-K-Cl cotransporter, NKCC1, and downregulation of K_v1-type potassium channels, respectively. However, it remains unclear if these requirements are met in central axon terminals to generate action potentials that can then propagate to the periphery.
To image spiking in neurons with intact central terminals, we first validated our technique for optical detection of GABA-evoked spikes in cultured neurons. Using dissociated dorsal root ganglion (DRG) neurons from GCaM6f+ mice, we sought to determine the proportion of neurons in which puffed GABA can evoke spikes after enhancing NKCC1 function and/or blocking K_v1 channels. As predicted, we found a significantly greater proportion of neurons

displayed GABA-evoked spike initiation only when the two experimental manipulations were combined. Then, using an ex vivo preparation in which the dorsal root ganglion is still attached to the spinal cord, two-photon imaging at the DRG revealed that GABA applied to axon terminals in the spinal dorsal horn evoked antidromically propagating spikes only under the conditions described previously. By acutely reproducing the changes required for central terminal GABA-evoked induction of action potentials in peripheral nerves, we have shown that, like in the soma, PAD-induced spiking in central axon terminals requires joint changes in the chloride reversal potential and excitability.

Title: Purinergic dose response analysis in mouse dorsal root ganglion neurons

Authors: R. W. HUGHEN, K. J. VOLL, J. C. JENSEN, L. R. KEMKER, A. R. LIGHT, *J. ZHANG;
Anesthesiol., Univ. of Utah, Salt Lake City, UT

Abstract: Adenosine triphosphate (ATP) is the ubiquitous energy source for metabolism. Importantly, ATP is also an extracellular signaling molecule involved in many processes including pain and fatigue. ATP is released into the interstitium through channels, transporters and exocytosis. Physiological or pathophysiological conditions such as muscle exercise or tissue damage significantly increase the extracellular ATP concentration. Levels of extracellular ATP are detected by a group of purinergic receptors (P2 receptors), some of which are highly expressed in nociceptors (e.g., P2X3 and heteromeric P2X2/3 receptors). Our lab observed that ATP is one of the most potent metabolites in activating muscle-innervating dorsal root ganglion (DRG) neurons. To further pursue an ATP dose response curve for the DRG neurons, we did FURA2 calcium imaging experiments. DRGs were collected from male C57Bl mice that had hindlimb skeletal muscles injected 2 weeks previously with the retrograde fluorescent dye (2*Z*)-2-[(*E*)-3-(3,3-dimethyl-1-octadecylindol-1-ium-2-yl)prop-2-enylidene]-3,3-dimethyl-1-octadecylindole (Di-I). Primary neural cultures were made two weeks after the Di-I injection to allow the dye to be transported to the cell body in the DRGs. For each imaging experiment, Di-I labeled neurons (i.e., muscle-innervating cells, usually over 20% of the image field) are identified and analyzed separately from non-labeled neurons, as described before (Light et al

2008). Di-I labeled cells were also collected individually using a micropipette for RNA-Seq analysis. In the calcium imaging experiments, we challenged the cells with serial log concentrations ATP from 1nM - 10mM. We also investigated the ATP degradation/hydrolysis rate in aqueous solution. We found 50% degradation of ATP occurred about 20 min after it was dissolved in solution. Because ATP hydrolyzes predominantly to adenosine diphosphate (ADP), we also investigated the ADP dose response curve of the same concentration range to understand possible inhibitory/antagonistic effects of ADP on DRG neurons. We challenged the cells with ATP and ADP separately during the same experiment to see if different cells responded to ATP than ADP at a given concentration. We used specific antagonists 2',3'-*O*-(2,4,6-Trinitrophenyl) ATP (TNP-ATP) and pyridoxalphosphate-6-azophenyl-2',4'-disulfonic acid (PPADS) to identify specific P2 receptors being activated. Our RNA-Seq data indicated at least 10 different P2 receptors on individually collected DRG neurons capable of responding to ATP. Of these, P2X3,4,5,7 and P2Y1,2, and 14 are most likely the major contributors to the activation of DRG neurons by ATP/ADP.

Title: Mu and delta opioid receptors on muscle innervating group III/IV afferent neurons modulate muscle fatigue and ache

Authors: J. ZHANG[1], *A. R. LIGHT[3], R. W. HUGHEN[3], H. HUANG[1], W. TANG[2], J. C. JENSEN[2], S. A. LOW[4], G. SCHERRER[5];
[1]Anesthesiol., [2]Univ. of Utah, Salt Lake City, UT; [3]Anesthesiol., Univ. of Utah Dept. of Anesthesiol., Salt Lake City, UT; [4]Univ. of Arizona Col. of Med., Tuscon, AZ; [5]Anesthesiology, Mol. and Cell. Physiology, and Neurosurg., Stanford Univ. Sch. of Med., Palo Alto, CA

Abstract: We used double mutant mice with both a delta opioid receptor reporter linked to green fluorescent protein (DOReGFP) and a Mu opioid receptor reporter linked to mcherry (MORmcherry) to determine the functional organization of opioid receptors on Group III and IV neurons that signal muscle pain and fatigue, and also are the afferent arm of the exercise pressor reflex. We used DiI (1,1'-Dioctadecyl-3,3,3',3'-Tetramethylindocarbocyanine Perchlorate) injected into the gastrocnemius muscle of seven, 30 day old, ketamine/zylazine anesthetized mice to retrogradely label dorsal root ganglion (DRG) neurons innervating this skeletal muscle. To determine the activation of DiI labeled neurons by exercise induced metabolites (a combination of ATP, lactate and protons) we used calcium imaging with Fura 2 as in Light et al, 2008. Our results from 815 cells (114 of which were labeled with DiI from 7 different mice (both male and female) confirmed the findings of Scherrer et al, 2009 and Bardoni et al, 2014 that about 31% of all DRG neurons express mu receptors, and 12% of all DRG neurons express delta receptors. Several differences between opioid receptors on all DRG neurons vs. opioid receptors on DiI labeled (muscle innervating neurons) were found. 1. More DiI labeled neurons (66%) expressed opioid receptors. 2. Delta receptors were much more common in DiI labeled neurons (40%) than in non muscle labeled neurons (7%); mu receptors were also more common (43% in DiI labeled neurons vs 29% in neurons not labeled with DiI). 3. As in Light et al, 2008 and Jankowski et al, 2013 about 41% of DiI labeled neurons responded to metabolites and half of these responded to low levels of metabolites (likely non-nociceptive) while the other half responded to high levels of metabolites (likely nociceptive). 4. Opioid receptors were very common on muscle labeled neurons responding to metabolites (77%) with 44.7% of these being mu receptors and 42.6% being delta receptors. 5. Delta receptors were more common in low metabolite responding neurons (50% delta, 33% mu), while mu receptors were more common in high metabolite responding neurons (56% mu, 32% delta). Thus, mu and delta opioid receptors likely play a larger role in regulating muscle innervating neurons than regulating other types of afferent neurons (e.g.,skin, viscera). Also delta opioid receptors likely play a larger role in modulating low metabolite responding neurons (which signal fatigue and activate the exercise pressor response) while mu receptors play a larger role in modulating high metabolite responding neurons (which signal ache).

Title: Neonatal growth hormone treatment blocks the priming effects of early life injury on adult hypersensitivity to inflammation

Authors: *Z. K. FORD[1], X. LIU[1], B. KATRAGADDA[1], K. J. GREEN[1], R. C. HUDGINS[1], M. P. JANKOWSKI[1,2];
[1]Dept. of Anesthesia, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Dept. of Pediatrics, Univ. of Cincinnati, Cincinnati, OH

Abstract: Exposure to injury as a neonate has the potential to prime the nervous system to subsequent re-injury later in life, which can have lasting effects on nociceptive processing in adulthood. Thus, strategies designed to mitigate the long term consequences of early life insult on adult hypersensitivity to peripheral injuries are of utmost importance. We have previously shown in a murine inflammatory pain model that injecting 3% carrageenan into the hairy hindpaw skin of neonatal mice produces a transient, but target-specific, decrease in growth hormone (GH) levels, which corresponded to observed mechanical and thermal hypersensitivity both *in vivo* and when assessing the response properties of cutaneous afferents with our *ex vivo* somatosensory system recording preparation. Systemic treatment with low dose GH blocked inflammation-induced hypersensitivity both behaviorally and electrophysiologically, while restoring the cutaneous quantities of GH back to naïve levels. In order to explore if GH was also proficient in preventing the priming effects of early life insult on adult hypersensitivity to cutaneous re-injury, we treated postnatal day 7 (P7) neonates with GH or vehicle at the time of cutaneous inflammation and re-inflamed the periphery 4-5 weeks later. For comparison, a third cohort of mice received vehicle as neonates, but no cutaneous inflammation. We then assessed DRG gene expression and mechanical and thermal responsiveness in these groups 1-28d post adult inflammation. We found that double-inflamed mice were hypersensitive to both mechanical and heat stimuli for up to 3 weeks, while GH-treated mice returned to baseline levels within one week, similar to animals that only received carrageenan injection as young adults. Corresponding changes in mechanically and thermally sensitive receptors/channels were also found in our groups after adult inflammation in the DRGs. Results indicate that a GH treatment in neonatal mice may have the ability to block the priming effects of early life insult on adult hyper-responsiveness to both mechanical and thermal stimuli after cutaneous re-injury. This data may provide a potential therapeutic strategy to prevent the transition from acute to chronic pediatric inflammatory pain.

Title: Prenatal alcohol exposure has enduring effects on spinal glial-immune responses following minor peripheral nerve damage leading to enhanced neuropathic touch hypersensitivity

Authors: *J. J. SANCHEZ[1], M. S. SUN[2], S. DAVIES[2], D. D. SAVAGE[2,3,4], E. D. MILLIGAN[2,5];
[1]Neurosciences, [2]Neurosci., [3]Psychology, [4]Pediatrics, [5]Anesthesiol., Univ. of New Mexico, Albuquerque, NM

Abstract: A hallmark of neuropathic pain is increased sensitivity to light touch, clinically known as mechanical allodynia. Glial cells (astrocytes and microglia) contribute to ongoing allodynia in various animal models such as a localized sciatic nerve chronic constriction injury (CCI), a classic rat model of peripheral neuropathy. Released glial proinflammatory cytokines like interleukin-1β (IL-1β) that activate IL-1 receptors on pain neurons and other nearby glia are critical in mediating allodynia. Patients with fetal alcohol spectrum disorder experience sensitivity to light touch and have aberrant immune responses. Studies in animal models of prenatal alcohol exposure (PAE) demonstrate increased withdrawal responses to mildly noxious thermal stimuli. Therefore, we examined whether PAE causes a lifelong enhancement of allodynia and spinal glial activation in response to standard-CCI (4-suture loose ligation) or a minimal CCI (1-suture) model that does not produce allodynia in non-PAE animals.
Methods: Saccharin (Sac controls) or PAE dams consumed 5% ethanol (v/v) four hours each day throughout pregnancy. Adult male offspring (4 mo. or 1 yr.) were assessed for hindpaw light touch withdrawal thresholds (Von Frey test for allodynia) prior to sham or CCI surgery and after surgery. On day 28 after surgery, 4 mo. rats received intrathecally (i.t.) either vehicle or BIRT-377, an antagonist to lymphocyte function-associated protein 1(LFA-1), which is expressed by spinal microglia and immune cells during their activation and migration. Allodynia was re-assessed daily for 4 days, followed by transcardial saline/paraformaldehyde perfusion for immunohistochemical detection of lumbar dorsal spinal cord glial activation markers.

Results: 4-suture CCI enhanced allodynia in 4 mo. and 1 yr. PAE rats compared to controls, and 1 suture CCI induced unilateral allodynia in both 4 mo. & 1 yr. old PAE rats, but not in Sac controls. In 4 mo. 4-suture CCI PAE rats, bilateral astrocyte and microglial activation was highest while 1 yr. 4 suture CCI PAE revealed elevated ipsilateral astrocyte and microglial activation. Curiously, 1 yr. 1-suture CCI PAE did not induce increased microglial activation. Finally, in 4 mo. old PAE rats, i.t. BIRT-377 caused complete reversal of allodynia while corresponding astrocyte and microglial activation remained elevated. Ongoing studies are examining the effects of BIRT-377 on spinal glial & IL-1β responses.
Conclusions: Results indicate that PAE causes lifelong enhancement of spinal glial-immune reactivity that may underlie a susceptibility to developing chronic neurological disorders including neuropathies in humans.

Title: Involvement of CD137L in peripheral nerve injury-induced neuropathic pain

Authors: ***L. CAO**, J. T. MALON, R. LEEMING;
Univ. of New England, Biddeford, ME

Abstract: CD137L, also known as 4-1BBL, is a co-stimulatory molecule involved in many immune functions. CD137L-mediated signaling can promote monocyte/macrophage proliferation, migration, and production of proinflammatory factors; however, CD137L-mediated microglial responses have not been studied extensively. Here, we sought to investigate the role of microglial CD137L in the development of peripheral nerve injury-induced neuropathic pain using a murine model, spinal nerve L5 transection (L5Tx). First, compared to wild type (WT) controls, B6_CD137L knockout (KO) mice displayed significantly decreased L5Tx-induced mechanical and heat hypersensitivity starting at day 3 post-L5Tx until day 35 post-L5Tx when the experiment was terminated. To determine the role of microglial CD137L, an anti-CD137L neutralizing antibody (Ab, clone TKS-1) was intrathecally injected into WT BALB/c mice daily from day 0 (before surgery) to day 7 post-L5Tx. The neutralizing Ab significantly reduced

L5Tx-induced mechanical hypersensitivity but not the heat hypersensitivity. Further, we evaluated the microglial M1 vs M2 responses following L5Tx in both CD137L KO and WT mice via qRT-PCR and immunohistochemistry. Preliminary results suggest there may be less sustained M1 and M2 responses in CD137L KO mice compared to WT mice. Altogether, our data indicate that spinal cord CD137L contributes to the maintenance of peripheral nerve injury-induced neuropathic pain-like behaviors, which may be in part due to a reduced activation of spinal cord microglial cells.

Title: Glial inhibition through single transcutaneous electrical nerve stimulation reduces knee osteoarthritic pain in rats

Authors: *S.-C. HAHM[1,2], E. SONG[1,2], H. JEON[1,2], Y. YOON[3], J. KIM[1,2];
[1]Dept. of Publ. Hlth. Science, Grad. Sch., Korea Univ., Seoul, Korea, Republic of; [2]Dept. of Physical Therapy, Korea Univ. Col. of Hlth. Sci., Seoul, Korea, Republic of; [3]Dept. of Physiol., Korea Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Transcutaneous electrical nerve stimulation (TENS), noninvasive intervention, is commonly used for treatment of acute or chronic pain in several pathologic conditions, such as osteoarthritis (OA). However, analgesic effects of TENS and its mechanisms are still unclear. The aim of this study is to investigate the efficacy of single TENS for pain treatment in rats with knee OA and its mechanisms related to glial cell inhibition. OA was induced by injecting monosodium iodoacetate (4 mg / 50 μl) into the synovial space of the right knee joint. High frequency (HF)-TENS (100 Hz), low frequency (LF)-TENS (4 Hz), or sham-TENS with 100 μs pulse duration and sub-motor threshold was applied for 20 minutes on the ipsilateral knee joint. Knee bend score (KBS), paw withdrawal threshold (PWT) and weight bearing were measured before and after TENS application. Immunohistochemistry for microglia and astrocyte was performed in the spinal L3-5 segments. In order to test the effects of glial cells inhibition on OA pain, minocycline, L-α-aminoadipate (LAA) or artificial cerebrospinal fluid (aCSF) was injected intrathecally. KBS and PWT were measured before and after drug delivery. Both HF- and LF-

TENS significantly decreased KBS and increased PWT, but did not recover the decreased weight load of ipsilateral side during locomotion. Both HF- and LF-TENS inhibit activated microglia in L3-5 compared to sham-TENS. Spinal astrocyte significantly reduced in L3-5 by LF-TENS and in L3 by HF-TENS. Both minocycline and LAA decreased KBS and increased PWT compared to aCSF. These results suggest that both HF- and LF-TENS alleviate OA pain in rats through inhibition of activated microglia and reduction of astrocyte expression in the spinal cord.

Title: Activation of microglial C3aR1 by the VGF-derived peptide TLQP-21 may contribute to nerve-injury induced hypersensitivity

Authors: ***J. L. COOK**, M. RIEDL, K. KITTO, C. HONDA, C. FAIRBANKS, L. VULCHANOVA;
Univ. of Minnesota, Minneapolis, MN

Abstract: VGF is a neuropeptide precursor whose expression is rapidly and robustly increased in dorsal root ganglion and dorsal horn neurons following peripheral nerve injury. We have demonstrated that the VGF-derived peptide TLQP-21 contributes to both the development and maintenance of hypersensitivity after peripheral nerve injury and inflammation, and that intrathecal administration of TLQP-21 results in thermal hyperalgesia. The receptor for TLQP-21 was found to be the complement
3a receptor C3aR1. We have determined that C3aR1 appears to mediate the spinal effects of TLQP-21, as TLQP-21-evoked thermal hyperalgesia is inhibited dose-dependently by the C3aR1 antagonist SB290157. We aimed to examine whether the spinal effects of TLQP-21 were mediated by a direct interaction with this receptor, rather than activation of the complement

pathway and generation of C3a. It was found by Cero et al that the terminal arginine of TLQP-21 is required for activation of C3aR1, and that an arginine-to-alanine (R21A) substitution disrupted this. We generated a modified TLQP-21 peptide, with the R21A substitution (TLQP-R21A). When injected intrathecally, TLQP-R21A (1 nmol) demonstrated an attenuated thermal hyperalgesia compared to TLQP-21 (1 nmol), indicating that the spinal effect of TLQP-21 is largely mediated by activation of C3aR1. To examine potential cell types that respond to TLQP-21, we performed calcium imaging in cultured primary microglia. Stimulation with TLQP-21 evoked calcium mobilization in the cultured primary microglia, and this failed to occur in cultures prepared from C3aR1 knockout mice, indicating that the effect of TLQP-21 requires C3aR1. To visualize the interaction of TLQP-21 with C3aR1 in cultured primary microglia, we employed Click-iT chemistry. Cultures were incubated with an azide-modified TLQP-21, and then through a copper-catalyzed Click-iT reaction, were stained with a fluorescently-labeled alkyne. Preliminary results show a staining pattern that is consistent with receptor internalization, which provides further evidence of direct activation of C3aR1 by TLQP-21 in microglia. To determine whether C3aR1 upregulation after nerve injury may contribute to the involvement of TLQP-21 in hypersensitivity, we examined changes in receptor expression using quantitative real-time PCR. We found that C3aR1 mRNA expression is increased in the ipsilateral lumbar spinal cord compared to the contralateral side in spared nerve injury animals, and not in sham controls. This points to a potential mechanism for increased signaling by TLQP-21 following injury.

Abstract: Increasing evidence supports that both microglia and satellite glial cell (SGC) activation play a causal role in neuropathic pain development after peripheral nerve injury, yet the activation mechanisms and their contribution to neuropathic pain remain elusive. To address this issue, we generated *Ikkβ* conditional knockout mice in which IKK/NF-κB-dependent proinflammatory SGC activation is abrogated selectively in dorsal root ganglion (DRG). In these mice, nerve injury-induced proinflammatory gene expression and macrophage infiltration into the DRG were severely compromised. Likewise, nerve injury-induced spinal cord microglia activation and pain hypersensitivity were significantly attenuated in these mice compared to control mice. However, macrophages recruited into the DRG *per se* have minimal effects on spinal cord microglia activation suggesting a causal effect of SGC activation on spinal cord microglia activation. In an effort to elucidate the molecular mechanisms, we found that IKK/NF-κB-dependent SGC activation induced *St3gal2* expression in sensory neurons and subsequently leads to aberrant increase in ganglioside GT1b in afferent axons in the dorsal horn. In the spinal cord, GT1b functions as an endogenous agonist of toll-like receptor 2 (TLR2) to activate microglia and thereby induces pain central sensitization. Taken together, we present a novel mechanism for spinal cord microglia activation in nerve injury-induced neuropathic pain that is dependent on SGC activation, GT1b increase in the dorsal horn, and activation of microglial TLR2.

Title: Differential immune responses depending on genetic heterogeneity contribute to the phenotype of neuropathic pain among mouse strains

Authors: *K. ISAMI[1], S. IMAI[2], A. SUKEISHI[1], Y. NAKAZATO[2], K. NAGAYASU[1], H. SHIRAKAWA[1], T. NAKAGAWA[2], K. MATSUBARA[2], S. KANEKO[1];

Abstract: [Introduction] The differential neuro-immune responses due to diverse genetic factors can impact on neuronal adaptive responses associated with a phenotype of pain. However, the precise mechanisms are poorly understood. To address this issue, we compared the vulnerability of neuropathic pain in four strains of inbred mice with differential genetic backgrounds. Furthermore, we investigated how immune genetic heterogeneity can influence the pain phenotype via immune responses using these mice.
[Methods] In this study, four strains of inbred mice (C57BL/6J (B6), C3H/He (C3), DBA/2 and A/J) were used. Partial sciatic nerve ligation model was used as a neuropathic pain model, and mechanical allodynia was assessed by using von Frey filaments. Bone marrow (BM) chimeric mice were generated by intravenous injection of BM cells derived from donor mice into recipient mice irradiated with 8 Gy of gamma ray.
[Results] After the nerve injury, the most severe neuropathic pain was observed in B6, while C3 showed lower responses than other strains. In C3, the immunoreactivity of CD206-positive anti-inflammatory M2 macrophages were remarkably increased in the dorsal root ganglia (DRG) after the nerve injury, while the number of Iba1-positive activated microglia in the spinal cord was smaller than that of B6. To determine whether the phenotype of peripheral immune cells affects spinal microglial activation, we generated BM chimeric mice between B6 and C3. Behavioral and immunohistochemical studies revealed that B6 donor chimeric mice showed significant severe mechanical allodynia and decreased ratio of M2/M1 macrophages in DRG only 3 days after the nerve injury, compared to C3 donor chimeric mice, suggesting that the differential phenotype of DRG macrophages partially participated in the early phase of neuropathic pain. By contrast, differential responses of spinal microglia depended on the phenotype of recipient mice, rather than the phenotype of DRG macrophages, which mainly contributed to the development and maintenance of neuropathic pain.
[Conclusions] Taken together, our findings suggest that differential responses of immune/glial cells, especially microglia, contribute to the differential vulnerability of neuropathic pain on genetic heterogeneity.

Abstract: Microglial activation in the spinal cord plays a central role in the development and maintenance of chronic pain following a peripheral nerve injury. To date, there has not been a thorough assessment of microglial activation brain regions associated with pain and reward. To this end, we used a mouse model of neuropathic pain, whereby the left sciatic nerve was loosely constricted (chronic constriction injury) and assessed microglial activation in several brain regions two weeks following injury. We found significant upregulation of microglial markers of activation in brain regions associated with pain and affect, including the thalamus and prefrontal cortex, and amygdala. Activation was consistently most robust on the contralateral side. Regions not directly involved in pain or affective processing, such as the motor cortex, did not display microglial activation on either side. This study confirms that peripheral nerve injury induces microglial activation in regions involved with pain and affect.

Title: Resident macrophages in dorsal root ganglia: phenotype, function, and neuronal surveillance

Authors: *S. A. SCARNEO, T. J. ARABATZIS, B. K. DRAGOO, R. GEGUCHADZE, D. C. MOLLIVER, K. E. HANLON;
Biomed. Sci., Univ. of New England, Biddeford, ME

Abstract: Chronic pain is a major clinical problem that has a profound effect on quality of life and poses a significant burden on the U.S. health care system. A substantial proportion of patients report inadequate management of pain and patients are often plagued by deleterious side effects. The development of persistent pain requires plasticity of primary afferent nociceptors, which drive lasting changes in central circuits. Pro-inflammatory mediators released by immune cells contribute to the sensitization of nociceptors in response to injury, suggesting that modification of inflammatory pathways may alter the perception of persistent pain. To date most attention directed towards the inflammatory component of pain has been focused on neuro-immune interactions *at the site of injury* in peripheral tissues; our recent evidence suggests macrophage activity in dorsal root ganglia (DRG) in response to distant noxious stimuli. mRNA of CCL-2, a chemokine primarily responsible for the recruitment of monocytes, is upregulated in rat DRG following peripheral injury. Changes in expression of CSF1 (M-CSF), a growth factor known to induce macrophage proliferation, has also been shown in both DRG and spinal cord following peripheral nerve injury. Further, the purinergic receptors P2Y12 and P2Y13, expressed on both macrophages and DRG neurons, have been shown to modulate anti-nociceptive effects. We have recently obtained evidence that 1) macrophages are present in mouse DRG surrounding sensory neuron cell bodies, and 2) that peripheral noxious insults (hindpaw injection of complete Freund's adjuvant or capsaicin) induce changes in macrophage phenotype and function. Our findings suggest that macrophages in DRG monitor nociceptor activity and respond to intense stimulation with functional changes. These data are critical for determining whether DRG macrophages exert positive or negative influences on nociceptor sensitization in response to peripheral insult or injury and may lead to novel therapeutic approaches for the management of persistent pain.

Title: Release of exosomes containing miRNAs by macrophages in neuropathic pain

Authors: R. SIMEOLI, *M. A. MALCANGIO;
King's Col. London, London, United Kingdom

Abstract: Immune cells contribute to the mechanisms underlying neuropathic pain, at the site of nerve damage in the periphery, in the dorsal root ganglia (DRG) and in the dorsal horn of the spinal cord. At the site of injury and in the DRG, macrophages infiltrate in response to a chemokine gradient and release mediators able to sensitize neurons thereby contributing to peripheral sensitization, which together with central sensitization, is fundamental for the generation of allodynia, hyperalgesia and spontaneous pain. Here we started to explore whether macrophages release exosomes containing microRNAs (miRs) and regulate sensory neuron activity in the DRG. Exosomes are small vesicles (30-150 nm) containing RNA and protein cargos that are secreted by all cells types, including immune cells. Exosomes are considered to be highly specified enablers of intra- and extracellular communication, and recent evidence has indicated that microglia/macrophages can release and phagocytose exosomes. In our study, RT-qPCR of intracellular levels of selected miRs in cultured peritoneal macrophages demonstrated presence of miR 21-5p, Let 7b-5p, miR 155-5p and miR 134-5p. Furthermore, macrophages incubation with LPS for 3 hours resulted in significant release of exosomal markers TSG101 and CD81. Exosomes, isolated from the cell media were subjected to RT-qPCR to determine their contents. In particular, LPS stimulation induced release of miR-155, miR-21, miR-let7b, but not miR-134. Then, we evaluated whether the overexpression of miR 21-5p in macrophages could affect their phenotype. Transfection of peritoneal macrophages with miR-21-5p induced up-regulation of pro-inflammatory markers nuclear factor-κB (NF-κB) and inducible nitric oxide synthase (iNOS) and down-regulation of anti-inflammatory markers IL-10 and arginase-1. Furthermore, flow cytometry of miR 21-5p transfected macrophages confirmed in these cells a significant reduction of M2 phenotype in favor of M1. These transfection data *in vitro* indicate that an increase in intracellular miR-21-5p levels induces a shift in macrophage polarization from resting M2 phenotype to M1 pro-inflammatory phenotype. Flow cytometry analysis of leukocytes ($CD45^+$ cells) isolated from 7 day-neuropathic mice demonstrated a significant infiltration of macrophages ($F4/80^+$ $CD11b^+$ cells) in ipsilateral DRG and especially $CD206^-$ $CD11c^+$ cells (M1 macrophages) whilst $CD206^+CD11c^-$ cell (M2 macrophages) numbers were

comparable in sham and injured DRG. Future studies will assess whether the release of exosome containing miRs from macrophages contributes to the ongoing nociceptive neuron activity under neuropathic pain states.

Title: Neuro-immune activation in the sensory ganglia account for the development of herpetic neuralgia

Authors: *T. M. CUNHA[1], J. R. SILVA[2], J. TALBOT[2], A. H. LOPES[2], G. R. SOUZA[2], G. LUCAS[2], J. C. ALVES-FILHO[2], F. Q. CUNHA[2];
[1]Univ. Sao Paulo-FMRP, Ribeirao Preto, Brazil; [2]Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: Herpetic neuralgia is the most important symptom of herpes zoster disease, which is caused by Varicella zoster. Nevertheless, the pathophysiological mechanisms involved in herpetic neuralgia are not totally elucidated. Here, we examined the neuro-immune interactions at the sensory ganglia that account for the genesis of herpetic neuralgia by using a murine model of Herpes simplex virus type-1 (HSV-1) infection. The cutaneous HSV-1 infection of mice results in the development of a zosteriform-like skin lesion followed by a time-dependent increase in pain-like responses (mechanical allodynia). Leukocytes, composed mainly of macrophages and neutrophils, infiltrate infected DRGs and account for the development of herpetic neuralgia. Infiltrating leukocytes are responsible for driving the production of TNF, which in turn mediates development of herpetic neuralgia through down-regulation of the inwardly rectifying K^+ channel, Kir4.1, in satellite glial cells. These results revealed that neuro-immune interactions at the sensory ganglia play a critical role in the genesis of herpetic

neuralgia. In conclusion, the present study elucidates novel mechanisms involved in the genesis of herpetic pain and open new avenues in its control.

Title: Membrane-type 1 matrix metalloproteinase controls the release of algesic myelin basic protein epitopes and pain after constriction nerve injury

Authors: ***S. HONG**[1], A. G. REMACLE[2], J. DOLKAS[3], W. CHOI[4], S. HULLUGUNDI[3], M. ANGERT[3], T. L. YAKSH[3], T. NISHIHARA[5], A. Y. STRONGIN[2], V. I. SHUBAYEV[3]; [1]Dept. of Anesthesiol. and Pain Med., Catholic Univ. of Korea Col. of Med., Seoul, Korea, Republic of; [2]Sanford-Burnham Prebys Med. Discovery Inst., La Jolla, CA; [3]Dept. of Anesthesiol., UCSD, La Jolla, CA; [4]Sungkyunkwan Univ. Col. of Med., Seoul, Korea, Republic of; [5]Ehime Univ. Col. of Med., Toon, Japan

Abstract: Myelin basic protein (MBP) is an auto-antigen we have implicated in the development of severe pain arising from innocuous touch (mechanical allodynia). The specific mechanisms of this pro-algesic MBP activity remain obscure. Herein, we have demonstrated that following chronic constriction injury (CCI) to rat sciatic nerve, membrane-type (MT)1-matrix metalloproteinase (MT1-MMP/MMP-14) contributes to the release of the pro-algesic MBP69-86 peptide and then to mechanical allodynia. Specifically, MT1-MMP was constitutively expressed in the intact sciatic nerve. However, there was a gradual MT1-MMP increase starting at day 3 post-CCI, especially in Schwann cells and macrophages. Inhibition of MT1-MMP activity, using the selective, function-blocking human DX2400 monoclonal antibody, administered once into the sciatic nerve at day 3 post-CCI, attenuated mechanical allodynia. Morphologically, CCI nerves displayed Wallerian degeneration (axonal degeneration, edema, myelin ovoids and immune cell infiltration) after IgG1 treatment, whereas greater numbers of uncompromised axons were observed in CCI nerves treated with DX2400. DX2400 treatment also prevented

MBP degradation and reduced the level of the liberated MBP69-86 peptide at the CCI site. In teased out sciatic nerve myelinated fibers, we observed that after nerve injury, a decline in intact MBP was accompanied by accumulation of the membrane MT1-MMP and the MBP69-86-reactive fragment in close proximity to the nodes of Ranvier. Finally, we confirmed our earlier *in vitro* findings that MT1-MMP liberated the 69-86 MBP fragments from the intact MBP, and *in vivo* observations that the MBP69-86 peptide (rat sequence) injection into the intact nerve was sufficient to produce a robust and lasting state of allodynia. These data implicate MT1-MMP as a key protease in sustaining MBP-induced pain and an important therapeutic target in painful neuropathy.

Title: Facial pain hypersensitivity and trigeminal pathology in an animal model of CNS inflammation and demyelination

Authors: *K. C. THORBURN[1], J. W. PAYLOR[2], C. A. WEBBER[3], I. R. WINSHIP[2], B. J. KERR[4];
[1]Pharmacol., [2]Psychiatry, [3]Anat., [4]Anesthesiol. and Pain Med., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Trigeminal neuropathic pain is a well-recognized complication of the demyelinating disease multiple sclerosis (MS). The mechanisms underlying MS-related trigeminal neuropathic pain are poorly understood. This can be attributed, at least in part, to the lack of an animal model

that exhibits trigeminal pathology similar to that described in MS. Experimental autoimmune encephalomyelitis (EAE) is an animal model characterized by central nervous system inflammation and demyelination that is commonly used to study the pathophysiology of MS. We show here that mice with EAE exhibit increased sensitivity to air puffs applied to the whisker pad. The increased sensitivity to air puff stimulation is accompanied by immune cell infiltration and glial activation at several points along the trigeminal primary afferent pathway. Specifically, we found increased numbers of T cells and macrophages in the trigeminal ganglia (TG) of mice with EAE. We also observed a significant, but transient, increase in satellite glial cell expression of GFAP in the TG of EAE animals. Further investigation of the TG in EAE animals has revealed that the neuronal injury marker, ATF3, is also transiently increased. Additionally, recent preliminary data suggest that there are more calcitonin gene-related peptide (CGRP)-positive neurons in the TG of EAE animals. At the level of the trigeminal root entry zone, we found significant numbers of immune cells, demyelination and a transient decrease in GFAP immunoreactivity in EAE mice. Finally, we observed T cell infiltration, microglia/macrophage activation, demyelination and reactive astrocytes throughout the trigeminal brainstem complex in EAE animals. Interestingly, the pattern of trigeminal demyelination seen in EAE mice is similar to that previously described in people with MS-related trigeminal neuropathic pain. This is the first study to show orofacial sensory disturbances and trigeminal demyelination in EAE. Collectively, our data suggest that EAE may be a useful model for understanding MS-related trigeminal neuropathic pain conditions such as trigeminal neuralgia.

Title: Mechanism of thrombospondin-4 and alpha2delta-1 dependent processes in modulating excitatory synaptogenesis underlie neuropathic pain processing in nerve injury models

Authors: *Y. P. YU[1], B. VO[1], D. Z. LUO[2];
[2]Anesthesiol., [1]Univ. of California Irvine, Irvine, CA

Abstract: We have shown previously that spinal nerve ligation-induced peripheral nerve injury leads to increased production of extracellular matrix glycoprotein Thrombospondin-4 (TSP4) and of voltage gated calcium channel (VGCC) accessory subunit α2δ-1. Furthermore, interdependent interactions of TSP4 and α2δ-1 result in excitatory synaptogenesis that correlates with behavioral hypersensitivity. However, very little is known about the mechanism underlying TSP4/α2δ-1 mediated synaptogenesis. We examined this issue using a primary dorsal root ganglion (DRG)/spinal cord neuron co-culture system as an *in vitro* model that mimics the connectivity between primary DRG sensory neurons and secondary spinal cord neurons. We have found that TSP4 interacts specifically with pre-synaptic α2δ-1 at the central terminals of DRG neurons to promote synaptogenesis, but TSP4 interactions with post-synaptic α2δ-1 at spinal cord neurons or α2δ-1 at DRG neuronal somas are not synaptogenic. Early gabapentin treatments can block initiation of excitatory synaptogenesis mediated by TSP4/α2δ-1 dependent processes, but delayed gabapentin treatments have no effect on already formed excitatory synapses. Furthermore, excitatory synaptogenesis mediated by TSP4/α2δ-1 dependent processes is T-type VGCC function dependent as it can be blocked by T-type VGCC specific blockers, but not by N-type, L-type and P/Q-type VGCC blockers. Together, these findings support that nerve injury-induced excitatory synaptogenesis in dorsal spinal cord is likely initiated by aberrant TSP4 interactions with pre-synaptic α2δ-1 that activate a synaptogenic pathway involving T-type VGCC functions. Blocking this pathway preemptively may provide beneficial effects in preventing injury-induced aberrant excitatory synaptogenesis and chronic pain states.

Title: Chronic constriction injury of the sciatic nerve results in limited changes of polymodal spinal convergent neurons responses in the anesthetized rat

Authors: *J. ALLARD[1], C. LE CUDENNEC[2], V. CASTAGNÉ[2];
[1]E-Phys, Clermont-Ferrand, France; [2]Porsolt SAS, Le Genest-Saint-Isle, France

Abstract: Chronic constriction injury (CCI) following loose ligation of the sciatic nerve induces robust behavioral mechanical and thermal hypersensitivity in rats. The aim of the present work was to assess whether “basic” electrophysiological recordings of spinal neurons in CCI and SHAM-operated rats, including lamina I nociceptive specific (NS) and lamina V wide dynamic

range (WDR) projection neurons, reflected this expected hyper-reactivity. Spinal neurons innervating the glabrous skin of the hind paw were recorded under pentobarbital or isoflurane anaesthesia in 2 experiments including 10 CCI and SHAM rats each. Spontaneous activity, evoked and post-discharge responses to mechanical (von Frey probe, calibrated pinch) and thermal (Water Jet) stimuli were measured on the side ipsilateral and contralateral to the surgery. The experiments performed under pentobarbital or isoflurane anaesthesia focussed on WDR and NS neurons, respectively. A total of 166 neurons were recorded, yielding approximately 20 neurons for each combination of side, pathophysiological and anaesthetic condition. Neurons recorded under pentobarbital included mostly WDR profiles with receptive field covering the digits. Neurons recorded under isoflurane included mostly NS profiles with receptive field covering the palm of the paw, half of them being confirmed projection neurons by antidromic stimulation from the cervical cord. In the pentobarbital experiment, evoked responses and to a greater extent post-discharge responses were slightly increased on the injured side in CCI rat compared to the treated side in SHAM rats. Comparing the side ipsilateral to the surgery with the contralateral side showed that on the ipsilateral side responses altogether tended to be *increased* in CCI rats, but *decreased* in SHAM rats. In the isoflurane experiment, responses altogether were almost similar on the treated side in CCI and SHAM rats. Evoked responses were similar when comparing the ipsilateral to the contralateral side in CCI and SHAM rats. In contrast, post-discharge responses were greatly increased on the ipsilateral side to the injury in CCI rats compared to the contralateral side. No difference was observed in SHAM rats.The present experimental conditions did not provide evidence for the expected sensitization of spinal neurons in CCI rats. We suspect that more stringent criteria of inclusions are necessary to unravel the spinal neural substrate at the origin of behavioral hypersensitivity. Our data also suggest that the choice of appropriate control conditions is needed to interpret the effects of CCI on the activity of spinal neurons.

Title: Myelin basic protein auto-antigen in pain from light touch

Authors: *S. K. HULLUGUNDI[1,2], A. V. CHERNOV[3], A. G. REMACLE[3], K. A. EDDINGER[1], M. ANGERT[1,2], J. DOLKAS[1,2], J. B. LEUNG[1], A. Y. STRONGIN[3], T. L. YAKSH[1], V. I. SHUBAYEV[1,2];

Abstract: Myelin basic protein (MBP) is a known auto-antigen detected in multiple sclerosis patients. Our previous studies have shown that immunodominant MBP epitopes are proteolytically released in sciatic nerves after chronic construction injury (CCI). A single injection into the sciatic intact nerve of the pure peptides that represented these MBP epitopes was sufficient to produce a sustained state of neuropathic pain. The MBP peptides produced mechanical, but not thermal pain hypersensitivity, as determined using von Frey and Hargreaves testing. These data imply the role of myelinated A-afferents, which are conventionally known to transduce touch stimuli, in pain transduction. The present study is focused on understanding the mechanisms underlying the activities of the pro-algesic MBP peptides in Schwann cell and myelinating DRG cultures. The ability of the endogenous and exogenous pro-algesic MBP peptides to undergo axonal transport is also being assessed. Finally, mechanical hypersensitivity induced by MBP was transiently inhibited with gabapentin (a ligand of voltage-gated calcium channel α2δ1), an interleukin (IL)-6-neutralizing antibody, and was diminished in T-cell deficient athymic nude rats. In contrast, therapeutics such as lidocaine (sodium channel blocker), ketorolac (COX inhibitor), MK801 (NMDA antagonist) and TAK242 (toll-like receptor (TLR)-4 inhibitor) failed to reverse MBP-induced pain. Together, our data predominantly implicate adaptive T cells but not innate immune cells, such as microglia, in mediating MBP-induced pain. Because our initial studies have been accomplished in females, we now focus on the comparative analyses of the effects of nociceptive MBP peptides in female vs. male animals. In summary, MBP presents a novel pharmacological target in the nociceptive cascades activated in demyelinating disorders and painful neuropathies.

Title: 5-hydroxymethylcytosine and ten-eleven translocation proteins in the dorsal root ganglia—expression and dynamic regulation in neuropathic pain

Authors: *M. CUMMINS[1], A. CHAMESSIAN[2], M. QADRI[1], M. HENDRICKSON[1], T. BUCHHEIT[1], T. BERTA[3], T. VAN DE VEN[1];
[1]Anesthesiol., [2]Duke Univ., Durham, NC; [3]Anesthesiol., Univ. of Cincinnati, Cincinnati, OH

Abstract: Epigenetic mechanisms are increasingly recognized to contribute to the pathology of chronic pain conditions. 5-hydroxymethylcytosine (5hmC) is a recently discovered epigenetic modification with wide-ranging roles in neuronal processes such as development, learning and memory and synaptic transmission. Although much is known about 5hmC in the central nervous system, it is not yet known whether this epigenetic mark is present in the somatosensory neurons of the dorsal root ganglia (DRG) or if it plays a role in the pathogenesis of neuropathic pain due to nerve injury. Thus, the aim of this current study was characterize the expression and nerve injury-induced dynamics of 5hmC and the 5hmC-generating Ten-eleven translocation (TET1-3) proteins in the DRG. We found that 5hmC is present in both neurons and glia of the DRG and that 5hmC levels increase in the DRG after peripheral nerve injury. In addition, all three TET family members were found to be expressed in DRG cells, but with distinct expression patterns. TET1 and TET3 demonstrated exclusively neuronal expression, while TET2 was found broadly in neurons and non-neuronal cells. Interestingly, TET3 was preferentially expressed in small and medium diameter, Peripherin-positive DRG neurons and was the only TET family member whose expression was altered by peripheral nerve injury, indicating that TET3 may play a distinct role in nociception under normal and pathological conditions. Taken together, our study suggests that 5hmC and TET proteins may be important contributors to the pathogenesis of neuropathic pain and warrant further investigation. To test the specific contributions of TET1-3 in neuropathic pain, we are currently conducting studies using shRNA-mediated knockdown of TET1-3 *in vivo*.

Title: Autonomic dysfunction contributes to nociceptive plasticity after spinal cord injury

Authors: *S. M. GARRAWAY[1], S. PARVIN[2];
[1]Physiol., Emory Univ. Sch. of Med., Atlanta, GA; [2]Emory Univ., Altanta, GA

Abstract: Chronic neuropathic pain is a major consequence of spinal cord injury (SCI). As a result of its unpredictable onset, various etiologies and expressions, the underlying neural mechanisms of chronic neuropathic pain are poorly understood. SCI also often results in autonomic dysfunction which typically includes compromised respiratory function. There is evidence in support of significant cellular and anatomical overlaps between maladaptive sympathetic and sensory processing. However, a thorough investigation into their interactions after SCI has not been demonstrated.

The objective of the study was to investigate temporal changes in sensory nociceptive processing and autonomic dysfunction after SCI in adult Long Evans rats with a lateral hemisection or contusion SCI, or sham surgery at the thoracic (T) 8 spinal cord. Specifically, we focused on the development of thermal and mechanical hypersensitivity and parallel changes in respiratory rates (RRs). At weekly time-points ranging from 24 hours to 7 weeks after injury, thermal sensitivity was assessed with the tail-flick and Hargreaves tests, while mechanical responses to von Frey filaments and brush stimulation to the trunk skin were evaluated. Changes in RRs were assessed using highly sensitive non-contact electric field sensors (EPIC, Plessey Semiconductors) that measure breathing frequencies. RRs were monitored before and after SCI, and during behavioral pain tests.

Our results showed that SCI increases basal respiratory rates, an increase that is maintained for several weeks after injury. SCI rats had increased thermal and mechanical sensitivity. Moreover, they showed a greater increase in their RRs in response to mechanical and thermal stimulation, although this effect depended on the type of injury. In SCI rats with a hemisection, RRs were increased during thermal testing. In contrast, an increase in RRs in response to mechanical testing was typically seen in subjects with a moderate contusion injury. Mechanical allodynia and stimulation-induced increases in RRs were in part driven by increased sympathetic activity, as these effects were significantly attenuated following administration of propranolol, a β-adrenergic antagonist (20mg/kg).

Overall, these preliminary observations reveal that maladaptive sensory processing after SCI is influenced by autonomic dysfunction. They also suggest that interactions between sensory and autonomic dysfunction after SCI may depend on the type or severity of injury.

Title: Changes in chloride co-transporter and cytoskeletal proteins in mice with EAE: Implications for pain processing in Multiple Sclerosis.

Authors: *M. YOUSUF[1], K. ZUBKOW[1], B. J. KERR[2];
[1]Neurosci. and Mental Hlth. Istitute, [2]Dept. of Anesthesiol. and Pain Med., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Multiple Sclerosis (MS) is an autoimmune inflammatory disorder of the central nervous system. It manifests with a multitude of physical and cognitive symptoms. More than half of MS patients also complain of neuropathic pain. Neuropathic pain can arise as a result of hyperexcitability of spinal dorsal horn neurons. Various proteins are important for regulating the balance between excitation and inhibition in the CNS to prevent hyperexcitability. The Na^+-K^+-Cl^- co-transporter 1 (NKCC1) is one such transporter that is crucial for determining the strength and polarity of GABA, the principle inhibitory neurotransmitter in the CNS. NKCC1 on presynaptic terminals in the dorsal horn regulates primary afferent depolarization. We set out to identify whether changes in the expression of NKCC1 arises in mice with experimental autoimmune encephalomyelitis (EAE), an animal model commonly used to study MS, that may relate to pain hypersensitivity in this model. qRT-PCR analysis of dorsal spinal cord revealed a marked decrease in mRNA levels for NKCC1 at disease onset and peak, time points when pain behaviours are prominent in the disease. A similar pattern of expression was found at the protein level for both NKCC1 and phosphorylated NKCC1, in the dorsal spinal cord. In contrast, we find that in the DRG, protein levels of NKCC1 are significantly elevated at the onset of clinical signs in EAE. An accumulation of NKCC1 in the DRG with a reduction in the dorsal horn may be the result of impaired anterograde transport from the cell bodies of DRG neurons. We find that the

axon-specific microtubule associated protein, tau, is downregulated after the onset of symptoms. Furthermore, kinesin levels are also decreased at the onset of clinical signs in EAE. These results suggest that the axon cytoskeleton is integral for mediating the levels of the chloride co-transporter NKCC1 in the axon terminals of the dorsal horn. Early disease associated damage to peripheral cytoskeleton proteins may prevent NKCC1 transport leading to a reduction in presynaptic inhibition, hyperexcitability and enhanced nociceptive behaviours early in the disease course of EAE.

Title: SIRT3 and mitochondrial ROS play an important role in HIV neuropathic pain induced by the antiretroviral therapy in rats

Authors: S. LIU, T. IIDA, H. YI, K. TAKAHASHI, D. LUBARSKY, *S. HAO;
Dept Anesthesiol., Univ. of Miami, Miami, FL

Abstract: Highly active antiretroviral therapy (HAART) has markedly increased survival of patients with HIV/AIDS. However, nucleoside reverse transcriptase inhibitors (NRTIs) induce neurotoxicity and cause a painful peripheral neuropathy. While there has been a major shift away from some neurotoxic NRTIs in current antiretroviral therapy, a large number of HIV patients alive today have previously received them, and many have developed painful peripheral neuropathy. The molecular mechanisms by which NRTIs contribute to the development of neuropathic pain, are not known. Mitochondrial oxidative stress is involved in the neuroinflammatory diseases. Sirtuin-3 (SIRT3) is a class III lysine deacetylase that is localized to the mitochondria, and regulates mitochondrial respiration and oxidative stress resistance enzymes, such as manganese superoxide dismutase (MnSOD). SIRT3 deacetylates MnSOD and

activates MnSOD to scavenge ROS (mitochondrial anti-oxidative mechanisms (SIRT3-MnSOD)). Few studies show the effect of SIRT3-MnSOD on HIV neuropathic pain. Here, we examined if SIRT3 and mitochondrial oxidative stress played a role in HIV neuropathic pain. Neuropathic pain was induced by systemic 2',3'-dideoxyinosine (ddI, one of NRTIs). The lowered mechanical threshold (mechanical allodynia) induced by ddI, lasted for 5 weeks. Systemic ddI induced the downregulation of SIRT3, and decreased the activity of MnSOD in the spinal cord dorsal horn. Intrathecal injection of Mito-tempol (MitoT, a mitochondria-targeted superoxide scavenger), or recombinant SIRT3 increased mechanical threshold. Intrathecal Mito-T suppressed MitoSox (mitochondrial superoxide marker) profile neuron number in the spinal cord dorsal horn. Based on these results above, we suggest that SIRT3 and mitochondrial oxidative stress play an important role in HIV neuropathic pain induced by NRTIs. The study will provide preclinical evidence for novel pharmacotherapy in patients with HIV-related pain.

Title: Mitochondrial reactive oxygen species facilitate excitatory synapses on spinothalamic tract neurons in neuropathic pain

Authors: ***C. BAE**, J. WANG, A. BITTAR, H. SHIM, J.-H. LA, S.-J. TANG, J. CHUNG; Dept. of Neurosci. and Cell Biol., Univ. of Texas Med. Br. At Galveston, Galveston, TX

Abstract: Synaptic plasticity is important for normal brain functions such as learning and memory. Dysregulated synaptic plasticity is implicated in the development of various neurological conditions including neuropathic pain. However, the underlying mechanism of synaptic plasticity in neuropathic pain conditions is poorly understood. We previously reported that the level of mitochondrial reactive oxygen species (mROS) is correlated with the extent of allodynia induced by intradermal capsaicin. This indicates that the sensitization of the spinal

dorsal horn neurons is affected by mROS. The present study explored the possible involvement of mROS in the plasticity of excitatory synapses on the spinal dorsal horn neurons in neuropathic condition by using 3 types of mice: mitochondrial superoxide dismutase (SOD2) knock-out (SOD2-KO), SOD2-overexpressing (SOD2-OE) transgenic, and wild type (WT). Neuropathic mice were generated by spinal nerve ligation (SNL) surgery. Pain levels were determined by measuring the foot withdrawal frequency to von Frey filament stimulation before and after SNL up to 14 days. Miniature excitatory postsynaptic currents (mEPSC) in identified spinothalamic tract neurons (STTn) were recorded from the spinal cord slices using patch clamping. Patch clamp recordings were done 7-14 days after SNL. SOD2-KO showed greater but SOD2-OE manifested less mechanical allodynia than WT mice after SNL. Comparable with the pain behavior, SNL increased the frequency of mEPSC in STTn in the order of SOD2-KO > WT > SOD2-OE. The amplitude of mEPSC did not differ either among three genotypes or between sham- and SNL-operated mice. Thus, we conclude that mROS are important molecules increasing activities of excitatory synapses on STTn, thereby contributing to neuropathic mechanical allodynia.

Title: A single intrathecal delivery of the adenosine 2A receptor agonist, ATL313, produces sustained antinociception by promoting A2BR- and PPAR-gamma-mediated anti-inflammatory processes in the spinal cord of rats.

Authors: ***A. J. KWILASZ**[1], S. M. GREEN FULGHAM[1], H. P. PATEL[1], L. CHANTE DURAN-MALLE[1], S. TILDEN[1], J. RIEGER[2], S. F. MAIER[1], L. R. WATKINS[1]; [1]Psychology and Neurosci., Univ. of Colorado-Boulder, Boulder, CO; [2]Adenosine Therapeut., Charlottesville, VA

Abstract: Neuropathic pain affects approximately 4 million people in the U.S. and remains refractory to analgesics in many patients. We have previously found that adenosine 2A receptor (A2AR) agonists such as ATL313 generate profound anti-inflammatory effects and produce

sustained reversal of mechanical allodynia when administered intrathecally (IT) in rat models of neuropathic pain, including chronic-constriction-injury (CCI). In this study, we further explore spinal cord mechanisms related to the sustained antinociceptive effects of ATL313. Male Sprague Dawley rats received CCI surgery which produces long-lasting mechanical allodynia for several months. On day 14 following CCI, a single IT administration of ATL313 effectively reversed mechanical allodynia for four weeks. IT delivery of an A2BR antagonist, MRS1754 but not an A2AR antagonist, ZM241385, one week after ATL313 administration, permanently reversed the sustained antinociceptive effect. This effect was correlated with increased spinal cord A2BR mRNA expression in ATL313-treated animals that received CCI but not sham surgery. Moreover, IT delivery of the peroxisome-proliferator-activated receptor gamma (PPAR-γ) antagonist, GW9662, temporarily reversed the sustained antinociceptive effect produced by ATL313. Isolation of spinal cord cells from animals treated with ATL313 *in vivo* revealed that these cells release IL-10 and cyclic adenosine monophosphate (cAMP). These results suggest that IT A2AR agonists produce sustained reversal of neuropathic pain by promoting A2BR- and PPAR-γ-related anti-inflammatory signaling in spinal cord, associated with release of cAMP and IL-10.

Title: Time course characterization of bone loss following K/BxN serum transfer in male and female mice

Authors: S. WOLLER[1], A. MARTINEZ-MARTINEZ[2], M. CORR[1], T. L. YAKSH[1], *J. JIMENEZ-ANDRADE[2];
[1]UCSD, La Jolla, CA; [2]Univ. Autónoma De Tamaulipas, Reynosa, Mexico

Abstract: Joint pain is the primary reason individuals with arthritis seek medical care. Unfortunately, arthritic pain is difficult to treat, and current treatments are fraught with undesirable side effects. It is commonly thought that pain is evoked by inflammation and / or joint damage, leading to a peripheral and central sensitization. However, the severity of pain often does not correlate well with these factors. We hypothesize that, while inflammation leads to sensitization of joint terminals, over time, changes occurring within the joint itself (e.g. bone loss / remodeling) may contribute to the ongoing pain state. Therefore, our goal was to characterize the time-course of changes occurring within cortical and trabecular bone of the femur, tibia, and ankle joint of arthritic mice using μCT analysis.
Using the K/BxN serum transfer model of arthritis, we have shown that male C57Bl/6 mice develop clinical signs of arthritis peaking around 12 days after serum transfer and declining thereafter. Inflammation is accompanied by a robust tactile allodynia (TA) commensurate with the onset of inflammation. Importantly male, but not female mice show TA persisting well beyond the resolution of inflammation (day 28). For this reason, bones of arthritic male and female mice were analyzed on day 0 (naïve), day 10, and day 28.
We quantified arthritis-induced changes in the femur, tibia, talus, and calcaneus. For trabecular bone, we determined trabecular bone mineral density (tBMD), percent bone volume (BV/TV), trabecular thickness (Tb.Th), trabecular number (Tb.N), trabecular separation (Tb.Sp), the degree of anisotropy (DA); while for cortical bone, BMD (cBMD), cortical area (Ct.Ar), and cortical thickness (Ct.Th) were examined.
In the distal femur and proximal tibia, we found that arthritic male, but not female, mice showed a significant decrease in tBMD, BV/TV, Tb.N at day 28 as compared to age- matched naive mice. There were no major changes in the cortical bone of the femoral or tibial mid-diaphyses. In the talus, there were no significant changes in any trabecular bone parameters in female or male arthritic mice as compared to naïve. In the calcaneus, tBMD and BV/TV are significantly decreased in male and female arthritic animals as compared to naïve. While there was no difference in Tb.Th or Tb.Sp, we found a significant decrease in Tb.N over time in arthritic females.
Together, these results suggest that K/BxN serum transfer-induced arthritis results in sex-dependent changes in TA and bone loss in different bones. Additional work will determine whether these bone changes are associated with long-term mechanical hypersensitivity in arthritic mice.

Title: Alterations in afferent pathway signaling and neurogenic inflammation following spinal cord injury

Authors: *J. R. YASKO[1], E. E. YOUNG[2], K. M. BAUMBAUER[2];
[1]Dept. of Neurosci., Uconn Hlth., Farmington, CT; [2]UConn, Storrs, CT

Abstract: Spinal cord injury (SCI) can lead to a devastating loss of function and intractable chronic pain.Pain is consistently ranked as one of the most significant health concerns among patients, and many report receiving inadequate pain relief. Pain following SCI is unique because it is one of few instances where pain is generated centrally. However, evidence has supported that the cells within the spinal cord are not the only cells in the nociceptive system impacted by SCI and that primary afferent nociceptors also play an integral role in the development and maintenance of chronic SCI-induced pain. Studies examining the contribution of primary afferents to SCI pain have shown that sensory neurons exhibit spontaneous activity following SCI. The neurons that exhibit spontaneous activity are sensitive to capsaicin, possess the TRPV1 receptor, and their spontaneous activity can be reduced by silencing the nociceptor specific sodium channel, Nav1.8. Sensitization of the primary afferent nociceptors can also contribute to the development of neurogenic inflammation whereby proinflammatory molecules are released from the peripheral terminals of nociceptors, resulting in peripheral inflammation and enhancement of pain. Here we examine how SCI impacts sensory neurons, as well as the skin and muscle in which they innervate. Mice were given a severe SCI using compression clips (60 g of force) at the level of T10-11, producing complete paralysis below the level of the forelimbs. To determine the time course of alterations in targets of interest, mice were sacrificed 24 hr following SCI and skin, muscle, and dorsal root ganglia (DRG) were collected at, above, and below the level of SCI. Tissue was then processed and analyzed for changes in gene expression using real-time RT-PCR. Analysis of DRG tissue revealed significant increases in TRPV1, TRPA1, calcα (CGRP), TrkA, and P2X3. Similar increases in gene expression were observed in DRGs collected from all levels with respect to the site of injury, for the exception of TRPV1, which showed significantly greater increases in expression above the level of injury. Analysis of hind and forepaw muscle showed significant increases in the expression of TRPV1 and calcα in hindpaw muscle, TRPA1 in forepaw muscle, and TrkA in hind- and forepaw muscle. Ongoing experiments are examining the time course of additional changes in gene and protein expression,

alterations within individual afferents, and how severity of injury impacts these changes. Our data suggest that SCI results in early sensitization of afferent pathways and the development of neurogenic inflammation in a temporally specific manner.

Title: Antinociceptive effect of a modified protonectin isolated from Parachartergus fraternus wasp

Authors: *P. GALANTE[1], J. GONÇALVES[2], E. F. SCHWARTZ[2], L. P. SILVA[2], M. MORTARI[2];
[1]Univ. of Brasilia, Brasília, Brazil; [2]Univ. of Brasília, Brasília, Brazil

Abstract: Neuroactive compounds are of great interest for their relevant potential to design new drugs, important to prevent and/or treat diseases such as chronic pain, as well as to develop other pharmacological tools. In this context, the study of wasp venoms has lead to the discovery of neuroactive molecules, however most peptides have yet to be identified or characterized. The social wasp *Parachartergus fraternus* has a remarkable peculiarity: although these wasps live in community, their venom act by irreversibly and non-lethally paralyzing their prey, which differs from other social wasps, which typically uses the venom only for protection against prey. This difference in the mode of action suggests the presence of compounds with activity in the nervous system. For this reason, the aim of this study was the identification and isolation of antinociceptive peptides in the venom of *P. fraternus.* The venom of *P. fraternus* was analyzed by two complementary strategies: HPLC fractionation followed by MALDI-TOF analysis and cDNA library construction and sequencing. A specific fraction was identified by mass spectrometry, however sequencing of this fraction was unable to unambiguously determine between Leucine and Isoleucine. Using the transcriptomic approach, the sequence of the precursor encoding this peptide was identified. The precursor encodes a propeptide of 61 amino acids with a putative signal peptide. The sequence of the mature peptide was determined and a

synthetic peptide with two amino acid substitutions was produced by solid phase synthesis. Antinociceptive activity of both peptides was evaluated by the hot plate model in Swiss mice (n=4-6/group). The peptides were infused via i.c.v. at doses of 16 and 8 nmol/animal four days after the implantation of the guide cannula. Morphine (16nmol/animal) was used as positive control and vehicle solution was used as negative control (2μL/animal). The analgesic activity of the natural isolated peptide was shown to be effective at 8 nmol/animal ($p<0.05$) in the time points of 90, 120 and 240 min whereas the higher dose of 16 nmol/animal showed a decreased effect, probably due to neurotoxicity. The synthetic peptide had a dose-dependent response, where the highest dose (16 nmol/animal) showed antinociceptive activity that did not differ ($p<0.05$) from morphine in all time points tested. The synthetic peptide did not show hemolytic activity. Animals injected with the higher dose of the synthetic peptide did not show motor deficit in the antinociceptive test. This synthetic peptide tested showed the potential to contribute to the development of neuroscience in the elucidation of synaptic transmission and in the design of new drugs.

Title: Methylglyoxal produces endoplasmic reticulum stress response in drg neurons

Authors: *P. BARRAGAN-IGLESIAS, T. J. PRICE;
Sch. of Behavioral and Brain Sci., The Univ. of Texas at Dallas, Dallas, TX

Abstract: The endogenous reactive metabolite methylglyoxal (MGO) has been suggested to play a causal role in the pathogenesis of diabetic peripheral neuropathic pain. Evidences suggest that MGO activates TRPA1 and $Na_{V1.8}$ channels in sensory neurons to produce pain. However, these events may occur only at very high concentrations and the mechanisms underlying MGO-induced pain over the longer term are not known. Recently the endoplasmic reticulum (ER) stress pathway was proposed to regulate the excitability of the nociceptive system, potentially via a direct action in DRG neurons. We hypothesized that MGO induces ER stress in DRG leading to a sensitization of these neurons. Our preliminary results using primary DRG cultures and WB

show that MGO (1 micromolar, 3-48 h) produces an up-regulation of ER stress markers BiP, p-PERK and p-eIF2 alpha. Remarkably, chronic ER stress response was observed with long exposure to MGO (24-48 h). Moreover, the integrated stress response inhibitor ISRIB (200 nanomolar, 24 h) attenuated the effects of eIF2α phosphorylation produced by MGO exposure. Experiments *in vivo* and *in vitro* are ongoing in our lab to determine the mechanisms and downstream targets associated with MGO-ER stress response to promote chronic pain.

Title: AKAP-dependent modulation of GRK2 maintains delta opioid receptor incompetence

Authors: *A. D. BRACKLEY[1,2], R. GOMEZ[3], K. A. GUERRERO[3], N. A. JESKE[2,3,4]; [2]Pharmacol., [3]Oral & Maxillofacial Surgery, [4]Physiol., [1]UTHSCSA, San Antonio, TX

Abstract: We recently identified a novel, non-internalizing role for G protein-coupled receptor kinase 2 (GRK2) in maintaining delta opioid receptor (DOR) analgesic incompetence at the plasma membrane. However, the mechanism that maintains constitutive GRK2 association with DOR remains to be elucidated. Previous studies have shown that PKA phosphorylation of GRK2 plays an important role in its plasma membrane targeting. A-kinase anchoring protein 79/150 (AKAP), a scaffolding protein expressed in sensory neurons that resides at the plasma membrane, scaffolds protein kinase A (PKA) and mediates downstream signal transduction. In the present study, we sought to determine whether constitutive DOR desensitization by GRK2 is directed by PKA via AKAP-scaffolding. siRNA-mediated knockdown of AKAP in primary neuronal cultures significantly increased basal DOR association with GRK2. Complementary studies in primary sensory neurons from AKAP wildtype mice demonstrated that DOR can be primed for activation, but not in AKAP (-/-) neurons. In overexpression studies with wildtype and mutant AKAP, only AKAPΔPKA significantly reduced plasma membrane DOR:GRK2 association and consequently increased DOR activity in sensory neurons without the need for priming. Furthermore, AKAP expression augments GRK2 phosphorylation by PKA in the

cytosol and plasma membrane targeting of GRK2. These findings suggest that AKAP scaffolds PKA to increase plasma membrane targeting of GRK2 and maintain DOR analgesic incompetence.

Title: Depression attenuates allodynia and hyperalgesia of neuropathic pain via spinal dorsal horn glucocorticoid receptor.

Authors: *X. WEI[1], F. LUO[2];
[1]Inst. of Psychology,Chinese Acad. of Sci., Beijing City, China; [2]Inst. of Psychology,Chinese Acad. of Sci., Beijing, China

Abstract: Our previous study improved that depression attenuate chronic pain in rats, but the certain neural mechanisms in spinal dorsal horn (SDH) remain to be elucidated. Glucocorticoid receptors (GRs) is a classical nuclear receptor. Recent work demonstrated that GRs' function is disabled in some related brain regions of depressive-like rats. Besides, GRs expression is up-regulates in ipsilateral SDH of neuropathic pain rats. Thus, SDH GRs may play a crucial role in the depressive-like rat with neuropathic pain. This research divided male SD rats into 4 groups: Sham, Olfactory bulbectomy (OB), Spinal nerve ligation (SNL), and OB+SNL, group. First, OB was carried on following the open-field and sucrose consumption baseline tests. 14 days later, SNL or Sham surgery was executed. Mechanical allodynia and thermal hyperalgesia was tested 7 days after SNL. Then, Western Blot was carried out to analyise the expression of GRs in SDH. The locomotive distance and rearing number in the open-field test were significant up-regulated, meanwhile sucrose consumption score was down-regulated after OB. Ipsilateral mechanical paw withdraw threshold (PWT), as well as thermal paw withdraw latency (PWL), of OB+SNL group was up-regulated compared with SNL group. Western blotting results revealed that in OB group

cytoplasm GR level was increased, yet nucleus GR level was decreased (vs. Sham group) ; and in SNL group nucleus GR level was increased (vs. Sham group). What's more, OB+SNL group nucleus GR level was significantly lower than that of SNL group. Pearson correlation analysis revealed that, both mechanical PWT and thermal PWL were negatively correlated with nucleus GR levels. In order to explain the possible neural mechanism, GR selective agonist dexamethasone (Dex) was applied intrathecally on the 15th day following OB operation for 1 week, 4ug daily. Mechanical PWT and thermal PWL of SNL and OB+SNL group were significantly down-regulated by Dex. In SDH, nucleus GR levels were significantly up-regulated by Dex, especially in SNL and OB+SNL group, which were significantly higher than that of Sham and OB group. BDNF plays a crucial role in occurrence and development of neuropathic pain. The effect of OB or/and SNL surgeries on expression of BDNF was similar with that of nuclear GR in SDH. BDNF expression was also up-regulated by Dex, especially in the SNL and OB+SNL group which showed enhancement of mechanical allodynia and thermal hyperalgesia. In conclusion, because of nuclear translocation dysfunction in SDH induced by OB, GRs were not able to regulate their responsive protein such as BDNF, eventually leading to attenuation of neuropathic pain caused by SNL.

Title: Ngf r100w defines a role of p75ntr in nociception

Authors: *W. YANG[1], K. SUNG[2], C. WU[2], W. MOBLEY[2];
[1]Dept. of Neurology, Ruijin Hosp., Shanghai City, China; [2]Dept. of Neurosciences, Univ. of California at San Diego, SAN DIEGO, CA

Abstract: Nerve growth factor (NGF) exerts multiple functions on target neurons throughout development. The recent discovery of a point mutation in NGF(NGFR100W) in patients with hereditary sensory and autonomic neuropathy, type V (HSAN V) made it possible to distinguish the signaling mechanisms that lead to two functionally different outcomes of NGF: trophic versus nociceptive. We performed extensive biochemical, cellular and live imaging experiments to examine the binding and signaling properties of NGFR100W. Our results show that, similar to

the wildtype NGF (wtNGF), NGFR100W was capable of binding to and activating the TrkA receptor and its downstream signaling pathways to support neuronal survival and differentiation. However, NGFR100W failed to bind and stimulate the 75kD neurotrophic factor receptor (p75NTR)-mediated signaling cascades. Furthermore, NGFR100W no longer had the ability to induce hyper-potentiation of dorsal root ganglion (DRG) sensory neurons as detected by single cell patching clamp assay. Ceramide, a downstream signaling molecule to p75NTR appeared to play a significant role in NGF-induced hyper-sensitization of DRG neurons. Intraplantar injection of NGFR100W into adult rats induced neither thermal nor mechanical hyperalgesia either acutely or chronically. Taken together, our studies provide evidence that NGFR100W retains trophic support capability through TrkA but no longer engages the p75NTR signaling pathways. These results may, at least in part, explain the increase in pain threshold thus a loss of pain perception in HSAN V patients.

Title: Behavioral, molecular and electrophysiological changes induced by skin incision: implications for the development of chronic pain

Authors: *K. K. RAU[1], C. HILL[3], B. HARRISON[2], G. VENKAT[2], H. KOENIG[1], S. COOK[3], A. RABCHEVSKY[4], B. TAYLOR[4], T. HAI[5], J. PETRUSKA[2];

Abstract: Tissue damage is one of the major etiological factors in the emergence of chronic/persistent pain, although mechanisms remain enigmatic. Using incision of the back skin of adult rats as a model for tissue damage, we observed sensitization in the nociceptive cutaneous trunci muscle reflex enduring to 28 days post-incision (DPI). Previously, we have shown that skin incision induces altered gene regulation in sensory neurons that is maintained long after the skin has healed and is resistant to standard clinical interventions (e.g., nerve block, NSAID). To determine if the enduring behavioral changes we observed with the cutaneous trunci muscle reflex corresponded with a long-term impact of tissue damage on sensory neurons, we examined the temporal expression profile of injury-regulated genes and the electrophysiological properties of traced dorsal root ganglia (DRG) sensory neurons. In this study, the mRNA for the injury/stress-hub gene Activating Transcription Factor 3 (ATF3) was upregulated and peaked within 4 DPI, after which levels declined but remained significantly elevated out to 28 DPI, a time when the initial incision appears healed and tissue-inflammation largely resolved. Accordingly, stereological image analysis indicated that some neurons expressed ATF3 only transiently (mostly medium-large neurons), while in others it was sustained (mostly small neurons), suggesting cell-type-specific responses. In retrogradely-traced ATF3-expressing neurons, Calcium/calmodulin-dependent protein kinase type IV (CAMK4) protein levels and isolectin-B4 (IB4)-binding were suppressed whereas Growth Associated Protein-43 (GAP-43) and Neuropeptide Y (NPY) protein levels were enhanced. Electrophysiological recordings from DiI-traced sensory neurons 28 DPI showed a significant sensitization limited to ATF3-expressing neurons. Thus, ATF3 expression is revealed as a strong predictor of single cells displaying enduring pain-related electrophysiological properties. These findings may represent a new consideration for the impact that tissue damage may have on the health and well-being of individuals and on developing strategies for treatment.

Title: Metabolic reprogramming of nociceptors initiated by HIF-1 alpha mediates the transition of pain from acute to chronic

Authors: *O. K. MELEMEDJIAN, Q. J. BANKS;
Dept. of Neural & Pain Sci., Univ. of Maryland Dent. Sch., Baltimore, MD

Abstract: Acute pain is an essential physiological response to injury, allowing for quicker recovery by promoting protection of damaged tissue. In some cases, this acute, protective pain becomes chronic, a debilitating condition which persists after the initial injury has healed. Furthermore, the molecular bases for how chronic pain is initiated and maintained are not well understood. Since metabolism is inextricably linked to every aspect of cellular function and the shift from acute to chronic pain would require metabolic changes that can maintain the chronic pain state, we hypothesized that metabolic reprogramming leads to the transition of acute pain to chronic. Utilizing nerve growth factor (NGF)-induced hyperalgesic priming, we tested this hypothesis. Intraplantar injection of NGF evokes tactile hypersensitivity that resolves within 72 hours. However, the animals that received NGF become primed for developing prolonged hypersensitivity following the intraplantar administration of prostaglandin E2 (PGE_2). We determined that NGF triggers local translation of the transcription factor hypoxia-inducible factor 1-alpha (HIF-1 alpha) which is retrogradely transported to the soma of sensory neurons where it initiates the reprogramming of cellular metabolism. Using Extracellular flux analysis, we determined that pain is associated with a distinct metabolic phenotype where sensory neurons display increased glycolysis and reduced oxidative phosphorylation. Moreover, during the primed phase the animals do not display tactile hypersensitivity and the sensory neurons exhibit normal oxidative phosphorylation. Crucially, reversing these metabolic changes alleviates pain. Hence, these findings provide novel insights into the role of metabolic reprogramming of nociceptors in the development and maintenance of chronic pain.

Title: Small-animal neuroimaging analysis of placebo analgesia

Authors: ***Y. L. CUI**[1], Y. ZENG[1,2], Q. ZENG[2], D. HU[1], W. YANG[3], E. HAYASHINAKA[1], Y. WADA[1], Y. WATANABE[1];
[1]Imaging Application Group, RIKEN Ctr. for Life Sci. Technologies, Kobe, Japan;
[2]Bioelectromagnetics Laboratory, Sch. of Medicine,, [3]Dept. of Neurobiology, Sch. of Medicine,, Zhejiang Univ., Hangzhou, China

Abstract: Placebo analgesia is a kind of pain relief that follows the administration of an inert treatment and is thought to result from expectation and implication. Placebo analgesia is a high-order neuropsychological process that activate intrinsic descending pain control system. Neuroimaging studies in human implicate a hierarchical recurrent system is involved in placebo analgesia, including cortical (prefrontal cortex), subcortical (amygdala), midbrain (periaqueductal gray), medulla (rostral ventromedial medulla), and spinal cord. However, the underlying neural and molecular mechanisms in detail are still poorly understood. To address this issue, we tried to establish an animal model of placebo analgesia in neuropathic pain rats using Pavlovian conditioning, in which neuropathic pain was caused by tight ligation of the lumber 5/6 spinal nerves (SNL) and Pavlovian conditioning was established with a painkiller (gabapentin) as the unconditioned stimulus. We show here that after a few trials of paired stimulation of gabapentin with conditioning stimulus, the inert treatment (saline, i.p.) alone also induced analgesia in some animals. Such placebo analgesia was completely blocked by naloxone (i.p., 5mg/kg), a mu-opioid receptor antagonist. In order to identify the brain regions involved in placebo analgesia, we also assessed the regional brain activity in these animal using small-animal neuroimaging method combing 2-deoxy-2-[^{18}F]fluoro-D-glucose positron emission tomography (PET) imaging with statistical parametric mapping analysis. Small-animal neuroimaging results showed that regional brain activity was increased in the medial prefrontal cortex and anterior insular cortex, and suppressed in the primary somatosensory cortex and primary motor cortex in the placebo analgesia group as compared with naloxone group. These results suggest that placebo analgesia could be established in animals using Pavlovian conditioning and that the brain regions identified in the present study could be involved in placebo analgesia.

Title: *In vivo* characterization of a selective monoacylglycerol lipase inhibitor ABD-1970 in rodents and activity in models of pain

Authors: *J. R. CLAPPER, J. L. BLANKMAN, A. R. COPPOLA, A. KNIZE, G. SIMON, J. CISAR, O. WEBER, M. NIPHAKIS, C. HENRY, I. FRASER, C. GRICE, A. EZEKOWITZ, G. O'NEILL;
Abide Therapeut., San Diego, CA

Abstract: Monoacylglycerol lipase (MGLL) is the primary regulator of 2-arachidonoylglycerol (2-AG) an endogenous ligand of the cannabinoid (CB) receptors CB1 and CB2. Selective blockade of MGLL inhibits the hydrolytic degradation of 2-AG resulting in elevated 2-AG levels in the CNS and periphery, and CB1/2-dependent anti-nociceptive and anti-inflammatory effects. In the rodent brain and select peripheral tissues, MGLL inactivation also reduces levels of the catabolic product of 2-AG hydrolysis, arachidonic acid, a metabolic precursor to pro-inflammatory prostanoids. Here, we present a comprehensive in vivo characterization of a selective covalent inhibitor of MGLL, ABD-1970. ABD-1970 is orally active in rodents producing a rapid and potent inhibition of MGLL and elevation of 2-AG in the brain. In vivo blockade of 2-AG hydrolysis was also associated with reduced levels of arachidonic acid and prostanoids PGE_2, PGD_2 and $PGF_2\alpha$ in the brain. Using activity-based protein profiling to comprehensively profile the in vivo selectivity of ABD-1970 against other serine hydrolases, α/β-hydrolase domain-containing 6 (ABHD6) and rodent-specific carboxylesterase 1c (CES1c) were the only off-targets identified, albeit at doses above those required for in vivo pharmacological activity at MGLL. In time course experiments, MGLL activity was inversely correlated with ABD-1970 concentrations in the blood and brain with recovery of MGLL activity observed as the compound was eliminated from the body. Furthermore, ABD-1970 was efficacious in the rat incisional model of acute post-operative pain, the rat formalin and complete Freund's adjuvant models of inflammatory pain and the rat chronic constriction injury model of neuropathic pain. In the formalin model, ABD-1970 produced enhanced activity in combination with standard of care agents, pregabalin and morphine. Integrated analysis of compound exposure, brain target engagement, and 2-AG levels reveal a strong relationship between PK, central biomarkers and efficacy in models of pain. Importantly, acute administration of ABD-1970 lacked effects on total exploratory activity in an open field test. These results identify ABD-1970 as a highly potent and selective in vivo active inhibitor of MGLL and underscore the therapeutic potential of selective MGLL inhibitors for the treatment of acute and chronic pain.

Title: *In vitro* characterization of a selective monoacylglycerol lipase inhibitor ABD-1970 in human systems

Authors: *J. L. BLANKMAN, C. HENRY, A. KNIZE, G. SIMON, J. CISAR, O. WEBER, M. NIPHAKIS, J. R. CLAPPER, A. COPPOLA, I. FRASER, C. GRICE, A. EZEKOWITZ, G. O'NEILL;
Abide Theraputics, San Diego, CA

Abstract: Monoacylglycerol lipase (MGLL) is a serine hydrolase enzyme that converts monoacylglycerols into fatty acids and glycerol. The MGLL substrate 2-arachidonoylglycerol (2-AG) is an endogenous ligand of the cannabinoid receptors CB1 and CB2, which are the molecular targets of the psychoactive component of *Cannabis sativa,* Δ^9tetrahydrocannabinol (THC). Inhibition or genetic inactivation of MGLL results in accumulation of 2-AG in the brain and periphery and CB1/2-dependent anti-nociceptive and anti-inflammatory effects. Additionally, MGLL inactivation in mice reduces levels of arachidonic acid (AA) and pro-inflammatory prostanoid metabolites in a subset of tissues including the brain, liver and lung. MGLL inhibition may therefore provide therapeutic benefit via enhancing cannabinoid receptor signaling and reducing prostanoid signaling.
To further evaluate the therapeutic potential of MGLL inhibition, we have developed ABD-1970, a potent and selective MGLL inhibitor. ABD-1970 is a hexafluoroisopropyl carbamate that covalently inhibits MGLL in vitro with IC_{50} values of <50 nM across species. The selectivity of ABD-1970 for MGLL amongst other serine hydrolases has been extensively profiled using gel- and mass spectrometry-based activity-based protein profiling (ABPP) technologies.
ABD-1970 has been used to explore the effects of MGLL inhibition in human systems in vitro. We determined that MGLL is expressed and active in many regions of the post-mortem human brain. Homogenates prepared from human brain cortex readily hydrolyze 2-AG and we confirmed that this activity is largely mediated by MGLL by its sensitivity to ABD-1970 treatment.

Though MGLL inhibition has been shown to reduce prostanoid production in mice, the effects of MGLL inhibition on prostanoid production and signaling in human systems is not well understood. Cyclooxygenase (COX) inhibitors, such as non-steroidal anti-inflammatory drugs (NSAIDs), dramatically reduce prostanoid production in humans and carry both therapeutically beneficial effects as well as gastro-intestinal and cardiovascular side-effects. To compare the effects of MGLL and COX inhibition in human cells, ABD-1970 and the NSAID indomethacin were tested in three paradigms: 1) prostanoid production in stimulated human whole blood, 2) prostanoid production in stimulated human endothelial cells and 3) collagen-induced platelet aggregation. The results of these assays clearly differentiated MGLL inhibition from COX inhibition as ABD-1970 was without effect in all three assays whereas indomethacin produced robust suppression of prostanoid production and platelet aggregation.

Title: A sex comparison of cannabidiol-tetrahydrocannabinol interactions on antinociception

Authors: *S. C. BRITCH, R. M. CRAFT;
Psychology, Washington State Univ., Pullman, WA

Abstract: The current study investigated sex differences in cannabidiol (CBD)-tetrahydrocannabinol (THC) interactions on antinociception and locomotor activity in rats.

Experiment 1 tested the hypothesis that CBD enhances THC-induced antinociception on tests of acute pain. A single dose of CBD (0, 10 or 30 mg/kg i.p.) was administered 15 min before a single dose of THC (0, 1.8, 3.2, 5.6 or 10 mg/kg i.p.). Rats were tested for antinociception on warm water tail withdrawal and paw pressure tests at 15, 30, 60, 120, 240 and 360 min post-THC injection. A 10-min locomotor activity test was also completed after nociceptive testing at each time point. Experiment 2 tested the hypothesis that a long CBD pretreatment time would enhance THC's effects more than a short pretreatment time. CBD 0 or 30 mg/kg was injected 13 hr or 15 min before THC 0 or 1.8 mg/kg, and rats were tested at 30, 60, 120, 240, 360 and 480 min post-THC injection, using the same behavioral tests as in Experiment 1. In both Experiment 1 & 2, THC caused dose- and time- dependent antinociception that was significantly greater in females than males. THC also caused dose- and time-dependent hypolocomotion, with no consistent sex differences. CBD enhanced THC-induced antinociception at later time points (240 & 360 min) on both nociceptive tests. In addition, CBD enhanced THC-induced hypolocomotion at 240 & 360 min, although when given alone, CBD increased locomotion at these later time points. CBD modulation of THC's effects was not sex-dependent on any measure. In Experiment 2, CBD-THC interactions did not consistently differ between rats tested with the long vs. short CBD pretreatment times. The present results suggest that CBD can slightly enhance THC-induced antinociception and hypolocomotion long after administration in both sexes, but the drug interaction was more robust on locomotion than on antinociception.

Title: Curcumin is an effective analgesic for burn pain: evidence from animal and human tissue based experiments

Authors: *J. L. CLIFFORD[1], B. P. CHEPPUDIRA[2], A. TREVINO[2], A. GREER[2], M. M. SALAS[2];
[1]US Army Ctr. For Envrn. Hlth. Res., Frederick, MD; [2]US Army Inst. for Surgical Res., San Antonio, TX

Abstract: Recovery and healing from severe burn injuries involves intensely painful procedures including wound debridement, dressing changes, and strenuous physical and occupational therapy. Although opioids are available to treat severe pain, a multitude of side effects including development of tolerance and dependence, accompany routine use of opioids for severe pain. In order to reduce the amount of opioids necessary for burn patients, alternative analgesics with reduced side effect profiles deserve exploration. Curcumin, a major constituent of turmeric (*Curcuma longa*), which has been utilized medicinally for centuries, has potential as an analgesic. Although curcumin is well tolerated for human consumption, its use as an analgesic in burn wound care has not yet been studied. We have assessed the effect of curcumin treatment (100uM, 24 hr) on the activity of several inflammatory signaling mediators in heat shocked (20 min, 45C or 55C) cultured HaCaT, human keratinocyte-derived cells. Curcumin treatment suppressed baseline phosphorylation levels of NF-kB and the heat shock induced phosphorylation of p38 MAPK. We also determined the effect of locally administered curcumin (SC injection, 100ug in 100ul vehicle, daily for 5 days) on two different types of pain behavior, mechanical allodynia and thermal hyperalgesia, in a full thickness thermal injury (FTTI) rat hindpaw pain model. Curcumin attenuated thermal hyperalgesia after the 2nd day of injections and attenuated mechanical allodynia after the 4th day of injections. Curcumin did not elicit any analgesic effects on the contralateral (non-injured) hindpaw; indicating it does not have CNS mediated effects on nociception. Finally, we have determined the effect of curcumin on pain signaling in human peripheral nerve tissue using a unique dental pulp in-vitro assay system. Curcumin pre-treatment (20 min., 100ug/100ul vehicle) suppressed the release of the pain neurotransmitter calcitonin gene-related peptide (CGRP) which is caused by treatment with capsaicin. These results indicate that curcumin has potential as an analgesic for burn pain management, and could reduce the amount of opioids administered to burn patients.

Title: Impact anesthesics consumpsion of pacients in protocol the kidney transplant with m-entropy monitoring backgroud

Authors: *C. SORIA-FREGOZO[1], A. CASTELLANOS ALVARADO[2], M. MIRANDA BELTRAN[2], A. ZEPEDA GONZALEZ[3], I. GONZALEZ HERNADEZ[3], M. PEREZ VEGA[2]; [1]Univ. de Guadalajara, Lagos de Moreno Jalisco, Mexico; [2]Univ. de Guadalajara, Guadalajara, Mexico; [3]Inst. Mexica del Seguro Social, Guadalajara, Mexico

Abstract: More than 500 million of persons in the word present kidney failure. In Mexico the kidney injury is of the principal cause of hospital attention. In Hospital of Specialty of CMO, IMSS is performer around of 13,000 general anesthesia in patients for year and is performer a proximity 160 kidney transplants of towards living donor kidney. The patients with injury kidney need surgery under general anesthesia frequently, and not exist a protocol that permit optimize the anesthesic consumption and see the impact with the M-entropy monitoring in the patients with kidney transplant. Impact in the anesthesics consumption of patients in protocol of kidney transplant with M-Entropy monitoring *vs* clinical variables simple monitoring. One hundred four patients were enrolled in this study, of protocol of patients reaccept of kidney transplant and towards living donor kidney with M-entropy monitoring and clinical variables simple monitoring; 22 patients donors with entropy monitoring (DE) group, 27 patients donors with clinical variables simple monitoring (DH) group, 23 patients reaccepts of kidney transplant with entropy monitoring (RE) group and 31 patients reaccept of kidney transplant with clinical variables simple monitoring (RH) group. In the premedication of the anesthesia, the fentanil consumption was significantly less in the DE group *vs* with the DH group and this was less in the group RE *vs* with RH group. Midazolam consumption was similar in allgroups. During the induction of the anesthesia the fentanil consumption was significantly less in the RE group *vs* RH group and in the maintenance of the anesthesia the fentanil consumption was significantly less in the RE group *vs* RH group and the fentanil consumption was less DE group *vs* DH group . In the induction of the anesthesia the propofol consumption was less in the DE group *vs* DH group. In the maintenance of the anesthesia, the desfluarano consumption was less in the DE and RE groups. The use with M-Entropy monitoring impact in anesthesics consumption in the groups of patients with kidney injury with entropy monitoring *vs* with clinical variables simple monitoring, decreased thecost, anesthesia awareness and in the quality of the attention of patients in protocol of kidney transplant.

Title: Positive allosteric modulation of cannabinoid CB1 receptor signaling suppresses chemotherapy-induced peripheral neuropathy

Authors: *R. SLIVICKI[1], P. KULKARNI[2], K. MACKIE[1], G. THAKUR[2], A. HOHMANN[1]; [1]Indiana Univ., Bloomington, IN; [2]Bouvé Col. of Hlth. Sci., Northeastern Univ., Boston, MA

Abstract: Activation of cannabinoid CB1 receptors either directly (via agonistic action) or indirectly (elevation of endocannabinoid tone through inhibitors of endocannabinoid deactivation) suppresses pathological pain. However, unwanted central 'side' effects (e.g. psychoactivity, tolerance) constrain therapeutic dosing. We hypothesized that positive allosteric modulation of CB1 receptor signaling would suppress neuropathic pain produced by chemotherapy treatment while bypassing cardinal signs associated with direct CB1 receptor activation. In addition, we sought to examine the potential for synergistic interactions between positive allosteric modulation of CB1 and inhibitors of endocannabinoid deactivation. We, therefore, compared the therapeutic efficacy of GAT211, a positive allosteric modulator of CB1 receptor signaling, with URB597, an inhibitor of fatty-acid amide hydrolase (FAAH), and JZL184, an inhibitor of monoacylglycerol lipase (MGL) using a mouse model of chemotherapy-induced peripheral neuropathy. Within-subjects dose-response curves were constructed for GAT211, URB597, and JZL184; ED_{50} values were generated and used in fixed combinations to determine if the combination treatments produced antinociceptive effects that were additive or synergistic. GAT211 produced a CB1-dependent suppression of mechanical and cold allodynia induced by the taxane chemotherapeutic agent paclitaxel. Isobolographic analysis revealed synergistic interaction of GAT211 with inhibitors of either FAAH or MGL. Moreover, GAT211 did not produce cardinal signs of cannabinoid receptor activation (hypothermia, motor ataxia, catalepsy, tail flick antinociception) in wildtype mice but produced signs of catalepsy in transgenic mice lacking either FAAH or MGL. Therapeutic efficacy of GAT211 was preserved

over a dosing period of 19 days with no appreciable signs of tolerance developing to its antinociceptive efficacy. By contrast, JZL184 initially displayed therapeutic efficacy but tolerance developed with repeated dosing. Thus, positive allosteric modulation of CB1 represents a promising strategy for harnessing the therapeutic potential of the endocannabinoid signaling system to suppress neuropathic pain without producing tolerance to therapeutic efficacy or detrimental CNS side-effects observed with orthosteric CB1 agonists. Moreover, our studies also suggest that CB1 positive allosteric modulators may show greater therapeutic potential compared to sustained inhibition of MGL, as manifested by absence of both tolerance and cardinal signs of CB1 intoxication.

Title: Bisphenol A inhibits nerve conduction in the frog sciatic nerve with an efficacy comparable to those of local anesthetics

Authors: N. MAGORI[1], *K. MIZUTA[2,1], T. FUJITA[1], H. YAMAGATA[1], C. WANG[1], R. HIRAO[1], R. SUZUKI[1], E. KUMAMOTO[1];
[1]Saga Med. Sch., Saga, Japan; [2]RIKEN Brain Sci. Inst. - Wako, Saitama, Japan

Abstract: Bisphenol A (BPA) is a monomer component in chemical products such as polycarbonate plastics and thus the products including BPA are widely used in various materials including food packaging. Owing to a lipophilic property of BPA, BPA is easily absorbed into the human body through food and drink in contact with materials containing BPA. Since BPA has an estrogenic action albeit this activity is comparatively weak, BPA interferes with normal endocrine function as an endocrine-disrupting chemical and therefore exerts a toxicological action on animals. BPA affects not only the endocrine system but also various physiological functions including nerve activity. Although BPA is reported to inhibit nerve conduction, this action has not yet been examined fully. In order to know a detail of the inhibition, we examined the effect of BPA on compound action potentials (CAPs) recorded from the frog sciatic nerve by using the air-gap method. Since BPA has been reported to bind to a local anesthetic (LA) receptor site on human cardiac Na^+ channels, the BPA result was compared with those of LAs. Treatment of the sciatic nerve with BPA (0.5 mM) for 20 min resulted in a decrease in CAP peak

amplitude to about 40 % of control. The CAP amplitude did not recover to control for up to 1 hour, when this amplitude was about 65 % of control, in nerves returned to drug-free solution. The CAP peak amplitude reduction produced by BPA was concentration-dependent with a half-maximal inhibitory concentration (IC_{50}) value of 0.31 mM. The BPA activity was resistant to an estrogen-receptor antagonist 4-hydroxytamoxifen. 4-Hydroxytamoxifen itself reduced CAP peak amplitude with the IC_{50} value of 0.26 mM, a value comparable to that of BPA. A natural estrogen 17β-estradiol at a maximally dissolvable concentration (0.05 mM) had an action similar to that of BPA. LAs (prilocaine and pramoxine) inhibited CAPs in a concentration-dependent manner. When compared with these and available LA data in the frog sciatic nerve, the efficacy of BPA in inhibiting CAPs was similar to those of pramoxine, ropivacaine and levobupivacaine (0.21, 0.34 and 0.23 mM, respectively), while being larger than those of prilocaine, procaine, lidocaine and cocaine (IC_{50} = 1.8, 2.3, 0.74 and 0.80 mM, respectively) and smaller than that of tetracaine (0.014 mM). In conclusion, BPA has an ability to inhibit nerve conduction in a manner independent of estrogen receptors with an efficacy comparable to those of some LAs. Such a conduction inhibition could contribute to at least a part of the effect of BPA on the nervous system.

Title: Antinociceptive effects of light therapy on acute and chronic pain models

Authors: ***M. M. IBRAHIM**[1,2], K. B. GILBRAITH[3], A. MOUTAL[2], X. YANG[2], L. CHEW[2], T. MILNES-LARGENT[2], F. PORRECA[2,3], T. P. MALAN[3,4], T. W. VANDERAH[2,3], A. PATWARDHAN[3,2], R. KHANNA[2];
[1]Univ. of Arizona Dept. of Anesthesiol., Tucson, AZ; [2]Pharmacol., [3]Anesthesiol., Univ. of Arizona, Tucson, AZ; [4]Pharmacol., university of Arizona, Tucson, AZ

Abstract: Managing chronic pain is challenging. Opioids are commonly prescribed for chronic pain despite weak evidence for long-term efficacy. The Centers for Disease Control and Prevention recommend non-opioid therapy for chronic pain. While some evidence points to light therapy being beneficial in certain medical conditions, this approach remains to be explored for acute and chronic pain. Here, we investigated the possible antinociceptive effects of several light emitting diodes (LED), in the visible spectrum, on naïve and neuropathic pain rats. Green LED (wavelength 525 nanometers) exposure for eight hours for five days increased withdrawal latency to a noxious thermal stimulus, which persisted for four days following termination of last exposure. The antinociception was mediated via actions on central mu-opioid receptor pathways unrelated to stress. No apparent side-effects were noted and motor performance was not impaired. Blocking pain-modulatory pathways by inactivation of the rostral ventromedial medulla prevented expression of light-induced antinociception. Antinociception was prevented by opaque contacts despite LED exposure or by green contacts exposed to room light, but not in rats with pigmentation arguing for a role of the visual system. Pharmacological and proteomic profiling of dorsal root ganglion (DRG) neurons from green-LED exposed rats identified changes in calcium channel activity, including a decrease in the N-type (CaV2.2) channel, a primary analgesic target. Tetrodotoxin-sensitive and -insensitive sodium currents in DRGs were unchanged by green-light exposure. Finally, green-LED exposure reversed thermal and mechanical hyperalgesia in rats with spinal nerve ligation or injection of envelope glycoprotein 120 of HIV-1. Thus, green-LED therapy represents a novel, non-pharmacological approach for managing chronic pain.

Title: Pharmacological profile of LIA a novel analogue of lidocaine

Authors: *M. DECIGA-CAMPOS[1], F. J. LÓPEZ-MUÑOZ[2];
[1]Escuela Superior De Medicina IPN, D.F. Mexico, Mexico; [2]Farmacobiología, Inst. Politécnico Nacional, CINVESTAV-Sur, Mexico

Abstract: N-(2,6-dichlorophenyl)-2-(4-methyl-1-piperidinyl)acetamide (LIA), a lidocaine analogue, has potential applications in treating neuropathic pain. The aim of this work was to characterize the pharmacological activity of LIA related with central nervous system activity. Anesthetic effect was tested in guinea pigs and mice. Ambulatory activity, anti-anxiety effect, sodium pentobarbital (PB)-induced hypnosis and pentylenetetrazol (PTZ)-induced seizures test were evaluated in mice to determine the possible central nervous system activity. LIA (2%) presents, similar to lidocaine (2%), anesthetic activity on the corneal reflex, infiltration anesthesia and tail immersion test. LIA (1-100 mg/Kg, i.p.), similar to lidocaine (1-100 mg/Kg, i.p.), presents a dose-dependent sedative-hypnotic effect in mice. Both compounds did not produce anti-anxiety activity in mice. LIA did not prevent PTZ-induced seizures. However, LIA itself did not produce seizures at high doses in mice, as lidocaine does. High doses of lidocaine produce seizures and vasoconstriction. In this study, we found that LIA shares a similar pharmacological profile as lidocaine´s but without the primary adverse effects of seizures.

Title: Compound action potential inhibition by various antidepressants in the frog sciatic nerve

Authors: R. HIRAO[1], T. FUJITA[1], A. SAKAI[1], C. WANG[1], R. SUZUKI[1], N. MAGORI[1], *M. ISHIMATSU[2], E. KUMAMOTO[1];
[1]Saga Med. Sch., Saga, Japan; [2]Nishikyushu Univ., Kanzaki, Japan

Abstract: An inhibition of action potentials conducting on nerve fibers possibly contributes to at least a part of antinociception produced by analgesics and their adjuvants. We have previously reported the inhibitory effects of a variety of drugs involved in antinociception on fast-conducting and voltage-gated Na^+-channel blocker tetrodotoxin-sensitive compound action potential (CAP) recorded from the frog sciatic nerve. Among the drugs, there are opioids, local anesthetics, α_2-adrenoceptor agonists and anticonvulsants. The aim of the present study was to examine the effects of various antidepressants on frog CAP and then to compare their results obtained with those of analgesics and their adjuvants. The experiments were performed by applying the air-gap method to the sciatic nerve isolated from frogs. Duloxetine, fluoxetine [serotonin and norepinephrine reuptake inhibitor (SNRI) and selective serotonin reuptake inhibitor (SSRI), respectively], amitriptyline and desipramine (tricyclic antidepressants; tertiary

and secondary amines, respectively) reduced the peak amplitude of the CAP with the half-maximal inhibitory concentration (IC_{50}) values of 0.39, 1.5, 0.16 and 1.4 mM, respectively. The duloxetine value was similar to those of anticonvulsants (lamotrigine and carbamazepine), a local anesthetic ropivacaine and an α_2-adrenoceptor agonist dexmedetomidine (0.44, 0.50, 0.34 and 0.40 mM, respectively) while the amitriptyline value was close to those of local anesthetics levobupivacaine and pramoxine (0.23 and 0.21 mM, respectively). The fluoxetine and desipramine values were similar to those of local anesthetics (lidocaine, cocaine and prilocaine: 0.74, 0.80 and 1.8 mM, respectively). They were larger than that of a local anesthetic tetracaine (0.013 mM) while being smaller than those of opioids. We have previously reported that a μ-opioid receptor agonist tramadol and ethylmorphine have the IC_{50} values of 2.3 and 4.6 mM, respectively; morphine and codeine (5 mM each) reduce CAP peak amplitude by only 15 and 30 %, respectively. In conclusion, the four antidepressants inhibited CAPs with efficacies comparable to those of some anticonvulsants and local anesthetics and also of α_2-adrenoceptor agonist, and with more effectiveness than those of opioids. It is suggested that these antidepressants have an ability comparable to those of some anticonvulsants, local anesthetics and α_2-adrenoceptor agonist in inhibiting nerve conduction.

Title: Latex extract of Euphorbia bicolor displays nociceptive and antinociceptive properties in cultured sensory neurons and evokes pain behaviors in rats

Authors: *P. BASU, C. MAIER, D. L. AVERITT;
Biol., Texas Woman's Univ., Denton, TX

Abstract: Opioid-based narcotics are a major component of pain management, but are problematic due to negative side effects mediated by the central nervous system. Pain management can be optimized through discovery of potent non-opioid therapeutics, as well as

targeting the peripheral nervous system. A subpopulation of sensory neurons expresses the transient receptor potential V1 ion channel (TRPV1), gated by capsaicin and noxious heat. TRPV1 activation induces release of proinflammatory peptides, including calcitonin gene-related peptide (CGRP), contributing to peripheral sensitization and hyperalgesia. Potent agonists targeting TRPV1, such as capsaicin and resiniferatoxin, produce peripheral analgesia via TRPV1 desensitization and temporary ablation of nociceptors. Resiniferatoxin is extracted from the latex of *Euphorbia resinifera.* In the same family but native to the Southern United States, *Euphorbia bicolor* shares similar phytochemicals including the irritant *Euphorbium* and thus may share nociceptive and analgesic properties. We hypothesized that *E. bicolor* latex would induce a transient increase in CGRP release from sensory neurons, attenuate capsaicin-evoked CGRP release, and evoke nociception. Rats were decapitated and trigeminal ganglia removed, dissociated, and cultured for 5 days. Cells were washed and treated with buffer for 15 minutes. Fractions were collected as basal release and the cells were then treated with *E. bicolor* latex (0, 12.5, 25, 50, 100, 300 μg/mL) for 15 minutes followed by stimulation with capsaicin (50 nM). CGRP was quantified by ELISA. Another set of rats received an intraplantar injection of *E. bicolor* latex (0, 25, 50, 100, 300, 500 μg/ml) and thermal hyperalgesia and mechanical allodynia were examined at 20, 40, 60 min, 2, and 4 hr post-injection. Here we report that *in vitro E. bicolor* latex induced a twofold increase in CGRP release from sensory neurons similar to capsaicin stimulation. Furthermore, capsaicin-stimulated release was significantly reduced following 50 and 100 μg/mL of latex treatment. *In vivo, E. bicolor* latex evoked significant thermal hyperalgesia and/or mechanical allodynia within 20 min at the 50-500 μg/ml concentrations. There was no significant difference in thermal or mechanical sensitivity in males compared to females. Our data indicate that *E. bicolor* latex is an irritant that displays nociceptive properties *in vivo*, and displays nociceptive and antinociceptive properties *in vitro*. Current studies are ongoing to analyze latex content by HPLC and to determine whether *E. bicolor* displays analgesic properties potentially via the TRPV1 channel, similar to its relative *E. resinifera*.

Title: Creating a localized and dynamic somatotopic map of area 3b using cutaneous vibratory stimulation.

Authors: *J. C. TANNER, T. HEARN, S. HELMS TILLERY;
SBHSE, Arizona State Univ., Tempe, AZ

Abstract: Somatosensory area 3b receives input encoding tactile sensations possessing small receptive fields. Area 3b is vital in fine motor feedback tasks and localizing discrete sensation. However, a majority of area 3b exists in the postcentral gyrus' anterior bank. Intrasulcal implantation poses hazards to vasculature and cortical health. To avoid damage, we used penetrating arrays with electrodes on multiple shanks, staggered between shanks, to record parallel and orthogonal to the bank's surface. Using such arrays, we aim to create a somatotopic face map, assess cutaneous response to frequency modulated stimulation, and gauge electrode viability. Analysis and results should translate to other cutaneous maps and activities, such as the grasping or digital manipulation.

Two 16-channel Modular Bionics N-Form electrode arrays (2x2 shank structure with four electrodes per shank at custom depths) were implanted in the facial representation of somatosensory cortex in two Maccaca mullata. Electrode connections were housed in a laser sintered chamber designed to lie flush with the non-human primates' (NHPs') cranium. Frequency modulated vibratory stimulation was delivered to eight locations on the NHPs' face contralateral to the implant. Neural recordings were performed using a Ripple Grapevine Neural Interface System and custom MATLAB software. Vibratory stimulation was achieved using a custom device controlled by MATLAB software. Stimulation force was consistently between 2 and 10 mN, delivered at 10 Hz to 130 Hz on 20 Hz intervals.

Electrodes were implanted without difficulty into somatosensory cortex, providing stable signals for LFP recording immediately. Multiple analyses were performed in attempts to define localized responses. Isolating the frequency with the strongest Fourier response, Peak Response Frequency (PRF), indicated that stimulation frequency is broadly represented across stimulation locations and electrodes. Percent Voltage Response (PVR) shows localization of four locations and stimulation frequency-dependent response intensity. Finally, investigating Phase Lag Index (PLI) indicated interchannel desynchronization during increased voltage responses.

Analyses provided complementary insights into the cortical response to cutaneous vibrations on the face. PRF offered stimulation frequency identification, but at the cost of both electrode and stimulation site localization. PVR offered some intensity mapping but provided localization for channels and locations. PLI suggests insight into (de)synchronization that can use PRF's broad activity and PVR's localization to create a more comprehensive map.

Title: Complex feature coding in the somatosensory cortex through stimulus specific supra-linear integration

Authors: *S. PLUTA[1], H. ADESNIK[2];
[1]Mol. Cell Biol., Univ. of California Berkeley Dept. of Mol. and Cell Biol., Berkeley, CA;
[2]Univ. of California, Berkeley, Berkeley, CA

Abstract: Rodents explore their environment by actively palpating objects with a large array of facial vibrissa. However, due to technical limitations, how somatosensory cortical neurons encode complex multi-whisker interactions during active sensation is poorly understood. To address this question, we developed a novel multi-pneumatic actuator capable of testing arbitrary patterns of single and multi-whisker touch in awake, whisking mice. Contrary to research using anesthetized animals, we found that the majority of layer 5 pyramidal neurons display supra-linear multi-whisker integration during active sensation. Surprisingly, supra-linear integration primarily resulted from multi-whisker disinhibition rather than super-additive summation; when stimulated alone, adjacent whiskers typically drove suppression, but when stimulated in specific combinations with other nearby whiskers, adjacent whiskers were highly facilitating. In the minority of pyramidal neurons that lacked adjacent whisker suppression, linear or sublinear integration was observed. Therefore, higher order tactile features may be extracted during touch through a stimulus specific disinhibitory circuit. We are currently optogenetically deactivating descending cortical projection neurons to elucidate their role in surround suppression and nonlinear integration.

Title: Encoding touch perception for an intrafascicular peripheral nerve interface

Authors: E. PATRICK[1], A. KUNDU[1], K. OTTO[1], J. PRINCIPE[1], R. BASHIRULLAH[1], *A. GUNDUZ[2];

Abstract: Somatosensory feedback is necessary to achieve highly functional peripheral neuroprosthetics. The development of neural interfaces that are capable of peripheral nerve stimulation to provide the missing sensory information is a topic of current research. The challenge facing all interface technologies is to provide stimulation patterns that will induce realistic sensory percepts with high spatial sensitivity. The Implantable Multimodal Peripheral REcording and Stimulation System (IMPRESS) is a novel interface designed for highly specific intrafascicular recording and stimulation due to its high channel count and electrode density. This work provides fundamental information for development of an encoding strategy to be used in the IMPRESS interface.
A combination of rate and population encoding is anticipated to be used in our biomimetic approach. The design constraints that need to be understood are then 1) the spatial extent of axon recruitment for a given stimulus and 2) the endogenous firing patterns corresponding to different mechanoreceptors that encode tactile pressure intensity. Our experimental procedure consists of tactile stimulation of the glabrous skin of the rat hind paw and subsequent recording via microelectrodes placed in the main fascicle of the sural nerve and the L5 dorsal root ganglion (DRG). The efficacy of encoding stimulation patterns are tested by providing stimulation through the intrafascicular sural nerve electrodes and recording from the DRG-implanted electrodes. A computational model for prediction of recruitment of individual fibers is validated and tuned by the results of this experimental work.

Title: Subnucleus muralis: first relay for sensory input from the glabrous orofacial skin

Authors: *A. CALLADO PÉREZ[1], D. KLEINFELD[2], M. DESCHÊNES[1];
[1]Univ. Laval, Quebec, QC, Canada; [2]UCSD, San Diego, CA

Abstract: Quadrupeds frequently investigate objects of interest and congeners with their narial pads. Yet, few studies have examined the sensory physiology of these ethologically important organs. Here, we show that injection of cholera toxin beta subunit into the narial pad leads to terminal labeling in the transition zone between the interpolaris and caudalis subnuclei of the trigeminal sensory complex, i.e. subnucleus muralis. We also provide physiological evidence that muralis cells respond to mechanical stimulation of the narial pad or the nasal and buccal mucosae. Some muralis cells are also activated by inhalation of ammonia vapor. Response latencies indicate that these sensory inputs are conveyed by Aδ and C-fibers. Yet, none of the muralis cells responded to vibrissa deflection. Sindbis-GFP injection into subnucleus muralis leads to anterograde labeling in the facial nucleus and the superior salivatory nucleus. Projection to the facial nucleus was also confirmed by transsynaptic labeling after pseudorabies injection into the superior lip. Together with prior studies that demonstrated that subnucleus muralis receives input from the cornea, our results suggest that this trigeminal subnucleus might process sensory inputs from the glabrous skin of the face : the narial pads, the lips and external epithelium of the eyes.

Title: Tactile afferent responses to mechanical pink noise bursts of varying amplitude and duration in humans.

Authors: *M. AMANTE[1], R. WATKINS[1], S. BOCHEREAU[2], R. ACKERLEY[1], J. WESSBERG[1], V. HAYWARD[2];
[1]Physiol., Univ. of Gothenburg, Göteborg, Sweden; [2]UPMC Paris, Paris, France

Abstract: In vision and audition, the perceived intensity of a short stimulus is dependent on its duration. The same phenomenon was recently reported for the sense of touch in a psychophysical study (1). Bursts of mechanical pink noise was chosen to mimic the broadband vibration characteristics of textures and surfaces encountered in daily life. Similar to the other senses, it was found that shorter bursts were consistently perceived as weaker than bursts of the same intensity but longer duration. Hence, there is perceptual duration-intensity constancy for tactile stimuli of short duration. The aim of the present study was to explore to what extent this reflects coding of intensity in peripheral tactile receptors. We used the microneurographic technique to record the responses of single, identified tactile receptor units in the median nerve in healthy volunteers. We constructed a stimulator probe with a speaker coil motor mounted on a one-axis actuator with acceleration and force sensors. The motor was driven by pink noise bursts with varying intensity and duration (100 - 700 ms; 2-40 m/s^2). Interstimulus intervals were 300 - 800 ms. The aim was to produce controlled skin vibrations rather than a sliding stimulus; hence, the rounded tip (4 mm diam.) of the probe was covered with fine grit sandpaper (P600) to achieve high friction. Single afferent units were classified as SA1, SA2, FA1 or FA2, and the receptive field of each unit was mapped using von Frey hairs. The probe was positioned to contact the receptive field of the single unit using normal (90 degrees angle to the skin) and tangential probe orientations, and the normal contact force was kept at 40 mN under closed-loop actuator control. The tangential probe orientation consistently elicited weaker responses compared to a normal orientation. Increasing the duration and/or amplitude of the stimulus predictably resulted in increased receptor responses in all classes of afferents, allowing for estimation of the interdependence of amplitude and duration in the population of activated afferents. However,

coding of stimulus intensity can in theory rely on several factors, or their combination: i) Recruitment and single nerve discharges in tactile receptors that are stimulated near their mechanical thresholds; ii) increased number of elicited nerve discharges in the recruited receptors; iii) increased average or peak firing rates. Hence, there is a putative role for afferents that are activated both at near- and supra-threshold intensity in the coding of intensity in the tactile system.

Title: Diversity of rapidly adapting and slowly adapting responses in mouse hairy skin

Authors: ***Y. BABA**, E. A. LUMPKIN;
Dermatol., Columbia Univ. Med. Ctr., New York, NY

Abstract: Cutaneous mechanosensory neurons can be classified by physiological characteristics, including threshold (low and high), conduction velocity (Aβ, Aδ, and C), and adaptation (rapidly adapting: RA and slowly adapting: SA). Recent studies have begun to establish the relationship between physiological characteristics and receptive field structures in mouse hairy skin. For example, neurons innervating guard hairs (GH) are reported to be Aβ RA low-threshold mechanoreceptors (LTMRs), whereas neurons innervating touch domes (TD) are thought to be Aβ SAI LTMRs. Using an ex vivo skin-nerve preparation, we surveyed the relationship between Aβ and Aδ afferents and receptive fields. Surprisingly, more than half of the GH-associated afferents produced SA responses. Most TD neurons were Aβ SAs; however, we observed Aβ SA afferents that did not respond to TD stimulation. About 70% of afferents did not contact GHs or TDs. This group included D-hair afferents, which were very sensitive LTMR neurons (median von Frey threshold: 0.2 mN) that responded to movement of zigzag hairs. Most showed low Aβ and Aδ conduction velocities and RA responses. About half of this sub-group showed SA

responses to strong stimulation. Other SA afferents were classified into two groups; high-threshold afferents, akin to A mechanonociceptors (AM), and field LTMRs. Both types responded to skin indentation rather than zigzag hair movement. The former had relatively high thresholds, and conduction velocity ranged low Aβ and Aδ. Field LTMRs displayed low thresholds and conduction velocities in the Aβ and fast Aδ. Finally, we observed a group of high-threshold RA afferents that did not respond to zigzag hair stimulation or punctate stimuli, but instead to wide-field compressive stimuli. These data show that at least three types of RA neurons (GH-RA, zigzag-RA/D-hair, and wide-high-threshold-RA) and six types of SA neurons (TD-SA, TD-GH-SA, GH-SA, zigzag-SA/D-Hair, field-LTMRs, and high threshold skin-indentation-SA which is conventionally named AM). This classification scheme can account for about 90% of Aβ and Aδ LTMRs in the hairy skin of the proximal hind-leg in C57BL/6J mice.

Title: Optimizing ultrasound parameters for tactile sensation

Authors: *J. B. CHOI[1], K. W. CHO[1], M. K. SONG[1], M.-K. JEONG[2], S. I. KIM[1], I. Y. KIM[1], D. P. JANG[1];
[1]Hanyang Univ., Seoul, Korea, Republic of; [2]Daejin university, Kyeonggi, Korea, Republic of

Abstract: There are various receptor types or free nerve endings underneath skin. Human tactile sensation is basically a combination of these receptors, and each receptors have own characteristics for mechanical, vibrational stimulation on skin surface. Recently, focused ultrasound have been reported as a new tool for evoking tactile sensation in skin. The Russian researcher, L. R. Gavlirov, first reported the effect of focused ultrasound stimulation on human hand, and found that focused ultrasound stimulation evoked various skin sensations, but its underlying mechanism was unknown. Another study performed by researchers in University of Bristol found that modulating the pulse frequency of focused ultrasound stimulation induces receptor specific tactile sensations in human hand, but the underlying mechanism of focused ultrasound stimulation in skin tissue remains unknown yet. The main reason of unknown mechanism is lack of reliability in experiment result since these studies have to explain focused

ultrasound stimulation induced tactile sensations based on subjective explanation of human subjects. The tactile sensations induced by focused ultrasound stimulation are not a kind of 1common feelings in everyday life, most of subject have difficulty with explaining the tactile sensations induced by focused ultrasound stimulation in their hands. In this study, therefore, we aim to find optimized ultrasound parameters for stimulating mechanoreceptors in skin, based on subject's experience and neural response from animal. Recent result shows that the amount of radiation force which includes pressure level, impedance difference, and attenuation ratio could be the prime parameters of focused ultrasound stimulation, but further experiment would be required. Configuring the database from the experiment result of human subject's report and spiking patterns of animal subjects associated with stimulation parameters (frequency, duration, and so on), could be the basic principles and resources for the development of tactile display in the future.

Title: Voltage sensitive dye imaging of leech local bend network

Authors: *E. FATHIAZAR, S. MEISER, A. TRENDE, J. KRETZBERG;
Dept. for Neurosci., Univ. of Oldenburg, Oldenburg, Germany

Abstract: Touch location discrimination on leech body wall is as precise as the human fingertip, while the nervous system of leech is rather small. Each leech mid-body ganglion contains 400 individually characterized neurons and is able to control local reflexes entirely from sensory inputs, via interneuron computation, resulting in motor neuron activity and corresponding behavior. In the local bend reflex the leech locally bends away the body wall from the location of a light tactile stimulus. While the encoding of touch stimuli was studied in terms of spiking attributes of sensory cells [1], the principles of sensory information processing on the level of interneurons remains to be investigated.
Here we used voltage sensitive dye (VSD) imaging to reveal the network of neurons involved in local bend reflex. A series of signal processing steps, e.g. movement artifact removal and moving

average, were applied to the raw VSD signal to overcome the noise and artifacts. A simultaneous intracellular recording of one cell was used to relate the VSD signal to the real membrane potential and to test the effect of this cell'. We performed these recordings in a semi-intact skin preparation with the ganglion attached to a patch of skin, which was stimulated with a mechanical poker to elicit the local bend response [1].
VSD signals of up to 100 simultaneously recorded neurons located on the ventral surface of the ganglion were analyzed with a statistical classification approach. More than half of the visible cells were classified as stimulus-activated, showing significantly different activity between with and without skin stimulation. In addition to the mechanosensory cells, in particular the so-called AP cell was found as one of the stimulus-activated cells consistently between preparations. Double intracellular recordings and anatomical studies revealed that the AP cell receives inputs from all mechanosensory pressure (P) cells with stronger contralateral connections.
The next analysis step aims at identifying network topology and causal relations between different cell types. Since leech interneuron spikes measured in the soma are small (usually < 5 mV), the computation of sensory information is probably based on the considerable graded membrane potential changes occurring during tactile stimulation. We compare the performances of different time series analysis techniques (Granger causality, convergent cross mapping, information theoretic approaches) applied to these small and noisy signals for revealing network structures matching physiological knowledge and identifying stimulus-dependent network states.

Title: Afferent responses to tactile stimulation by natural textures during active touch in humans

Authors: ***M. DIONE**, R. WATKINS, R. ACKERLEY, J. WESSBERG;
Univ. of Gothenburg, Goeteborg, Sweden

Abstract: Significant advances have been made in the last 20 years to provide amputee individuals with limb prostheses enabling the execution of movements. In the close future, one can expect that prostheses will also supply relevant tactile feedback back to the nerves for the restoration of natural touch sensations after limb amputation. However, it is still unclear how afferent information is conveyed from the skin to the brain during natural active touch to elicit specific tactile percepts in healthy individuals. In the present study, we used microneurography to record from Aβ-mechanoreceptive afferents in awake human subjects. We studied afferent responses when the skin was stimulated by subjects actively stroking across natural textures. During active touch, specific skin dynamics are reflected as global variations in the lateral force. During a lateral stroke, there is an initial increase in lateral force, a phase of stable sliding and a final decrease in lateral force. This specific force pattern could elicit a specific firing pattern in the different mechanoreceptor classes. In humans, the skin also stretches during active touch, and this could provide a relevant code to characterize the level of friction exerted by textures. In the present study, afferent responses were recorded from the left median nerve (7 FA1, 4 FA2, 4 SA1, 7 SA2) while participants were asked to produce lateral stroking movements of the index or middle finger over a range of natural textures, using comfortable force and preferred slow or fast speeds. Finger position, acceleration, EMG, and the forces applied on the textures were also recorded. For all units, at least one texture was tested in most of the conditions. Our results confirmed that the different classes of afferent unit have specific signature that relate to the global changes in lateral force occurring during active touch. SA2 units responded more at movement initiation and termination, SA1 at sliding initiation, FA2 and FA1 during sliding. In addition, for 1 FA1, 1 FA2 and 1 SA2 a larger number of textures was tested (n= 15 to 18). For these units, we computed the correlations between the mean firing rate and the friction coefficient. Correlations were significant in all units but were positive for the SA2 and negative in the FA units. We conclude that the mechanoreceptor classes respond differentially to the dynamic motor events occurring during to active touch and that the level of skin stretch coded by SA2 units is relevant to produce tactile coding of natural textures in humans. We hope human microneurography data will inspire research on sensory feedback to restore natural sensations in limb injured individuals with nerve-wired bionic limbs.

Title: Top-down driven functional heterogeneity among inhibitory neurons improves tactile representation and detection

Authors: *C. A. DEISTER[1], M. GOMEZ-RAMIREZ[1], J. VOIGTS[2], C. I. MOORE[1];
[1]Neurosci., Brown Univ., Providence, RI; [2]Massachusetts institute of Technol., Cambridge, MA

Abstract: Neurons in sensory cortices show functional dynamics in evoked rates and patterns. These dynamics may shape perceptual behaviors by improving the detectability or discriminability of ambiguous stimuli. Feedforward and feedback interactions among cortical areas drive these dynamics, but we do not have a complete cellular/circuit level understanding of how. Recent work provides correlative and causal links between receptive field properties and the activity of feedback projections in the performance of sensory detection tasks. But, if and how these two phenomena are linked are not known.
To address this, we trained mice to perform a vibrissa-motion detection task. Mice become more sensitive to weak stimuli after many days of training. We imaged populations of GCaMP6f expressing pyramidal neurons and parvalbumin-positive (PV+) interneurons in layers 2/3 and 5a of vibrissa somatosensory cortex (vS1; barrel cortex). Putative ensembles of pyramidal and PV+ neurons showed evoked rate and correlation changes that predicted successful detection. While these neuron's responses were specifically correlated with task performance, the majority of these neurons were generally responsive to the same vibrissa deflections before training. In contrast, when we imaged the activity of S2->S1 projections or local somatostatin-containing (SST+) interneurons, we found weak trial-to-trial correlations or rate changes evoked by weak deflections before training. Significant correlations and reliable and predictive evoked rate changes emerged among many (~40%) SST+ neurons. The activity of S2->S1 projections showed similar task-related changes. Imaging identified SST+ alongside pyramidal neurons showed that 'task-recruited' SST+ neurons were positively correlated with predictive pyramidal neurons, but only on perceived trials. Simple, but plausible, network models were made from conductance-based integrate and fire neurons in order to make a circuit level hypotheses informed by our imaging data. A simple model in which top-down input creates transient 'imbalances' in classical feedforward sensory-driven excitatory and inhibitory coupling explained our data well. Our results suggest that the sparse nature of the cortico-cortical layers of vS1 and general cortical interneuronal diversity can be exploited by top-down inputs to create or reinforce conjoint representations between incoming thalamic sensory relay and ongoing cortico-cortical activity. We are currently employing discrimination tasks in order to help determine if the described dynamics are a general mechanism for emphasizing specific, but distinct, sensory features.

Title: Hidden sources of variability modulate populations of sensory neurons

Authors: *M. WHITEWAY[1], D. A. BUTTS[2];
[1]Applied Mathematics, [2]Biol., Univ. of Maryland, College Park, MD

Abstract: Sensory cortex not only represents information from sensory receptors, but also incorporates other sources of input from recurrent and top-down connections. Unlike sensory stimuli, these other sources of input are difficult or impossible to control experimentally, and as a result contribute to neuronal variability in most experimental contexts. However, such sources of variability are likely to play an integral role in sensory cortex function. We introduce a new computational model, based on a type of neural network called an autoencoder, to identify these sources of variability. We first show that the autoencoder performs better than other common "latent variable" models including principal component analysis, independent component analysis, and factor analysis, across a variety of measures using simulated data. We then apply this model to a publicly available dataset (Peron et al. Neuron 2015), where large populations of neurons in mouse barrel cortex are recorded during a decision-making task using two-photon imaging. Across many experiments this method robustly identifies a small number of variables contributing to the cortical population activity. Some of these variables are correlated with the stimulus, while others are correlated with non-stimulus trial variables. These results suggest the activity of a large proportion of neurons in primary sensory cortex is modulated by hidden sources of variability that are not directly related to the stimulus. Identifying such sources of variability thus sets the foundation for understanding the role of such variables in sensory cortical function.

Title: Tactile spatial acuity of the neck using a two-point orientation discrimination task

Authors: K. MORROW, *M. ZIAT;
Psychology, Northern Michigan Univ., Marquette, MI

Abstract: This study explores the tactile acuity of the neck using a two-point orientation discrimination (2POD) task with 16 human participants (10 female, M= 19.53, SD= 1.16). A modified drafting compass was used to deliver pressure stimuli in two orientations (vertical and horizontal), and participants were asked to discriminate the orientation of the two compass points at eight locations on the neck. Using a two-up, one-down staircase method, thresholds were found for each site. A one-way repeated measures ANOVA shows a significant effect of the factor location [$F(7, 70) = 4$, $p= 0.01$] . Post-hoc analysis shows that the very front of the neck is slightly more sensitive than other locations. Additionally, all the other tested sites presented uniform spatial tactile acuity with an average threshold of 13.75 mm. The uniform spatial resolution of the neck can be advantageous for perceiving directional information used for potential clinical applications such as sensory substitution or brain-computer interfaces.

Title: Sensorimotor and tactile discrimination deficits in barrel cortex following Alzheimer's disease: the role of nucleus basalis of Meynert in somatosensory information processing

Authors: *B. SADEGHI[1,2];
[1]The Neurosci. Res. Ctr., Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of;
[2]Intl. Inst. of Biochem. and Biophysics (IBB), Univ. of Tehran, Tehran, Iran, Islamic Republic of

Abstract: Integration of neuronal responses across multiple whiskers is crucial for an effective facial vibrissae somatosensation. In memory processing, the main origin of the cholinergic projection to the neocortex appears to be the magnocellular neurons in the region of the nucleus basalis of Meynert (NbM). Here, in order to identify the prominent mechanisms underlying the modulation of the somatosensory information processing in cases with Alzheimer's disease (AD) as a cognitive degenerative disorder, the effects of chemical lesions to the nbM on the temporal characteristics of response integration evoked by multiple whisker stimulations were investigated in the barrel cortex of male Wistar rats. Animals were randomly distributed into three groups; control group, sham operated and rats that received bilateral excitotoxic lesion (by ibotenic acid in Alzheimer's group). In order to assess behavioral and cognitive functions via the determination of characteristics of excitatory and inhibitory receptive fields (RFs), passive avoidance learning (PAL) task was done and extracellular single-unit recordings from layer V barrel cortex neurons of anesthetized rats were performed following the single or paired, rostral and caudal deflection of two neighboring principle and adjacent whiskers (PW, AW) in the same row at varying interstimulus intervals (ISIs). Results show that nbM lesion significantly decreased response magnitude but did not affect response latencies. Response onset latency to both PW, AW in ibotenic acid (IBO)-injected animals were not significant compared with the control group; but unlike the AW, the magnitude of ON response to PW deflection in IBO-injected animal was significantly lower (nearly 20%) than control group. Unit's discharges to subsequent deflection of AW were reduced. The magnitude of responses were significantly reduced at each inter-deflection interval in nbM lesioned group. The excitatory RFs of units were extended in nbM lesioned animals and nbM lesion increased surround inhibition. Results from the PAL task reveal that step-through latency was decreased in rats with AD which gives an indication of memory loss. It has been suggested that interactions of nearby whiskers and the resulting facilitation and inhibition in the barrel cortical neurons have an important role in translating discrete information from individual whiskers to a continuous space. Thus, the nbM has an important role in regulating the balance of excitation and inhibition in the barrel cortex and can influence the temporal integration of tactile inputs and stimulus perception in AD by modulating the sensory information processing.

Title: Brain encoding of stimulus velocity within a saltatory pneumotactile array in the human perioral somatosensory system using fMRI

Authors: *R. CUSTEAD[1], H. OH[2], Y. WANG[2], S. M. BARLOW[3];
[1]Communication Disorders, Neurosci., Univ. of Nebraska at Omaha Sch. of Communication, Lincoln, NE; [2]Biol. Systems Engineering, Ctr. for Brain, Biol. & Behavior, [3]Communication Disorders, Biol. Systems Engineering, Ctr. for Brain, Biol. & Behavior, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: BACKGROUND: Processing dynamic tactile inputs is a key function of somatosensory systems. Spatial velocity encoding mechanisms by the nervous system are crucial for skilled movement production and recovery of motor function following neurological insult. Little is known about tactile velocity encoding in trigeminal networks associated with external sensory inputs to the face, or the somatosensory consequences of movement. OBJECTIVE: To use high resolution functional magnetic resonance imaging (fMRI) to investigate neural substrates of velocity encoding in the human orofacial somatosensory system during saltatory, pneumotactile inputs to the unilateral orofacial skin. METHODS: Participants - 20 neurotypical, right-handed adults, age 19-30 years. A multichannel, scalable pneumotactile array (Galileo Somatosensory) consisting of 7 TAC-Cells was used to present 5 stimulus conditions: 5 cm/s, 25 cm/s, 65 cm/s, ALL-ON synchronous activation, and ALL-OFF, to the hairy skin of the right perioral lower face. A T1-weighted MPRAGE sequence (0.9mm isotropic, TE=3.37ms, TR=2400ms) was followed by 3 functional scans using a 3T Siemens Skyra (32-ch head coil). Functional images: T2*-weighted EPI sequence, 41 slices (2.5x2.5x2.5mm, TE=30ms, TR=2.5s, FOV=220mm). Using SPM12, acquired brain volumes/subject were realigned, and smoothed with an isotropic Gaussian kernel (FWHM=8 mm). The spatial organization of cerebral and cerebellar blood oxygen level-dependent (BOLD) response as a function of stimulus velocity was analyzed using general linear modeling (GLM) of pooled group fMRI BOLD data. RESULTS: Sequential saltatory inputs to the lower face produced localized, predominantly contralateral BOLD responses in primary somatosensory (SI), secondary somatosensory (SII), primary motor (MI), supplemental motor area (SMA), posterior parietal cortices (PPC), and insula, whose spatial organization was highly dependent on velocity. Additionally, ipsilateral sensorimotor, insular and cerebellar BOLD responses were prominent during the lowest velocity

presentation (5 cm/s). CONCLUSIONS: Results indicate significant modulation in the spatial extent and region of BOLD signal as a function of stimulus velocity, reflecting a dynamic sensorimotor network underlying the processing of saltatory pneumotactile stimuli presented to the human trigeminal system. This regional modulation may be related to unique velocity processing and motor planning networks associated with tactile discrimination of movement across orofacial skin.

Title: Lower-limb cutaneous reflexes evoked via discrete and continuous mechanical foot sole stimulation

Authors: *R. M. PETERS, R. L. MILDREN, M. G. CARPENTER, J.-S. BLOUIN, T. INGLIS; Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Cutaneous reflexes are traditionally evoked using high-frequency electrical pulses delivered either to the whole nerve (Aniss *et al*., 1992) or to specific skin regions (Zehr *et al*., 2014). While this approach has uncovered interesting reflex properties (e.g., gait phase-dependent reflex reversal; Zehr *et al*., 2014), two disadvantages of electrical stimulation exist: 1) it non-specifically activates all mechanoreceptor classes, and 2) it entrains afferents to a non-physiological input (e.g., 300 Hz pulse train). Here we have taken the novel approach of using mechanical stimuli to elicit lower-limb reflexes, which rely on natural mechanotransduction, and given the frequency selectivity of plantar skin receptors (Bent and Strzalkowski, 2014), can bias the population response toward specific afferent classes. Subjects were 20 healthy young adults (mean age = 25.6, SD = 3.4). Stimuli consisted of either 600 *discrete* sinusoidal pulses (one cycle at 30 Hz) or 120 s of *continuous* stochastic vibration (bandwidths: 0 to 30 Hz and 0 to 300 Hz), delivered to the plantar skin overlying the right first metatarsal head at amplitudes of 3 and 10 times perceptual threshold (PT). Surface and indwelling EMG recordings were obtained from Tibialis Anterior while participants maintained a constant level of ankle dorsiflexion (12.5 and 25% of MVC). Responses were obtained by either stimulus-triggered EMG averaging (discrete), or by computing the coherence and cross-covariance between the stimulus acceleration/force and

EMG (continuous). Regardless of stimulus type, peak responses were observed at latencies (~90-100 ms) consistent with expectations of a cutaneous-mediated spinal reflex (Kavounoudias *et al*., 2001; Forth & Layne, 2007). Larger reflex responses were observed with higher-amplitude stimulation (10 vs. 3 PT), as well as with greater background EMG (25 vs. 12.5% MVC). For continuous stimuli, significant coherence was commonly observed only up to ~30 Hz. Given discrete and continuous methods provide similar reflex response estimates, and the advantages of continuous stimuli in terms of trial duration and the ability to probe a broad-range of frequencies, we argue that stochastic stimulation is a powerful new technique for studying cutaneous reflex function.

Title: An information theory analysis of the response of the in silico Pacinian corpuscle to noisy and complex stimuli

Authors: *J. QUINDLEN, B. J. YOUNG-DIXON, E. T. BLOOM, V. H. BAROCAS;
Biomed. Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: The Pacinian corpuscle (PC) is a cutaneous mechanoreceptor that responds to 20-1000 Hz vibrations, which are transmitted through the PC's end organ to its central nerve fiber

(neurite). We previously developed a mechanical and neural model of PC mechanotransduction. The model outputs neural activity resulting from a vibration applied to the PC's outer surface. The model accounts for transmission of vibration through the PC's outer core, subsequent strain on the neurite, opening of mechanogated channels, and generation of action potentials. The neural signal in response to vibration at different frequencies and amplitudes was simulated for 10 Hz - 1kHz vibrations. Simulations resulted in variable firing rates (FRs) at low amplitudes followed by a static region at higher amplitudes, at which the FR was equal to the indentation frequency.
The purpose of the current study was to draw insight into the transmission of information by the PC in response to vibration and observe the effect that a noisy mechanical input (e.g., due to noise in the stimulus itself or inaccuracy arising from transmission through the skin) has on the signal's mutual information. The mutual information of neurite firing resulting from stimulation at different frequencies was calculated in noise-free and noisy vibrations with two different output parameters: FR and interspike intervals (ISIs). Vibrations of 75, 100, 150, and 160 Hz were chosen for analysis because they can have either overlapping outputs (i.e. same FR) or distinct outputs (i.e. different FR) based on the stimulation amplitude. Gaussian white noise was added to the input to simulate a noisy vibration. FRs and ISIs of the generated neural signals were measured and mutual information was calculated to observe the rate and temporal information transmitted by the signal. The mutual information calculated from the ISI of the noise-free signals was 0.96 bits, which decreased to 0.90 bits for low noise (1 to 20 dB SNR), 0.81 bits for medium noise (-7 to 13 dB), and 0.73 bits for high noise (-19 to 1 dB). The rate codes showed no mutual information change for all chosen noise values (-19 to 20 dB SNR). Thus, the presence of noise has a greater effect on the temporal coding of the PC's neural signal. The next step is to quantify the information contained in a complex (multi-frequency) mechanical vibration. The effect of variables such as the base frequency, dissonance, and phase difference between waveform components will be investigated to draw parallels to published psychophysical experiments. The overall aim is to quantify the information content transmitted in response to simple and complex vibrations and to observe the effect of noise on this value.

Title: Peripheral nerve stimulation in mice via non-invasive focused ultrasound

Authors: ***M. DOWNS**, G. Z. X. YANG, Q. WANG, E. E. KONOFAGOU;
Biomed. Engin., Columbia Univ., New York, NY

Abstract: Background. The use of focused ultrasound (FUS) to non-invasively modulate neurons has recently gained interest as a potential technique to treat neurological disorders. It has been shown to have both a stimulatory and inhibitory effect when applied to ex vivo peripheral nerves, mainly harvested from the crab and frogs, with one study stimulating, and recording from the vagus nerve in vivo with rats. Thus far, there have been no studies determining if stimulating peripheral nerves with FUS can have physiological effects with an in vivo model. Research Questions. Two questions regarding the use FUS as a technique to stimulate peripheral nerves are addressed herein: 1) Can FUS be used to stimulate peripheral nerves in the mouse model and elicit a physiological response (muscle activation)? 2) Can the FUS nerve stimulation be suppressed by administering an activation inhibitor to the targeted region? Results. Focused ultrasound was used to target the saphenous nerve in mice while recording EMG responses from the tibialis anterior muscle. Voltage (0.1-0.9V), duty cycle (1-90%) and duration (4ms-1s) were varied to determine threshold parameters for safe and efficient stimulation. 8 anesthetized mice had both hind limbs stimulated for a total of n = 16 limbs. Safe (no detectable tissue damage or morphological changes via H&E) EMG and muscle movement responses were observed for parameters up to 0.9 V at a 90% duty cycle for 10 ms FUS stimulation duration. There was an average delay of 25.4 ms between FUS stimulation and EMG response. Reduction of the output FUS intensity and duty cycle, but extending the duration did not elicit EMG responses. EMG responses increased linearly with the output intensity while maintaining a 90% duty cycle with a 4-9ms FUS stimulation duration. EMG response were significantly reduced during FUS stimulation 10 minutes after administering 0.5% lidocaine to the area targeted on the saphenous nerve. Conclusion. The findings of this study demonstrate that we can safely stimulate the saphenous nerve in mice and elicit muscle activation. This muscle activation was inhibited after application of a lidocaine nerve block to the targeted region of the saphenous nerve demonstrating that the nerve was stimulated by FUS. These findings demonstrate feasibility of ultrasound-induced peripheral nerve stimulation that provides opportunities for noninvasive stimulation of deep-seated nerves.

Title: Modulation of olfactory-driven behavior by metabolic signals: Role of the piriform cortex

Authors: *D. AL KOBORSSY[1], V. CANOVA[2], M. THEVENET[2], S. GARCIA[2], B. PALOUZIER-PAULIGNAN[2], D. A. FADOOL[1], A. K. JULLIARD[2];

Abstract: Olfaction is one of the major sensory modalities that regulates food consumption and is in turn regulated by the feeding state. Olfactory sensitivity is increased by fasting, decreased after satiety, and is perturbed by metabolic disorders and weight gain. These accumulated data strongly suggest that the olfactory bulb (OB) subserves as a metabolic sensor, and herein, we explore the role of further processing areas to similarly detect metabolic cues. Because mitral cells of the OB are glucose and insulin sensitive under the dependence of the Kv1.3 ion channel, we explored the presence of targeted receptors in the piriform cortex (PC) of Wistar rat. Using immunocytochemical approaches we now demonstrate that Kv1.3 labeling is localized to the lateral olfactory tract (LOT) and in layers 2 and 3 of the PC. Glucose transporter type 4 (GLUT4) and insulin receptor kinase (IR) were detected in the LOT, and PC layers 1, 2, and 3. In brain slices of the PC, we current-clamped principal cells in the whole-cell configuration to explore changes in excitability to glucose and insulin. 61% of sampled pyramidal cells (n=13) lost spike adaptation and significantly decreased initial instantaneous frequency (IF) (47.2 +/- 1.6 Hz control vs. 25.0 +/- 1.4 Hz low glucose) in response to a bath concentration change from 5 to 1 mM glucose. All sampled pyramidal (n=3) and semi-lunar cells (n=3) decreased initial IF by 28% and 33%, respectively, within 10 minutes of applying insulin (172 nM) to the bath. The spike firing frequency of 77% of sampled pyramidal cells (n=13) decreased (10.5 +/- 4 Hz control vs. 6.7+/- 4.3 Hz low glucose) in response to bath applied low glucose. Lastly, we tested

whether bilateral infusion of metabolic signals into the anterior PC could alter olfactory processing. Cannulated fasted rats received either insulin (172 nM), glucose (10 mM), margatoxin (a Kv1.3 peptide blocker, at 0.1 nM) or vehicle microinjections, and were immediately tested for olfactory discrimination using a habituation/dishabituation paradigm in conjunction with measured sniffing frequency inside a customized plethysmograph chamber. Using a cohort of 20 rats, all three molecules decreased olfactory discrimination and modified response onset and sniff frequency, with the most pronounced effect being attributed to insulin. These data suggest that metabolic signals can modulate complex olfactory behavior by acting directly on the PC; the higher cortical region receiving communication from the OB. Our working hypothesis concerning metabolic processing and neuromodulation attributed to energy homeostatic state, must be expanded to incorporate that of additional central olfactory targets.

Title: Long-lasting enhancement of odor-evoked periglomerular activity after olfactory fear conditioning

Authors: *M. D. KASS, J. P. MCGANN;
Psychology, Rutgers Univ., Piscataway, NJ

Abstract: Olfactory fear conditioning can selectively alter the neural representations of odor stimuli as early as the primary sensory input to the brain (Kass et al 2013). This plasticity could be related to learning-induced changes in olfactory bulb glomerular circuitry, which controls sensory input gain and is dynamically regulated by neuromodulatory and cortical networks involved in fear learning. Here, we performed *in vivo* cell type-specific optical neurophysiology to evaluate the effects of olfactory fear conditioning on periglomerular (PG) circuitry in adult mice. Fear conditioning consisted of a single day of training with 10 trials of a ~15 sec odor (the

CS^+) paired with a footshock (or 10 shock or odor alone trials for control groups). We compared odor-evoked GCaMP signals in GAD65-expressing PG cells 1 day before, 1 day after, and 1 month after training in each individual mouse, and measured odor-evoked freezing in a novel context at similar post-training time points. During imaging and test sessions, subjects were presented with a panel of 4 odors including the CS^+ and 3 unexposed odors. Fear conditioned mice exhibited stimulus-evoked freezing that generalized across all 4 odors (after non-discriminative conditioning) and that was observed even 1 month after learning, whereas little freezing was observed in control animals. In parallel, we found that fear conditioning resulted in a robust, non-specific enhancement of odor-evoked GCaMP signals in GAD65-expressing PG cells. This generalized enhancement occurred just 1 day after learning and persisted up to 1 month. These data show that fear conditioning causes relatively rapid and long-lasting changes in olfactory coding. Such changes might decrease discrimination between threat-predictive and neutral stimuli and promote generalized anxiety.

Title: Prenatal and early postnatal exposure to odorized food changes response properties of mitral cells in the mammalian olfactory bulb

Authors: *A. LIU[1,4,2,3], N. N. URBAN[1,4,5,3];
[1]Ctr. for Neurosci., [2]Med. Scientist Training Program, [3]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [4]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [5]Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Early sensory experience can dramatically shape the adult anatomy and function of sensory circuits. In the olfactory bulb (OB), odor exposure through odorized food (food/odor pairing) fundamentally changes the structure of the glomerular module in a receptor-specific manner. We previously showed that prenatal and early postnatal odor exposure using methyl salicylate not only increases glomerular volume as measured by the coalescence of OSN axons but also increases the number of mitral and tufted cells (MTCs) connected to activated glomeruli. Increasing MTC number of a given glomerulus may increase the total output of that glomerulus,

and increase the total strength of lateral inhibition mediated by connected cells. Odor experience may also alter strengths of synaptic connections throughout the OB circuit. Here, we analyze the functional impact of this long-term odor exposure paradigm on population activity of MTCs. We use viral vector expression of GCaMP6s in mitral cells (MCs) to measure changes in odor-evoked responses following prenatal and early postnatal odor exposure. Dams are fed with food scented with methyl salicylate, an odorant known to activate selective dorsal glomeruli in the OB. Previous work in rodents suggest that odor-evoked changes in MTC firing rates are smaller when the odor presented is familiar. However, in our preliminary results we observe that odor presentation elicits larger amplitude odor responses in MCs from animals that experienced food/odor pairing than from naïve control animals. Larger responses were observed to both low and high concentrations of the familiar odorant, methyl salicylate, but the increase was larger at higher concentrations of odor presented. Specifically, MCs in odor-exposed animals showed a steeper slope of the concentration response function that was specific to the paired odor (Kruskal-Wallis test with Dunn's multiple comparisons test, n=35 cells, mean±SD of ΔF/F, 1% vs. 10% methyl salicylate stimulus, 1.14±0.11 vs. 1.30±0.22, $p<0.05$), while control animals did not (n=13 cells, mean±SD of ΔF/F, 1% vs. 10% methyl salicylate stimulus, 1.07±0.01 vs. 1.09±0.05, n.s.). In contrast, MCs in both odor-exposed and control animals did not demonstrate different concentration-dependent increases in response amplitudes when presented with increasing concentrations of a novel odor, hexanal (odor-exposed: n=35 cells, mean±SD of ΔF/F, 1% vs. 10% hexanal stimulus, 1.42±0.30 vs. 1.61±0.43, n.s; control: n=13, 1.15±0.08 vs. 1.17±0.08, n.s.). These odor specific responses suggest that odor exposure through a food-based paradigm significantly changes sensitivity of mitral cell response in an unexpected way.

Title: Task dependent modulation of olfactory representation

Authors: ***I. FUKUNAGA**[1], A. T. SCHAEFER[2,3];
[1]Francis Crick Institute, Mill Hill Lab., London, United Kingdom; [2]Neurophysiol. of Behaviour

Lab., Francis Crick Inst., London, United Kingdom; [3]Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: A ubiquitous feature of sensory processing in the brain is the presence of feedback and neuromodulatory connections: in many areas such connections are as dense as the feed-forward components. As this likely endows the brain with powerful functions such as emphasizing the behaviourally relevant aspect of environmental stimuli, it is crucial to understand how they contribute to the local circuit operations, as well as its underlying circuit mechanisms.
So far a variety of modulatory effects have been described across animal models. In contrast to modulations induced by general physiological changes such as during running, modulations that occur when animals attend to specific stimulus attributes are likely to be distinct, involving different circuit mechanisms.
To investigate this, we used the mouse olfactory system, as it allows for rapid behavioural task changes, and because the primary sensory region, the olfactory bulb (OB), is easily accessible for physiological experiments and already a major recipient of feedback and neuromodulatory inputs.
We sought to study the odour representation in the OB when animals are engaged in different behavioural tasks. GCaMP6f was expressed via AAV1 in OB neurons and the signals imaged repeatedly through chronically implanted window, in particular from the glomerular layer in awake, head-fixed mice. The same set of neurons could be imaged over weeks, where day-to-day responses to odours in individual neurons remained stable.
Diverse changes in odour representations were observed in the OB neurons as the task nature changed, with 32.7 ± 7 % of neurons in a given field of view showing significant changes. This change was present on a behaviourally relevant timescale, with changes present at least in the first 600 ms of odour response. Furthermore, the change was odour-specific, and occurred in a way that emphasized the aspect of olfactory stimuli relevant to the task. This was true for both GABAergic (Vgat-expressing) and non-GABAergic neurons. Consistent with its role in emphasizing the task-relevant stimulus attributes, the fluctuations of neuronal representation correlated with behavioural performance.
Overall the results suggest that the nature of sensory representation can change with specific behavioural demands even in the very first stages of processing. This experimental approach provides a promising way with which to investigate mechanisms underlying stimulus specific modulation.

Title: Experience-dependent lateralization in rat olfactory system

Authors: *Y. COHEN[1,2], D. PUTRINO[3,4], D. A. WILSON[1,2];
[1]EBI, Nathan Kline Institue, Orangeburg, NY; [2]Dept. of Child and Adolescent Psychiatry, New York Univ. Langone Med. Ctr., New York, NY; [3]Dept. of Rehabil. Med., Weill Cornell Med. Col., White Plains, NY; [4]Burke Med. Res. Inst., Ny, NY

Abstract: Lateralization, or cortical asymmetry, is a multifaceted phenomenon occurring at both the structural and functional levels, and can be expressed both as a stable trait and/or dynamically during behavior and development. For example, the piriform cortex (PCX) of rats performing a two-alternative forced choice odor discrimination task shows experience- and state-dependent asymmetry in odor-evoked local field potential (LFP) oscillations and inter-hemispheric coherence (Cohen et al., 2015). Specifically, odor-evoked LFP beta oscillations in the left PCX are more robust during initial learning than the right PCX. In contrast, the right PCX shows beta band enhancement at the late stages of learning while the left PCX changes return to baseline. With over-training, this asymmetry in cortical activity disappears. Importantly, the design of this study (Cohen et al., 2015) was based on behavioral performance which allowed us to detect the physiological changes at different performance levels.
To further explore asymmetry in the olfactory system during learning, here we used four different approaches: 1) Direct manipulation of the olfactory inter-hemispheric pathway. The anterior commissure (AC) is the inter-hemispheric pathway between the bilateral primary olfactory cortices, amygdala and entorhinal cortex. We cut the fibers of the AC to examine if and how olfactory tasks are modified by impairing olfactory cross talk between hemispheres. 2) Using the same design as before (Cohen et al., 2015), we examined a possible lateralization in orbitofrontal cortex during the odor learning. 3) Utilizing unilateral optogenetic stimulation of cortical networks as conditioned stimuli in a fear conditioning paradigm, directly testing whether one hemisphere is superior to the other for this form of odor learning or recall. 4) Screening PCX for lateralization in molecular markers related to plasticity to begin to understand the mechanisms of this widespread cortical asymmetry related to odor learning. Our results suggest that inter-hemispheric communication is essential for normal odor learning, especially in a reversal task. The OFC, similar to the PCX shows strong performance-dependent asymmetry, though this OFC asymmetry has distinct features different from that in the PCX. Finally,

PKC_{gamma} expression, a marker for synaptic plasticity, shows asymmetry in PCX layer I, that matches the emergence and recovery of LFP asymmetry over the course of learning.

Syst., Res. Ctr. for Genet. Med., washington, WA; [5]Dept. of Biol. Sci., Univ. of Baltimore Country, Baltimore, MD

Abstract: As a way to facilitate mating and breeding cycles, female sexual maturation and receptivity are often facilitated by the presence of male odors in the environment. The vomeronasal system, the accessory olfactory bulb in particular, is one of the primary brain circuits translating these signals into adaptive behavioral or neuroendocrine responses. We previously reported that the amount of GABAergic granule interneurons integrating in the AOB of female mice increases of about 50% in response to male odor stimulations occurring after puberty. One possible explanation for the timely occurrence of this circuit rearrangement could be the need for this pathway to improve its sensitivity to new sensory stimuli once they become salient signals for mating and reproduction. This indeed might imply the addition of newborn interneurons in olfactory sub-circuits elaborating these signals. To explore this possibility, here we provide evidence of a tight correlation between the activity-dependent modulation of AOB neurogenesis and the onset of female cycling at puberty. We further show that only male stimuli produced by putative mating partners - unrelated and unfamiliar mature males - are affecting the survival of newborn neurons in the female AOB. Genetic identity of the donors or their early postnatal experience do not prevent this to occur, as shown by exposing mature female mice to cues from either kin-related or unrelated littermates. Moreover, peri-pubertal exposure of female mice to male odors results in increased interest (investigation time) for the familiarized stimuli.

Unexpectedly, this response is accompanied by a drastic decrease in sexual receptivity shown to their male donors. Concurrently, male odor familiarization results in higher responsiveness of newly generated AOB granule cells, as assessed through c-Fos expression analysis, thus confirming the active recruitment of AOB newborn cells into circuits responsive to the familiarized signals. Collectively these data show that the activity dependent rearrangement of GABAergic circuits in the AOB occurs as female mice being to display attractive responses to male cues after puberty: it is contextual to the onset of mating behaviors, it depends on the sexual maturity of the male donors and it concurs with the recruitment of adult born neurons into AOB circuits encoding mate preference. Interestingly, the addition of new GABAergic neurons into these circuits correlates with a change in the behavioral effects of the sensory stimuli they elaborate. The time-scale of this process is compatible with a direct involvement of AOB neurogenesis in shaping the vomeronasal responses to mating signals after puberty.

Title: Weighting of antagonistic sensory pathways underlies plasticity in behavioral response valence to olfactory cues

Authors: ***A. H. HARTMANN**[1], N. D. DWYER[2], C. I. BARGMANN[3], P. SENGUPTA[1]; [1]Brandeis Univ., Waltham, MA; [2]Univ. of Virginia, Sch. of Med., Charlottesville, VA; [3]Howard Hughes Med. Inst., The Rockefeller Univ., New York, NY

Abstract: Animals must integrate sensory inputs with contextual information, such as internal state or external cues, to execute adaptive behavioral responses. An important goal of neuroscience is to determine how this information is encoded within the nervous system. Behavioral plasticity can stem from genetic, molecular, and circuit level changes in neural function, allowing the organism to thrive in a dynamic environment. The nematode *C. elegans* is

an advantageous model organism for interrogating the neuronal circuits and molecular pathways involved in sensory processing and integration. *C. elegans* responds precisely, but flexibly, to sensory stimuli of multiple modalities, and sensory responses have been shown to be modulated by the animal's experience and state. The ability to rigorously control environmental conditions and experience, together with the array of available experimental tools, makes *C. elegans* an excellent system in which to interrogate the mechanisms underlying context-dependent behavioral plasticity.
I have found that antagonistic sensory pathways converge to mediate the behavioral response of *C. elegans* to the volatile odorant, hexanol. Specifically, the AWC sensory neurons are required for worms to exhibit attraction to hexanol, while the ASH/ADL nociceptive neurons appear to facilitate behavioral aversion to this chemical. Consistently, both AWC and ASH show calcium responses to removal and addition of hexanol, respectively. Differential weighting of these antagonistic pathways as a function of context and experience appears to drive flexibility in the animal's behavioral response to hexanol. I have found that environmental conditions such as population density alters the balance between these pathways; these behaviors can be recapitulated by genetic manipulations that specifically affect either the attractive or aversive circuit. I aim to identify the genes, neurons and circuits that alter response valence to olfactory cues, thereby describing how behavioral plasticity is encoded within a neural ensemble.

Title: Compartmentalized modulation of sensory and interneuronal activities for odor adaptation in *C. elegans*

Authors: *K. ASHIDA, H. SHIDARA, K. HOTTA, K. OKA;
Dept. of Biosci. & Informatics, Keio Univ., Yokohama-Shi, Japan

Abstract: Neuronal compartments are characterized by distinct physical-chemical characteristics and functional roles. The modulations of dendritic compartments are recently reported in some animals (Augustine *et al.*, 2003; Losonczy *et al.*, 2008; Cichon and Gan, 2015; Ogawa and Oka,

2015; Prešern *et al.*, 2015), but modulations of these dendritic compartment modulations for odor adaptation remains unclear in *C. elegans*. We, therefore, identified that compartmentalized modulations on sensory neurons and interneurons for odor adaptation with fluorescent imaging techniques. A 5-min odor pre-exposure reduces the odor attraction of worms. This phenomenon, which is named early adaptation, requires AWC sensory neurons and AIY interneurons (Hirotsu and Iino, 2005; Yamada *et al.*, 2009). However, modulations between AWC and AIY neurons have not been examined yet. Because AWC senses odors, and AIY receives inhibitory glutamatergic inputs from AWC, we investigated the modulations of neuronal activities with genetically encoded Ca^{2+} and glutamate indicators *in vivo*.Simultaneous Ca^{2+} imaging of AWC and AIY revealed that neuronal activities did not change in AWC neurons on pre-exposure. On the other hand, AIY neurons showed region-specific modulations of neuronal activity. Glutamate inputs to AIY also showed compartmentalized modulations. This study is the first reports of compartmentalized modulations of glutamate (input) and neuronal activity (output) on interneurons in *C. elegans.* Our results propose new insight for neuronal circuit study in *C. elegans.*

Title: Perceiving and responding to stochastic olfactory stimulus in the *Drosophila* larva

Authors: *D. KIM[1], R. MORENO-BOTE[2], M. LOUIS[1];
[1]EMBL-CRG Systems Biol. Program, Ctr. For Genomic Regulation, Barcelona, Spain; [2]Dept. of Information and Communication Technologies, Univ. Pompeu Fabra, Barcelona, Spain

Abstract: The *Drosophila* larva navigates odor gradients by alternating runs with turns: they run up the gradient and turn while moving down the gradient. So far, deterministic stimuli have been used to study the control of larval chemotaxis. Little is known about the behavioral responses elicited by stochastic olfactory stimuli analogous to those encountered in nature. We address this problem by studying the control of reorientation decisions under sensory uncertainty (noise) during larval chemotaxis. We express the light-gated ion channel Channelrhodopsin-2 in olfactory sensory neurons (OSNs). Activating the OSNs with light allows us to stimulate larvae with a precision and reproducibility that is impossible to achieve with real odors. We mimic up- and down-gradient olfactory experiences and reproduce run-to-turn transitions by introducing

temporal ramps of increasing and decreasing light intensities. By quantifying the timing of run-to-turn transitions as a reaction time, we find that larvae exhibit robustness against weak Gaussian white noise corrupting deterministic olfactory stimuli. In the presence of strong noise, larvae show a delay (<1 sec) in their mean reaction time compared to the noise-free condition. However, strong noise does not impair chemotaxis severely. Finally, we describe the underlying decision-making process by applying a model commonly used in cognitive neuroscience: a diffusion model coupled with a linear-nonlinear model fed with OSN activity predicted from the stimulus. Our model suggests that invertebrates are capable of accumulating sensory evidence to enhance the robustness of perceptual decisions driven by noisy sensory evidence.

Title: Learning-related changes in mitral and tufted cell responses reflect changes in sniffing behaviour

Authors: ***R. JORDAN**[1,2], I. FUKUNAGA[1], M. KOLLO[1], A. T. SCHAEFER[1,2];
[1]Neurophysiol. of Behaviour, Francis Crick Inst. Mill Hill Lab., London, United Kingdom;
[2]Dept. of Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Sensory circuit activity has often revealed correlates of information about behavioural context. These representations are generally thought to be driven by top-down input from higher centres, however it is conceivable that they could be evoked largely by learned changes in active sampling behaviours, e.g. sniffing or whisking. The olfactory bulb (OB) is ideal for mechanistic study of contextual modulation, with abundant input from higher centres, strong modulation of neural activity by sniffing, and the propensity for rapid learning of olfactory tasks in mice. Thus, we investigated the origin of contextual changes of mitral and tufted cells (MTCs) using whole cell recordings in awake mice, either passively exposed to odours (n = 21) or engaged in olfactory go/no-go task learning (n = 20 cells). While general physiology of MTCs between the

two behavioural states was similar (R_{inp},τ_{mem}, firing rate, V_{rest}, and odour responses, $p > 0.05$, t-test), response changes in learning mice were twice as numerous and significantly more diverse than in controls (0.2 ± 1.5 mV, vs -0.3 ± 1.0 mV; $p < 0.05$, Bartlett test). The learning-specific changes largely comprised increases in excitatory response. Notably, sniffing behaviour also underwent a variety of task-related changes (mean inhalation duration -2 ± 25 ms, vs 1 ± 10 ms; $p < 10^{-4}$, Bartlett test) depending on the motivational state of the animal (quantified by the anticipatory lick rate, $R^2 = 0.5$, $p < 0.005$). Both sniff and response changes occurred prior to earliest estimates of decision time (170 ms), making them potentially relevant for behaviour. Indeed, learning-related changes in sniffing showed strong relationships with changes in odour response, particularly in responses undergoing increases in excitation (R^2 up to 0.7, $p < 10^{-7}$). Correlating sniff change and Vm change across all putative mitral cells showed that changes in sniff rate alone accounted for almost 40% of variance in odour responses ($R^2 = 0.38$, $p = 0.001$). Sniff behaviour could modulate membrane potential by up to $\Delta Vm = 2.5$ mV in absence of either odour or learning when sniff rate changes were e.g. evoked by unexpected non-olfactory stimuli. The magnitude of ΔVm strongly depended on theta modulation properties of the cell ($R^2 = 0.37$, $p = 3 \times 10^{-4}$) and its odour response ($R^2 = 0.63$, $p = 0.003$), supporting a causal link between sniff changes and changes in membrane potential and odour responses. Overall, we conclude that contextual modulation of sensory circuit activity can be driven, at least in part, simply by active changes in stimulus sampling behaviour rather than necessarily being a consequence of top-down inputs or plasticity in the olfactory bulb.

Title: Stabilization of olfactory learning by noradrenergic modulation in the olfactory bulb

Authors: ***C. LINSTER**[1], Y. THENNAISIE[2], M. MIDROIT[2], X. YIN[2], J. FOREST[2], M. RICHARD[2], A. DIDIER[2], N. MANDAIRON[2];
[1]CPL & Neurobio. and Behavior, Cornell Univ., Ithaca, NY; [2]Neuroplasticity and Neuropathology of Olfactory Perception, INSERM/CNRS, Lyon Neuroscience Research Center, LYON, France

Abstract: Among other central inputs, the olfactory bulb receives abundant noradrenergic (NE) projections from the locus coerulus (LC). These modulatory inputs have been shown to regulate olfactory bulb processing through changes in excitability, dynamics and plasticity. Specifically, NE in the olfactory bulb has been associated with low concentration odor detection, signal to noise modulation and discrimination of highly similar odorants. Previous studies used pharmacological or lesioning methods to investigate the role of NE modulation in the olfactory bulb, which puts temporal constraints on the behavioral paradigms that are possible. We use optogenetic inactivation of NE inputs to the olfactory bulb to manipulate NE modulation on a shorter temporal times scale. Briefly, mice were injected with Lenti-hSyn-NpHR-EYFP in the LC and simultaneously implanted with bilateral optical fibers in the olfactory bulb. After time for expression of the NpHR-EYFP in LC terminals in the OB, mice were trained to perform a simultaneous go-no-go task for 20 trials massed in a day, and then tested for recall of the odor discrimination either 4 hours or 24 hours after the training session during 5 trials. We found that decreasing the release of NE in the olfactory bulbs during learning of an odor discrimination has no impact on learning and recall after 4 hours, but severely impaired recall after 24 hours. These findings suggest a role of NE release in the OB not for expression of learning but for the maintenance of the long term memory. To further test this hypothesis, we tested these mice on a reversal learning. Mice were trained on a given odor contingency for 10 trials (with or without blockade of NE inputs), after which the contingency of odors was switched. Mice with impaired NE inputs learned the reversal significantly faster than controls, further suggesting that the formed memory is more labile when NE is decreased in the OB. Further experiments showed that the impact of NE on memory stabilization would be mostly due to activation of alpha1 receptors. All together, these data highlight a role of bulbar NE projections for the expression of olfactory memories. Long term maintenance of these memories is affected even when NE release is manipulated only temporarily during learning.

Title: Ontogenic development of morphometric heterogeneities between vomeronasal pathways: the social rodent Octodon degus as a case in point.

Authors: P. FERNANDEZ-ABURTO, S. DELGADO, K. BULDRINI, G. MARIN, *J. MPODOZIS;
Univ. of Chile, Santiago, Chile

Abstract: In mammals, the vomeronasal system (VNS) has been largely associated with the coordination of social and sexual interactions. This system detected mainly pheromone-like semiochemicals, orchesting the neuroendocrine and behavioral responses of the organisms in a context-dependent manner. The VNS features two types of chemosensitive neurons segregated in the vomeronasal organ (VNO), each expressing either V1R or V2R receptor. In turn, vomeronasal neurons extend its axons to glomeruli located in the accessory olfactory bulb (AOB), forming two segregated subdomains: anterior (aAOB) and posterior (pAOB), respectively. Secondary projection neurons of both subdomains innervate multiple forebrain regions mainly associated to neuroendocrine regulation. Functionally, it has been suggested that V1R neurons detect small and volatile molecules while V2R neurons detect high and non-volatile molecules. It has been recently shown that several species of caviomorph rodents exhibit marked differences in morphometric parameters between AOB subdomains. Both, aAOB or pAOB-bias has been observed in these species, in association with conspicuous differences in life-style traits (semiarid vs semiaquatic environments). Whether and to which extent these differences are innate or arise in an experience dependent manner remains unexplored. We studied the ontogeny of the VNS in the hystricognath rodent *Octodon degus.* At adult stage, *O. degus* exhibit a highly heterogeneous AOB, in which the aAOB have twice overall volume than the pAOB, and features more and larger glomeruli. We found that segregated projections of the VNO neurons to its corresponding AOB subdomains were clearly distinguishable at prenatal stages. However, at the AOB the anatomical organization and the expression of neural maturation markers reached an adult pattern only from P15. Measurements of the overall AOB volume start showing a bias towards the aAOB by P15, but this bias becomes evident at the glomerular layer (GL) only by P30. This bias increase in posterior stages, reaching an adult-like pattern only at P180. In addition, and most interestingly, we found that these morphometric differences were less marked in GL for animals raised in captivity when compared with animals raised in the wild. Furthermore, we found that these morphometric differences were absent in the GL of *O. lunatus,* a sister-group that exhibit a low extent of social behavior. We conclude that morphometric differences between vomeronasal pathways arise in postnatal stages, suggesting that active semiochemical experience associated with the social context may be influencing the establishment of this heterogeneity.

Title: Quantitative genetic differences in the olfactory bulbs of forebrain-specific Ctgf knockout mice

Authors: *H.-C. CHANG[1], L.-J. LEE[1,2,3];
[1]Grad. Inst. of Anat. and Cell Biol., [2]Grad. Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Connective tissue growth factor (CTGF) is indispensable in the development of the connective tissue. In the nervous system, CTGF is expressed in some distinct areas, such as the olfactory bulb, but its function is largely unknown. In order to investigate the role of CTGF in the nervous system, forebrain-specific Ctgf knockout (FbCtgf KO) mice were made. In FbCtgf KO mice, altered neuronal patterning in the glomerular layer of olfactory bulbs and abnormal olfaction-related behavior were noticed. To pinpoint the molecular mechanism underlying these behavioral and cytoarchitectural changes, we analyzed the gene expression profiles in the olfactory bulb using next-generation RNA sequencing techniques. Unexpectedly, the expression of genes involved in the TGF-beta pathway which is downstream of CTGF signaling were not significantly changed. Besides related genes of TGF-beta signaling pathway, about 29 genes and their isoforms were significantly downregulated. Most of them take part in cell proliferation, cell migration, cell differentiation and cell death. Interestingly, the expression levels of Erythroid differentiation regulator 1 (Erdr1), myosin heavy chain 14 (Myh14) and Gm16286, were increased significantly. Erdr1 regulates cell proliferation, cell migration, and the maintenance of cell population. Myh14 is required in controlling of cytoskeleton activities and the maintenance of cell shape. Both of Erdr1 and Myh14 are highly expressed in olfaction-related brain regions. According to relative expression pattern and biological function, these genes may closely interact with CTGF. Our data widen the view to explore the function of CTGF in the nervous system.

Title: Developmental myelination of the lateral olfactory tract and anterior commissure

Authors: L. N. COLLINS[1], *P. C. BRUNJES[2];
[1]Psychology, Univ. of Virginia, Charlottesville, VA; [2]Dept Psychol, Univ. of Virginia Dept. of Psychology, Charlottesvle, VA

Abstract: The olfactory system employs two large myelinated tracts: the lateral olfactory tract (LOT), comprised of mitral/tufted cell axons coursing from the olfactory bulb to the ipsilateral olfactory cortices, and the anterior commissure (AC) which coordinates olfactory information between the left and right hemispheres. The current work is a comparison of the development of myelin in the two tracts of the mouse. Oligodendrocyte maturation was visualized by quantifying cells expressing markers for a) the oligodendrocyte lineage: Olig2, b) proliferative precursor cells: PDGF, c) intermediate pro-oligodendrocytes: CC1 and NG2 and d), mature, myelinating oligodendrocytes: MBP and MOBP at postnatal days (P)10, 20, and 30. In the LOT the late markers MBP and MOBP were already heavily expressed by P10. In the AC, early markers (PDGF, NG2, CC1) were prevalent at P10. By P20 their expression was decreased and both MBP and MOBP were abundant. Electron microscopy was used to track the proportion of myelinated to unmyelinated axons as well as axon caliber. Myelinated axons did not appear in the AC until P15; by P30 18% of axons were myelinated. These results suggest that myelination begins earlier in the LOT than the AC. More focused work confirmed that the LOT is myelinated 3-4 days prior to the AC and that both the AC and LOT exhibit a period of rapid myelination (LOT: P8-11; AC: P11-15). Additionally, the effects of sensory deprivation on the myelination of the AC and LOT were examined. Pups underwent unilateral naris occlusion on P1 and were reared until P30. EM analysis revealed that naris occlusion did not significantly change the number of myelinated axons in the AC relative to that of controls, but did reduce the axon caliber of myelinated fibers. The results suggest that the LOT and AC have different developmental histories and that sensory deprivation affects axon caliber of fibers carrying olfactory information

Title: Apolipoprotein E4 mediates olfactory network excitability and short term habituation

Authors: *K. PENG[1,3,4], P. M. MATHEWS[1,5], E. LEVY[1,5,4], D. A. WILSON[2,3,6];
[1]Ctr. for Dementia Res., [2]Emotional Brain Inst., Nathan Kline Inst., Orangeburg, NY; [3]Neurosci. & Physiol., [4]Biochem. & Pharmacol., [5]Psychiatry, [6]Child and Adolescent Psychiatry, NYU Langone Med. Ctr., New York, NY

Abstract: While expression of the apolipoprotein E ε4 allele (ApoE4) is well appreciated as the greatest genetic susceptibility factor for Alzheimer's disease (AD), more recent findings suggest that ApoE4 expression leads to cognitive deficits, neurodegenerative risk and brain atrophy independently of AD. In human ApoE4 carriers, the onset of impaired odor identification correlates with the onset of episodic memory decline. Olfactory perception relies upon the spatiotemporal pattern of transfer of odor-evoked activity in the olfactory bulb (OB) to the piriform cortex (PCX). From the PCX, odor information travels to the entorhinal cortex and hippocampus for future retrieval.
We examined olfactory behavior and physiology in 6 and 12 month old mice humanized for ApoE4 compared to mice humanized for the common neutral-risk ε3 allele (ApoE3), neither of which develops AD-related amyloid pathology. Testing odor habituation, a measure of short-term memory, we found deficits in ApoE4 compared to ApoE3 mice at 6 months of age, although this behavioral deficit did not persist into older age groups. Given that the synaptic mechanisms of short-term habituation originate within the connections between the OB and the PCX, we recorded spontaneous and odor-evoked local field potentials (LFPs) in both regions from anesthetized mice. At 6 months of age, no genotype differences in spontaneous LFPs without the presence of odors were seen in either region. However, odor presentation triggered hyperactive LFPs in the OB of 6 month old ApoE4 compared to ApoE3 mice. At this age, no odor-evoked genotype-dependent differences in LFPs were found when recording from the PCX. At 12 months of age, spontaneous LFPs were found to be hypoactive in the PCX, but not the OB, of ApoE4 mice compared to ApoE3 mice. Meanwhile, the presence of odor at 12 months triggered an age-dependent increase in evoked LFPs activity in the PCX of ApoE4 mice.
Thus, regional olfactory system function is impaired in an age- and ApoE genotype-dependent manner. Our findings suggest that early olfactory network abnormalities in ApoE4 OB coinciding with short-term memory impairments may be a precursor to later network dysfunction in the PCX. Further studies are required to determine the extent to which evoked

hyperexcitability spreads throughout the brain and whether changes in circuit activity may compromise other cognitive tasks in ApoE4 carriers.

Title: Regulation of interneuron distribution by the fate of cortical projection neurons

Authors: ***Z.-X. NIOU**, H.-W. HSING, S.-J. CHOU;
ICOB, Academia Sinica, Nankang District, Taipei City, Taiwan

Abstract: The two major neuronal types in the mammalian cortex are the excitatory projection neurons and the inhibitory interneurons (INs). The projection neurons are generated in the dorsal telencephalon (dTel) and migrate to their destination by radial migration. The GABAergic interneurons are primarily generated in the medial ganglionic eminence (MGE) of ventral telencephalon (vTel) and enter the cortex by tangential migration. Here, using a panel of IN markers, we demonstrate that although the IN density is consistent in different regions in the cortex, the IN distribution patterns are different in the six-layered neocortex and in the three-layered piriform cortex. To study how IN distribution is regulated, we used Lhx2 conditional knockout (cKO) mice, in which Lhx2 is deleted by Emx1-Cre, as a model. In Lhx2 cKO cortices, the lateral neocortex is refated to generate an ectopic piriform cortex. We found in the ectopic piriform cortex, the density of INs is similar to that in the wild type cortex and the distribution of INs is similar to that in the PC in the wild type littermates. This findings suggest that the fate of projection neurons regulates the distribution of the INs.

Title: Studies on olfactory neural circuit development mediated by local caspase activity and cIAP-1 during the mouse postnatal development.

Authors: *S. MOON, S. KIM, B. CHO, C. MOON;
DGIST, Daegu, Korea, Republic of

Abstract: Correct connections between neurons are directly linked to the precise function of our brain. Between the olfactory epithelium (OE) and the olfactory bulb (OB), there have simple neural connections which form the olfactory neural map. Incorrect coalescence of olfactory sensory neurons (OSNs) at the glomerulus could cause the problem such as the failure of odor encoding and discrimination. Therefore, making proper synapse and maintenance of olfactory neural connectivity is important during the postnatal development. Despite the significance of this process, only few studies about periods of axon path-finding, synapse formation and refinement have been reported in the olfactory system. Especially, the mechanism about the maintenance and remodeling of olfactory neuronal circuits is still unknown.
In this study, we hypothesized that there are critical periods and regulator(s) to establish the stable adult olfactory neural connections. To investigate this topic, we focused on caspases and the cellular inhibitor of apoptosis-1 (cIAP-1). Because recent studies indicated non-apoptotic roles of caspases such as neuronal plasticity, neuronal growth and regeneration, and degeneration of axons and dendrites. And cIAP-1 is one of the best known regulator of caspase function. To check whether cIAP-1 level is significant to modulate the olfactory neural connectivity or not, we checked the cIAP-1 expression level in the olfactory system by comparing WT mice to cIAP-1 KO mice. According to our preliminary results, cIAP-1 level was up-regulated until 7 weeks during the postnatal development stages. At this point, caspase 3 was activated when cIAP-1 was ablated. Using immunohistochemistry, we confirmed local caspases activity at the axonal part of OSNs in the cIAP-1 KO mice. These results suggest that cIAP-1 may inhibit the local activation of caspases, and which may stabilize the olfactory neural circuit during the specific periods of postnatal development.
Our studies would be helpful to understand how regenerated OSNs maintain the proper olfactory neural connectivity during the post-natal development.

Title: Role of extracellular matrix chondroitin sulfate proteoglycan expression in the human olfactory system connectivity

Authors: *F. J. HAMATI[1], K. K. PILOBELLO[1], A. BOYER-BOITEAU[1], H. PANTAZOPOULOS[1,3], C. BERCIU[2], E. H. HOLBROOK[5], S. BERRETTA[1,3,4];

Abstract: Chondroitin sulfate proteoglycans (CSPGs), one of the main components of the brain extracellular matrix, play an important role in axon guidance and modulation of synaptic stability during development. The olfactory system represents an ideal model to study these functions, as CSPGs are robustly expressed in this system and neuronal differentiation, synaptic stabilization, and axon outgrowth continue throughout life. Axons from olfactory receptor neurons (ORNs) travel across the olfactory mucosa (OM) and to odor-specific glomeruli in the olfactory bulb (OB). CSPGs may play guidance and stabilization roles which may be central to the discriminatory function of the GLs in the OB. Thus, we postulated that CSPGs form organized extracellular structures surrounding ORN axons, potentially guiding them from the OE the correct odor-specific OB glomeruli.
Human post-mortem OBs (n=10, age- and sex-matched), rodent OM (n=8) and OM tissue biopsies from healthy human subjects (n=15) were used for immunocytochemistry and electron microscopy studies. An antibody (CS56) raised CSPGs with a CS-6 sulfation pattern and the lectin *Wisteria Floribunda agglutinin* (WFA) were used to investigate the relationship between distinct CSPGs with ORN axons labelled using anti-olfactory marker protein antibody.
Our results show that, in human, CSPG/CS-6 are closely associated with ORN axons, forming dense aggregates subjacent the olfactory epithelium (OE), and deeper channel-like structures which encapsulate ORN axon bundles, following them from the OE, through the OM and into the glomerular layer of the OB. Other CSPGs, labeled with WFA, are associated with the medial side of the glomeruli and throughout the OB's inner layers. Consistent with these results, electron micrographs of rodent OM show extracellular CSPG/CS-6 aggregates deposited around ORN axon bundles.
These findings are consistent with the hypothesis that CSPGs play a key role in organizing and

guiding ORN axons from the OE into OB glomeruli and maintaining the glomerular structure and connectivity with the tufted and mitral cells. These results are relevant to the pathophysiology of schizophrenia (SZ), a disorder with CSPG expression abnormalities in several brain regions including the OE. Notably, people with SZ, and first-degree relatives, present with odor identification deficits. We suggest that CSPG abnormalities in the olfactory system of individuals with SZ may disrupt the guidance of ORN axons, thus destabilizing connections within the odor-specific glomeruli contributing to the observed olfactory deficits.

Title: Salivary oxytocin concentration is correlated with the subjective feeling of body ownership during the rubber hand illusion

Authors: ***M. IDE**[1,2], M. WADA[1];
[1]Dev. Disord. Sect., Dept. of Rehabil. for Brain Functions, Res. Inst. of NRCD, Tokorozawa, Saitama, Japan; [2]Japan Society for the Promotion of Sci., Chiyoda, Tokyo, Japan

Abstract: Oxytocin is known to be a neuropeptide that promotes lactation, maternal bonding and birth. Recent studies have reported that oxytocin modulates social recognition and thus seems to be related to empathic behaviours. Multiple studies have suggested that the oxytocin modulates social brain networks, which are related to empathy (e.g., insular cortex). These networks are also activated during the rubber hand illusion (RHI), which is an illusory body ownership caused by the brush stroking that were synchronously applied to a rubber hand and a participant's hand. It is intriguing to investigate whether oxytocin affects illusory changes in the body ownership, such as in the RHI. In this study, we examined the relationship between salivary oxytocin

concentration and the subjective feeling of rubber hand ownership in each participant. In the behavioural task (N = 10), brushes were stroking synchronously or asynchronously to the participant's hand and a rubber hand. Each condition included 4 sessions, and each session lasted 3 minutes. The synchronous and asynchronous stroking conditions were conducted on separate days (within 4 days). Saliva (2 ml) was sampled before and after the behavioural tasks, and oxytocin concentration was measured with ELISA method. We found that participants who had higher concentrations of salivary oxytocin tended to feel stronger ownership of the rubber hand ($r = 0.79$, $p = 0.0067 < 0.01$). In contrast, the salivary oxytocin concentrations did not change after the occurrence of the RHI in the present condition. Additional analysis showed that the participants with higher autistic traits tended to feel a weaker body ownership of rubber hand in the RHI task ($r = -0.71$, $p = 0.018 < 0.05$). Our results suggest that a salivary oxytocin concentration can predict degree of subjective feeling of body ownership during the RHI, and it might modulate our sensation of body ownership. We speculate that oxytocin modulate the illusory body ownership by affecting brain activity in the insular cortex and anterior cingulate gyrus, because these regions are also known to be related to body image and self-consciousness.

Title: Prediction error responses in the mouse posterior parietal cortex are dependent on molecular diversity of clustered protocadherin α

Authors: ***K. YOSHITAKE**[1,2], H. TSUKANO[1], R. HISHIDA[1], T. YAGI[3,2], K. SHIBUKI[1,2]; [1]Niigata Univ., Niigata, Japan; [2]CREST, AMED, Tokyo, Japan; [3]Osaka Univ., Osaka, Japan

Abstract: Predictive coding is a theoretical concept which helps us to understand higher brain functions. According to this idea, the brain predicts what is going to happen under a particular situation based on prior experience. Therefore, one of essential brain functions is to predict the coming sensory input, and to minimize the prediction error (difference between the prediction and actual sensory inputs). This prediction error minimization process must be dependent on past

experience and learning. Previously, we have reported that prediction errors between whisker and visual inputs were detected in the posterior parietal cortex (PPC) of mice. We recorded neuronal activities in PPC using flavoprotein fluorescence imaging. Visual stimulation with grating patters moving forward/backward alone, or forward/backward whisker-shift stimulation alone hardly activated PPC in anesthetized mice. However, anti-phase combination of moving grating patterns and whisker stimulation (grating moving forward plus backward whisker shift, or grating moving backward plus forward whisker shift), which is very unlikely in natural environment for mice, produced prediction error responses in PPC. In contrast, in-phase combination of grating patterns and whisker stimulation failed to produce any clear activity in PPC. We have reported that cortical depression and retinotopic map shifts were induced by prediction errors between visual and whisker inputs in the primary visual cortex (V1) of young mice that had worn a monocular prism goggle, suggesting that the prediction errors detected in PPC were used to reduce in the prediction errors at the V1 level. Obviously, prediction and prediction errors are expected to be dependent on past experience and learning. To test this possibility, we investigated the prediction error responses in PPC of dark-reared mice from birth to 4 weeks of age. As expected, the dark-reared mice could not show any prediction error responses in PPC. However, this dark reared effect was cancelled after the mice returned to a normal light-dark cycle for 2 additional weeks. These results suggest that prediction error responses in PPC require previous experience. Clustered protocadherins (cPcdhs) comprising cPcdh-α, β, and -γ, encode a large family of cadherin-like cell-adhesion molecules specific to brain. Both of the prism-induced depression in V1 and the prediction error responses in PPC to the anti-phase combination of visual and whisker stimulation were impaired in mice with reduced cPcdh-α diversity. These results strongly suggest that the molecular diversity of cPcdh-α is important for the experience-dependent PPC functions to produce prediction errors.

Title: Multisensory versus unisensory integration: cooperation vs. competition

Authors: *B. A. ROWLAND, J. W. VAUGHAN, D. ZHU, B. E. STEIN;
Neurobio. & Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Although multisensory superior colliculus (SC) neurons are best known for their ability to integrate signals across modalities (multisensory integration), they also integrate cues within a given modality (unisensory integration) - but these yield different products. Whereas two spatiotemporally concordant cross-modal cues evoke an enhanced physiological response, two synchronized and spatially proximal within-modal (e.g., visual) cues typically yield no enhancement. The response is no greater than the response to one of the cues alone. It is as if the unisensory integrative mechanism "discards" one of the two inputs. This contrast in the multisensory and unisensory computations is poorly understood. One possibility is that the non-enhancement in unisensory "integration" merely reflects the limited bandwidth available within a single sensory channel. However, the present study supports the idea that integration is taking place in both cases but using entirely different computational mechanisms. Individual multisensory SC neurons were tested with multiple spatially-aligned visual (V1, V2) and auditory (A) cues presented individually and in combination at multiple stimulus onset asynchronies. Responses to the cues presented individually (V1, V2, A) and in different combinations (V1A, V2A, V1V2) were compared in a moment-by-moment analysis. Whereas multisensory integration characteristically evoked large enhancements early in the response window (the IRE, or initial response enhancement), responses to within-modal pairs (unisensory integration) were equivalent to those evoked by an individual cue at each moment in time. When the within-modal cues (i.e., V1V2) were separated in time, the response profiles revealed the engagement of a competitive dynamic that actively suppressed responses to the delayed cue in the pair, resulting in an overall response that was not enhanced. Interestingly, similar products are obtained with cross-modal cues when a neuron's multisensory integrative capability is impaired. These observations indicate that unisensory integration, like multisensory integration (see accompanying posters by Cuppini et al., and Yu et al.), has a native competitive computation that is engaged when there are multiple inputs. Only in the case of multisensory integration is this native state overridden by experience during development. The result is the transition from competition to cooperation in the maturation of multisensory integration.

Title: Superadditivity: a defining characteristic of multisensory integration?

Authors: *B. E. STEIN, R. L. MILLER, B. A. ROWLAND;
Neurobio. and Anat., Wake Forest Sch. Med., Winston Salem, NC

Abstract: Multisensory neurons in different regions of the brain integrate concordant information from multiple sensory sources to enhance responses. This often amplifies the physiological salience of biologically significant events and the likelihood of adaptive responses. Model areas in which this has been studied in the cat include the midbrain (i.e., the superior colliculus, SC) and cortex (the anterior ectosylvian sulcus, AES). The responses to concordant cross-modal cues in both regions can exceed the sum of the responses to the individual component cues (superadditivity); however, prior work suggests that such products are associated with brief, weakly-effective cues. More recently it has been shown that the products of multisensory integration are not uniform throughout the course of a response, but are largest near its onset, a region termed the initial response enhancement (IRE, see Rowland et al., 2007). The IRE coincides with a period in which the behaviors mediated by these circuits (detection, orientation, localization) are typically effected. To determine whether, in fact, superadditivity in the responses of SC and AES neurons was strictly associated with weakly-effective brief cues, or was a more general characteristic of the multisensory transform, the present study examined SC and AES neuronal responses to a wide variety of cross-modal stimulus combinations. The results demonstrate that a superadditive IRE is a near-ubiquitous phenomenon in both SC and AES neurons. It was present regardless of whether or not the cross-modal component stimuli employed were highly efficacious, and regardless of the physical properties of these stimuli (e.g., moving/stationary, short/long duration, small/large, high/low intensity). These observations challenge the notion that superadditivity is only reliably linked to brief, weakly-effective cues and reveal that superadditivity (within the IRE) is a hallmark property of multisensory integration. The results suggest that the IRE may play a larger sensory and sensorimotor role than is currently appreciated.

Title: Cross-modal competition: the native multisensory computation

Authors: ***L. YU**[1], J. XU[1], B. A. ROWLAND[2], B. E. STEIN[2];
[1]East China Normal Univ., Shanghai City, China; [2]Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Multisensory neurons in the superior colliculus (SC) typically integrate spatiotemporally concordant cross-modal cues in a synergistic fashion. However, this capacity for "multisensory enhancement" only develops after experience with covariant cross-modal cues. Prior work has suggested that, in the absence of this experience, the native multisensory computation is one that either reflects only the most efficacious component stimulus of a cross-modal pair or an average of the responses to the two unisensory inputs. The present study investigated this phenomenon in visual-auditory SC neurons of animals reared in complete darkness (precluding visual-nonvisual experience). The results show that the native multisensory computation is neither a "winner take all," nor an “averaging” operation, but a competition between the two inputs. This competitive mechanism was revealed only when two stimuli of very different effectiveness were combined, and the potency of their competition became more evident as the difference in their effectiveness increased. At very different effectiveness levels the multisensory response became significantly lower than the most effective unisensory comparator response, revealing an operation very much like the inhibitory (i.e., competitive) interactions between spatially disparate stimuli seen in normally-reared animals. In short, all multisensory SC neurons at all stages of life may be capable of integrating cross-modal cues, but with different operational principles. The multisensory maturational process, via the acquisition of cross-modal experience, appears not to reflect the construction of a computation from a “blank slate,” but rather a transition from one of competition to one of cooperation. In this way SC neurons, and presumably multisensory neurons elsewhere in the brain, become capable of identifying the common origin of cross-modal signals. By then enhancing their access to the sensorimotor circuitry of the SC, they also enhance the likelihood of an SC-mediated adaptive response.

Title: The specificity in multisensory learning reveals a native competitive interaction among sensory representations.

Authors: ***C. CUPPINI**[1], M. URSINO[1], E. MAGOSSO[1], B. A. ROWLAND[2], B. E. STEIN[2]; [1]Univ. of Bologna, Bologna, Italy; [2]Dept. of Neurobio. and Anat., Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract: The midbrain superior colliculus (SC) integrates information from different senses (visual, auditory, somatosensory) in mediating attentive and orientation behaviors. Its trisensory neurons are able to integrate information across each of the possible pairings of these modalities, thereby facilitating this role to a variety of biologically relevant events. However, these integration capabilities are not an inherent characteristic of the SC neuron; rather, they are acquired during postnatal life based on experience with cross-modal cues. Recent evidence has revealed that neurons do not generalize their experience-based multisensory integration capabilities across modality-pairings. For example, experience with visual-somatosensory cues confers the ability to integrate information from these modalities, but not from visual-auditory cue pairs. Thus, neurons "learn" to integrate information only from those cross-modal pairs with which they had explicit experience (Xu et al., 2015). This learning also requires functional inputs from association cortex (i.e., the anterior ectosylvian sulcus, AES) (REF). Here we describe an artificial neural network model that explains how these phenomena can be implemented within the AES-SC circuit. The model is based on a few simple assumptions: 1) all modality-specific inputs to SC are mutually competitive by default, 2) tectopetal inputs arising from AES are trained by cross-modal experience to bypass this competition, consequently interacting in cooperative ways, 3) this training obeys simple Hebbian learning rules, and 4) after training, SC responsiveness becomes dominated by these AES inputs. The model was tested for accuracy by

repeatedly simulating exposure to auditory, visual, and somatosensory stimuli alone or combined in all possible modality-pairings. It accurately replicated the empirical findings and suggests that the native state is one of cross-modal competition.

Title: Seeing with ears, how we create an auditory representation of space with echoes and its relation with vision.

Authors: *A. TONELLI[1], L. BRAYDA[2], M. GORI[1];
[1]U-VIP Unit for Visually Impaired People, [2]Robotics, Brain and Cognitive Sci., Fondazione Inst. Italiano Di Tecnologia, Genoa, Italy

Abstract: We will present an overview of our works that explore the relation between vision, auditory space perception and alternative ways to compensate for the lack of vision. Several studies show that vision is essential in the domain of space perception influencing also other sensory modalities, a proof is the Ventriloquist effect. Vision can interact with audition even when a visual stimulus is not provided during an auditory task, but just observing the setup with eyes open can improve audio accuracy. Interestingly we found that the improved performance in complex auditory space task occurs already after a brief observation of the environment performing the task blindfolded. These findings suggest that vision is important on an on-line evaluation of complex auditory cues thanks to an internal representation. Moreover, this representation appears to be useful in reverberant environments helping to compensate for the mismatching due to the reverberation itself. Another example for the importance of vision in space perception is provided by blind people whereas there were found impairments in performing complex spatial auditory tasks. These results suggest that the visual system plays an important role during development calibrating the audio system in space perception. However these impairments are not present in blind people whom have developed echolocation.

Echolocation is the ability to understand the environment through echoes thanks mainly self-generated clicks. It has also been shown that echolocation, other than help to have better spatial abilities, contributes to functional benefits in real life. Therefore echolocation seems to compensate for the lack of vision. For these reasons we decided to teach echolocation to naïve sighted people. We started with sighted people testing them in some tasks of echolocation, such as depth or detection task. Moreover, we investigate if other than help to understand the external space, echolocation could influence the space surrounding the body, as for example the peripersonal space (PPS). Our data suggest that sighted people can learn echolocation after a brief training. Thanks to this training sighted people, without vision, are able to understand the environment and what there is inside. Moreover, echolocation can modify how the PPS is perceived. All this information demonstrated how human are sensible to echoes and that spatial information can be acquired not using vision, also in people that normally would acquire the same information through it. If also sighted people can echolocate it could be developed a targeted training to teach echolocation to blind people.

Title: Recalibrating the body: visuotactile ventriloquism aftereffect

Authors: ***M. J. SAMAD**, L. SHAMS;
Psychology, UCLA, Los Angeles, CA

Abstract: Background: The visuotactile ventriloquism effect is a recently reported effect showing that somatotopic tactile representations (namely, representation of location along the surface of one's arm) can be biased by simultaneous presentation of a visual stimulus in a spatial localization task along the surface of the skin. Aim: Here we investigated whether the exposure to discrepancy between tactile and visual stimuli on the skin can induce lasting changes in the somatotopic representation of space. Methods: We conducted an experiment investigating this question by asking participants to perform a localization task that included unisensory and bisensory trials, before and after exposure to spatially discrepant visuotactile pairs. Subjects localized brief flashes of light and brief vibrations that were presented along the surface of their forearms, and were presented either individually (unisensory conditions) or were presented simultaneously at the same location or different locations. We then compared the localization of

tactile stimuli in unisensory tactile conditions before and after the exposure to discrepant bisensory stimuli. Moreover, using the Bayesian causal inference model of multisensory perception, we examined whether any change in localization performance was best accounted for by a change in sensory representations, or a priori biases, or a combination of the two. Results: After exposure, subjects did indeed exhibit a shift in their tactile localizations in the direction of the visual stimulus that was presented during the exposure phase. Moreover, this recalibration was best accounted for by a shift in the tactile representations of space as opposed to a change to the prior expectation of the location of the stimuli. Conclusions: These results demonstrate that the somatotopic spatial representations are capable of rapidly recalibrating after a very brief exposure to spatially discrepant visuotactile stimuli. They also suggest that this change may be implemented at the level of the encoding of these tactile stimuli.

Title: Allocentric and egocentric contributions to the updating of visual object orientation

Authors: *N. NIEHOF, J. J. TRAMPER, C. F. DOELLER, W. P. MEDENDORP;
Donders Institute, Radboud Univ., Nijmegen, Netherlands

Abstract: We tested the role of allocentric and egocentric spatial reference frames in the coding and updating of object orientation during head motion. When the body is stationary, allocentric visual information affects the perception of object orientation. For example, subjects make systematic errors in judging the verticality of a line (an estimate of the gravity direction), in the presence of a tilted visual frame. However, it is not yet clear how and to which extent subjects remember the orientation of this line after intervening head and frame rotation. We examined three types of errors subjects could make in this updating task. If subjects anchor the line to the visual frame, updating errors will depend on the magnitude of the intervening frame rotation. If subjects code the line relative to the head, updating errors will relate to the intervening head rotation. If subjects store the line relative to gravity, errors would be linked to their subjective vertical, which was measured separately. Ten subjects were asked to remember the orientation of a line stimulus, briefly flashed within a tilted frame, while the head was oriented at a clockwise

roll tilt of 30°. Subjects then rotated their head to upright, and made a two-alternative forced choice on whether the orientation of a second line, always flashed in an upright frame, was clockwise or counterclockwise relative to the initial line orientation. Furthermore, each subject's subjective vertical was determined through a verticality judgment of a single line in a tilted frame, in both the upright and tilted head position. Results show that subjects make systematic errors in the updating task. Regression analyses indicate that these errors were related to the subjective vertical and the head orientation, but showed no significant relation to the visual frame orientation. These findings suggest that subjects represent orientations both allocentrically, relative to gravity, and egocentrically, relative to the head in space. Our results support the notion that the brain uses multiple reference frames in parallel to code and update visual object orientations.

Title: Improving visual responses in the superior colliculus by tactile noise

Authors: *N. HUIDOBRO[1], B. DE LA TORRE-VALDOVINOS[2], I. MENDEZ-BALBUENA[3], E. MANJARREZ[4];
[1]Inst. de Fisiologia, Benemerita Univ. au, Puebla, Mexico; [2]Ciencias Computacionales, Cucei, Univ. de Guadalajara, Guadalajara, Mexico; [3]Facultad de Psicologia, Benemerita Univ.

Autonoma De Puebla, Puebla, Puebla, Mexico; [4]Inst. de Fisiologia, Benemerita Univ. Autonoma De Puebla, Puebla, Mexico

Abstract: Recently we demonstrated that an optimal level of tactile noise applied in the human finger increases the amplitude of EEG visual evoked potentials (Mendez-Balbuena et al., J Neurophysiol.114:2132, 2015). This finding suggested that such increase was produced by the synaptic interaction between multisensory neurons located in the superior colliculus. The aim of the present study was to examine, in an animal preparation, whether the multisensory neurons in the superior colliculus can reproduce such phenomenon. We obtained multiunit recordings of neurons from the superior colliculus in three pentobarbital-anesthetized cats. The visual evoked responses were elicited by the application of periodic stimuli with a pair of white LEDs. Simultaneously, we added three levels of continuous tactile noise on the central pad of the hindlimbs by means of a Chubbuck mechanical stimulator-transducer. The waveclus spike sorting software was employed to classify the unitary activity of collicular neurons. For all the subjects, we found that the total number of neuronal spikes measured from the peristimulus histogram exhibited an inverted U-like form as a function of the tactile noise level (i.e., we found that there is an intermediate optimal level of tactile noise producing an increase in the firing frequency of these collicular multisensory neurons). In order to compare the total number of spikes between zero noise (ZN), optimal noise (ON) and high noise (HN), we performed the one-way repeated measures ANOVA test to examine the statistical significance of the change in the total number of spikes between the three conditions (ON, ZN and HN) in the unitary responses of 85 neurons. The results showed significant differences between the three conditions ($p<0.0001$). The post hoc Tukey test revealed statistically significant differences between ZN and ON ($p<0.0001$) and between ON and HN ($p<0.0001$). In contrast, no significant differences were found between conditions ZN and HN. Based on these results it is tempting to speculate that the multisensory neurons located in the superior colliculus could contribute to the cross-modal stochastic resonance found in the human EEG recordings during the visuo-tactile interaction.

Title: Frontal and auditory cortical activity in ferrets using selective attention in a multisensory task-switching paradigm

Authors: *S. M. TOWN, J. K. A. NORDMARK, J. K. BIZLEY;
UCL Ear Inst., London, United Kingdom

Abstract: Cognitive flexibility is a critical component of natural behavior, often impaired in neuropsychiatric disorders. When listening, we can choose whether to attend or ignore a sound source but the neural mechanisms involved in selective attention are unclear. Here we trained 5 ferrets to localise auditory (A, noise burst) or visual (V, light flash) stimuli that could occur at one of three locations. Trials could be A, V or AV. In the AV condition A and V stimuli were presented from separate locations and animals were cued by trial history to localise one modality while ignoring the other. Subjects performed extended blocks in which they localised either auditory or visual stimuli and reliably switched between A and V localisation over several test sessions.

During task performance, we simultaneously recorded multi-unit activity in primary auditory cortex (AC) and frontal cortex (FC) of two ferrets. AC units responded more strongly to auditory than visual stimuli with rapid changes in firing at stimulus onset / offset whereas FC units responded similarly across modalities with slower modulation in firing rate. To study the effects of attention, we compared population activity in FC and AC on correct and error trials when animals localized unisensory stimuli or attended to one modality in the AV compound. In AC we found little modulation of activity by attended modality but did observe changes in firing rate between correct and error trials during anticipatory activity in the 500 ms prior to stimulus onset. In FC we observed attentional modulation of baseline activity prior to stimulus onset and also following the animal's response. In each case, modulation was only observed on correct (and not error) trials. Furthermore the pattern of attentional effects was consistent with firing patterns for unisensory localization. For example, FC activity following behavioral response was greater for AV stimuli in attend-A than attend-V conditions, and also greater for A than V stimuli presented alone.

Our findings support a role for frontal cortex in maintaining representations of attended modality. In future our recordings offer the ability to study attentional modulation of functional connectivity between frontal and sensory cortices at both the level of both single unit activity and local field potentials.

Title: Multisensory integration using an aging brain

Authors: *M. BARNETT-COWAN;
Dept. of Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: There is a long history of using psychophysical techniques to quantify, understand and treat changes in unisensory function that occur during the aging process. While it is well understood that sensory acuity declines with age, how the central nervous systems continues to integrate multisensory cues with unreliable sensory information available in later life is less clear. Perceptual binding of multisensory events occurs within a limited time span known as the temporal binding window. It has been shown that the ability to discriminate simultaneity, temporal order, and causal relationships among stimuli can become increasingly difficult as we age. Failure to correctly identify whether multisensory events occur simultaneously, what their temporal order is, or whether they should be causally bound can lead to inaccurate representations of the physical world, poor decision-making, and dangerous behaviour. Here I review work in our lab that has shown that i) older adults have an extended temporal binding window compared to younger adults, but which is task-specific, ii) older adults are less aware of the perceived onset of a fall compared to younger adults, and iii) the representation of the duration of multisensory events during a fall is distorted during a fall, particularly for older adults. These results and future work will be discussed in the context of developing new falls prevention assessment techniques to help prevent falls in later life.

Title: One bout of open skill exercise improves multisensory perception in older adults

Authors: *A. SETTI[1], J. M. O'BRIEN[1], G. OTTOBONI[2], A. TESSARI[2];
[1]Sch. of Applied Psychology, Univ. Col. Cork, Cork, Ireland; [2]Dept. of Psychology, Univ. of Bologna, Bologna, Italy

Abstract: Inefficient multisensory perception of temporally asynchronous stimuli characterises older age. The time frame during which proximal information is integrated becomes extended, with negative consequences. Older adults, and more so, fall prone older adults, show higher susceptibility to the Sound-induced Flash Illusion (SiFI) than young adults, i.e. the illusory perception of two flashes when one single flash is presented with two beeps. Neural correlates of susceptibility to the illusion are cross-sensory interactions in early visual areas (V1) and Superior Temporal cortex. Older fallers who improve their balance with a programme of exergame training also show decreased susceptibility to the illusion. The present study aimed at testing the SiFI in older adults who are functionally able and regularly exercise to compare them with a control group of relatively sedentary older adults. Specifically, we assessed whether one bout of exercise improved performance on the SiFI and whether habitual exercise was predictive of SiFI performance. Additionally, we tested whether Open skill exercisers (i.e. exercise requiring responding to unpredictable environments e.g. aerobics classes, tennis) would show more benefit than Closed skill exercisers (i.e. exercise in predictable environments, e.g. swimming, running) or controls (e.g. reading club), based on the hypothesis that Open skill exercise provides a more stimulating multisensory environment fostering rapid multisensory training and adaptation. Fifty community-dwelling participants (17 Open skill; 17 Closed skill; 16 controls) with a mean age of 69, were tested on the SiFI and the Digit Span Forward test (results not reported here) before and after one session of their regular exercise or control activity. A 3 way ANOVA conducted on perceptual sensitivity d′ scores with Group, Time and Stimulus Onset Asynchrony as factors revealed a Time × Group interaction. Only Open skill exercisers' sensitivity improved after exercise. Random permutation ANOVA confirmed this significant Time × Group interaction. Habitual exercise (MET-minute, International Physical Activity Questionnaire Short Form) was not predictive of performance after exercise nor did it correlate with overall SiFI sensitivity.
In conclusion, Open skill exercisers were the only group showing immediate benefits, however no correlation with day-to-day exercise was found. This partially supports the hypothesis that both arousal and exercise mode contribute to perceptual sensitivity modulation in ageing. Beta

band activity, which evidence has shown to be modulated by exercise and is associated with SiFI, could underlie these effects.

Title: Integration of human visual and vestibular heading direction during eccentric viewing conditions.

Authors: *B. T. CRANE;
Otolaryngology, Univ. of Rochester, Rochester, NY

Abstract: Visual heading perception is strongly eye position dependent while vestibular or inertial headings are not. This study examined visual and inertial heading integration with eccentric eye positions in 5 humans. Experiments had randomly interleaved trials in which eye position was centered, 20° left, or right. A fixation was monitored using a binocular video eye tracking. The fixation point disappeared during the stimulus and eye position was maintained at the location. The stimulus was 2s of visual motion through a star field or analogous inertial motion. After each stimulus, subjects reported whether they felt each stimulus was consistent with motion left or right of the midline. In the visual only condition with eccentric viewing positions the average point of subjective equality (PSE) in which motion was equally likely to be perceived as left or right of center was 10° in the direction of gaze. Thus, visual heading perception was shifted in the direction opposite gaze, a shift consistent with retinatopic coordinates. When the experiment was conducted with an inertial stimulus in darkness, eccentric viewing positions had a smaller and opposite effect than they had with visual stimuli. The PSE with inertial stimuli in darkness was 5° in the opposite direction of gaze. Since eye position had opposite effects on the perceived directions of visual and inertial headings, provided a novel method of studying visual-vestibular multisensory integration that does not require the stimuli to be artificially offset from each other. Visual and inertial integration was studied by varying the coherence of the visual stimulus. When a 90% visual stimulus was used with an concurrent

inertial stimulus the PSE was shifted 7° in the direction of gaze, which dropped to 3° for 50% coherence, and -3° at 35%. Thus decreased visual coherence caused the heading perception to shift towards what was observed with a purely inertial stimulus. These findings were consistent with a Bayesian integration at low visual coherence but suggested closer to ideal performance that Bayesian predictions at high visual coherence.

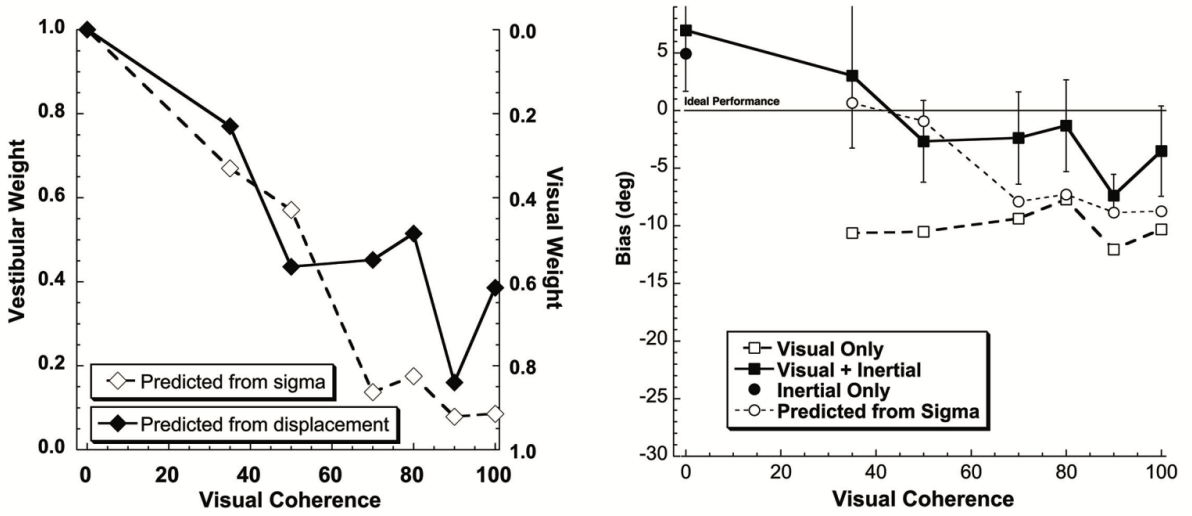

Figure. The left panel shows the predicted weights of the vestibular and visual cues based on the sigma or width of the psychometric function (open symptoms) and biases or displacement of the mean of the psychometric function (filled symbols). For high visual coherence the displacement predicts a higher vestibular weight than would be suggested by the sigma. The right panel plots the obserserved baises of the visual condition (open squares), inertial condition (filled circle) and combined (filled squares). The predictions of Bayesian integration based on the relative reliability of each (as determined by sigma) is shown with open circles. The observed responses (filled squares) are closer to ideal performance for high coherence visual stimuli that Bayesian integration suggests.

Title: Age-related changes in multisensory temporal acuity and links to cognition.

Authors: *M. T. WALLACE[1], S. H. BAUM[2], R. A. STEVENSON[3];
[1]Hearing and Speech Sci., [2]Vanderbilt Brain Inst., Vanderbilt Univ., Nashville, TN; [3]Psychology, Univ. of Western Ontario, London, ON, Canada

Abstract: Background: In order to integrate sensory information across modalities into coherent, unified percepts, our nervous systems rely on the timing of sensory inputs. The temporal fidelity of sensory processing, however, declines with age, which has been hypothesized to result in decreased multisensory integration in older adult. Furthermore, sensory perception is the building block of myriad cognitive functions, and impairments in sensory processing, including those associated with healthy aging, can subsequently impact those cognitive functions.
Methods: To test the impacts of decreased temporal precision associated with healthy aging, we ran participants (18-79 years old, N = 48 with data collection ongoing) through a, extensive battery of perceptual and cognitive tests. First, participants' multisensory temporal fidelity was tested with a simultaneity judgment task used to extract each individual's "temporal binding window" (TBW), or the window of time within which an auditory and visual stimulus are bound into a single unified percept. As a measure of audiovisual integration, the well-characterized McGurk Effect was used, in which participants integrate a visual "ga" with an auditory "ba" to perceive the syllable "da." Finally, a number of cognitive tests were conducted, including the Buschke Selective Reminding Task, Choice Reaction Time, Critical Flicker Fusion, and Connor's Continuous Performance Task.
Results: Older adults showed significant decreases in multisensory temporal fidelity, indexed by wider TBWs. Additionally, older adults showed decreases in multisensory integration, as indexed by the McGurk effect. Importantly, correlations showed that, in older adults, decreases in temporal fidelity were correlated with decreases in multisensory integration ($p = 0.02$, $r=0.41$). Within older adults (45-70 years old), hierarchical clustering analysis demonstrated links between these perceptual processes and higher-order cognitive measures. For example, audiovisual temporal processing was linked to performance on the Selective Reminding Task.
Implications: These results suggest that changes in multisensory temporal fidelity commonly observed in healthy aging can have downstream impacts not only on perceptual abilities such as multisensory integration of speech signals, but also on higher-order cognitive processes.

Title: Event-related potentials associated with somatosensory interaction with audio-visual speech processing

Authors: *T. ITO[1,2,3], H. OHASHI[2], E. MONTAS[2], V. L. GRACCO[2,4];
[1]Gipsa Lab, CNRS, St Martin D Heres Cedex, France; [2]Haskins Labs., New Haven, CT; [3]Univ. of Grenoble Alpes, Grenoble, France; [4]McGill Univ., Montreal, QC, Canada

Abstract: Speech perception is an interactive process involving both the auditory and visual modalities. Recent studies demonstrate that somatosensory input can also influence the process of auditory speech perception (Ito et al. 2009; Gick and Derrick 2009). However, it is unknown whether and to what extent somatosensory inputs modulate audio-visual speech perception. To address this question, we explored the neural consequence of somatosensory interactions with audio-visual speech processing under audio-visual speech processing conditions. Specifically, using the McGurk effect (the perceptual illusion that occurs when the auditory component of one sound is paired with the visual component of another sound, leading to the perception of a third sound) we assessed whether somatosensory orofacial stimulation influenced event-related potentials (ERPs) during audio-visual speech perception. We recorded ERPs from 64 scalp sites in response to audio-visual speech processing and somatosensory stimulation. We applied an auditory stimulus /ba/ synchronized with the video of congruent facial motion (the production of /ba/) or incongruent facial motion (the production of the /da/: McGurk condition). The congruent and incongruent audio-visual stimulations were randomly presented with and without somatosensory stimulation associated with facial skin deformation. We recorded ERPs under auditory alone, somatosensory alone, and auditory-somatosensory stimulus conditions. The subjects were asked to judge whether the production was /ba/ or not. We observed a clear McGurk effect in the behavioral responses with the subjects identifying the sound as /ba/ in the congruent audio-visual condition, but not in the incongruent condition. Concurrent somatosensory stimulation modified the ability of participants to correctly identify the production as /ba/ relative to the non-somatosensory condition. We found ERPs differences associated with the McGurk effect in the presence of the somatosensory conditions. ERPs for the McGurk effect reliably diverge around 280 ms after stimulation onset. The results demonstrate a clear multisensory convergence of somatosensory and audio-visual processing in both behavioral and neural processing and suggest that somatosensory information encoding facial motion also influences audio-visual speech processing.

Title: Stepping to injected colored rhythms effect gait entropy more for auditory stimuli than visual.

Authors: *J. FUJAN-HANSEN, T. J. RAND, M. MUKHERJEE;
Univ. of Nebraska At Omaha, Omaha, NE

Abstract: Introduction: Healthy adult systems rely upon a balance of sensory inputs to maintain strong posture and locomotion. This finely turned feedback is the result of contributions from our visual, auditory, vestibular and proprioceptive systems. This crucial balance is often altered as a result of pathology or extended time spent in space. Therefore, there is a direct need for techniques designed to discover effective locomotor restoration. The purpose of this study was to determine the degree to which injected colored rhythms can effect spatio-temporal gait patterns of healthy young adults via visual and auditory stimuli.
Methodology: This project utilized Virtual Reality technology along with auditory afferent feedback to affect spatio-temporal gait patterns in healthy young adults. Subjects participated in either visual or auditory groups. The former walked on a treadmill tied to optic flow presented via Virtual Reality technology. The optic flow was comprised of a simulated walkway which required subjects to make heel contact with their right foot with the incoming virtual tiles. The latter group also walked on a treadmill, but without any optic flow. They instead listened to an auditory stimulus to which they were instructed to match right heel strikes with the auditory beats. Both the visual and auditory stimuli were presented to the participants in three different noise structures: pink, white and periodic. Sample Entropy of spatio-temporal data was used to assess the ability of the individuals to flexibly alter the structure of their gait to match the sensory stimuli.
Results: Significance was found to exist in the spatial domain of step length during the auditory stimulus between both the pink and white noise structures ($p<0.045$), as well as the white and periodic ($p<0.046$). Differences within the temporal domain of stride time in the auditory stimulus did not reach significance. Significant differences were not found to exist in either the temporal nor spatial domains of the visual stimulus. Upon further analysis, half of the participants in the visual condition responded differently than the other half.
Conclusions: The results from this project illustrate that auditory stimuli with characteristic

temporal structures enable entrainment more than visual stimuli. This may be because visual stimuli demonstrate strong individualistic patterns.

Title: Prestimulus beta-band power predicts perception of the sound-induced flash illusion on a trial-by-trial basis

Authors: ***J. KEIL**, M. KAISER, J. BALZ, D. SENKOWSKI;
Charité Med. Sch., Berlin, Germany

Abstract: The sound-induced flash illusion (SIFI) is a well-known example for the influence of auditory information on visual perception. Presenting multiple auditory stimuli alongside a concurrent single visual stimulus can induce the illusory perception of multiple visual stimuli. Interestingly, the perception of the illusion fluctuates between trials, resulting in a bistable multisensory perception. Recent research identified a number of possible cortical mechanisms to explain the occurrence of the illusion. We, and others, have suggested that alpha-band power in visual cortical areas and beta-band power in the superior temporal gyrus predict the perception of the SIFI. Furthermore, neurotransmitter concentration in the latter cortical area significantly correlates with the SIFI perception. Moreover, it was recently proposed that the individual alpha-band frequency predicts the SIFI perception. These findings suggest an essential influence of the cortical state prior to stimulus onset on subsequent perception.
In the current experiment, we went beyond the broad dichotomy of illusion versus veridical perception. We assessed the relationship between oscillatory neural activity prior to stimulus onset and the subsequent perception on the single trial level. To this end, we recorded high-density EEG from 26 subjects and analyzed oscillatory neural activity between 5 and 40 Hz in

the 500 ms interval prior to stimulus onset. Subsequently, we computed a binomial regression between single-trial oscillatory neural activity and upcoming perception in each subject. Across subjects, we found that beta-band power and, to a lesser extent, alpha-band power predict the perception of the SIFI on a trial-by-trial basis. Our results thus corroborate previous findings on the crucial influence of the prestimulus cortical state, as reflected in oscillatory neural activity, on upcoming perception. Importantly, by showing a close link between oscillatory neural activity and perception on a trial-by-trial basis, the current results extend our knowledge on the relationships between cortical states and perception.

Title: Prestimulus high gamma oscillations in the sensorimotor cortex predict response speed to visuotactile stimuli

Authors: *D. SENKOWSKI[1], M. KREBBER[1], J. KEIL[1], D. FRIEDMAN[2], P. DUGAN[2], W. DOYLE[3,4], O. DEVINSKY[2,4], E. HALGREN[5], T. THESEN[2];

Abstract: Neural oscillations serve many purposes in the human brain, including the integration and routing of information across cortical areas. Previous research has also demonstrated the behavioral relevance of pre- and poststimulus neural oscillations in various frequency bands, such as delta, alpha, beta, and gamma oscillations. Thus far, it is not well understood how prestimulus high gamma power (> 80 Hz) relates to behavioral outcomes. In this intracranial EEG study we investigated how pre- and poststimulus gamma and high-gamma power in the sensorimotor cortex affects response speed to visuotactile target stimuli. Three epilepsy patients with subdurally implanted electrode arrays were presented with brief unisensory visual, unisensory tactile, or bisensory visuotactile stimuli via LEDs and solenoid tappers mounted to a

handheld foam cube. Alternating between blocks, individuals were instructed to respond either to visual or tactile inputs of unisensory or bisensory stimuli. For each individual, single-trial time-frequency resolved correlations between oscillatory power and response times were calculated using permutation tests with cluster-based correction for multiple comparisons. In all patients, increased prestimulus gamma power (about 60-140 Hz) in the sensorimotor cortex contralateral to the stimulated hand predicted longer reaction times to visuotactile stimuli when attention was directed to the visual modality. Prestimulus gamma power did not consistently correlate with the behavioral responses when paying attention to tactile stimuli. When analyzing the relationships between poststimulus power and response times a more heterogeneous pattern of positive and negative relationships across electrode sites emerged. Interestingly, the patterns of relationships between poststimulus power and behavioral responses were similar for the two attention conditions. We conclude that prestimulus gamma and high-gamma power in the sensorimotor cortex impedes responses to visual inputs of visuotactile target stimuli. Our study provides evidence for the behavioral relevance of prestimulus high gamma power in the processing of multisensory visuotactile stimuli.

Title: Adapting to visual and auditory low frequency modulated stimuli induced enhanced tactile frequency discrimination

Authors: ***S. BADDE**[1], L. THOMASCHEWSKI[2], H. STOFFREGEN[2], B. RÖDER[3]; [1]Dept. of Psychology, New York Univ., New York, NY; [3]Biol. Psychology and Neuropsychology, [2]Univ. of Hamburg, Hamburg, Germany

Abstract: Human perception includes redundant information across multiple sensory systems, for example, when recognizing objects. The present study tested whether tactile vibration frequency processing assesses overlapping neural systems with those involved in sound and

visual frequency processing. We measured tactile discrimination thresholds for vibrating stimuli (either 25, 30 or 200Hz) in a 2IFC task. Each trial was preceded by an adaptation phase in which either nothing (baseline), a flickering checkerboard (visual adaptation) or a sine tone (auditory adaptation) was presented for 12 seconds. Adapting stimuli always had a frequency of 25 or 30Hz. Tactile frequency discrimination performance within the same frequency range as the adapting stimulus was improved both in visual and in auditory conditions compared to the baseline condition. In contrast, tactile frequency discrimination performance for the 200Hz standard did not significantly differ between conditions, demonstrating frequency specificity of the adaptation effect. Adapting to frequency modulated visually and auditory stimuli induced frequency specific changes in tactile frequency discrimination suggesting overlapping neural representations of frequency across tactile, auditory, and visual modalities.

Title: Intra- and multisensory interactions in congenitally deaf CI users

Authors: *I. FENGLER, D. BOTTARI, S. SOURAV, A. K. VILLWOCK, B. RÖDER;
Biol. Psychology and Neuropsychology, Univ. of Hamburg, Hamburg, Germany

Abstract: Event-related potentials (ERP) are attenuated if the eliciting event was preceded by another event processed in overlapping neural circuits. These refractory effects (RFE) have been observed within and across sensory systems and can be used to assess intra- and multisensory processing capacities. Indeed, previous work has demonstrated quicker recovery of visual ERPs in congenitally deaf individuals, which was interpreted as evidence for compensatory changes within the visual system. In the present study, we assessed auditory, visual, and crossmodal RFE in a group of congenitally deaf recipients of a cochlear implant (CI). We expected larger crossmodal RFE for auditory stimuli following a visual stimulus but a lack of or reduced crossmodal RFE for visual stimuli following an auditory stimulus, which would indicate persisting changes in the crossmodal balance of cortical processing. Brief (50 ms) white noise

bursts and light flashes were used as standard stimuli. They were presented with an inter-stimulus interval (ISI) of either 1,000 or 2,000 ms. Mean amplitudes of auditory and visual ERP recorded from midline electrodes were analyzed as a function of group, electrode site, preceding ISI (short vs. long), and modality of the preceding stimulus (same vs. different). Both CI users and controls displayed unimodal and crossmodal RFE for auditory as well as visual ERP. These results suggest a recovery of multisensory interactions between the auditory and visual system despite transient auditory deprivation from birth.

Title: The causal role of the dorsolateral prefrontal cortex and somatosensory cortex in tactile-visual cross-modal working memory

Authors: *D. ZHAO[1,2], Y. KU[2,3];
[1]Sch. of Psychology & Cognitive Sci., East China Normal Univ., Shanghai, China; [2]The Key Lab. of Brain Functional Genomics, MOE & STCSM, Sch. of Psychology and Cognitive Science, East China Normal Univ., Shanghai, China; [3]NYU-ECNU Inst. of Brain and Cognitive Science, NYU Shanghai and Collaborative Innovation Ctr. for Brain Sci., Shanghai, China

Abstract: The neural activity in the dorsolateral prefrontal cortex (DLPFC) has been associated with information integration across sensory modalities. Connections between the DLPFC and sensory cortices of different sensory modalities subserve the integrative function of the DLPFC. However, the causal role of the DLPFC in cross-modal working memory (WM) has not yet been established, and it is also unclear how top-down signals from the DLPFC influence activity of bilateral primary somatosensory cortices (SIs) in tactile-visual cross-modal WM. In the present

study, we applied single-*pulse trans*cranial magnetic stimulation (sp-TMS) to certain cortical areas of human participants at various time points, while they performed a tactile-visual delayed matching-to-sample task with a 2-second delay. sp-TMS over the contralateral DLPFC and contralateral SI at both an early sensory stage, 100ms after the onset of vibrotactile stimulation (200-ms duration), and an early maintenance stage, 300ms after the onset, significantly impaired the accuracy of task performance, and sp-TMS over the contralateral DLPFC and ipsilateral SI at a late maintenance stage (1600ms and 1900ms) also significantly disrupted the accuracy. Furthermore, significant correlations were observed between deteriorating effects of sp-TMS at 300ms over the contralateral SI and contralateral DLPFC on task performance. Taken together, these results indicate that the DLPFC plays an essential part in tactile-visual cross-modal WM, and cooperates with the contralateral SI in the early delay, and with the ipsilateral SI in the late delay respectively.

Title: Modification of the central state of excitability using sustained electrical stimulation of the posterior roots in spinal cord injured humans

Authors: *M. R. DIMITRIJEVIC[1,2], M. KRENN[3,4], R. COBELJIC[5], E. SRNDIC[3], K. RIBARIC[6], W. MAYR[3];
[1]Baylor Col. Med., Houston, TX; [2]Fndn. for Movement Recovery, Oslo, Norway; [3]Med. Univ. of Vienna, Vienna, Austria; [4]Vienna Univ. of Technol., Vienna, Austria; [5]Rehabil. Clin. - Dr Miroslav Zotovic, Belgrade, Serbia; [6]Euromedic Hosp., Belgrade, Serbia

Abstract: The posttraumatic chronic condition of the spinal cord usually results in a variety of impaired movement and alteration of muscle tone. In this study, we describe modification of the central state of excitability of the spinal cord below the level of lesion. Therefore, we conditioned the lumbosacral spinal network using transcutaneous electrical stimulation of the posterior roots. For activation of the lumbosacral segments, we used for electrical stimulation surface electrodes on the T11-T12 vertebrae referenced to large paraumbilical electrodes. The sustained external input was applied using a “low” (5 - 50 Hz) or “high” (50 - 100 Hz) stimulation rate.
In five subjects (1 female) with chronic, traumatic, motor complete spinal cord injury we applied

a conditioning paradigm. We used two different test inputs for analyzing the modification of the central state of excitability. First, externally evoked posterior root reflexes (PRR) elicited by transcutaneous spinal cord stimulation and passive multi-joint hip and knee flexion for “low” and “high” stimulation rates, respectively.
In the major leg muscles, the motor output was recorded electromyographically by surface electrodes. In the case of “low” frequency stimulation, the analysis reveals a facilitation or a suppression of PRR responses in respect of different rates of the applied conditioning stimulation. Nevertheless, the effect on modification of the central state of excitability can also vary within different muscle groups of the same subject. For sustained stimulation rates higher than 50 Hz, a clear suppression of the motor output can be observed in subjects with increased central state of excitability during a passive motor task. In this cases, the activation of the leg muscles is nearly complete reduced.
The preliminary results suggest a projection of sensory axons to dorsoventral network that can be influenced by different range of stimulation rates. Finally, this study enables a methodology for understanding of the pathophysiology of spinal cord injury and restoration of functional movement.

Title: Internal multisensory stochastic resonance in visual and auditory pathways

Authors: *I. MENDEZ-BALBUENA[1], P. ARRIETA[2], N. HUIDOBRO[3], E. MANJARREZ[3]; [1]Facultad de Psicologia, Puebla, Mexico; [2]Facultad de Medicina, [3]Inst. de Fisiologia, Benemerita Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: The aim of the present study was to demonstrate the electrophysiological occurrence of the internal multisensory stochastic resonance in the visual and auditory sensory modalities. We performed two experimental conditions (EC) in eight subjects; i.e., we applied, to both left and right eyes and ears: continuous visual noise of constant intensity versus continuous auditory noise of different amplitude levels (EC1), as well as auditory noise of constant intensity versus continuous visual noise of different amplitude levels (EC2). We examined whether a particular modulated Gaussian noise level can improve the EEG coherence. To quantify the EEG coherence we measured the area under the coherence curve above the significance level. The frequency window was 1-45 Hz. In order to obtain a general measure of the change of EEG synchronization in a particular level of noise, for each of the 30 electrodes we summed up all 29 possible combinations of pairwise coherence. For each noise level we subtracted the corresponding value to zero noise (ZN). We defined this number as the global weighted coherence relative to ZN (GRWC). We found that the GRWC values for all the subjects exhibited and inverted U-like function of the noise intensity. We compared the GRWC between low noise (LN), optimal noise (ON) and high noise (HN). The mean percentage of change in EC1, between LN and ON, was 1347.2 ± 578.2 % (mean ± SE), and in EC2 was 371.9 ± 139.5 % (mean ± SE). We performed the nonparametric Friedman test to examine the statistical significance of the change in the GRWC, between LN, ON and HN conditions. For EC1, the results showed significant differences between the three conditions: ($Ch2\ (2)=12.2$, $p<0.002$). The post hoc Wilcoxon test revealed statistically significant differences between LN and ON ($p<0.004$) and between ON and HN ($p<0.004$). For EC2, the results also showed significant differences between the three conditions: ($Ch2\ (2)=13$, $p<0.002$). The post hoc Wilcoxon test revealed statistically significant differences between LN and ON ($p<0.008$) and between ON and HN ($p<0.006$). In contrast, in both EC, no statistically significant differences were found between LN and HN conditions. Our electrophysiological study extends the psychophysical experiments by Manjarrez et al., (2007) in the context of an EEG paradigm. Furthermore it shows that the EC1 is more effective to produce a higher GRWC than the EC2. Our results demonstrate that visual and auditory noise could potentially modulate the EEG coherence amplitude by following the principles of the multisensory stochastic resonance phenomenon.

Title: Effect of an olfactory stimulus on color perception

Authors: *K. TAMURA[1], T. OKAMOTO[1,2];
[1]Fac. of Arts and Sci., [2]Grad. Sch. of Systems Life Sci., Kyushu Univ., Fukuoka, Japan

Abstract: Olfactory perception is known to be altered by observing different colors. Conversely, few studies have investigated whether visual perception is influenced by olfactory inputs. As color perception is generally less stable than other types of visual perception, we hypothesized that the perception of specific colors would be enhanced by olfactory input. To test this hypothesis, we analyzed event-related potentials (ERPs) in the brains of subjects presented with different color-odor combinations. Twenty volunteers (ten females) with normal color vision were tested under two conditions, control and odorant, the order of which was randomized. In the odorant condition, 0.1% decanal (vol/vol)—perceived as a citrus-like smell and associated with orange colors by 7/12 students—was volatilized in the experimental room. In both conditions, participants were required to state what color was presented in the preceding 1.5 s. Each participant viewed four types of color groups (orange, green, blue, and pink), each consisting of five color phases equally spaced by 10 degrees of hue angle, as specified in CIELAB color space. The ERPs of each participant were recorded using electroencephalography throughout the experiment. A positive peak was observed around 300 ms (p300-like component), just after the participants started to report the color. The mean amplitude of the p300-like component measured under the odorant condition was significantly smaller than that obtained in the control condition. In addition, within the odorant condition, the mean amplitude was significantly smaller in response to the orange group compared to the other color groups. Contrary to our hypothesis, the results indicate that the citrus-like smell suppressed the p300-like component in response to the orange group. We suggest that cross-modal interactions between visual and olfactory senses can influence (occasionally decrease) the perception of specific colors that are co-presented with a smell.

Title: Visuo-tactile motion processing in congenitally deaf humans

Authors: *A. K. VILLWOCK, D. BOTTARI, B. RÖDER;
Univ. of Hamburg, Hamburg, Germany

Abstract: Sensory deprivation has been shown to partially have a strong impact on the development of the spared modalities. However, to date, little is known about the impact of auditory deprivation on the development of multisensory processing. In the present study, we investigated the consequences of congenital deafness on the processing of visuo-tactile motion stimuli. To this aim, we recorded the event-related potentials (ERPs) in congenitally deaf signers (N = 21) and matched hearing controls during a visuo-tactile motion discrimination task. The visual and tactile stimulators were either moving congruently, that is, both moving upwards or downwards, or incongruently, that is, one stimulus moving upwards, the other downwards. The motion of standard stimuli was continuous, while deviants included an interrupted motion in one of the two modalities. Participants had to respond to rare deviants in both modalities, but only to those going into a specific direction. We expected an enhanced behavioral performance in the deaf group compared to hearing controls. Furthermore, we hypothesized to find a more anterior distribution of the ERPs in the deaf group compared to the hearing group after the visuo-tactile stimulation, indicating crossmodal plasticity. Deaf individuals committed more false alarms in the incongruent motion condition. In the ERPs to standard stimuli, the deaf group displayed a more anteriorly distributed potential compared to the hearing controls at a time window around 150 ms after stimulus onset. Moreover, we observed a delayed effect of motion congruency in the ERP of the deaf group compared to the hearing control group. These results suggest crossmodal reorganization - namely, an enhanced responsiveness to dynamic visuo-tactile stimulation in auditory areas - and an altered timing of the multisensory processing of motion direction after congenital deafness.

Title: Rapidly induced auditory plasticity by imagined visual stimuli

Authors: *C. C. BERGER, H. H. EHRSSON;
Karolinska Institutet, Stockholm, Sweden

Abstract: The spatial recalibration of auditory perception that follows exposure to synchronous but spatially discrepant audiovisual stimuli—the ventriloquism aftereffect—has become a classic demonstration of the plasticity of the auditory system. This recalibration in auditory perception is considered to be an adaptive response that results from the repeated translocation of auditory stimuli towards the spatially discrepant visual stimuli. Recent evidence suggests that visual mental imagery can also lead to a translocation of perceived auditory stimuli (Berger & Ehrsson, 2013, 2014). In light of these findings, we investigated whether imagined visual stimuli led to the same rapidly induced auditory plasticity as real visual stimuli in four separate psychophysics experiments (n = 96). In our main experiment, we examined whether imagining a visual stimulus (white disk; visual angle = 1.72°) at the same time as a white noise burst (50 ms; rise/fall time = 5 ms) repeatedly for 30 s exposure periods led to a significant shift in the participants' point of subjective equality (PSE) of spatially localized auditory stimuli during subsequent test phases. We found a significant leftward shift in the participants' PSEs during post-exposure phases when the participants imagined visual stimuli in the center of the screen and the auditory stimuli were simultaneously presented 8° to the left during the exposure phases (i.e., rightward adaptation); and we found a significant rightward shift in the participants' PSEs when the auditory stimulus was presented 8 ° to the right during the exposure phases (i.e., leftward adaptation), compared to a control condition in which imagined visual stimuli and real auditory stimuli were presented in the center [$F(2, 46) = 15.29$, $p < .001$, $\eta^2_G = .17$]. This result was consistent with a 'real' visual stimulus version of the experiment in which the visual stimuli were actually presented rather than imagined [$F(2, 46) = 26.76$, $p < .001$, $\eta^2_G = .25$], and a comparison of the effect between the real-stimulus and imagined stimulus experiments revealed that there was no significant difference in

the ventriloquism aftereffects for these experiments [$t(46) = .067$, $p = .504$]. Furthermore, a control experiment revealed that the visual imagery-induced aftereffect did not transfer across different sound types ($ps > .05$). This result was consistent with findings from an additional control experiment using real visual stimuli as well as findings from previous studies. These findings are the first to demonstrate the cross-modal plasticity of our perceptual systems induced by mental imagery.

Title: Interaction of attentional and movement-related modulation of evoked potentials in the primary and secondary somatosensory cortices

Authors: *J. R. TENNANT, M. S. ADAMS, W. R. STAINES;
Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Previous research suggests that the prefrontal cortex contributes to attention-related disinhibition of movement-related gating in the primary somatosensory cortex. Brown et al. (2015) provided evidence for this phenomenon by demonstrating that continuous theta burst stimulation applied over the dorsolateral prefrontal cortex results in an impaired ability to disinhibit task-relevant somatosensory information. Currently however, the precise stages of processing for these attentional and movement-related modalities are not well defined. We hypothesized that when attention is directed away from the somatosensory modality or somatosensory feedback is not task-relevant, gating would be enhanced. Conversely, when attention is directed towards the somatosensory domain or somatosensory feedback is task-relevant, we predicted a release of gating would occur. Somatosensory evoked potentials (SEPs) were elicited via median nerve stimulation at the wrist, and measured using EEG over the contralateral somatosensory cortex in five experimental conditions. In a baseline condition (rest), SEPs were evoked while participants maintained a neutral wrist position with no specific instructions for directing their attention. A passive movement condition was included to assess task-irrelevant movement-related gating. In this condition, SEPs were recorded while participants' stimulated wrists were moved through a random pattern of flexion/extension

movements within a 60-degree range. In an active tracking condition, participants' stimulated wrists were similarly passively moved through a range of flexion and extension movements for 7 seconds. Participants were then required to actively mirror the movements with their opposite limb, facilitating a measure of task-relevant movement-related gating. In a counting condition, participants counted the total number of stimulations received at rest, requiring an attentional focus on the somatosensory modality without a motor task requirement. Conversely, in a visual condition, participants attended to and traced a visual waveform presented on a screen using a wrist movement device to control a cursor, while receiving stimulation. Preliminary results provide evidence for attentional and movement-related modulation of somatosensory afferents in both the primary (N20-P27) and secondary (P100) somatosensory cortices, consistent with our hypotheses. These findings will provide a greater understanding of the somatosensory gating process, and be used for the investigation of post-concussive alterations.

Abstract: Sensory motor circuits in the spinal cord are constructed with a fine specificity that coordinates motor behavior. Analysis of the dorsoventral connectivity patterns in an animal

model showed that the projections of sensory axons to discrete dorsoventral domains of the spinal cord without regard for motor neuron subtype or the presence of motor neurons [1]. By implications, the clustering and dorsoventral settling position of motor neuron pools serve as a determinant of the pattern of sensory input specificity and thus motor coordination. The mechanisms that direct sensory connections with their motor neuron pattern remain unclear. In this study, patterns of spinal sensory-motor output initiated by epidural spinal cord stimulation of lumbar posterior human cord determinant of the patterns of sensory inputs rate and strength.
Six subjects (two females) with chronic, traumatic, motor complete spinal cord injury were studied. The injury level was between Th2 and Th6. The epidural spinal cord stimulation consisted of a cylindrically shaped electrode array and a pulse generator (Pisces-Quad electrode, Model 3487A and Itrel 3, Model 742, Medtronic Inc., Minneapolis MN, USA). Across subjects, the rostrocaudal positions of the electrodes ranged from vertebral levels Th11-L1. The motor output was recorded electromyographically in the major leg muscle. For analysis, the root mean square value (E_{RMS}) of the signal was calculated in a window of 3 s.
The E_{RMS} was facilitated in all muscle groups by 66.3% between a stimulation rate of 2.1 Hz and 10 Hz. Above 10 Hz, the modification of the motor output with increasing stimulation rates showed a progressive suppression. Therefore, the E_{RMS} declined around 19%, 51% and 66% for a stimulation rate of 16, 20 and 30 Hz, respectively. At a sustained stimulation of 100 Hz, the responses were nearly diminished.
In our human data, we have found crucial evidence of consistently reproducibly patterned response. In contrast, the animal research has different motor behavior, but it predicts some interesting cluster activity which we interpret in our subjects without variability. Moreover, if this pattern response is augmented or suppressed, we can demonstrate the same effect on the result of independent motor unit's activity from background activity.
Intriguing differences between results and the insights gathered gives us the opportunity to discuss the significance of the patterned response modifying the motor control in spinal cord injury subjects. 1. Sürmeli G. et al. 2011, Cell, 147(3):653-65

Title: Visual selectivity for mouth movements predicts auditory response in human superior temporal sulcus

Authors: *L. L. ZHU, M. S. BEAUCHAMP;
Baylor Col. of Med., Houston, TX

Abstract: Speech perception is a multisensory process entailing the use of both visual information from the talker's face and auditory information from the talker's voice. Posterior temporal cortex, comprising superior temporal sulcus and superior temporal gyrus (pSTS/STG), is thought to be a key brain locus for the integration of visual and auditory speech information. However, we know relatively little about the neuroanatomical organization of this region that enables integration. Previous studies have shown that sub-regions of the pSTS/STG show preferential responses to different categories of visual stimuli and different categories of auditory stimuli, but little is known about the relationship between these different axes of selectivity. In natural environments, we usually see visual mouth movements at the same time as we hear vocal speech. This association in environment statistics could have neural consequences: we hypothesized that regions of the pSTS/STG with a preference for *visual* mouth movements should respond strongly to *auditory* stimuli, especially speech. As a control, we examined regions of the pSTS/STG that previous studies have shown are selective for visual eye movements. To test this hypothesis, we used blood oxygenation level dependent (BOLD) functional magnetic resonance imaging (fMRI) to scan twenty subjects. In the first experiment, we mapped voxels by their visual preference and measured the response to speech stimuli consisting of auditory recordings of short stories. In pSTS/STG, visual mouth-movement preferring voxels showed greater responses to auditory speech than eye-movement preferring voxels (LH: 1.6±0.2% vs. 0.1±0.1%, $p<8.6x10^{-5}$; RH: 1.2±0.2% vs. -0.2±0.1%, $p<4.0x10^{-6}$). In the second experiment, we compared the response of visual mouth-movement preferring voxels to auditory vocal vs. non-vocal sounds. Mouth-movement preferring voxels showed greater response to vocal than non-vocal sounds (1.2±0.1% vs. 0.5±0.1%, $p=5.9x10^{-6}$). Our study demonstrates that subregions of the pSTS/STG respond strongly to both visually-presented mouth movements and auditory speech, suggesting that these stimulus features are coded together in small populations of neurons.

Title: Cross-modal interactions of haptic-visual roughness matching in the bilateral fusiform gyrus

Authors: *J. YANG[1], Y. YU[1], H. SHIGEMASU[2], H. KADOTA[2], K. NAKAHARA[2], Y. EJIMA[1], J. WU[1];

Abstract: Humans effortlessly distinguish numerous different categories of material (such as a stone, metal, wood etc.) at a glance and can recognize many specific somatosensory feelings at the same time. This suggests that information about an object is built by different sensory modalities that converge somewhere in the human brain to form representations that are invariant to the input modality. The fusiform gyrus (FG) is located between the lingual gyrus and parahippocampal gyrus and is primarily involved in the higher function of visual texture perception. However, recent neuroimaging studies suggest that the FG represents textures in a way that reflects not only visual but also non-visual object properties, such as haptic roughness. Therefore, the FG is considered a multisensory hub that plays an important role in haptic-visual texture integration/interaction processing. In the present study, we therefore used the modified delayed-match-to-sample paradigm to reveal FG activations related to cross-modal interactions of haptic-visual roughness matching. Eighteen healthy subjects were asked to remember the roughness of the first stimulus (visual or haptic) during an encoding phase and to identify a stimulus that was the same or was closely related in roughness to one of five stimuli (visual or haptic) during the recognition phase. In essence, the recognition phase consists of a recall of information about the roughness of the first stimuli, a comparison of the roughness of the first stimulus to the ongoing stimuli and a resolution of a final decision. Therefore, the activations of cross-modal tasks (HV, haptic-visual and VH, visual-haptic) compared to the corresponding unimodal tasks (VV, visual-visual and HH, haptic-haptic) will reveal cross-modal specific activations. The results demonstrated that HV>VV contrast revealed significant activations in the bilateral FG that were not apparent in the VH>HH contrast. This finding suggests that the bilateral FG of humans mediates roughness information about objects in multimodalities. However, bilateral FG activation may be more important for roughness transformation from haptic to visual modalities compared to the opposite orientation.

Abstract: The feeling of a presence (FoP), the sensation that somebody is nearby when no one is actually present, is reported mainly by neurological and psychiatric patients but also by healthy individuals facing extreme situations. Recent findings demonstrated that sensorimotor conflicts between upper limb movements and somatosensory feedback on the back may induce FoP in healthy subjects, suggesting that FoP is caused by misperceiving the source and identity of sensorimotor signals of one's own body. Despite these new insights into the FoP, very little is known about its neural basis. Here we applied the same sensorimotor conflict in healthy volunteers, while brain activity was measured with a 64-channels EEG. We compared the oscillatory power and estimated the inter-site phase clustering by means of the weighted phase-lag index (wPLI), in response to the condition with a sensorimotor conflict with the condition without a sensory motor conflict. Our results indicate a modulation in the alpha frequency band (8-11Hz), over the left frontocentral sensors. The functional connectivity analyses indicated a desynchronization of the gamma frequency band (31-45Hz), between somatosensory areas and frontoparietal areas in the condition with sensorimotor conflict. Collectively, our results provide new insights into the neural correlates of the robotically induced psychotic-like state, and indicate the frontoparietal cortex as the critical network associated to it. Interestingly, the involvement of the frontoparietal areas is supported by previous finding from neurological FoP patients, which indicated that the FoP is associated with three distinct brain regions: temporoparietal, insular, and especially with the frontoparietal cortex.

Title: Attentional gating at early cortical processing stages is associated with changes in behavioural performance on a motor task with sensory conflict

Authors: *M. S. ADAMS, J. R. TENNANT, W. R. STAINES;
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: While there is evidence to show early modulation of modality-specific somatosensory cortical potentials when two stimuli are task-relevant, less is understood about the cortical and behavioural correlates of early modality-specific sensory gating. This study examined attention-related changes in early somatosensory and visual processing and the effect of an unattended sensory stimulus on cortical processing and behavioural performance. For Part 1, it was hypothesized that early visual and tactile cortical responses would be diminished when unattended; that early cortical responses to task-relevant stimuli would be unchanged in the presence of a cross-modal distractor stimulus; and that participants' ability to accurately grade the intensity of stimuli would be consistent whether they were presented alone or with a cross-modal distractor. For Part 2, it was hypothesized that continuous theta burst stimulation (cTBS) to the prefrontal cortex (PFC) would diminish the effect of the attentional gating, resulting in similar ERP amplitudes for attended and unattended stimuli.
Healthy participants underwent two experimental sessions. In the first, electroencephalography (EEG) was collected as participants performed a sensory selection task which required graded motor responses be made to the amplitudes of episodic visual and tactile stimuli presented individually or concurrently. Attention was randomly directed for each block to either visual or tactile stimuli, which were presented as single visual, tactile, or simultaneous cross-modal stimuli. Event-related potentials (ERPs) were timelocked to visual and tactile stimuli, creating attended and unattended stimulus conditions. In the second session, the task was repeated and EEG was collected pre- and post-cTBS to the PFC. The somatosensory N70 potential was significantly diminished when tactile stimuli were unattended. When visual stimuli were unattended, similar attenuation occurred later in the processing stream (visual P2). When unattended tactile stimuli acted as distractors, this early gating resulted in unchanged cortical responses to target stimuli and no decrease in grading accuracy. Conversely, since early visual gating was not observed, presenting these stimuli as unattended distractor resulted in smaller-amplitude cortical responses to attended stimuli and less accurate grading. This modality specific

gating was impaired following cTBS to the PFC. This study suggests that early gating of unattended stimuli supports modality-specific cortical processing of target stimuli as well as task performance. It also suggests a role for the PFC in early attentional gating.

Title: Converging evidence from ECoG and fMRI for an anterior to posterior distinction in the superior temporal gyrus for audiovisual speech processing

Authors: ***M. OZKER**[1], D. YOSHOR[2], M. BEAUCHAMP[2];
[1]UT Hlth. Sci. Ctr. At Houston, Houston, TX; [2]Baylor Col. of Med., Houston, TX

Abstract: During speech perception, visual information from the face of the talker can compensate for noisy auditory speech. We combined neural recordings from electrodes implanted in the brains of epileptic patients (electrocorticography or ECoG) and BOLD fMRI in normal subjects, to examine the neural mechanisms of multisensory speech perception. Subjects viewed audiovisual words with either clear auditory speech (AV) or noisy auditory speech (AnV), identifying the presented words with a button press. In ECoG, electrodes in superior temporal gyrus (STG) responded to words with a burst of high-gamma (70-100 Hz) activity. Electrodes in the anterior STG (n=16) showed more activity for AV speech while electrodes in the posterior STG (n=12) showed more high-gamma activity for AnV speech (*Anterior*: AV=175±40%, AnV=75±10%; *Posterior*: AV=80±20%, AnV=120±20%, mean±SEM, RM-ANOVA $p=10^{-5}$). To verify that the sharp boundary observed was not a result of abnormal brain organization in epileptic patients, we performed the same experiment with BOLD fMRI in healthy subjects. The same anterior-to-posterior boundary in responses was observed (*Anterior*: AV=0.32±0.02%, AnV=0.22±0.03%; *Posterior*: AV=0.27±0.03%, AnV=0.32±0.02%, $p=10^{-4}$). Adding noise to the auditory component of speech resulted in weaker responses in the anterior STG but not in the posterior STG, possibly because the posterior STG receives more visual inputs that compensate for the degraded auditory signals.

Title: Recovery of visual influence on auditory motion processing despite persisting cross-modal changes in sight-recovery individuals

Authors: *M. J. GUERREIRO, L. PUTZAR, B. RÖDER;
Univ. of Hamburg, Hamburg, Germany

Abstract: The extent to which atypical sensory experience early in life affects the subsequent development of multisensory interactions in humans remains largely unknown. In particular, although several studies have assessed the impact of a transient phase of congenital blindness on visual motion processing, no study has yet investigated its impact on multisensory interactions for motion processing. In the present study, we investigated this question by measuring visual and auditory motion aftereffects induced by adaptation to visual or auditory motion in a group of six cataract-reversal individuals (aged 16-43 years, M = 28.7, SD = 9.7, 4 females), in a group of 20 normally sighted controls (aged 15-63 years, *M* = 23.8, *SD* = 10.5, 10 females) and in a group of five visually impaired controls (aged 34-56 years, *M* = 43.0, *SD* = 7.9, 4 females). The results revealed no differences between groups in unisensory auditory motion aftereffects, in line with previous studies showing no differences in auditory cortical processing of auditory motion between sight-recovery individuals and normally sighted controls. By contrast, cataract-reversal individuals and visually impaired controls exhibited enhanced unisensory visual motion aftereffects, possibly indicating a higher visual cortical excitability in individuals who experienced some degree of visual deprivation. Most important, there were no significant differences between groups in visually-induced auditory motion aftereffects, indicating that visual motion signals were capable of influencing the perception of auditory motion in cataract-reversal individuals to a similar extent as in normally sighted controls and visually impaired controls. Yet, auditory-induced visual motion aftereffects occurred only in cataract-reversal individuals - but not in normally sighted controls or visually impaired controls -, indicating that only in individuals who lacked appropriate visual input early in life did auditory motion signals influence the perception of visual motion. In contrast to what has been reported for audio-visual speech perception, the present findings demonstrate a cross-modal influence of vision on audition for motion processing in individuals who recovered from a transient phase of congenital blindness. Additionally, only in congenital cataract-reversal individuals was visual motion processing influenced by auditory motion signals. Since this effect was motion direction specific,

we speculate about some possibly beneficial effects of cross-modal plasticity associated with the period of total blindness on visual recovery within the dorsal processing stream.

Title: Age-related hearing loss modulates functional connectivity between auditory and visual cortex

Authors: *S. PUSCHMANN, C. M. THIEL;
Univ. of Oldenburg, Oldenburg, Germany

Abstract: Previous work provided compelling evidence that a long-lasting auditory sensory deprivation leads to a cross-modal reorganization of auditory cortex, resulting in increased neural responses to non-auditory sensory input and changes in functional and structural connectivity to other sensory cortices. Recent data however indicate that such cross-modal neuroplastic changes may not only occur following severe and early-onset hearing impairments but rather also following moderate degrees of age-related high-frequency hearing loss (presbycusis). We here used functional magnetic resonance imaging (fMRI) to investigate how such potential cross-modal changes affect the processing of audiovisual information in older hearing-impaired subjects.
Older participants (N = 20, 61 ± 5 years) with a varying degree of high frequency hearing loss (high frequency threshold range: 10 - 67 dB HL) performed an auditory stimulus categorization task, in which they had to categorize rising vs. falling frequency-modulated tones presented alone or in the context of matching or non-matching visual motion. A motion only condition served as control for a visual take-over of auditory cortex.
BOLD response amplitudes as well as functional connectivity between auditory and visual cortex during audiovisual processing and at rest were analyzed as a function of high-frequency hearing thresholds. While hearing loss did not affect BOLD responses to auditory, visual, or audiovisual stimuli per se, we observed a significant hearing loss-related increase in functional connectivity between auditory cortex and the motion-sensitive visual area MT when processing matching audiovisual input. Similarly, resting state connectivity between area MT and auditory cortex

increased with hearing loss, suggesting a permanent, task-independent change in coupling between visual and auditory sensory areas with age-related hearing loss.
Our data provide first evidence for hearing loss-related changes in cross-modal functional connectivity in presbycusis. In line with the view that older hearing-impaired listeners tend to make use of additional visual motion cues, like lip-movements, to ease auditory comprehension in challenging listening environments, hearing loss specifically modulated the connectivity between auditory cortex and area MT, which is involved in visual motion processing, but did not affect auditory cortex coupling to earlier visual areas. Our results add up on the increasing evidence suggesting that cross-modal neuroplastic changes in the auditory system do not only occur in severe hearing impairments with early onsets, but also develop as hearing abilities decline in age.

Title: Mechanisms of Purkinje cell-dependent instructive signaling in the cerebellum

Authors: *A. BONNAN, J. RICHTER, C. A. BAKER, M. M. BOLTON, J. M. CHRISTIE; MPFI, Jupiter, FL

Abstract: The cerebellum is known to play a crucial role in motor learning. Purkinje cells (PC) give rise to the sole output of the cerebellar cortex and are therefore pivotal in this process. PCs can fire two different types of spikes: simple spikes (SS) in response to parallel fiber (PF) stimulation and complex spikes (CS) as a result of climbing fiber input. The CS is a multicomponent response that includes a burst of sodium spikes at the soma and a dendrite-wide Ca^{2+} transient. A classic theory of cerebellar function postulates that CFs carry instructive signals to PCs that guide learning. However, recent findings indicate that learning may occur independent of CF activity suggesting the existence of other candidate instructive signals. To study the mechanistic basis of instructive signaling, we used the vestibulo-ocular reflex (VOR), a compensatory eye movement in response to head motion that is subject to re-calibration through cerebellar-dependent plasticity. We used optogenetics to selectively manipulate PC activity during vestibular stimulation and probe for the consequences of this activity by examining the

gain of the VOR. Using subcellular targeting motifs to limit expression of channelrhodopsin to the PC soma, we were able to evoke activity either with or without dendritic Ca^{2+} influx during vestibular stimulation. We found that PC activity associated with dendritic Ca^{2+} was sufficient to induce a change in VOR gain after 30 min of pairing with vestibular stimulation. However learning did not occur when Purkinje cells were activated without a dendritic Ca^{2+} transient. Our results suggest that Ca^{2+} influx in PC dendrites is a key component for learning and point to PC dendrites as the initial site of plasticity as predicted by early theories.

Title: Synaptic learning rules in the cerebellum vary with the functional requirements of the circuit

Authors: *A. SUVRATHAN, H. L. PAYNE, J. L. RAYMOND;
Neurobiology, Stanford Univ., Stanford Univ., Stanford, CA

Abstract: The cellular anatomy is highly uniform throughout the cerebellum, and it has been widely assumed that the synaptic physiology is also uniform. In contrast, we report that the rules governing the induction of plasticity at an anatomically-defined type of synapse vary considerably across different regions of the cerebellum, in a way that appears to be tuned to the behavioral function.
In vivo, cerebellar climbing fibers encode errors during motor learning, and a single spike in a climbing fiber triggers a decrease in Purkinje cell firing on the next trial (Medina & Lisberger, 2008). We found a candidate synaptic mechanism at the parallel fiber-to-Purkinje cell (pf-PC) synapses *in vitro,* where a single pairing of parallel fiber and climbing fiber stimulation induced a transient depression of pf-PC synaptic strength. We show that both *in vivo* and *in vitro,* this single-trial plasticity is narrowly tuned for a climbing fiber delay of 120 ms, which precisely matches the delay in climbing fiber responses to errors during oculomotor learning. Although the

relationship between single-trial and long-term depression (LTD) is not fully understood, we found that LTD at these synapses had the same, stringent timing requirements for induction as the single-trial plasticity.
The timing requirements for plasticity in the cerebellar flocculus are unlike those described previously anywhere in the brain. There is a narrow window for association (tens of milliseconds), as observed for spike timing dependent plasticity (STDP), but, unlike STDP, this window is offset from coincident by >100ms. The properties of LTD at the pf-PC synapses in the flocculus are also unlike what has been described previously in other regions of the cerebellum. In the vermis, for example, which supports a range of functions, the pf-PC synapses have been reported to undergo LTD in response to a broad range of climbing fiber delays. Our analysis of single-trial plasticity at pf-PC synapses in the vermis suggests that different cells are tuned for different climbing fiber delays, so that the population average appears broadly tuned.
Our results demonstrate that cerebellar synaptic plasticity at parallel fiber-to-Purkinje cells synapses does not follow uniform rules for induction, but varies across functionally distinct regions of the cerebellum, and that the rules in the flocculus are precisely tuned to the functional requirements of the oculomotor learning it supports.

Title: Cerebellar cortex mechanisms supporting extinction and reacquisition of conditioned eyelid responses at different inter-stimulus intervals.

Authors: *H. E. HALVERSON, A. KHILKEVICH, M. D. MAUK;
Ctr. for Learning and Memory, Univ. of Texas At Austin, Austin, TX

Abstract: The cerebellar cortex is necessary for expression and extinction of properly timed conditioned eyelid responses (CRs) at different inter-stimulus intervals (ISIs). Cortical involvement in expression of CRs is clear, the mechanisms within the cortex supporting subsequent extinction and reacquisition of CRs at different ISIs have not been described.

Relating changes in Purkinje cell (PC) and molecular layer interneuron (MLI) responses to the rate of extinction and reacquisition of CRs at different intervals is necessary to establish the cerebellar rules governing these processes. Time demands at different ISIs could lead to different interactions between PCs and MLIs and the rate of CR extinction observed at short and long intervals. Before training a 12 tetrode hyperdrive array was implanted dorsal to the ipsilateral (to the trained eye) anterior lobe. Neuronal activity was recorded during initial CR expression and extinction with delay conditioning using a 550 ms tone conditioned stimulus (CS) and 50 ms periorbital shock (2-3 mA) unconditioned stimulus (US). After initial training with a 500 ms ISI, shorter (ISI 250) and longer (ISI 750) intervals were used to investigate interactions between PC and MLI responses during extinction and reacquisition. Eyelid PCs were identified by the presence of short latency US-evoked complex spikes. Eyelid MLIs were identified by a two step process using baseline firing properties and correlation with eyelid CRs. Reacquisition at longer ISIs would often show CRs with onsets that matched previous training at shorter ISIs early within a session. These CRs influenced by previous short ISI training would extinguish during the session. Extinction of CRs at longer intervals (ISI 500 and above) was faster than at shorter ISIs. Activity of eyelid PCs and MLI tracked CRs closely during extinction at longer ISIs and were more variable at shorter ISIs. These results suggest that time demands on the cerebellum during extinction lead to increased variability between PCs, MLIs and the rate of extinction of eyelid CRs.

Title: Zebrin positive and negative Purkinje cells in the vestibulocerebellum of pigeons differ with respect to the degree of modulation in response to optic flow stimuli.

Authors: *R. LONG[1], J. M. P. PAKAN[2], D. J. GRAHAM[3], D. R. WYLIE[4];
[1]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [2]Ctr. for Integrative Physiol., Univ. of Edinburgh, Edinburgh, United Kingdom; [3]Lervig Aktiebryggeri, Stavanger, Norway; [4]Neurosci. and Mental Hlth. Inst., Edmonton, AB, Canada

Abstract: Zebrin II (ZII, the isoenzyme aldolase C) is heterogeneously expressed by cerebellar Purkinje cells (PCs), such that there are alternating sagittal stripes with high ZII immunoreactivity (ZII+) interdigitated with stripes where PCs show little or no ZII immunoreactivity (ZII-). Within the vestibulocerebellum (VbC) in pigeons (Columba livia), it has been shown that a ZII+/- stripe pair constitutes a functional unit, in so far as the complex spike activity (CSA) of all Purkinje cells in the stripe pair prefer the same type of optic flow stimuli (see Figure). In this report we show that ZII+ and ZII- Purkinje cells show differences in the depth of modulation to optic flow stimuli. We recorded the CSA of Purkinje cells in the VbC of anesthetized pigeons in response to large (90^o horizontal X 75^o vertical) drifting sine wave gratings moving in 8 different directions (45^o apart). For all recordings, the stimulus was centered in the frontal part of visual field, and the spatial and temporal frequency were kept constant (0.5cpd, 0.5Hz). At some recording sites we made a small injection of a fluorescent tracer. At the end of the experiment, the pigeons were perfused, the brains extracted, sectioned, and processed for ZII. In this way we determined the ZII signature of each CSA recording site. The recordings were analyzed offline using Spike2 and individual cells were isolated based on waveform shape and amplitude. Direction tuning curves were constructed using SigmaPlot. We found that the depth of modulation was greater for the ZII+ Purkinje cells ($p<0.001$): the CSA was greater to motion in the preferred direction, and there was greater inhibition to motion in the anti-preferred direction. We suggest that the difference in modulation is due to a feedback mechanism to the inferior olive from the ZII+ Purkinje cells. The ZII+ Purkinje cells tend to project to areas of the vestibular nuclei that in turn project to the areas of the inferior olive giving rise to climbing fibres to those Purkinje cells. The ZII- Purkinje cells tend to project to areas of the vestibular nuclei that do not project back to the inferior olive.

Title: Two-photon imaging reveals long-term changes in cerebellar granule cell responsiveness following high-frequency mossy fibers stimulation

Authors: M. TOGNOLINA[1], L. MAPELLI[1], *E. D'ANGELO[1,2];
[1]Univ. of Pavia, 27100 Pavia, Italy; [2]Brain Connectivity Center, C. Mondino, Pavia, Italy

Abstract: The investigation of the spatiotemporal organization of neuronal activity in local microcircuits requires simultaneous and fast recordings from multiple neurons with a single-cell resolution. Although this can be obtained through optical techniques, a parallel signals detection requires the presence of multiple confocal excitation volumes that cannot be achieved through traditional confocal and two-photon microscopy. The use of a Spatial Light Modulator (SLM) to divide a coherent excitation light in multiple diffraction limited focal points, which can be configured in different patterns, enabled us to perform optical recordings from different neurons simultaneously. We recently developed an SLM-two photon microscope (SLM-2PM) able to resolve the spatiotemporal organization of activity in acute cerebellar slices through simultaneous calcium signal acquisitions from multiple granule cells (Gandolfi et al., 2014). The SLM-2PM was optimized to investigate the effect of a mossy fibers high-frequency stimulation protocol (HFS), that is known to induce long-term potentiation and depression (LTP and LTD) in the cerebellum granular layer. HFS indeed caused long-term changes of granule cells calcium responses (Ca-LTP and Ca-LTD) with impressive variations in signal amplitude (Ca-LTP +351.81±19.14% n=25, Ca-LTD -62.86±1.77% n=19, 30 min after HFS). Loose cell-attached patch-clamp recordings were performed in order to elucidate the underlying mechanisms. The signal variation during Ca-LTP and Ca-LTD showed a similar dependency on the pre-stimulation state as observed with loose cell-attached and local field potential measurements (Mapelli and D'Angelo 2007, Sola et al. 2004). Interestingly, Ca-LTP amplitude changes were several times larger than those reported for synaptic currents measurements (D'Errico et al. 2009). The amplitude changes observed in Ca-LTP could be explained by a combination of changes in granule cells intrinsic excitability and synaptic transmission leading conjointly to a large increase in the probability of spike generation (Armano et al., 2000).

Title: What do the cerebellar parallel fibers do? A 40 year history of controversy and denial.

Authors: *J. M. BOWER;
Numedeon Inc., Ashland, OR

Abstract: Almost 40 years ago, as a first year graduate student newly joining the laboratory of Dr. Wally Welker at the University of Wisconsin, I had an idea for an experiment. Using high-density micro-electrode mapping techniques, Dr. Welker and his colleagues had recently discovered an unusual 'fractured' pattern of tactile afferent projections to the granule cell layers of the lateral hemispheres of the rat cerebellum. The maps were of a finer grain than any previously recorded and immediately suggested that overlying Purkinje cells would respond, via the parallel fibers, to tactile inputs originating from many locations on the body surface. Accordingly, I proposed that my thesis be based on constructing an equally fine-grained map of Purkinje cell activity in response to the multiple different types of tactile inputs projecting to the granule cell layer. In my thesis proposal I suggested that this experiment would be the first *in vivo* study using peripheral stimuli, to examine the expected parallel fiber beams of activated Purkinje cells and would therefore, allow direct study, for example, of the Marr/Albus theory of parallel fiber learning. Unfortunately, the Purkinje cell responses recorded in those experiments strongly and surprisingly suggested that parallel fibers did not directly drive Purkinje cell output and therefore, that theories like Marr/Albus theory that are based on strong parallel fiber inputs can not be correct.
This poster presentation will consider the ensuing almost 40 year effort to ignore, discount, obfuscate or dismiss this basic experimental result, as well as present the accumulated experimental data suggesting that the original result was in fact correct. The poster will also consider the implications of these results for theories of cerebellar function, like that of Marr/Albus, while also raising the epistemological question as to how neurobiologists can hope to make progress in understanding a structure as complex as the human brain, if they are unwilling, over 40 years, to question core assumptions about the structural organization of the circuits they study. The poster will also consider the benefits and risks of top down theories in directing experimental research as well as the potential importance and use of "bottom up" models in understand unexpected experimental results. Finally, the poster will describe a particular model-based hypothesis for what the parallel fibers may in fact be doing.

Title: Diacylglycerol kinase gamma contributes cerebellar motor coordination through regulation of protein kinase C

Authors: R. TSUMAGARI[1], S. KIKUNAGA[1], Y. FUJIHARA[2], M. IKAWA[2], S. UEDA[1], M. YAMANOUE[1], S. KAKIZAWA[3], H. HARA[4], *Y. SHIRAI[1];

Abstract: Diacylglycerol kinase (DGK) is an enzyme that converts diacylglycerol to phosphatidic acid, and can attenuate PKC activity. So far, 10 subtypes of mammalian DGKs have been identified. Among them, DGKγ is abundantly expressed in neuron, especially in cerebellar Purkinje cells. PKCγ is also expressed there and involved in cerebellar motor coordination and the morphological control of Purkinje cells. PKCγ directly interacts with and phosphorylates DGKγ. Therefore, it is expected that DGKγ has important roles in cerebellar motor coordination and the morphology of Purkinje cells. However, the function of DGKγ in neuron is still unknown. So, we developed DGKγ knockout (KO) mice and tested their cerebellar motor coordination in rotarod test. DGKγ KO mice significantly fell in a short time compared to WT, suggesting the impairment of motor coordination. Next, we investigated the morphology of cerebellar Purkinje cells by Golgi staining to explore the mechanism underlying the impairment of motor coordination. The numbers of branches of cerebellar Purkinje cells decreased in the KO mice. In addition, the numbers of branches and length of dendrites in the primary cultured Purkinje cells from the KO mice significantly decreased, and the abnormality was rescued by PKC inhibitor, GF109203X, treatment. Furthermore, the phosphorylation of PKCγ was elevated in cerebellum from KO mice. These results suggested DGKγ contributes cerebellar motor coordination through regulation of PKC.

Title: Evaluation of roles of cerebellar Golgi and basket/stellate cells in the vestibuloocular reflex motor learning: a computational study

Authors: *K. INAGAKI, Y. HIRATA;
Chubu Univ., Kasugai / Aichi, Japan

Abstract: The vestibuloocular reflex (VOR) is one of the most popular model systems to study motor learning due to its clear function (stabilization of our vision) and ease in recording its input (head rotation) and output (eye movement) signals. The motor learning of the VOR requires the cerebellar flocculus. The flocculus receives sensory and motor information via mossy and climbing fibers, and outputs motor related activities to vestibular nuclei via Purkinje cell axons. Between these inputs and outputs lies a neuronal network containing rich inhibitory interneurons such as Golgi, basket, and stellate cells. While most of the previous studies on VOR motor learning have focused on responses of Purkinje cells, little attention has been paid to roles of cerebellar inhibitory interneurons due to a difficulty in identifying and recording those neurons in cerebellar cortex in behaving animals. Herein, we have constructed a computational model of the VOR that explicitly implements the anatomically realistic floccular neuronal network structure so that activities of each inhibitory interneuron can be evaluated. The model also allows us to knock-out any specific interneuron(s) at any timing of VOR motor learning. The model consists of 20 Purkinje, 10K granular, 900 Golgi, and 60 basket/stellate cells each of which is described as an integrate and fire spiking neuron model. These neuron models are connected, preserving convergence/divergence ratios between neuron types (Inagaki et al, 2011). As bases of VOR motor learning, climbing fiber spike timing dependent LTD and LTP have been implemented at parallel fiber - Purkinje cell synapses. We first confirmed that the model reproduces quantitatively eye velocities and Purkinje cell simple spike firing modulations during various visual-vestibular mismatch experiments in naïve monkeys, and simulated successfully changes in Purkinje cell activities along with VOR gains after prolonged exposure to VOR gain up and down paradigms. We then knocked-out Golgi or basket/stellate cells during various visual-vestibular mismatch experiments. As predicted, both granule and Purkinje cell DC firing rates increased after knocking-out Golgi cells, while only Purkinje cell DC firing rate increased

after basket/stellate cells knock-out. Interestingly, VOR gain before motor learning was affected neither by knocking-out Golgi cells nor basket/stellate cells. These results suggest that the interneurons play little role in maintenance of normal VOR, and its major role may be in acquisition of new VOR gains.

Title: Training to induce adaptation of optokinetic response suppressed long-term depression in the cerebellar flocculus of mouse

Authors: *T. INOSHITA, T. HIRANO;
Kyoto Univesity, Sakyo-Ku, Kyoto, Japan

Abstract: Long-term depression (LTD) at parallel fiber to Purkinje cell (PF-PC) synapses in the cerebellum has been regarded as a main mechanism for motor learning. Previous studies showed the necessity of LTD in motor learning by blocking pathways involved in LTD induction. However, some of reported motor learning failures might have been caused not by LTD deficiency but by other defects in the cerebellar function. In addition, normal motor learning under LTD suppressed conditions was reported. Thus, contribution of cerebellar LTD to motor learning has been debated. In order to address this issue in a different aspect, we have tried to clarify whether LTD occurred at PF-PC synapse during motor learning in the cerebellum. Adaptation of oculomotor reflex has been widely used as a model of cerebellum-dependent motor learning. Optokinetic response (OKR) is a type of oculomotor reflex, and works to stabilize an image on the retina during movement of a visual field. In order to induce OKR adaptation, we applied sinusoidal horizontal rotation of a screen with vertical stripes for an hour. During the training, eye movement got faster to catch up the screen movement better. Cerebellar flocculus is a regulation center of oculomotor reflex and H-zone in the flocculus regulates horizontal OKR, whereas V-zone regulates vertical OKR. After the OKR adaptation training of an adult mouse (from 8- to 10-weeks old), we prepared slices from the flocculus and performed whole-cell patch-clamp recording from Purkinje cells in H-zone of the flocculus. We failed to induce LTD in slices of flocculus prepared from OKR-trained mice, whereas LTD was

successfully induced in those from untrained mice. There was no significant difference in paired pulse ratio of EPSCs at PF-PC synapses, suggesting presynaptic release probability was not altered by the training. These results suggest that LTD occured at PF-PC synapses in H-zone of the cerebellar flocculus during OKR adaptation training.

Title: Using eyelid conditioning to study the learning of movement sequences by the cerebellum

Authors: *A. KHILKEVICH, L. NGUYEN, M.-M. RICHARDS, J. ZAMBRANO, M. D. MAUK;
Ctr. for Learning and Memory, Univ. of Texas At Austin, Austin, TX

Abstract: The cerebellum is necessary for precise performance of temporally complex motor tasks, such as sequences of movements. However, in common motor tasks several brain regions are involved, which makes it hard to isolate the specific cerebellar contribution. Eyelid conditioning is a well-establish cerebellar-dependent paradigm, where the movement (conditioned response, CR) is entirely driven by the cerebellum. Here we developed a new eyelid conditioning training protocol to study how sequences of movements are learned and generated by the cerebellum. During the surgery rabbits were implanted with stimulation electrodes in the middle cerebellar peduncle and mossy fiber stimulation was used as a conditioned stimulus (CS). Previous studies (Kalmbach et. al 2009) have established that if the temporal gap between the offset of mossy fiber stimulation CS and the onset of US is larger than 400 ms, animals are not able to learn using mossy fiber stimulation as the CS. Using this knowledge, experiments were designed to train animals to produce a series of CRs and to determine whether the expression of a CR can serve as the CS for a subsequent CR. For that, rabbits were first trained at ISI 500 ms with CS also lasting 500 ms. After acquiring stable CRs, animals presented training sessions with the same CS (500 ms), but with two potential times for US: US_1 at CS offset and US_2 at 600 ms from CS offset. On a given trial, if eyelid position value at time 499 ms from CS onset was lower

than the target (3mm, half-sized CR), US_1 was presented to maintain robust responding of the first CR. If it was higher than the target, US_1 was omitted and US_2 was presented. All rabbits successfully acquired dual-peak CRs with the timing of the second peak appropriate for US_2. That result suggests that the cerebellum uses the first CR as the "CS" for the next CR, as the mossy fiber stimulation CS is not able to support learning with a 600 ms gap between CS offset and US_2. Results from several control experiments further support this notion. Additionally, we have successfully used this paradigm to train animals to produce a left eye CR -> right eye CR sequence. For both paradigms, times of first and second CR onset and peak show very high ($r > 0.8$) trial-to-trial correlation, consistent with the first CR serving as the CS for the second CR. Recordings from Purkinje cells with US evoked complex spikes show that the first and second CRs and encoded in the same way by the cerebellar cortex. In sum, our results provide a clear demonstration that the cerebellum can use the information about the first part of the movement to learn the next one.

Title: Climbing fibers reset Purkinje cell representations of behavior

Authors: M. L. STRENG, L. S. POPA, *T. J. EBNER;
Neurosci., Univ. Minnesota, Minneapolis, MN

Abstract: The cerebellum is essential for online motor control. Requisite for elucidating the principles of cerebellar function is an understanding of the interaction between the two main excitatory inputs to Purkinje cells: climbing fibers and parallel fibers, which trigger and modulate complex spike (CS) and simple spike (SS) discharges, respectively. Although several

hypotheses have provided insights into the interaction between SS and CS discharges, including error encoding, altering responsiveness to parallel fiber inputs, and movement timing, none fully explain or are completely consistent with the spectrum of experimental observations. To address this, we evaluated the modulation of SS motor signals by climbing fiber input during a manual, pseudo-random tracking task. Accurate performance on this task requires continuously monitoring the constantly changing salient behavioral parameters and adjusting for mismatches in hand movement relative to target movement, and we have previously shown that SS firing contains predictive and feedback representations of these limb kinematics and performance errors during pseudo-random tracking.
The hypothesis that climbing fiber discharge alters signaling in the SS firing was tested by assessing the SS encoding strength for position (X and Y), velocity (VX and VY) and position error (XE and YE) before and after CSs using temporal linear regression analysis. Additionally, we assessed for changes in the mean behavior and SS firing rates pre and post-CS, as well as any evidence for CS rhythmicity. We find that climbing fiber discharge dynamically controls the information present in the SS firing, triggering robust and rapid increases and decreases in the SS encoding of motor signals in nearly all of the 40 Purkinje cells (> 90%). The increases and decreases in encoding are not due to differences in SS firing rates or behavior before or after a CS. Nor can the changes in encoding be attributed to any intrinsic CS rhythmicity. Our results suggest a novel hypothesis about the function of CSs, in which climbing fiber input resets the Purkinje cell from its current encoding state to one better matched to or dictated by the present conditions. The CS-coupled changes in SS encoding demonstrate that the representation of motor information is dynamic, focusing on the most task-relevant information and provide a novel neural correlate in support of the view that the motor system processes and uses different behavioral parameters to meet task requirements.

Title: Modulating modulation: Purkinje cell activity in impaired and enhanced compensatory eye movement adaptation

Authors: *M. SCHONEWILLE[1], H. ZHOU[1], T. KOUDSTAAL[2], C. I. DE ZEEUW[2];
[2]Neurosci., [1]Erasmus MC, Rotterdam, Netherlands

Abstract: Identifying the neural code underlying the process of learning in the brain is one of the main challenges in neuroscience today. In cerebellar motor learning several plasticity mechanisms have been identified to contribute to the adaptation of behavior, but the weight of each contributor, and how they are integrated in neural code remains unclear. Here, we recorded the activity of Purkinje cells, the output neuron of cerebellar cortex, prior to, during and directly following an eye movement training session. For optimal correlation, we compared the activity to that obtained under conditions of impaired and enhanced learning. We demonstrate a direct correlation between Purkinje cell activity and behavior, strengthened by the potential to rescue impaired learning with learning enhancers. Our results indicate that both rate and spatiotemporal coding contribute to cerebellum-dependent learning.

Title: Purkinje neurons in action: From single cells to ensembles

Authors: *M. SENGUPTA, V. THIRUMALAI;
Natl. Ctr. For Biol. Sci., Bangalore, India

Abstract: The cerebellum is critical for motor learning and is present in all vertebrates. Purkinje neurons (PNs) in the cerebellum are key contributors to the functions of the cerebellum and have been extensively studied. One prominent question has been whether these neurons exhibit bistability *in vivo*. Using the fact that the cerebellum is structurally conserved in vertebrates and that zebrafish larvae are highly amenable to *in vivo* electrophysiology, we performed targeted whole cell patch clamp recordings from un-anaesthetized larval zebrafish Purkinje Neurons and showed for the first time, that these neurons were spontaneously active and showed two modes of activity, tonic spiking and bursting. Moreover, the bursts during the bursting mode were driven preferentially by Climbing Fiber (CF) EPSPs. Finally, to further determine the functional implications of this activity, we recorded fictive motor signals extracellularly from the tail while simultaneously whole-cell patching Purkinje neurons. We showed that the bursting activity in these neurons correlated well with motor bouts but the latencies of the bursts to the onset of the motor bout varied within and across cells. Accordingly, we propose that these neurons encode a distributed representation of an efference copy.
To determine if these neurons indeed show a distributed code, we need to monitor populations of neurons at the same time by using calcium indicators. Zebrafish Purkinje neurons have been previously studied using calcium activity imaging in the context of the optomotor response (Ahrens *et al*.2012, Matsui *et al*.2014), however the physiological basis of this activity has not been determined. Our latest experiments therefore involve calcium imaging in single Purkinje neurons while simultaneously patching from them. Our data shows that the dendrites are more active than Purkinje somas. This activity correlates well to CF driven bursts and calcium spikes in these cells but not to tonic sodium spiking. Ensembles of Purkinje neurons recorded simultaneously with fictive motor bouts also show distributed activity.
Future experiments are aimed at studying the same in the context of motor learning.

Title: Enhanced intrinsic excitability in cerebellar Purkinje cells following delay eyeblink conditioning in mice

Authors: *H. TITLEY[1], G. V. WATKINS[1], C. LIN[2], G. GRASSELLI[1], C. WEISS[2], J. F. DISTERHOFT[2], C. HANSEL[1];
[1]Dept. of Neurobio., Univ. of Chicago, Chicago, IL; [2]Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: Cerebellar learning is classically assumed to depend on synaptic plasticity mechanisms, such as long-term depression (LTD) or potentiation (LTP), although it is now suspected that other mechanisms are involved, too. One such candidate mechanism is non-synaptic intrinsic plasticity in Purkinje cells. Intrinsic plasticity depends on a down-regulation of calcium-dependent SK-type K channels, and in the hippocampus it is known to play a role in the learning of trace eyeblink conditioning. However, it remains unknown to what extent Purkinje cell intrinsic plasticity contributes to the memory engram following a cerebellar learning task. Here we show that after delay eyeblink conditioning, Purkinje cells in lobule simplex / lobule HVI were more excitable than controls consistent with an increase of intrinsic excitability. Whole cell recordings were obtained from acute cerebellar slices from mice 48 hours after the final training session. Groups of mice received over a period of repeated training sessions either distinctly paired trials of a tone co-terminating with a periorbital shock (conditioned mice), unpaired trials of only a tone or a shock (pseudoconditioned mice) or neither a tone or a shock (naïve mice). We found that Purkinje cells from conditioned mice had a higher spontaneous firing rate than cells from controls, and were more excitable in response to gradually injected currents. Furthermore, following the stimulation of parallel fibers or climbing fibers, the Purkinje cell responses from conditioned mice were more excitable showing a greater depolarization, increased number of spikes and complex spike spikelets and a reduced afterhyperpolarizaton. This increase in excitability may suggest that SK-dependent intrinsic potentiation occurs during eyeblink conditioning, as the conditioned mice also show reduced excitability changes following the application of an intrinsic plasticity protocol, suggesting that this mechanism may be saturated in conditioned mice.

Title: Role of the cerebellum in the initiation and termination of predictive optokinetic behavior in goldfish

Authors: S. MIKI[1], *R. BAKER[2], Y. HIRATA[1,3];
[1]Computer Sci., Chubu Univ. Grad. Sch. of Engin., Aichi, Japan; [2]Physiol. and Neurosci., New York Univ. Langone Med. Ctr., New York, NY; [3]Robotic Sci. and Technol., Chubu Univ. Col. of Engin., Aichi, Japan

Abstract: Optokinetic reflex (OKR) tracking is induced by the presentation of large field visual motion in nearly all vertebrate species. In response to visual velocity step stimuli the OKR exhibits two components: an initial rapid jump of eye velocity termed the "Direct" component, and a subsequent gradual rise termed the "Indirect" component (Cohen et al., 1977). Repetitive presentation of a visual velocity step stimulus induces OKR gain adaptation showing both an increase of the "Direct" component and a shorter time constant for the "Indirect" build-up (Marsh and Baker, 1997). When the repetitive visual velocity step stimulus is periodic with fixed ON/OFF periods, the OKR acquires a predictive behavior in which eye velocity starts to decrease before the termination of the stimulus ON period. This "Termination" component was first described in goldfish (Marsh & Baker, 1997), and later observed in carp and human (Miki et al., 2015). Herein, this predictive OKR behavior was further characterized by using periodic and non-periodic visual velocity step stimuli, and then the roles of the cerebellum were investigated by conducting acute and chronic cerebellectomy before and after the acquisition of the predictive behaviors. Goldfish were centered in a cylindrical water tank with eye coils binocularly placed on the cornea for eye position measurement by the search coil technique. In the periodic condition visual stimulation was projected onto tank wall and rotated clockwise at 20 deg/s for 8 seconds (ON period) and stopped for 8 seconds (OFF period). In the non-periodic condition, either the ON or OFF period was randomized between 1 and 15 seconds. After three hours of this visual paradigm in the periodic condition, eye velocity was observed to begin to increase significantly before initiation of the ON period. By contrast this "Initiation" component was not observed in the non-periodic condition. In chronically cerebellectomized goldfish using the periodic stimuli, there was no change in any of eye velocity parameters, i.e. the "Direct", "Indirect" "Termination" and "Initiation" components. In acutely cerebellectomized fish after periodic training, the adapted "Direct", "Initiation" and "Termination" components were lost, but some of the learned "Indirect" component remained. These results demonstrate that the cerebellum is required for both the acquisition and maintenance of the increased "Direct" component as well as the predictive "Initiation" and "Termination" of OKR tracking. Thus, the cerebellum appears necessary for acquiring the "Indirect" build-up, but maintenance of this component is not completely cerebellar dependent.

Title: Olivary Inputs to Zebrin stripes in the pigeon uvula: A retrograde study.

Authors: *D. WYLIE[1], I. CRACIUN[2];
[1]Dept. of Psychology, [2]Neurosciences and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada

Abstract: In the uvula of pigeons there are parasagittal zones defined with respect to the innervation of climbing fibers (CFs), the projection patterns of Purkinje cell (PC) outputs, and the response properties of PC complex spike activity (CSA) to "optic flow" stimuli. Additionally, the molecular marker zebrin II (ZII) is heterogeneously expressed in PCs such that there sagittal stripes of PCs with high ZII expression (ZII+), alternating with sagittal stripes of PCs with little to no ZII expression (ZII-). Previously we have shown that a ZII+/ - stripe pair in the uvula constitutes a functional unit, insofar as the CSA of all the ZII+ and ZII- PCs within the stripe pair prefer the same type of optic flow stimuli. As shown in the figure (left), there are three functional units in the uvula: (1) a medial ZII+/- pair where all PCs respond best to "contraction" optic flow; (2) an adjacent stripe pair where the PCs respond to either "expansion" or "ascent" optic flow patterns; and (3) a lateral stripe pair where all PCs respond best to "descent" optic flow. Although we have established that a ZII+/- stripe pair delineates a functional unit, other research, mainly in rodents, has emphasized ZII+ and ZII- bands receive input from different subnuclei of the inferior olive (IO). We carried out a retrograde tracing study to determine whether the ZII+ and ZII- bands of a stripe pair in the pigeon uvula receive differential input from the IO as opposed to input from the same area of the IO. Fluorescent Cholera toxin B (CTB) of different colours (red and green) was injected into ZII+ and ZII- bands of functional stripe pair, and the distribution of retrogradely labeled cells in the IO was analyzed. We found that injections in the ZII+ and ZII- bands of stripe pair did not result in retrograde labelling in different subnuclei, rather, spatially separate, but adjacent regions were labelled (see Figure right).

Abstract: Cerebellar climbing fiber (CF) inputs to Purkinje cells carry critical error signals and/or timing signals for motor control and learning. Recent studies suggest that Purkinje cells also play an important role in cognitive functions. CFs separately project from the higher order cortices and the periphery through the inferior olive to longitudinal clusters of Purkinje cells (cerebellar stripes), which are characterized by the presence or absence of aldolase C/zebrin II expression. However, detailed functions of these CF inputs to each cerebellar stripe during acquisition of skilled behaviors remain unknown. Here, we investigated the sensorimotor and cognitive aspects of CF inputs to the distinct cerebellar stripes in the cerebellar hemisphere (Crus II) by using chronic *in vivo* two-photon calcium imaging in mice learning a go/no-go auditory discrimination task. The lateral part of the Crus II received CF inputs that coincided with auditory cue; those to zebrin positive (Z+) stripes were initially synchronized to both go and no-go cues then concentrated to the go cue after cognitive learning, while those to zebrin negative (Z-) stripes were timed only to the no-go cue, which deteriorated throughout learning. CF inputs to the medial stripes were less timed and nonspecific to cues and zebrin expression. Population decoding of CF inputs clarified stripe-specific changes in the representation of lick rate, lick onset, cues and trials along with improvements in motor and cognitive behaviors. Our results indicate that CF inputs to the cerebellar stripes have distinct contribution in motor and cognitive processing. Such differential and parallel processing of sensorimotor and cognitive information in the distinct cerebellar microcircuits may collectively sophisticate goal-directed behavior.

Title: Locomotor activity modulates delay eyeblink conditioning in mice

Authors: C. ALBERGARIA[1], T. N. SILVA[1], D. PRITCHETT[1], *M. R. CAREY[2];
[2]PT507131827, [1]Fundacao Champalimaud, Lisbon, Portugal

Abstract: In mice, locomotor activity modulates sensory responses across visual, auditory and somatosensory cortices. Here we show that locomotion also modulates behavioral performance in delay eyelid conditioning, a cerebellum-dependent form of classical conditioning. We monitored both eyelid closures and running speed in head-fixed mice running voluntarily on a running wheel. We found that increased locomotor activity was associated with earlier onset of learning and more frequent and larger amplitude conditioned responses. The correlation between running and learning was specific to conditioned (vs. unconditioned) responses. It held across animals, sessions, and trials, and for conditioned stimuli of various modalities. In contrast to the previously described modulation of sensory cortical processing, we found that the influence of locomotion on conditioned responses was dissociable from effects of arousal (as measured by changes in pupil size). Locomotor activity on a motorized treadmill also modulated learning in a speed-dependent manner, further suggesting that locomotor activity per se, rather than arousal, mediates the effect. To investigate the underlying neural circuit mechanisms, we used direct optogenetic stimulation of cerebellar mossy fibers as a conditioned stimulus. Conditioned responses elicited by optogenetic stimulation within the cerebellar cortex were also positively modulated by locomotor activity, indicating that enhanced upstream sensory processing cannot account for the modulation of the behavioral response. We conclude that locomotor activity modulates learned performance in delay eyelid conditioning through mechanisms that are distinct from those underlying modulation of sensory cortical responses and that act downstream of mossy fiber inputs to the cerebellar cortex.

Title: Corticotropin-releasing factor increases the excitability of deep cerebellar pojection neurons by modulating the HCN current

Authors: *A. M. LIBSTER, Y. YAROM;
Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Corticotropin-releasing factor (CRF) is a neuropeptide that plays a major role in stress response. CRF is also released from climbing fibers that originate in the inferior olive nucleus and innervate the Deep Cerebellar Nuclei (DCN). Previous studies have shown that neurons of the DCN express CRF receptors and their firing rate is modulated by application of CRF. In the present study, we focused on the effect exerted by CRF on firing properties of the Big Projection Neurons (bPNs), and investigated the underlying biophysical mechanisms.
In vitro whole-cell patch recording were performed from bPN somata in coronal slices of cerebellum (prepared from C57BL/6 mice > p35). CRF (1-3 μM dissolved in HEPES buffered solution) was either added to the bath solution or injected locally via a patch pipette.
CRF application increased the firing frequency of the bPN. Local application of CRF to the bPN somata generated a prolonged episode of spikes firing, with a latency of several seconds, superimposed on a membrane depolarization. This response lasted for several minutes and was dependent on CRF concentration. Local application of CRF in the presence of TTX, revealed a small depolarization of the membrane potential, accompanied by a decrease in membrane resistance. voltage clamp recordings, with cell membrane potential, clamped to -70mV, have shown an increase in inward current, in the presence of CRF. Furthermore, this increase of inward current was blocked in the presence of ZD-7288, an Ih antagonist. The results suggest that the mechanism, underlying the CRF effect on bPN, is most likely an increase of Ih conductance.

Title: Transcranial direct current stimulation delivered to the cerebellum affects the rate of fine motor learning

Authors: *J. K. SAMRA, R. E. SHIMIZU, A. D. WU, B. J. KNOWLTON;
UCLA, Los Angeles, CA

Abstract: The present study investigated the effects of cerebellar transcranial direct current stimulation (tDCS) on fine motor learning and subsequent performance on both practiced and novel motor sequence tasks. In the first study, participants practiced three distinct key press sequences presented in non-repeating, interleaved order while undergoing either anodal, cathodal, or sham stimulation. After the practice session, participants completed a transfer

session without receiving any stimulation; they practiced three novel sequences, also non-repeated and interleaved. Only those participants who received anodal stimulation during the practice phase showed evidence of sequence-specific learning (p = .033). Participants who underwent cathodal stimulation were significantly slower at performing the keypress task than participants in the anodal (p = .023) and sham (p = .024) groups. In the second study, a 24-hour delay was introduced between the practice and transfer sessions in an attempt to reduce potential fatigue caused by the practice session and stimulation. During this transfer session, participants who had received anodal tDCS during practice on the previous day showed significantly better transfer performance than those in the sham condition (p = .020). These results suggest that cerebellar tDCS can affect both the learning and performance of fine motor sequences. These results also suggest that anodal cerebellar tDCS during practice enhances the generalizability of the resulting motor programs.

Title: Is mild essential tremor detrimental to activities of daily living?

Authors: *E. GOUBAULT[1], H. NGUYEN[2], S. BOGARD[3], F. AYACHI[3], G. FAUCHER[3], N. ROOFIGARI[3], É. LE[3], C. DUVAL[3];
[1]Sci. of Physical Activity, Univ. of Quebec At Montreal, Montreal, QC, Canada; [2]Univ. of Quebec at Montreal, Montreal, QC, Canada; [3]Univ. of Quebec at Montreal, Montréal, QC, Canada

Abstract: Background & aims. A recent trend in clinical research is the use of inertial sensor-based systems (ISS) to capture and assess voluntary and involuntary movements during activities of daily living (ADLs). Such technology may eventually prove useful to determine when involuntary movements become detrimental to daily activities. We recently proposed that the impact of involuntary movements on the voluntary motor behavior can be assessed using a Signal to Noise Ratio (SNR) approach, where the success of an activity depends on the magnitude of the intended voluntary movement (signal) and the magnitude of the involuntary movement (noise) present during that task. The aims of this study were to detect essential tremor (ET) during ADLs using ISS and determine whether they have a deleterious influence on the performance of those ADLs. **Method.** Healthy control participants (N=27, Age=63.93 ±7.67

years old) and participants diagnosed with ET (N=15, Age=62.4 ±8.25 years old) were asked to perform twice 11 ADLs presented randomly (reading, counting money, cutting-eating, eating soup, taking medicine, drinking water, picking-up an object, standing-sitting, walking, walking and taking care of a glass of water, walking and passing over an obstacle) while equipped with 17 inertial sensors (Animazoo IGS-180) positioned on each body segment. Participants diagnosed with ET, were either treated (N=5) or not (N=10) and possessed mild visible tremors at the time of the experiment. Using healthy controls data, we set success criteria based on the number of errors, as well as the time required to do the task. The threshold of success for time was set at the mean of healthy control participants plus 3 standard deviations. Power spectral analysis was used to assess tremor magnitude during each task. Chi-square tests were used for each task to determine the differences of failure in the two groups. **Results.** Amplitude of tremors during ADLs varied between 0.0021 g^2/Hz (correspond to a UPDRS score of 0.5) and 0.0485 g^2/Hz (correspond to a UPDRS score of 2) (mean=0.0158 g^2/Hz ±0.0146 g^2/Hz) for ET participants. Frequency of tremors during ADLs varied between 4.30 Hz and 6.44 Hz (mean=4.96 Hz ±0.64 Hz) for ET participants. Chi-square tests revealed no significant differences between the two groups in failure proportion ($p \geq 0.074$). **Conclusion.** The results of this study suggest that patients having mild treated or untreated ET were able to perform ADLs as well as healthy controls.

Title: Cerebellar neuromodulation and predictive processing in motor, cognitive, and social domains

Authors: ***A. M. D'MELLO**, C. I. C. THOMAS, C. J. STOODLEY;
American Univ., Washington, DC

Abstract: The cerebellum is thought to optimize both motor and non-motor behavior through the formation of internal models that enable effective predictive processing. Previous studies have shown that the posterolateral cerebellum is active during predictive processing in a variety of

tasks, yet the exact role of the cerebellum in such tasks has yet to be established. The right posterolateral cerebellum is thought to be involved in complex motor sequence learning, language, and social cognition. We investigated predictive processing in motor, cognitive and social domains following cerebellar neuromodulation with transcranial direct current stimulation (tDCS). Fifteen healthy young adults (15 male; mean age 19.9 ± 1.9 years) participated in three sessions (sham, anodal, and cathodal tDCS) each separated by one week. During each session, participants received 20min of 2mA sham, anodal, or cathodal tDCS over the right posterolateral cerebellum (1cm down and 4cm to the right of the inion). After neuromodulation, participants completed three task paradigms, each with both non-predictive and predictive components: a serial response time task (SRTT), a sentence completion task, and a social ball-playing task. Task and modulation conditions were counterbalanced within and between participants. We hypothesized that cerebellar tDCS would impact performance on trials requiring implicit predictive processing across paradigms: implicit sequence learning on the SRTT; semantic prediction on the sentence completion task; and implicit learning of reciprocal partnerships in the social ball-playing task. As anticipated, preliminary results suggest that cerebellar tDCS affected behavior when implicit learning and predictive processing were necessary, including motor learning (Friedman $p=0.012$), time to complete sentences with different levels of semantic predictability (Friedman $p<0.01$), and a trend effect on implicit learning of "good" vs. "bad" reciprocal partners in the ball-toss game (Friedman $p=0.08$). These findings support the idea that the cerebellum has a domain-general role in predictive processing, likely due to the implicit acquisition of information relevant to performance in both motor and non-motor contexts.

Title: Effects of training on independent finger movements

Authors: *S. A. WINGES, P. ACHARYA;
Kinesiology, Louisiana State Univ., Baton Rouge, LA

Abstract: Sense of hand shape and kinesthesia in our fingers relies on a variety of somatosensory information from skin and joint receptors of the hand. Dexterous fingers movements rely on this sensory information to aid everyday activities such as fastening buttons or snaps of a garment, picking up coins, or typing. It is understood that extensive practice is

required to become exceptionally skilled at dexterous finger movements such as typing or playing a musical instrument. The aim of this study was to examine whether enhanced resistance during tapping movements can be used to improve independent finger movements. If successful this could be a simple method to retrain these finger movements in individuals who have reduced dexterity. In healthy adults, individuated movements of middle, ring and little fingers are usually difficult to produce and simultaneously subjected to complementary or opposing movements of the adjacent digits. Thus we focused our study on training independent tapping movements of the middle, ring and little fingers in healthy individuals. Participants completed a handedness inventory and a questionnaire to assess what type of dexterous hand and finger movements they typically performed and if they had any particular hand and/or finger movement training. All participants were right-handed and performed tapping tasks with both their dominant and non-dominant hand. A flexible tape was used along the dorsal length of the finger during training. The task involved participants tapping one finger (instructed) for a period of twelve seconds. Individuated finger movements (Index, Middle, Ring, Little) were recorded using active markers (Codamotion 3D motion analysis system) placed on the distal end of each finger. Tapping movements during the central ten seconds of each trial were analyzed. Non-instructed finger movements were computed as the percentage of the displacement of the instructed finger movement. Non-instructed movement was largest for the Middle and Ring fingers prior to training and remained the largest after training as well. For some participants, by the end of training, the extent of non-instructed movement decreased below the pre-training levels although this effect was not sustained in the post test. It was concluded that this method may be effective but longer or multiple training sessions may be required to see sustained changes in non-instructed digit movement.

Title: Apparently purposeful variability in joint kinematics and fingertip forces during one- and two-digit manipulation

Authors: *B. B. EDIN;
Physiol. Section, Integrative Med. Biol., Umeå Univ., Umeå, Sweden

Abstract: Low variability is the hallmark of well-trained motor behaviors and this partly results from learning to cope with motor and sensory noise, i.e., that both the efferent output and the sensory signals that provides state and feedback information are inherently noisy. It has even been claimed that practically all human motor behaviors – from eye movements to hand trajectories – can be explained by optimal control models that minimize the impact of sensory and motor noise (Harris & Wolpert, 1998; Faisal et al 2008). There is, however, a kind of substantial variability at the actuation level that is unaccounted for by proposed models of motor learning (Van Beers 2009; Baddeley et al 2003; Diedrichsen 2005). For instance, Stimpel (1933) reported that when humans throw a ball towards a target, the dispersion of the elbow angle and release velocity are substantially larger than that of the final position hit by the ball. In the same vein, Bernstein (1967) described the highly variable trajectory of hammering movements by a blacksmith despite skillful target hitting.
We let participants pull and push an object using either the index finger or both the index and middle finger while recording the object's position and velocity, the fingertip forces, and the finger joint angles. No constraints were imposed on the kinematic or kinetics of the task but the timing of individual pull-push movements was provided by auditory cues. Series of pull-and-push movements were performed with different surface friction while the servo-controlled object emulated either viscosity or inertia.
The participants solved the task in highly idiosyncratic manners, e.g., increased the surface normal force or decreased the applied surface tangential force with decreasing surface friction. In contrast, the intrasubject variability was low in terms of the "objective task". Importantly, despite this low task variability, all participants showed a marked variability from trial-to-trial with respect to both joint kinematics and how the surface tangential force was partitioned between the digits. Moreover, the kinematics and kinetics did not covary.
Three possible reasons for this variability are proposed: (1) to counteract fatigue; (2) to keep sensorimotor transformations updated; and (3) to allow explorations of behaviors that may be useful under kinematic restrictions or when managing perturbations.

Title: Factors affecting cognitive-motor integration impairment and recovery in children post-concussion

Authors: *M. DALECKI[1], D. GORBET[2], A. MACPHERSON[1], L. E. SERGIO[2];
[1]Sch. of Kinesiology and Hlth. Sci., [2]Sch. of Kinesiology and Hlth. Science, Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Cognitive-motor integration (CMI) is required to perform rule-based visuomotor transformations, for example, when the spatial locations of the guiding sensory information and required motor action differ. We previously observed prolonged CMI deficits in children with a history of concussion who were classified as asymptomatic by current return to play protocols (Dalecki et al. 2016). In the current study, we examine factors that may influence the decline and recovery of CMI performance in children with a history of concussion.

Sixty-four children with a history of concussion (mean 14 months post-concussion; mean age 13 yr) and sixty-two age-matched controls with no previous concussion performed two eye-hand coordination tasks. In the direct interaction task, participants slid their finger on a touch screen to move a cursor from a central target to one of four peripheral targets. In the CMI task, targets were in a different plane from hand motion, and feedback was 180° reversed (i.e. decoupling between vision and action). We analyzed movement timing and trajectory variables, as well as the effects of age, sex, and sports experience (years of play).

In agreement with our previous study, we observed significant CMI movement timing and execution deficits in children with a history of concussion, and a significant relationship between the time since last concussion and CMI performance. In addition, in children with a concussion history, we found a significant relationship between CMI performance and sport experience, such that children with concussion history and higher sport experience outperformed those with concussion history and lower sport experience. Both effects were not present in the control group and could not be attributed to a general effect of age or sex. Furthermore, children with concussion history and higher sport experience had quicker CMI recovery times compared to their lower sport experience peers.

These results indicate an important role of sport experience in recovery from concussion, and are in line with other studies from our lab showing CMI deficits in young varsity athletes but fewer deficits in young elite athletes with a concussion history (Brown et al. 2015; Hurtubise et al. 2015). We suggest that children and young adults with a concussion history but higher sport experience have more motor skill-related neurological reserves. This reserve may in turn reduce CMI performance declines and improve CMI recovery post-concussion. Imaging studies suggest the neural correlates of these reserves exist in more efficient fronto-parietal networks, which are known to heavily contribute to CMI.

Title: Perception and motor control rely on different spatial reference frames.

Authors: *O. L. BOCK, N. A. BURY;
German Sport Univ., Koln, Germany

Abstract: We have reported before that in absence of visual cues, judgements of the vertical are aligned mostly with gravity, less often with the long axis of the own body, and rarely otherwise (Bury and Bock, SfN 2015, 335.17). Here we evaluate whether the same alignment holds for vertically oriented hand movements. Twenty-four young, healthy volunteers were blindfolded, tilted into different angles of roll, and asked to silence an alarm by flipping a switch “down” with their dominant hand. The switch was constructed such that it could be flipped in any direction in the participants’ frontal plane. Before the actual experiment, all volunteers practiced the task while standing upright with eyes open (i.e., with congruent visual, gravitational and egocentric information about “down”). We found that 20/24 participants deflected the switch in accordance with their body orientation, rather than in accordance with gravity. Some of these participants deflected the switch consistently towards their own feet, while others deflected it consistently in other egocentric directions. Among the remaining four participants, two deflected the switch in accordance with gravity while the other two couldn’t be classified unequivocally. We conclude that motor control may rely on distinct internal representations of the vertical, and that the predominance of egocentric responses may adversely affect human operation under water and in spaceflight.

Title: Extrinsic and intrinsic dynamics in visuomotor tracking

Authors: *D. SUSILARADEYA, F. GALÁN, K. ALTER, A. JACKSON;
Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: During visuomotor tracking of slow targets, humans produce submovements at frequencies around 2 Hz. This rhythmicity could reflect properties of the extrinsic feedback loop, with submovement frequency determined by visual processing delays. Alternatively, an intrinsic rhythmicity within the motor system could enhance motor responses at submovement frequencies. We tested these two hypotheses using 2D bimanual finger force tracking of a circularly-moving target. We added two experimental manipulations of visual feedback: time delays (of 100-400 ms) and sinusoidal perturbations (at 1-5 Hz).
Perturbations produced time-delayed force responses which at submovement frequencies were phase-shifted by 180° leading to large cursor errors. Moreover, the frequency of both submovements and perturbations associated with large errors decreased with additional feedback delay. These observations are consistent with time delays in the extrinsic feedback loop driving submovements. However the frequency distribution of submovements, and the force response to perturbations at different frequencies, suggested that these time delays increased slightly with frequency. Moreover, the force response to perturbations at 2-3 Hz had a larger amplitude that that for higher or lower frequencies, and this was independent of delay time. These results are consistent with intrinsic dynamics within the feedback loop causing a frequency-dependent phase shift and a resonance at submovement frequencies.
We modelled a feedback controller driven by discrepancies between delayed sensory predictions (based on efference copy) and delayed feedback of errors. Intrinsic dynamics within the feedback loop were represented by a first order recursive filter. This model was able to reproduce all the features of our data. Stable tracking required that sensory prediction delays accurately matched actual feedback delays, suggesting that humans can quickly adjust this in the presence of artificially increased delay. However, the intrinsic dynamics of the feedback loop remained constant across conditions, suggesting that these are instantiated by static or slowly adapting circuits. We speculate that these intrinsic dynamics could reflect the recursive properties of a state estimator that combines an internal prediction with noisy, delayed sensory information.
In conclusion, the frequency composition of human visuomotor tracking in the presence of

perturbed visual feedback reveals the contribution of both extrinsic and intrinsic dynamics to the generation of submovements.

Title: Hand postures can be classified and reconstructed from kinematic synergies identified through linear approaches

Authors: ***N. S. BHATT**, V. SKM;
Applied Mechanics, Indian Inst. of Technol. Madras, Chennai, India

Abstract: Human hand is a sophisticated, complex and redundant mechanical system controlled by a relatively well developed central nervous system. Redundancy in the hand helps humans to perform tasks such as making postures or grasping objects with ease, especially in uncertain environments. In our study, seven subjects (3 females) performed 70 different postures including daily life postures, ASL (American Sign Language) and aesthetic postures (Indian dance form Bharatnatyam). Each posture was 5 trials each (a total of 350 trials). Sixteen (15+1 reference) 1.8 mm Liberty Electromagnetic tracking sensors (Polhemus, USA) were placed on each finger phalanx and we measured position and orientation data at 120Hz. We considered the hand as a 21-DOF system and computed 21 joints (4 DoFs for the digits and 5 DoF for the thumb). Our results suggest that there is a linear relationship between DIP-PIP joint for all fingers across subjects. For projecting data into linear space we employed two techniques, Principal component analysis (PCA) and Unsupervised Linear Discriminant Analysis (ULDA). We found PCA with 2 PCs gives reconstruction error of ±1 degree, which shows PCA with first two PCs effectively reduce dimensionality. Our results further show that adding 3rd PC reduces the error to ±0.5 degree but describes the finer features of the postures. In some applications, dimensionality reduction alone may not be sufficient. To discriminate two postures from each other we employed the K-Means supervised learning classifier on the dimensionality reduced data. Our results from this analysis suggest that some aesthetic postures and ASL are misclassified, implying that there is a measure of similarity between these postures. We suggest that these two linear dimensionality reduction techniques (PCA & LDA) come with a trade-off between

accurate joint angle reconstruction and posture classification. We further suggest that these two techniques must be used to complement information from each other, but not as a replacement for the other. We further suggest that analyzing such high dimensionality data within the framework of non-linear approaches such as Gaussian Process Latent Variable method (GPLVM) may offer more insights into the true nature of control for this highly redundant system.

Title: Human dorsal premotor cortex transfers information to primary motor cortex hand representation during the preparation for an upcoming grasp: a dual-site TMS study

Authors: ***M. VESIA**[1,2], J. C. CULHAM[3], G. JEGATHEESWARAN[1,2], R. ISAYAMA[1,2], A. LE[4], R. CHEN[1,2];
[1]Univ. of Toronto, [2]Krembil Res. Inst., Toronto, ON, Canada; [3]Dept. of Psychology, The Brain and Mind Inst., Western Univ., London, ON, Canada; [4]Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Dorsal premotor cortex (PMd) is involved in the selection, preparation and execution of voluntary action. Monkey neurophysiology and human neuroimaging studies indicate that PMd encodes grasp. We hypothesized that the functional connection between PMd and the primary motor cortex (M1) is increased during preparation for grasping. Paired-pulse transcranial magnetic stimulation (TMS) with two coils was used to test functional interactions between left PMd and ipsilateral M1 (and within left M1) while at rest or during preparation to grasp objects with either a precision grip or a whole-hand grasp. The test stimulus (TS) was applied to M1 with a small branding iron style coil (50 mm diameter). The TS intensity was adjusted to evoke motor evoked potential (MEP) amplitudes of ~1mV. Another branding iron coil (40 mm diameter) was used to deliver the conditioning stimulus (CS) to PMd. The CS was set at 90% of the active motor threshold (AMT). Interstimulus intervals (ISI) of 4, 6, and 8 ms between CS and

TS were used. We show that when planning to grasp objects with either a precision grip or a whole-hand grasp, PMd facilitates M1 excitability in the hand representations. We also found that MEP amplitudes in hand muscles during grasp preparation are associated with the pattern of muscle activity used in the upcoming grasp. The degree of MEP facilitation was larger when conditioning PMd compared to conditioning M1 (paired-pulse M1). Consistent with findings reported in the monkey, these results provide causal evidence that human PMd transfers grasp-related information to M1 hand representation during the preparation for an upcoming grasp. This new basic understanding of the high-level, intention-related activity in human frontal circuits during goal-directed hand actions may better inform decoding algorithms used to operate neural cognitive prosthetic devices.

Title: Effects of a GABA(A)alpha2,3 modulator AZD7325 on corticospinal excitability in healthy volunteers

Authors: ***G. SAMUSYTE**[1], L. WEBBER[2], J. ROTHWELL[1], M. KOLTZENBURG[1]; [1]Sobell Dept. of Motor Neurosci. and Movement Disorders, UCL Inst. of Neurol., London, United Kingdom; [2]AstraZeneca R&D, Alderley Park, United Kingdom

Abstract: Paired-pulse transcranial magnetic stimulation (TMS) is a non-invasive method to study corticospinal excitability (CSE) and the action of GABA modulating drugs in humans. Short interval intracortical inhibition (SICI), one of the biomarkers of CSE, was shown to be enhanced by a single dose of benzodiazepines, but not drugs acting selectively through GABA(A)alpha1 receptors. As alpha5 subunits of GABA(A) receptors are less densely expressed in the cortex than alpha2,3 subunits, it has been suggested that GABA(A)alpha2,3 receptor signalling is responsible for the modulatory effects on SICI. Availability of the novel GABA(A)alpha2,3 positive allosteric modulator AZD7325 allowed us for the first time to investigate this hypothesis in humans. GABA(A)alpha2,3 modulation of CSE was assessed in 12 healthy male volunteers (24±4 years) in a phase I randomized, double-blind, placebo-controlled,

3-way cross-over study. SICI was obtained at baseline and 1, 2, and 8 hours after a single dose of 2 mg, 10 mg of AZD7325 or matched placebo. To avoid “floor effect”, a range of conditioning stimuli (CS) was used (50-80% of resting motor threshold (RMT), interstimulus interval 2.5 ms). Test stimulus (TS) intensity was set to produce a response of 1 mV. Absolute and relative SICI change from baseline was assessed. Increase in inhibition was expected at the time of maximum plasma concentration (Cmax) of the drug, i.e. 1-2 hours post-dose. In addition, sedation and psychomotor performance were assessed. Baseline CSE parameters did not differ between the treatments. AZD7325 did not have an effect on RMT, but both 2 and 10 mg doses increased TS intensity at Cmax when compared to placebo. There was a consistent, however non-significant, absolute and relative increase in SICI at CS 60% and 70% RMT at Cmax after the intake of 10 mg of AZD7325 (absolute change of 6-17% of test response, relative change of 7.5-11%). Interestingly, the largest increase in SICI at CS 70% RMT (relative change of 26%) was observed at 8 hours after intake of AZD7325, and was close to reaching statistical significance after 10 mg dose. There was no significant effect of AZD7325 on sedation and psychomotor performance when compared to placebo. In conclusion, 2 and 10 mg doses of AZD7325 were non-sedating and did not impair psychomotor performance. At Cmax, increases in SICI with AZD7325 did not reach statistical significance, but increased TS intensity is suggestive of a possible rightward shift and/or change in slope of the input-output curve. Larger studies employing higher doses of AZD7325 and an active comparator are needed to further explore the hypothesis of GABA(A)alpha2,3 modulation of SICI.

Title: Human somatotopic organization during finger movement revealed by gaussian population receptive fields

Authors: *W. SCHELLEKENS[1,2], N. F. RAMSEY[1,2];
[1]UMC Utrecht, Utrecht, Netherlands; [2]Neurol. & Neurosurg., Brain Ctr. Rudolf Magnus, Utrecht, Netherlands

Abstract: Cortical sensorimotor areas in the human brain have been shown to exhibit somatotopic organizations at least at the macroscopic level [1]. However, the existence of a somatotopic organization on a microscopic level (e.g. individual digits) is much less certain, especially in motor areas [2]. The population Receptive Field (pRF) approach, that has been proven successful in retinotopic mappings of visual cortex [3], could shed more light on this issue. The current study investigates if an orderly somatotopy of finger representations can be obtained using fMRI and pRF analysis.
During a 7T fMRI session, 6 healthy volunteers executed a finger movement task that required the sequential flexion or extension of all fingers of both hands separately. During the task the subject's finger positions transitioned from flexed towards extended or vice versa. Similar to pRF analyses in visual neuroscience, a Gaussian convolved with a hemodynamic response function was fitted to the timeseries of each voxel, thereby obtaining the center and sigma of a voxel's best Gaussian fit. The Gaussian center illustrates a voxel's preferred finger representation, while the sigma illustrates the degree of response to adjacent fingers. The presence of an orderly somatotopy of individual finger representations was assessed for several Brodmann areas using a linear regression on the coordinates of the obtained centers.
Somatotopic organizations of finger representations were found in all subjects in the contralateral hemisphere with respect to the cued hand. During flexion, the following Brodmann areas showed a significant somatotopy in somatosensory cortex: BA1 ($T_{(5)}$=9.99, p<.001); BA2 ($T_{(5)}$=2.77, p=.039); BA3a ($T_{(5)}$=5.68, p=.002); BA3b ($T_{(5)}$=5.18, p=.004), and motor cortex: BA4p ($T_{(5)}$=5.44, p=.003); BA6($T_{(5)}$=3.64, p=.015). During extension only somatosensory cortex showed somatotopic organizations: BA1 ($T_{(5)}$=8.48, p<.001); BA3a ($T_{(5)}$=3.77, p=.013); BA3b ($T_{(5)}$=4.61, p=.006).
In the current study we show that the somatotopic organization of finger representations can be obtained in individual subjects' sensorimotor cortex with the use of a Gaussian pRF approach. The pRF analysis results in a preferred finger representation per voxel, as well as a degree of response to finger representations adjacent to the preferred one. The pRF approach shows that

motor cortex has a detailed microscopic somatotopic organization, and that its classification can be revealed with integrative models of sensorimotor activation.

Title: Effects of absolute force level and direction of changes in force on accuracy in a cyclic isometric low level force pinch task

Authors: M. LEWIS, K. MULLER, M. DUNN, R. T. EAKIN, *L. D. ABRAHAM; Kinesiology and Hlth. Educ., Univ. of Texas at Austin, Austin, TX

Abstract: Previous research has described relationships between force production accuracy and absolute force level in static and dynamic force production tasks. This study examined whether greater error in a cyclic visuomotor isometric force tracking task would occur at the lower force reversal point than when the same force level was the high end of a similar task performed over a lower force range. Thirty right-handed volunteer participants, 6 men and 24 women (18 - 30 yrs), free from any neurological disorder or physical ailment, were tested. The participants performed an isometric pinch tracking task, which required generating matching forces with both the thumb and index finger of the preferred hand to move a cursor on a computer screen up and down a 45-degree diagonal line, trying to stay coincident with a track ball cycling between two force levels four times for each trial. The forces required to complete the task were scaled so that the peak force required for each digit was 12% of that individual's mean maximum voluntary contraction (MVC) digit flexion force. All participants were tested in ten trials under each of two conditions in random order. One condition required cycling between force levels of 3% MVC and 6% MVC; the other condition required cycling between 6% and 12% MVC. Tracking error data were analyzed from the ten performance trials by each participant at the 6% MVC level; in one condition this level was at the high end of the task range and in the other condition this level was at the low end of the task range. The four cycles of the track ball in each trial yielded three reversal data points at the 6% MVC force level. Consistent with the force / force variability principle, the results showed that for both the thumb and index finger absolute error was greater

at higher force levels than lower force levels, while in each range greater error was seen at the low end reversal than the high end reversal. Importantly, as previously reported by Park (2012), higher error was seen for both digits at the 6% MVC level when that was the low end of the target force range than when that was the high end of the force range. This result supports the idea that the task of precisely reversing a decreasing force level to begin increasing pinch force is more difficult than the task of reversing an increasing force level to begin decreasing pinch force. Underlying mechanisms may be related to the dynamics of motor unit recruitment and isometric muscle force production during force reversals at low force levels.

Title: The lack of effect of a visual size illusion on grip aperture is independent of object size.

Authors: *J. B. SMEETS, E. BRENNER;
Vrije Univ. Amsterdam, Amsterdam, Netherlands

Abstract: There is an extensive literature debating whether visual size illusions influence the peak grip aperture in grasping. We found no effect for 7cm diameter disks on a Ponzo illusion (Brenner & Smeets, EBR, 1996). We interpreted this as evidence that grasping is not based on a visual estimate of size. Most studies that did find an influence of illusions used approximately 3cm diameter disks embedded in an Ebbinghaus illusion. Could it be that people do use size information for smaller objects because they combine information to maximise precision, and for smaller objects size judgments are no longer less precise than judgments of position (Smeets & Brenner, Current Biology, 2008). In order to avoid any possibility of parts of the illusion being interpreted as obstacles, we tested this possibility using a modified diagonal illusion. Participants grasped both small (1.5-2.5 cm) and slightly larger (4-5 cm) objects. The illusion had an effect of more than 10% on perceptual judgements, irrespective of object size. For the peak aperture during grasping movements, the effect of the illusion was negligible (less than 0.5%), again independent of object size. We conclude that the reported disagreement on the effect of illusion is not due to using differently sized objects.

Title: Measurements of recovery from finger muscle fatigue

Authors: ***M. O. CONRAD**, S. JAMES;
Sch. of Engin. and Computer Sci., Oakland Univ., Rochester, MI

Abstract: Localized muscle fatigue results from several factors including both metabolic and structural changes occurring with prolonged or repetitive muscle use. Methods of evaluating muscle fatigue include both techniques that track maximum force capacity of a muscle as well as

the analysis of surface electromyography (EMG) under controlled conditions to evaluate the amplitude and frequency of the EMG signal. While prior studies have extensively used such measures to evaluate the onset of fatigue, relatively few studies have focused on quantifying fatigue throughout the recovery phase. The aim of this study is to evaluate various methods of analyzing force and EMG signals to identify the most accurate method for analyzing muscle recovery post-fatiguing contractions. Muscle fatigue was evaluated in the first dorsal interosseous (FDI) and thenar eminence of the thumb during voluntary muscle contractions using a Biometrics DataLOG System (Biometrics Ltd, UK). Each subject exerted lateral pinch force on a custom pinch dynamometer completing two different fatiguing protocols. For the continuous protocol subjects exerted 50% MVC until exhaustion. During the intermittent protocol the subjects alternated 5 s exertions (50% MVC) with 5 s rest periods for 6 min. After every minute a MVC was recorded to note any changes in normalized force production. For one hour after completion of the fatiguing contraction muscle activity was monitored every 10 min. Normalized values of RMS amplitude, median frequency, and peak force exertions were compared between protocols and throughout the recovery phase of the experiment. Results indicate for both muscles during the intermittent protocol median frequency analysis indicated greater % fatigue than that observed in the RMS amplitude. The median frequency analysis appears more sensitive to recovery of muscle post-fatiguing contractions however median frequency and RMS results appear to be correlated for each muscle. Further research must be conducted to further understand the exact mechanisms contributing this these observations.

Title: Visuo-haptic asynchrony alters object lifting dynamics and weight perception

Authors: V. VAN POLANEN[1], *M. DAVARE[2,1];
[1]Movement Control and Neuroplasticity Res. Group, KU Leuven, Leuven, Belgium; [2]Inst. of Neurol., London, United Kingdom

Abstract: Object lifting requires precise scaling of fingertip forces according to the weight of the object. When lifting an object from a surface, lift-off occurs when the applied vertical load force overcomes the object weight. Thus a weight percept can be formed early during the loading phase of a lifting motion. Different sensory events inform the brain about the time of object lift-off: visual cues and haptic inputs (proprioception and fingertip mechanoreceptors) indicate when the object releases contact with the surface and starts to move. In real life conditions visual and haptic inputs about lift-off occur simultaneously. Here we used a virtual reality environment where a delay between visual and haptic feedback could be introduced in order to determine the relative contribution of vision and haptics in controlling fingertip force scaling and object weight perception. Participants were required to lift virtual objects simulated by a 3D computer screen with their thumb and index finger attached to force-feedback robots (Phantom). In half of the trials, vision was delayed by 100 or 200 ms, resulting in an asynchrony between haptic and visual information. Participants lifted two objects sequentially and one of the two lifts had a visual delay. They were subsequently asked to report which object was heavier. Object mass was varied according to an adaptive staircase procedure to determine the mass at which an object lifted with delay felt equal to an object lifted without delay. We found that objects are perceived as being heavier when vision is delayed with respect to haptic feedback. In addition, force scaling is altered in response to the altered visual information. This indicates that visual information about lift-off plays a significant role in controlling force scaling and forming weight perception. Because a visuo-haptic asynchrony mainly alters perception of sensory events occurring during lift-off and to a lesser extent during the static holding phase, our results suggest an important role of the dynamic changes occurring during object loading in generating weight perception.

Title: The effect of using a stylus in different planes and feedback configurations

Authors: J. M. ABDALLA[1], S. C. MONTGOMERY[1], C. A. AIKEN[2], *A. W. VAN GEMMERT[1];
[1]Kinesiology, Louisiana State Univ., Baton Rouge, LA; [2]Integrative Physiol. and Hlth. Sci., Alma Col., Alma, MI

Abstract: Since the 1970s, pen and digitizer-tablets were used as input devices with computers to investigate handwriting and drawing performance. This configuration's drawback is that the feedback and movements are not displayed in the same plane. Recent technological advances allow the display to be integrated within the digitizer (i.e., display-tablets), thus allowing feedback to be displayed in the same plane as the movement. Furthermore, whereas the traditional setup resulted in feedback displayed in the vertical plane on a monitor, display-tablets allow us to display feedback in the vertical and horizontal planes. As a result the question emerges whether vertical and/or horizontal movements with feedback in the same plane do differ from each other and whether movements are affected if the feedback is shown in the vertical plane while the movement occurs in the horizontal plane (i.e., the traditional configuration). The study's purpose was to identify any possible effects on motor performance while executing different graphic tasks in the three different configurations. Participants were asked to perform a handwriting-like and graphical aiming task. Preliminary data showed that the plane's orientation of the executed movement does not affect performance significantly. However, when the executed movements are dissociated from the feedback (i.e., the feedback is not in the same plane as the movements) performance deteriorates significantly (i.e., longer durations; less smooth movements). These results suggest that general conclusions drawn upon findings of research studies using protocols in which the feedback was displayed on a monitor in the vertical plane while the movements were made on an opaque digitizer tablet placed on a table should be accepted with caution.

Title: size constancy in grasping

Authors: *J. CHEN[1], R. RINAS[2], I. SPERANDIO[3], M. A. GOODALE[1];
[1]The Brain and Mind Inst., [2]Dept. of Psychology, Univ. of Western Ontario, London, ON, Canada; [3]Sch. of Psychology, Univ. of East Anglia, Norwich, United Kingdom

Abstract: When we look at an object from different distances, the size of the image of the object projected onto our retina varies, yet we still perceive the object to be the same size. This phenomenon, called size constancy, is not only important for a stabilized representation of the external world, but is also crucial for proper interactions with objects in the surrounding environment. So far, many studies have investigated how various depth cues affect size constancy in perception, but much less effort has been spent investigating how these cues affect size constancy in actions, such as grasping. Moreover, there is still some debate as to whether or not there is size constancy in grasping (i.e., whether or not people use the same grip aperture to grasp an object at different distances). Previous research in our lab showed that even patients with visual form agnosia exhibit excellent size constancy in grasping. This was true when the patients viewed the object binocularly, but not monocularly. A very recent study, however, demonstrated that grip aperture increases as viewing distance increases, even when participants viewed the object binocularly in a lit room with all environmental information available. We argue that the lack of size constancy in grip aperture reported in that study is the result of different distances between the hand and the target object when the viewing distance was manipulated. This change in hand-target distance might have introduced biomechanical differences, especially when grasping objects at a far distance. In the current study, we tested whether or not there is size constancy in grasping when this biomechanical confound is removed. To accomplish this, viewing distance was manipulated by changing the participants' head position while keeping the positions of the hand and object fixed. The first/closest distance was set at 15cm. The second distance was 1.5 times the first distance, and the final/furthest distance was 2 times the first distance. Stimuli consisted of spheres of three sizes: 2.5cm, 3.75 cm and 5 cm in diameter. Two extra sizes (1.25 cm and 6.25 cm) were also included but were not analyzed. Participants were asked either to grasp the sphere as quickly and accurately as possible with their thumb and index finger, or to manually estimate the diameter of the sphere using the same fingers. Participants showed excellent size constancy in both grasping and manual estimation (i.e. their grip apertures were unaffected by viewing distance), which suggests that grasping is governed by size constancy mechanisms when biomechanical differences are well controlled.

Title: Hand-held tools attenuate self-touch

Authors: *K. KILTENI, H. EHRSSON;
Karolinska Institutet, Stockholm, Sweden

Abstract: Human survival depends on the ability to perform quick and accurate movements with our limbs and with hand-held tools. To overcome the temporal delays and noise of the sensorimotor system, the brain uses internal forward models to predict the sensory consequences of actions as a function of motor commands (Miall and Wolpert, 1996; Franklin and Wolpert, 2011). Although it has been previously theorized that the brain forms forward models of hand-held tools (Imamizu et al., 2000, 2003; Higuchi et al., 2007; Imamizu, 2010; Imamizu and Kawato, 2012), direct experimental evidence supporting a link between tool use and predictions of forward models has been lacking. Specifically, whether these predictions are computed in the same way as those associated with limb movements without tools remains unknown. To address this question, we investigated whether the predictive attenuation of touch observed when touching one hand with the other (Blakemore et al., 1998, 1999; Shergill et al., 2003; Bays et al., 2005) would also be observed for touch applied with a hand-held tool. In Experiment 1 (n=12), we show that when the touch is applied with the index finger (no tool), it is attenuated only when the positions of the hands are aligned (distance between hands=0 cm) as during natural self-touch but not when the hands are placed at a distance of 25 cm ($t(71)=6.18$, $p<0.001$, CI=[0.29, 0.56]). In Experiment 2 (n=12), we demonstrate that self-touch with a hand-held tool (distance between hands=25 cm) is attenuated to the same degree as direct touch applied with the index finger when the hands are aligned ($t(71)=-0.40$, $p=0.687$, CI=[-0.25, 0.17]). Finally, in Experiment 3 (n=12), we show that touch is attenuated only when the tip of the tool is positioned so that it is aligned with the passive hand that receives the touch (distance between the tip and the hand=0 cm) but not when the tip of the tool is placed at a distance of 25 cm ($t(71)=11.14$, $p<0.0001$, CI=[0.69, 0.99]). In summary, the results demonstrate for the first time that the sensory consequences of actions involving hand-held tools are predicted and attenuated to the same extent –and under the same spatial principles– as actions involving the digits alone. Based on our findings, we propose that the brain uses a flexible strategy to predict the sensory consequences of movement: predictions are not made on the basis of the state of the body-part *per se* but rather on that of the *end-effector*, i.e., the digits during natural manual interaction or the tip of the tool during tool use. This computational mechanism allows hand-held tools to act as versatile natural extensions of the hands in terms of sensorimotor predictions.

Title: Quickness of load force production is limited by the quickness of grip force production

Authors: *M. UYGUR, L. FUNK;
Dept. of Hlth. and Exercise, Rowan Univ., Glassboro, NJ

Abstract: The ability to generate quick submaximal forces (i.e. neuromuscular quickness) is an important aspect of motor function that can deteriorate with aging or with the presence of neurological diseases. This function has been assessed through isometric force production tasks completed under instructions to produce each force pulse as quickly as possible to varying submaximal amplitudes. The slope of the regression line drawn between the peak values of brief force pulses and the peak values of rate of force development (named as rate of force development scaling factor; RFD-SD) quantifies the neuromuscular quickness. The R^2 obtained from the same regression line represents the robustness of RFD-SF as a controlled variable. To assess quickness, previous studies used ecologically valid tasks during which subjects were asked to grasp an instrumented cane-like device and to produce tangential force pulses (i.e. load force; LF) by pushing down on it. Although one has to produce a quick grip force (GF) pulse to generate the LF pulse in those conditions, only the quickness of LF was studied. Therefore, we do not know if the quickness of GF was a limiting factor for the quickness of LF. The aim of this study was to compare the RFD-SF and R^2 of GF and LF obtained in tasks when they acted together with those obtained in tasks when they acted individually. Twelve healthy young participants produced brief force pulses under three conditions: 1) gripping the GF-LF measuring device to produce both LF and GF pulses (GF-LF), 2) gripping the GF-LF measuring device to produce GF pulses (GF_{only}), and 3) pushing down on another device which was strapped to the subject's wrist to create LF pulses without using GF (LF_{only}). Results revealed a similar RFD-SF for GF and LF when they had to act together in GF-LF condition ($p>0.05$). However, RFD-SF for LF_{only} was higher than those obtained for LF in GF-LF condition ($p<0.01$) while RFD-SF values were similar between GF_{only} and those obtained from GF in GF-LF condition ($p>0.05$). Regarding R^2, results revealed similarly high values in all conditions with an exception of lower values obtained for LF in LF-GF condition. Overall, these findings reveal that quickness of grip force production could be slower than the quickness of load force production, suggesting the importance of quickness training of GF producing muscle especially in populations who are prone to falls.

Title: The impact of self-modulation of physiological tremor amplitude on its frequency components

Authors: *C. DUVAL[1,2], F. AYACHI[1], J.-F. DANEAULT[3];
[1]Sci. de l'activité physique, Univ. du Québec À Montréal, Montreal, QC, Canada; [2]Ctr. de recherche institut universitaire de gériatrie de Montréal, Montréal, QC, Canada; [3]Motion Analysis Lab. of Spaulding Rehabil. Hosp., Harvard, Boston, MA

Abstract: Aims: We have previously demonstrated that physiological tremor amplitude can be voluntarily modulated. However, what is not known is the impact of such modulation on the different frequency bands, and how it changes the time series characteristics in term of the nonlinearity and irregularity. We aim to determine the effect of modulation on physiological tremor characteristics. **Methods:** Finger physiological tremor (right hand) was recorded using a laser displacement sensor on 8 right-handed participants in a control condition and during a modulation of physiological tremor where they were asked to reduce the amplitude of their physiological tremor amplitude, without using co-contraction as a means to attempt to stabilize their finger. Each participant performed 3 trials of 45 s for the two conditions. Descriptors in temporal domain, RMS value, and frequency domain such as mean frequency (MNF), median frequency (MDF), the spectral index (FrI = MNF/MDF), high order central moments/statistic (SHOS) of the spectral density and power spectral entropy (SEn) were computed for the band-pass filtered signals to compare the two experimental conditions. **Results:** The results of the present study revealed significant differences, between the two experimental conditions, for RMS variable and the ratio *FrI*. We noted also a slight increase in MNF in the modulation condition compared to the control condition, indicating a slight shift of power towards high frequencies but this difference was not statistically different. The *SHOS* revealed a significant increase in the 2^{nd} moments (dispersion index) for the modulation condition, however, the spectral density shape remain asymmetric and leptokurtic during the two conditions. The *SEn* showed that spectral structures remained the same for the two conditions. Additionally, surrogate data test for nonlinearity, using time reversibility (*Tr*) and approximate entropy (*ApEn*), indicated that the recorded tremor signals had mostly nonlinear properties during both experimental conditions, but the signal during the modulation condition became more complex and irregular.

Using the Hilbert Huang Transform (EMD-HHT), we revealed a significant decrease of the amplitude for all intrinsic mode functions (IMFs) during the modulation trials, with important spectral shape alteration for the IMF-2 and IMF-3, which corresponded to the frequencies in the 7-11 Hz range associated oscillations generated within the central nervous system. **Conclusion:** These results suggest that voluntary tremor modulation will affect both the mechanical reflex and central neurogenic components of physiological tremor.

Title: Deficits in inhibitory force control in young adults with ADHD

Authors: *P. WANG[1], A. CHENNAVASIN[2], J. R. TUCKER[2], S. SAMIMY[1], M. REYNOLDS[1], C. HUANG-POLLOCK[3], K. A. NEELY[1];

Abstract: Attention-Deficit/Hyperactivity Disorder (ADHD) is a common, childhood-onset, heterogeneous neuropsychiatric disorder characterized by inattention and/or hyperactivity-impulsivity. ADHD persists into adulthood in up to 65% of individuals. In addition to the core behavioral features, motor impairments are reported in up to 50% of individuals and deficits in this domain may be associated with poor adaptive functioning in daily life skills, socialization, and self-direction. Although numerous studies have reported poor inhibitory control in ADHD, the button-press task that has been used in these studies records performance errors only via the presence or absence of a single key press. This all-or-nothing response makes it impossible to capture subtle differences in motor inhibition. In the current study, inhibitory control was measured using a continuous grip force task that provides a sensitive metric for understanding how inhibitory control is altered in ADHD. In this study, we used a classic go/no-go task as well as a grip force variant to measure motor inhibition in young adults aged 18 - 24 with (N = 40, 22 female) and without (N= 40, 22 female) ADHD. For each task, participants completed two blocks of 100 trials (25% no-go trials). The grip force task included two conditions: low (15% of maximal voluntary contraction) and high (60% of maximal voluntary contraction) amplitude.

Participants produced force for 750 ms with a 500 ms inter-trial-interval. In addition to the force task, participants completed a button-press task with an identical experimental timeline. As expected, adults with ADHD made more failed inhibits in the classic go/no-go paradigm, but also produced more force in no-go trials in both the low and high force amplitude grip force task. No between-group differences in mean force output were observed for go trials. Bivariate correlations revealed that the mean force produced in no-go trials was positively correlated with no-go failure rate for the classic go/no-go task, as well as self-reported measures of symptom severity on the Conners' Adult ADHD Rating Scales (CAARS-S:L), including Inattention/Memory Problems and Hyperactivity/Restlessness. This study provides a novel examination of motor output during inhibitory control. The results suggest that the current and most commonly used indices of inhibitory control are insufficiently sensitive to assess cognitive and motor impairments observed in adults with ADHD. Further, this work has important ramifications for studies examining the longitudinal course of the disorder.

Title: The development and validation of the moneybox test: a new measure of functional dexterity for people with huntington's disease

Authors: *S. P. CLINCH, M. BUSSE, M. LELOS, A. ROSSER;
Cardiff Univ., Cardiff, United Kingdom

Abstract: *Introduction:*
Loss of upper limb function is a common symptom in people with Huntington's disease (HD), a neurodegenerative disease that causes cognitive and motor abnormalities for which there is currently no cure. This can impact upon activities of daily living such as eating, getting dressed

and multi-tasking and can severely affect quality of life. As there is currently no sensitive upper limb outcome measure for people with HD there is an imperative for well defined, quantitative measures to track disease progression and to assess the impact of new therapeutic interventions. Here we describe the development and evaluation of the Moneybox test (MBT). This is a new functional dexterity multi-task assessment developed in accordance with translational neuroscience and physiological principles for people with a broad disease manifestation, such as HD.

Methods:

Participants with HD (n=30) and a healthy reference group (n=8) were recruited to perform the MBT whilst wearing small, non-invasive accelerometers on their wrists and chest, which were used to quantify involuntary movement. The MBT comprised 3 tasks, which required subjects to transfer tokens into a moneybox in order of size (baseline), value (dual task) with and without reciting the alphabet (triple task). This was tested alongside other well validated single and dual tasks including the Timed Up and Go and Letter Verbal Fluency, Stepping and the Stroop task, and Walking and Talking. Other measures specific to HD and quality of life were also recorded including the Unified Huntington's disease rating scale-total motor score (UHDRS-TMS), UHDRS-total functional capacity (TFC), Short Form-12 (SF-12) and the Problem Behaviors Assessment (PBA).

Results:

HD patients were grouped into stage of disease based on their UHDRS-TFC score. MBT performance was significantly reduced across every stage of disease compared to the healthy reference group. Uniquely the MBT significantly distinguished the subtle differences between the reference group and people with the earliest stages of HD. MBT performance significantly and more closely correlated with gold standard measures of impairment in HD such as UHDRS-TMS, UHDRS-TFC, SF-12 and PBA than any other single and dual outcome measures tested.

Conclusion:

The MBT provides a sensitive, affordable outcome measure for people with HD and is more sensitive across disease stage than other commonly used measures such as the Timed Up and Go task. Future work includes interpretation of accelerometer data to determine if involuntary movement increases with cognitive load in this disease population.

Title: Differential effects of left and right hemisphere stroke on a precision grip force task

Authors: B. KC, K. A. FERCHO, *L. A. BAUGH;
Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: A common occurrence of stroke, especially a stroke involving the territory of the middle cerebral artery (MCA) is the presence of persistent motor impairments in the distal upper extremity contralateral to the lesion. Of particular importance is the ability to modulate fingertip forces used in grasping control, as this ability is crucial to the completion of many activities of daily living. Although previous research has shown deficits in fingertip force modulation in both the affected (contralesional) and non-affected (ipsilesional) hand, the causes for these deficits has not been adequately explored. An increasing body of research has elucidated the differing roles the left and right hemispheres play in motor control. Specifically, it has been suggested that the left hemisphere is critical for predicting effector and task dynamics, whereas the right hemisphere is involved in steady-state final position control. The presented research examined the ability for stroke survivors to generate forces using their index finger and thumb during a precision-grip isometric force matching task. We predicted that performance on the task would be reduced when compared to control participants when testing both the "affected" and "non-affected limb". Further, we predicted that performance between those stroke participants with right hemisphere damage (RHD) and left hemisphere damage (LHD) would be dissociable, due to the differing role each hemisphere plays in motor control. Thirty-five right-hand dominant stroke participants (17 with the Left-Hemisphere affected) with mild upper-extremity hemiparesis and 50 healthy, age-matched control participants produced forces of 5, 10, 15, 20, 25, and 30 percent of maximal voluntary contraction using their index finger and thumb. As expected, when compared to healthy control participants, both RHD and LHD stroke participants displayed deficits in the force matching task. Additionally, there were significant differences in performance metrics between those with RHD and LHD, with those with RHD showing increased difficulty with the task, regardless of the hand used. Taken together, these results provide further evidence of the distinct roles the left and right hemisphere play in motor control, while simultaneously highlighting the necessity to consider the differential contribution each hemisphere makes to best enhance post-stroke recovery of the fine fingertip forces required for successful object manipulation.

Title: Memory-guided force control in healthy older adults

Authors: *K. A. NEELY[1], S. L. BLOUCH[1], S. SAMIMY[1], A. CHENNAVASIN[2], M. REYNOLDS[1], N. DENNIS[3], M. DIAZ[3];
[1]Dept. of Kinesiology, [2]Dept. of Biomed. Engin., [3]Dept. of Psychology, Pennsylvania State Univ., University Park, PA

Abstract: Visual feedback is a rich source of information for guiding human motor performance and provides a basis for the formation of memory to guide performance in the absence of visual feedback. The goal of this study was to examine visually-guided and memory-guided precision force in healthy young and older adults. Previous work demonstrates that healthy young adults decrease force output as a function of time when visual feedback is not available. We hypothesized that the rate of the decay of force output would be greater for healthy older adults. Two groups of participants, young adults (YA: N = 33, mean age 20.9 years) and older adults (OA: N = 34, mean age 69.4 years), completed 20-second trials of isometric force with their index finger and thumb, equal to 25% of their maximum voluntary contraction. The visual display contained a movable force bar and a stationary target bar. Participants were instructed to move the force bar vertically to overlap the target bar, which indicated the target amplitude. In the full vision condition, visual feedback was available for the duration of the trial. In the no vision condition, visual feedback was provided for the first 8 seconds of the trial. In the remaining 12 seconds, participants were instructed to maintain the same amount of force in the absence of visual feedback. For each visual condition, mean force for each second in the last 12 seconds of each trial was submitted to a 4 (trial) by 12 (time) by 2 (group) mixed model ANOVA. In the full vision condition, OA produced more force than YA; however, no other main effects or interactions were observed. In the no vision condition, OA produced more force than YA, and a time by group interaction was revealed. To examine this interaction, we calculated the rate of decay of force over the 12 seconds without visual feedback. An independent samples t-test demonstrated that YA had a faster rate of decay of force compared to OA. This finding suggests that OA may be better able to store and/or access motor memories to guide force in the absence of visual feedback.

Title: Cortico-cortical and corticomuscular (de-)synchronization in discrete movements: how does ageing affect inter-hemispheric interaction?

Authors: *P. BABAEEGHAZVINI[1], S. SWINNEN[2], A. DAFFERTSHOFER[1];
[1]Fac. of Behavioral and Movement Sci., Vrije Univ. Amsterdam, Amsterdam, Netherlands;
[2]Dept. of Kinesiology, KU Leuven, Leuven, Belgium

Abstract: Many everyday tasks like tying your shoes require your hands to act in unison. Bilateral coordination, however, might be easier than moving hands or fingers independently. One reason for this could be an involuntary cross talk between hemispheres in the central nervous system. Cross talk may change as a function of age as, for instance, the integrity of the transcallosal fibers deteriorate. Yet it is unclear to what extent age-related structural changes yield a bias towards symmetry/asymmetry of bimanual performance and/or a lateralization/de-lateralization of cortical activity. To establish age-related changes in motor performance and in the cortical motor network, we compared 11 elderly (60-77 yrs) with 11 young participants (21-30 yrs) conducting bimanual coordination tasks with distinct degrees of difficulty. Participants controlled a cursor with left/right pinch-grip forces to follow a target. The degree of difficulty was manipulated by amplifying high-frequency components of one of the two forces when displaying the cursor - by this we sought to amplified the cross talk.
We recorded force production and defined the error of performance (E) via the distance between target and cursor. We also determined the Pearson correlation (ρ) and the F-statistics of Granger causality (G) between force traces as estimates of bimanual interference. All asymmetric tasks displayed increased E, ρ, and G rendering poor performance and strong left/right interference. The latter was stronger in the elderly as both E and F were larger than in the young group. E and F were positively correlated implying a Granger causal relation between left and right end-effectors to induce performance error.
Cortical and muscular activities were assessed through EEG and EMG, respectively. We reconstructed source activity using broadband LCMV beamformers with AAL-atlas-based regions-of-interest. Next to analyzing power changes, we focused on the amount of alpha and beta phase synchronization between bilateral M1, PM1, and SMA, and between M1 and contralateral finger flexors. In line with the behavioral outcome the asymmetric tasks revealed the most pronounced inter-hemispheric phase synchronization between bilateral M1 and PM1.

The bilateral phase synchrony discriminated the two groups: task-related synchronization was increased in the elderly. Cortico-muscular synchrony with the right first dorsal interosseous revealed a strong involvement of ipsilateral controllers only in the elderly. Taken together our results suggest an altered interhemispheric as well as cortico-muscular entrainment as prime cause for reduced dexterity of distal upper limb function in the elderly.

Title: Representation of finger movements from macaque area AIP, F5 and M1

Authors: *W.-A. SHENG, A. AGUDELO-TORO, H. SCHERBERGER;
Neurobio., Deutsches Primatenzentrum, Goettingen, Germany

Abstract: The ability to move individual fingers is a specific feature of primates. In the macaque brain, the anterior intrapariental area (AIP), the ventral premotor area (area F5), and the hand area of primary motor cortex (M1) are strongly linked to the planning and execution of hand grasping movements. Whereas previous studies of individual finger movements have focused on execution signals in M1, we investigated here the population coding of all three areas for individual finger control. A macaque monkey was trained in a delayed finger task with visual cues, in which the thumb, index and middle finger were flexed and hold individually or in combination with its neighboring fingers (5 conditions). A micro-switch manipulandum detected flexion movements and provided tactile feedback. The task consisted of several epochs, in which “fixation”, “cue”, “go”, and “hold” were used for decoding. Floating microelectrode arrays were implanted in AIP, F5, and M1 contralateral to the moving hand (64 channels per area), allowing us to record spiking activity simultaneously from about 200 single and multi-units. Firing rates of individual units from all areas showed similar patterns: they were tuned for single and multiple finger movements (cluster-based permutation test, $p<0.05$) with different amplitudes. In particular, neural activities of combined finger movements were no simple linear combinations of individual finger activities. Comparing the tuning onset of the three areas, AIP units had a significantly earlier tuning onset at the population level than F5 and M1 (cluster-based permutation test, $p<0.05$), giving evidence of visual input before movement. Another way to

show the visual component of AIP was to calculate the partial correlation coefficient (pcc) between a type of error trial and its two types of corresponding correct trials ("cue error pcc" for the pcc between one type of error trial and the type of correct trial with the same cue, and "movement error pcc" for the pcc between the same type of error trial and the type of correct trial with the same movement). The cue error pcc in AIP was higher than the movement error pcc throughout the whole trial, while in M1 the movement error pcc exceeded the cue error pcc before hold epoch and reached maximum shortly after hold. The tuning onset and the pcc both supported the "visuomotor grasping circuit" hypothesis of Jeannerod. In conclusion, decoding of finger movement conditions (1 out of 5) was best for M1 (75 %), and significantly worse for F5 (59%) and AIP (47%) (ANOVA, $p<0.05$), suggesting that finger movement execution signals are best represented in M1.

Title: Changes in the M2 projection to medullary precerebellar relay nuclei correlate with recovery of upper limb function after peri-rolandic injury in macaca mulatta

Authors: *W. G. DARLING[1], D. L. ROTELLA[2], M. A. PIZZIMENTI[2], J. GE[3], K. STILWELL-MORECRAFT[3], R. J. MORECRAFT[3];
[1]Dept of Hlth. & Human Physiol, [2]Hlth. and Human Physiol., Univ. of Iowa, Iowa City, IA; [3]Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: There is considerable interest in the role of spared descending neural pathways following injury to cerebral cortex because these projections may play a role in recovery of upper limb motor control. Using high-resolution tract tracing we previously found that isolated lateral frontal motor injury (F2 injury) results in an enhanced corticospinal projection (CSP) from spared supplementary motor cortex (M2) residing in the lesioned hemisphere (McNeal et al., 2010 J Comp Neurol 518:568), but this favorable, upregulated response is unequivocally blocked following combined lateral frontoparietal injury (F2P2 injury) (Morecraft et al., 2015 J Comp Neurol 523:669). We used the same experimental cases (4 F2 lesions, 4 F2P2 lesions) and 3 control cases to determine if a similarly polarized neuroplastic response occurs in the

projection to medullary precerebellar relay nuclei, specifically the lateral reticular nucleus (LRN) and epi-olivary subnucleus (EO) of the LRN. We also examined whether the distribution of the projection to the LRN and EO was correlated with measures of recovery of reaching and fine hand motor function. We found that the M2 projection to the contralateral dorsal region of the LRN was enhanced in F2 lesioned monkeys, but was variably enhanced or weakened among F2P2 lesioned monkeys that appeared to be related to variations in F2P2 lesion size/location. The M2 projection to the contralateral EO was variably enhanced and weakened in both F2 and F2P2 lesioned monkeys. These altered M2 corticofugal projections correlated positively with recovery of both reaching to and grasping small food objects with the contralesional hand in F2P2 lesioned monkeys. However, recovery of grasping in F2 lesioned monkeys was also positively correlated with recovery of grasping but negatively correlated with recovery of reaching. Thus, changes in the M2 projection to precerebellar nuclei may favorably affect recovery mechanisms underlying contralesional arm reaching and hand fine motor function after peri-Rolandic injury. This may occur through a number of cerebellar output systems, including the cerebellar-thalamic-cortical feedback loop directed to spared M2 in the lesioned hemisphere.

Title: Finger representations in sensorimotor cortex are not disrupted in musicians' dystonia

Authors: *N. EJAZ[1], A. SADNICKA[2], T. WIESTLER[2], K. BUTLER[3], M. EDWARDS[4], J. DIEDRICHSEN[1];
[1]The Brain and Mind Inst., Western Univ., London, ON, Canada; [2]Univ. Col. London, London, United Kingdom; [3]Univ. of Plymouth, Plymouth, United Kingdom; [4]St. Georges Univ., London, United Kingdom

Abstract: Musicians' dystonia (MD) is a neurological movement disorder that affects 1-2% of all professional musicians. It is considered a task-specific disorder that results in abnormal patterns of finger movements during musical performance. One leading hypothesis for the etiology of MD argues that repetitive movements result in abnormal representations of hand movements in the sensorimotor cortex (Byl et al., 1996). Specifically, the spatial distances of finger representations on the sensorimotor cortical sheet are thought to be reduced, resulting in

increased involuntary co-contractions during task-specific activity. Here, we use behavioral measurements and functional magnetic resonance imaging (fMRI) to determine whether sensorimotor representations are distorted in MD.
A cohort of professional musicians (N=8 without MD, N=9 with MD), were instructed to perform a finger individuation task with either hand. Participants made individuated force presses with an instructed finger at varying force levels, and the patterns of involuntary forces produced by the passive fingers of the instructed hand (enslaving), and by all fingers of the uninstructed hand (mirroring) were measured. In comparison to the control group, the MD group demonstrated increased enslaving ($t(16) = -3.15$, $p=0.006$) and mirroring ($t(16) = -2.978$, $p=0.009$) on both their affected and unaffected hands. Furthermore, similar to increases in magnitude, the patterns of enslaving were also different across groups ($\chi^2(1,6)=28.2$, $p<1e4$). Thus, in contrast to task-specific dystonic symptoms, these finger individuation deficits appear to be much more generalized.
We also probed the finger representations of the MD and non-MD group using 7T fMRI. Participants either made individuated force presses ('motor' condition) at low force levels or had single fingers passively lifted ('sensory' condition) inside the scanner. Although strong somatotopic organization was observed in the primary somatosensory cortex for both groups, we found no reduction in spatial distances as a result of dystonia in either the primary somatosensory (S1, $t(15)=-0.504$, $p=0.621$) or the motor cortex (M1, $t(15) = -1.468$ $p = 0.163$). Even when using more sensitive multivariate measures of pattern overlap, we found no significant difference in the arrangement of digit activation patterns between groups. This was true for both S1 and M1, and for both the motor and sensory task conditions.
To summarize, our results suggest that hand deficits in MD are partly generalized and not entirely task-specific, and furthermore challenge the notion that MD is caused by increased overlap of finger representations in the sensorimotor cortex.

Title: Theta burst stimulation primarily modulates motor cortex engagement for ipsilateral, not contralateral, finger movements

Authors: *J. A. MELTZER[1], A. FRANCOIS-NIENABER[1], B. BELLANA[1], M. HEBSCHER[1], T. DESCHAMPS[1], F. FARZAN[2];
[1]Rotman Res. Inst., Baycrest, Toronto, ON, Canada; [2]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Noninvasive brain stimulation (NIBS) is known to modulate cortical excitability, based on its effects on motor evoked potentials. Theta burst stimulation is considered either excitatory in its intermittent form (iTBS) and inhibitory in continuous form (cTBS). Many questions remain about the nature of these excitability changes: 1) whether they generalize to other regions of cortex, 2) how they affect task-induced activity in the stimulated region, and 3) how they affect distant regions, especially homologous areas in the contralateral hemisphere, which is highly relevant as several applications of NIBS are based on altering the balance of interhemispheric inhibition. To address these questions, we measured oscillatory neuronal activity before and after iTBS and cTBS, using magnetoencephalography (MEG). Specifically we studied the effects of left motor cortex stimulation on induced changes in oscillatory power associated with moving the left and right index finger.
12 right-handed participants performed a visually cued finger movement task, pressing a button with either hand. After ~25 minutes of MEG, participants underwent stimulation to left motor cortex, iTBS in one session, and cTBS in another. Next, they did another 50 minutes of the MEG finger movement task.
Finger movements induced the expected patterns of oscillatory reactivity in motor cortex - bilateral mu (8-12 Hz) and beta (15-30 Hz) power decrease, beta rebound, and gamma (65-85 Hz) increase, timelocked to movement onset. Beta rebound and gamma increase were strongly lateralized to left cortex for right-hand movements. Left hand movements, however, evoked bilateral activity in these measures.
The effects of TBS were mainly on activity associated with ipsilateral hand movements. Relative to iTBS, cTBS to left motor cortex induced increased gamma power in right motor cortex for right hand movements: i.e. inhibiting the dominant left motor cortex caused the right motor cortex to "come online" to support movement of the right hand. In contrast, the same stimulation *reduced* gamma power in the left motor cortex for left hand movements: i.e. inhibiting the left motor cortex reduced its involvement in left hand movements.
These findings suggest that NIBS may not have a strong effect on task activation in motor cortex for contralateral movements, suggesting that a similar level of activity is required to execute the movement regardless of the baseline state of excitability. Instead, NIBS may modulate the degree to which activity spreads to the other hemisphere. This provides empirical support to studies aiming to modulate transcollosal inhibition through NIBS, for example in stroke recovery.

Title: Task-dependent coherence across finger muscles

Authors: *C. M. LAINE, A. NAGAMORI, J. Y. SHIN, F. J. VALERO-CUEVAS;
Biomed. Engineering, Div. of Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstract: Multiple task-related muscles may be grouped together by the nervous system through the distribution of a shared control signal. This common intermuscular signal contains oscillations which may be useful in characterizing different neural control strategies. To date, the principles which determine the strength and frequency content of common oscillatory drive to groups of muscles are not well understood. In this study, we tested the hypothesis that the mechanical relationship between muscles, within the context of a given task, determines the spectral content of their shared neural drive. Ten healthy adults were asked to complete i) a static, isometric pinch using the thumb and index finger (2N force), ii) a sinusoidal, isometric pinch (1 to 3N force), and iii) rotation of a pinched object between the index finger and thumb of their self-reported dominant hand. Surface EMG signals were recorded from the first dorsal interosseous (FDI), abductor pollicis brevis (APB), and flexor digitorum superficialis (FDS). Coherence between the EMG signals recorded from each pair of muscles was analyzed (from 1 to 50 Hz) to determine if the frequency content of shared drive varied between muscle pairs. We found that during object rotation, both the FDI and APB muscles lost coherence (at nearly all frequencies) with the FDS muscle, while FDI:APB coherence increased at 10 and 40 Hz, and was unchanged at 20 Hz, relative to the isometric pinching tasks. During the sinusoidal modulation of pinch force, FDI:APB coherence was generally reduced compared with the other two tasks, while coherence between the FDI and FDS muscles (which are more directly synergistic) increased. In contrast, spectral power changed relatively little above 5 Hz across tasks. We interpret these findings as evidence that the spectral content of shared neural drive, as measured by intermuscular coherence, depends upon the mechanical contribution that each muscle makes to the task at hand, as well as the degree of function coupling required between muscles. We speculate that such dependence contributes to the known sensitivity of intermuscular coherence to movement and the dynamics of force production.

Title: Differences in movement-related, inter-regional phase-locking in young and elderly healthy subjects

Authors: ***N. ROSJAT**[1,2], S. POPOVYCH[1,2], L. LIU[1,2], B. A. WANG[1], T. I. TÓTH[2], C. GREFKES[1,3], G. R. FINK[1,3], S. DAUN[1,2];

Abstract: The vast majority of motor actions, including their preparation and execution, is the result of a complex interplay of various brain regions. Novel methods in computational neuroscience allow us to assess interregional interactions from time series acquired with in-vivo techniques like electro-encephalography (EEG). These methods provide different neuronal representations of movement (e.g. ERD, ERS, PLI). However, our knowledge of the functional changes in neural networks during non-pathological aging is relatively poor.
To advance our knowledge on this topic, we recorded EEG (64 channel system) from 18 right-handed healthy young participants (22-35 years, 10 female) and 24 right-handed healthy old participants (60-79 years, 12 female) during a simple motor task. The participants had to execute voluntary low frequency left or right index finger tapping movements.
We used the relative phase-locking value (rPLV) computed from the phases obtained by Morlet wavelet transformation of the Laplacian-referenced EEG data to identify the functional coupling of brain regions during the motor task. We analyzed the connectivity for electrodes lying above the left and right premotor areas (lPM: F3, FC3 and rPM: F4, FC4), supplementary motor area (SMA: Cz, FCz) and the left and right primary motor cortex (lM1: C3, CP3 and rM1: C4, CP4). We compared the resulting networks of significant phase-locking increase in time-intervals prior, during and after the movement.
Our analysis revealed an underlying coupling structure around the movement onset in the delta-theta frequency band (2-7 Hz), only. For young subjects, the connection from SMA to M1

contralateral to the moving hand showed a significant rPLV increase already in the preparatory phase of the movement. This synchronization remained significant during the movement and in a time intervalafter it. In elderly subjects, however, the change in rPLV between SMA and contralateral M1 was significant only during the execution of the movement. We furthermore monitored the behavioral performance of the two age groups and observed a lower movement speed in the elderly subjects. We therefore suggest that a lateralized rPLV between SMA and M1 prior the movement is needed to accurately initiate and perform the finger movements.

Abstract: Motor actions are generated by complex interactions of various brain regions. The same brain regions can build various functional networks depending on the action to be performed. Identifying the neural signals that encode an action's components (selection, preparation and execution) remains a difficult task.
In the current study, we seek to identify common neural markers of movement execution valid for both age groups in cortical motor regions. Therefore we recorded electroencephalography (EEG) data from 18 young (11F, 22-35 years) and 24 elderly (12F, 60-78 years) right-handed healthy subjects as they were performing a simple motor task. The task required participants to

execute a left or right index finger button press triggered by a visual cue or by an uncued voluntary choice.
In both age groups, we found significant phase locking in the delta-theta frequency band (2-7 Hz) in motor areas contralateral to the moving hand prior to movement execution. This phase locking occurred irrespective of how the action was initiated (with or without a visual cue) and was not significantly different in strength between the two age groups. However, the length of phase locking, particularly in the primary motor area contralateral to the moving hand, was much shorter in the elderly than in the young subjects, meaning that phase locking occurred later and finished earlier in time.
In addition, we monitored the performance of the two groups of participants and observed that movement and reaction times were significantly longer in the elderly. Moreover, the maximum phase locking value around movement onset was, in the young subjects, correlated with movement time at the electrodes located above the primary motor cortex. This correlation between the electrophysiological effect and the behavioral performance shifted to frontal regions in the elderly subjects.
In summary, our results suggest that phase locking in the delta-theta frequency band, i.e. the enhanced intra-regional synchrony in motor regions contralateral to the moving hand, constitutes a prerequisite for triggering the movement execution. We furthermore hypothesize that the earlier the significant phase locking occurs the better the motor action can be initiated and performed. Finally, we also suggest that, in elderly subjects, the additional recruitment of the frontal regions might constitute a mechanism to support the execution of the motor task.

Title: The frequency-specific modulation of ipsilateral activities in primary motor regions during preparation of two simple motor tasks

Authors: *B. A. WANG[1], S. VISWANATHAN[1,2], R. O. ABDOLLAHI[1], N. ROSJAT[1], S. POPOVYCH[3], S. DAUN[1,3], C. GREFKES[1,2], G. R. FINK[1,2];

Abstract: Task-dependent decreased powers over sensorimotor regions have been shown to be more widespread and less lateralized when it is close to the unilateral hand movement onset, which plays important role in the normal aging and recovery of the stroke patients. However, the mechanism underlying this change of less lateralization of powers is still largely unclear. In this study, we are interested in the mechanism by which the motor system drives the ipsilateral powers during motor preparation in order to keep the performance of movement under the control of two different initiating networks, namely, *Self-initiated* and *Visually-cued* actions. In order to answer our question, we collected 64-channel EEG data while participants performed self-initiated and visually cued button presses with their index fingers. We found a significant decrease of power in α-band (8-13 Hz) and β-band (14-30 Hz) over ipsilateral primary motor area (iM1) during movement preparation in both conditions. In *Self-initiated* condition, a significant spectral coherence between left M1 and right M1 was found in α-band for both hand movements. And, the higher LM1-RM1 coherence was associated with the more decrease of high-β (22-30 Hz) power over iM1. Additionally, we found a significant coherence between the supplementary motor area (SMA) and iM1 in the α-band prior to a left hand movement in the *Self-initiated* condition, which similarly regulates the high-β power over iM1. In *Visually-cued* condition, however, RM1 and premotor area (PM) has the significant coherence with iM1 in δ-θ-band (2-7Hz) only during left hand movement. Moreover, the higher coherence between the right PM and iM1 in δ-θ-band is correlated with more decrease of high-β power over iM1 during left hand movement. Our findings suggest that the ipsilateral β oscillations seem not merely the result of interhemispheric modulation, but involve additional task-dependent processing. Considered that the increased β oscillations are related with greater GABAergic inhibitory activity, we may conclude that the task-dependent control network is involved in the control of ipsilateral β oscillations by distinct neural control patterns, with the purpose of suppressing output to the muscles of the nonmoving hand from the ipsilateral cortex.

Title: Activation of indirect pathways between ventral premotor cortex and the spinal cord by transcranial magnetic stimulation

Authors: *K. L. BUNDAY[1], M. PEREIRA[1], M. DAVARE[1,2];
[1]Univ. Col. London, London, United Kingdom; [2]Dept. of Kinesiology, KU Leuven, Leuven, Belgium

Abstract: In humans it is well established that the ventral premotor cortex (PMv) plays a key role in controlling grasping movement. PMv conveys grasp-related information to the primary motor cortex (M1), which converts it into a grasp-specific motor command relayed to hand muscles via the corticospinal pathway. However, monkey studies have reported that PMv, as well as having a number of indirect projections to the cervical spinal cord (e.g. via M1 and the brainstem), provides direct projections terminating in the upper and lower cervical segments. Whether such projections exist and are functional in humans is unknown. Here we used transcranial magnetic stimulation (TMS) over PMv to condition H-reflexes elicited via low intensity peripheral nerve stimulation (PNS) whilst subjects sat at rest. The TMS coil was placed over the caudal part of the inferior frontal gyrus (cortical surface MNI coordinates: X=57.4, Y=17.7, Z=15.7). PNS was applied percutaneously to the median nerve in order to elicit H-reflexes in the flexor carpi radialis muscle. In order to time the arrival of the descending and ascending volleys onto the spinal motoneurons accurately we measured the central conduction time (CCT; measured from M1) and peripheral nerve conduction time (PNCT) for each individual subject. H-reflexes were either elicited alone (baseline) or conditioned by PMv TMS. We investigated 6 inter-stimulus intervals (ISI), namely -4, -2, 0, 2, 4 and 6 ms, where negative ISIs indicate that PNS is delivered prior to TMS, 0 ms indicates that PNS and TMS-evoked volleys converge at the same time on the spinal motoneurons, and positive ISIs indicate that TMS was given prior to PNS. In addition, we tested 3 TMS intensities (80%, 100% and 120% of resting motor threshold). Our results show that while threshold conditioning pulses over PMv had no effect on H-reflexes, both subthreshold and suprathreshold pulses increased the H-reflex amplitude compared to baseline H-reflexes. Specifically, subthreshold PMv conditioning pulses significantly facilitated H-reflexes at -2 and 4 ms ISIs, whereas suprathreshold conditioning pulses only facilitated H-reflexes at a 2 ms ISI. To ensure these effects were not due to a spread of activation from PMv to M1, we also conditioned H-reflexes with TMS over M1. Our results allow us to speculate that recruiting sub- or suprathreshold PMv projections reveals a different time course of indirect interactions with upper and lower cervical segments. PMv projections have a net and diffused facilitatory effect on spinal excitability; with subthreshold outputs interacting with both upper and lower segments and suprathreshold outputs only with lower segments.

Title: Digit position and forces covary during anticipatory control of whole-hand manipulation

Authors: ***M. MARNEWECK**[1], T. LEE-MILLER[2], M. SANTELLO[3], A. M. GORDON[2]; [1]Univ. Of California Santa Barbara, Santa Barbara, CA; [2]Teachers College, Columbia Univ., New York, NY; [3]Arizona State Univ., Tempe, AZ

Abstract: Theoretical perspectives on anticipatory planning of object manipulation have traditionally been informed by studies that have investigated kinematics (hand shaping and digit position) and kinetics (forces) in isolation. This poses limitations on our understanding of the integration of such domains, which have recently been shown to be strongly interdependent. Specifically, recent studies revealed strong covariation of digit position and load force during the loading phase of two-digit grasping. Here we determined whether such digit force-position covariation is a general feature of grasping. We investigated the coordination of digit position and forces during five-digit whole-hand manipulation of an object with a variable mass distribution. Subjects were instructed to prevent object roll during the lift. As found in precision grasping, there was strong trial-to-trial covariation of digit position and force. This suggests that the natural variation of digit position that is compensated for by trial-to-trial variation in digit forces is a fundamental feature of grasp control, and not only specific to precision grasp. However, a main difference with precision grasping was that modulation of digit position to the object's mass distribution was driven predominantly by the thumb, with little to no modulation of finger position. Modulation of thumb position rather than fingers is likely due to its greater range of motion and therefore adaptability to object properties. Our results underscore the flexibility of the central nervous system in implementing a range of solutions along the digit force-to-position continuum for dexterous manipulation.

Title: Sensorimotor deficits in Carpal Tunnel Syndrome: Relation between electrodiagnostic and grasp behavioral measures

Authors: *P. J. PARIKH[1,2], W. ZHANG[4], K. GRIMM[3], M. ROSS[5], M. SANTELLO[2]; [1]Univ. of Houston, Houston, TX; [2]Sch. of Biol. and Hlth. Systems Engin., [3]Psychology, Arizona State Univ., Tempe, AZ; [4]Physical Therapy, The City Univ. of New York - Col. of Staten Island, Staten Island, NY; [5]Neurol., Mayo Clin., Scottsdale, AZ

Abstract: Carpal Tunnel Syndrome (CTS) is an entrapment neuropathy of the median nerve resulting in sensorimotor impairments in the hand. Damage of the median nerve in the wrist affects patients' ability to use tactile feedback from the affected digits, and therefore sensorimotor integration and overall hand function. Accurate quantification of these phenomena can potentially aid in CTS diagnosis and prognosis. The clinical diagnosis of CTS is based on electrodiagnostic tests (EDT), which is also used to assess CTS severity. However, in clinical settings the decline in manual dexterity is often determined using measures such as pinch strength and sensory acuity that fail to capture more complex and critical aspects of hand function, i.e., the ability of integrating tactile feedback with planning, selection, and execution of motor commands. Our studies on the effects of CTS patients on the control of grasping and manipulation revealed an impaired ability to generate, store, and retrieve sensorimotor memories from past manipulations, thus preventing planning and execution of multi-digit forces on a trial-to-trial basis. The present study quantified the extent to which CTS-induced deficits in sensorimotor integration (SI) and results of EDT correlate. We used data collected on CTS patients with mild (n=12) and moderate (n=17) severity from our previous studies to determine, using regression analysis, the correlation between EDT and SI measures. Subjects performed a grip and lift task that required them to lift an inverted T-shaped object using their thumb and four fingers. We considered grip force and the net moment exerted on the object measured at the time of lift onset as measures of SI. In moderate CTS cases, longer median sensory nerve distal latency (MSNDL) predicted larger magnitude of moment applied to the object at lift-onset ($p=0.03$). Larger moment on the object can alter its orientation, thus potentially affecting manual dexterity. No correlation was found between EDT and SI measures in mild cases. Our findings suggest that EDT measures in patients diagnosed with moderate CTS have a greater informational content as these measures, in addition to electrophysiological deficits, determine

the degree of sensorimotor integration deficits. Conversely, no correlation between these measures in mild CTS patients raises the question of whether they may capture very different, yet potentially complementary dimensions of hand function in the early stages of median nerve compression.

Title: Learning and inter-limb generalization of novel visuomotor mapping with multiple fingers

Authors: *Q. FU, C. ZAMORANO, M. SANTELLO;
Arizona State Univ., Tempe, AZ

Abstract: Human machine interfaces usually require users to learn new visuomotor mappings with multiple degrees of freedom. However, neural and biomechanical constraints may limit the extent to which new mappings can be acquired, stored, and generalized. To improve the design and training efficiency of these novel mappings, it is important to understand how the central nervous system exploits the available solution in motor space. We addressed this question through an experiment that required human participants (n = 5) to learn a novel visuomotor mapping with four finger forces. Specifically, participants had to control a 2D cursor in a center-out task by exerting grip force with the fingertips of their dominant hand while grasping a stationary handle. The finger forces were scaled to single finger maximum voluntary contraction forces for each subject, then mapped to cursor positions by a 4×2 matrix, such that the index, middle, ring, and little finger moved the cursor along +x, −x, −y, and +y axes, respectively. We used three experimental sessions that consisted of cycles of 36 targets which were evenly spaced around the starting area. Participants performed 12 cycles in the training session on the first day, and came back 24 hours later for a 2-cycle retention test session, and a 5-cycle across-hand transfer test session. Performance was measured by movement time and submovement characteristics for each target acquisition. With regard to movement time, participants started with non-uniform performance across quadrants. This indicates a differential initial force coupling of different combinations of fingers. After training, however, participants reached each

target at similar durations across all quadrants. We also found that there was no significant change in the duration and distance of submovements through training with a total of 432 targets, but the number of submovements per target decreased. Interestingly, we found that the percentage of submovements that were aligned with the direction of single finger actuation significantly increased, suggesting a control strategy based on sequential, rather than simultaneous, force production by individual fingers. Finally, we found that the acquired mapping can be well retained and generalized to the non-dominant hand on the second day. These preliminary findings provide new insights on motor skill learning with multiple degrees of freedom.

Title: Cortical activity reflects differential contribution of feedforward vs. feedback mechanisms during object grasp and manipulation

Authors: *P. MCGURRIN[1], J. FINE[2], K. SCREWS[3], M. SANTELLO[2];
[1]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [2]Sch. of Biomed. and Hlth. Systems Engin., [3]Sch. of Sch. for Engin. of Matter, Transport, and Energy, Arizona State Univ., Phoenix, AZ

Abstract: Unique sensorimotor mechanisms appear to underlie manipulation using a grasp requiring self-selected (unconstrained) vs. predetermined (constrained) contact points. During unconstrained grasping, additional digit force corrections are required to compensate for variability in where the digits grasp the object relative to planned contact points. Our recent work demonstrated that a virtual lesion over primary motor cortex (M1) has a differential effect on the grasp execution depending on whether subjects used a constrained or unconstrained grasp. We believe that this is due to the different extent to which the sensorimotor system relies on feedback of digit placement to modulate forces. However, the offline M1 stimulation used in our previous work did not allow us to examine the corresponding spatial and temporal features of neural activation. Therefore, the present experiment used electroencephalography (EEG) to investigate activation in the larger grasping network during unconstrained and constrained grasping. Our hypothesis was that grasp type-dependent cortical activation would be associated with differential weighting of sensory feedback in the two grasp contexts. Six subjects performed a visually-cued grasp and lift task using a precision (thumb-index) grasp at unconstrained or

constrained locations. Trials were blocked such that the grasping context was similar across trials (blocked) or could vary from trial-to-trial (randomized). indicated by a visual ‘go’ cue on each trial In both contexts, we asked subjects to lift an object with an asymmetrical center of mass while minimizing tilt. Time-frequency analysis of EEG data revealed greater modulation in gamma band power (25-50 Hz) in the unconstrained than unconstrained grasping over left prefrontal and sensorimotor regions during the first 500 ms following the ‘go’ cue. Interestingly, this modulation was sensitive to whether subjects performed grasping trials in a blocked vs. randomized manner. Relative to the unconstrained context, increased gamma band activity was present in the constrained context during random trial presentation ($p < 0.05$), but decreased during blocks where the context was similar across trials ($p < 0.05$). Our findings are consistent with previous EEG work demonstrating changes in gamma power during motor memory retrieval tasks, and are the first to explore the involvement of specific frequency bands during grasping tasks requiring differential weighting of feedforward vs. feedback mechanisms.

Title: Theta and Beta-band activity reflects motor interference in dual-context sensorimotor adaptation

Authors: *J. M. FINE, D. MOORE, M. SANTELLO;
Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Phoenix, AZ

Abstract: An issue in sensorimotor learning during object manipulation is understanding how previously learned motor commands can be generalized to manipulating the same object in a new context. Object manipulation requires combining visual cues provided by object geometry and implicit knowledge of object properties to select appropriate grasp points and digit forces. If visual geometric cues do not match object properties -e.g., visual symmetry and asymmetric mass distribution - initial manipulation yields large errors. Further improvement must rely on implicit recall of object properties to adjust motor commands. We previously found that the information learned from lifting an asymmetrically weighted object is not readily transferred to a new context, i.e., after a 180° object rotation. Large errors (object tilt) occur during transfer trials that are akin to, or larger than initial learning. Despite these results, errors made on transfer trials do not allow discrimination of whether or not this interference arises from treating the second

context as novel, or a bias induced by the previous manipulation. To distinguish between these interpretations, we used electroencephalography (EEG) to examine the neural dynamics of participants while they learned to grasp and lift a visually symmetric but asymmetrically weighted object. After an initial learning block, participants performed nine transfer blocks. This consisted of lifting the object once after having rotated it 180° (transfer trials), followed by rotation back to the original context for four trials. Consistent with our previous work, transfer and post-transfer trials exhibited differing degrees of switching interference (error). Initial learning involves selecting appropriate motor commands while overcoming the conflict between explicit visual cues and object dynamics that is learned implicitly. Conflict during action selection and response uncertainty has been linked with increased theta activity (4-8 Hz) over the medial frontal cortex (MFC), and beta (15 - 30 Hz) suppression over primary motor areas during response planning. Therefore, if the second manipulation context is treated as novel, we expected similar theta and beta activity in early initial learning compared to transfer trials. EEG data revealed that frontal theta and motor beta activity was larger during learning in the initial context compared to the rotated transfer context. This preliminary analysis suggests that motor errors during transfer arise from a motor command bias, which is likely due to use-dependent repetition from initial learning and an inability to switch contexts immediately.

Title: Effects of visual cues of object shape and density differentially affect variability in anticipatory planning of digit placement and forces.

Authors: *T. LEE-MILLER[1], M. MARNEWECK[1], A. M. GORDON[1], M. SANTELLO[2]; [1]Biobehavioral Sci., Teachers College, Columbia Univ., New York, NY; [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Skilled object manipulation relies on precise anticipatory planning processes that in turn rely on visual estimates of object properties and prior grasping experience. The prevalent

theoretical framework about object manipulation is that sensory feedback plays a dual role: (1) acquiring information about object properties ('online' control), and (2) forming internal representations of object dynamics to anticipate the digit forces that will arise when manipulating objects ('feedforward' control). Visual information about an object to be grasped is used to select an appropriate grip type. A wide frontal-parietal cortical network plays a significant role for these visuomotor actions, in particular posterior parietal cortex being involved in planning of digit positions and forces during reach-to-grasp. Studies on anticipatory planning of object manipulation showed initial task failure (i.e., object roll) when visual object shape cues are incongruent with other visual cues, such as weight distribution/density (e.g., symmetrically shaped object with an asymmetrical density). This suggests that congruent and incongruent shape and density cues differentially influence anticipatory planning of digit forces and placement. We have recently shown differential modulation of digit placement and forces, but only when shape and density cues were congruent. When shape and density cues were incongruent, we found collinear digit placement and symmetrical force sharing. However, trial-to-trial variability in digit placement and forces were large. This is in line with the strategy that to generate a desired torque, a continuum of digit placement and force modulation may be employed. We tested whether shape and density cues would differentially influence the trial-to-trial variability of digit placement and forces during initial trials of a two-digit object manipulation task. Subjects grasped and lifted an object with the aim of preventing roll. In Experiment 1, the object was symmetrically shaped, but with asymmetrical density (incongruent cues). In Experiment 2, the object was asymmetrical in shape and density (congruent cues). In Experiment 3, the object was asymmetrically shaped, but with symmetrical density (incongruent cues). Results showed that even on unsuccessful trials, variability between digit placement and forces were correlated. Thus, though the congruency of visual shape and density cues affect overall outcome, the strategy employed is similar. This is in line with the theory of motor equivalence and influences our understanding of internal representations underlying planning and execution of grasping and manipulation.

Title: Cortical representation of finger sequences in humans

Authors: *A. YOKOI[1,2], J. DIEDRICHSEN[1];
[1]The Brain and Mind Institute,, Univ. of Western Ontario, London, ON, Canada; [2]Grad. Sch. of Frontier Biosci., Osaka Univ., Suita, Japan

Abstract: Understanding how the cortical motor regions control learned sequences of movements is one of the key issues in motor neuroscience. Here, using novel multivariate analysis techniques for human functional imaging data, we asked whether and how different areas along the hierarchy of motor and premotor regions represent different aspects of a sequence of finger presses, such as whole sequences, transitions between two consecutive presses, or individual finger movements.
We scanned the brain activation of 9 participants while they produce repetitive presses with one of the 5 single digits or one of 6 multi-digit sequences. All trials consisted of 6 finger presses executed at 4 Hz tapping speed. To determine to what degree the information was driven by control processes or by sensory re-afference, we also repeated all sequences using passive stimulation of the hand by replaying exactly the force patterns recorded during the previous active session.
To assess how these sequences are represented across different cortical regions we performed representation similarity analysis (RSA) on the local activity patterns in each region. We used a cross-validated distance measure, such that a systematically positive value indicates that the activation patterns for that pair of conditions were significantly different.
We found robust encoding for single finger movements in contralateral primary sensory and motor, as well as in dorsal premotor cortex, supplementary motor area, and parietal regions, both in the active and passive conditions. All areas also showed encoding for multi-digit sequences. However, this representation was only found for the active, but not for the passive condition. In primary sensory and motor cortex, the activation for each sequence was dominated by the pattern associated with the first finger in the sequence. In contrast, in premotor and parietal regions, the encoding for the multi-digit sequence was independent of the single-digit maps. These results suggest that premotor regions show a different neural state for each of the possible sequences. In

contrast, primary motor and sensory cortex receive a large descending input for the first finger press, after which the learned sequence can evolve using less synaptic activity.

Title: Dexterous individuated finger representations for neural prosthetic applications in the anterior intraparietal cortex of a tetraplegic human

Authors: ***T. AFLALO**[1], C. ZHANG[1], N. POURATIAN[2], R. ANDERSEN[1];
[1]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Neurosurg., UCLA, Los Angeles, CA

Abstract: The complexity of human and primate motor behavior is largely enabled by the dexterity of our finger movements. Work in neural prosthetics has demonstrated the feasibility of controlling the aperture of basic grasp types (e.g. power & precision grips) and while these studies are important steps towards empowering paralyzed individuals to perform activities of daily living, these basic grasp templates provide strong constraints on the neural prosthetic behavioral repertoire. Fine dexterous control of individuated finger movements is of recent evolutionary origin and is primarily mediated by the corticospinal tract. Other forms of hand behavior (e.g. hand-holds for climbing) can be controlled via other descending pathways. The anterior intraparietal cortex (AIP) in the posterior parietal cortex is a subregion of the cortical grasp network thought to emphasize transforming visual information about object shape into appropriate grasp plans, and similar to premotor cortex (F5/PMv), shows specificity for whole hand shapes suggesting a possible library of whole grasp actions. Given the distributed network controlling the hand, and a primary role in transforming visual information, it is unclear whether the functional properties of AIP are suitable for neural control of dexterous hand actions. We tested how populations of neurons in AIP coded individuated and combined finger movements and the suitability of these signals for closed-loop cortical control in tetraplegic patients implanted with Utah arrays for a brain-machine interface clinical trial. We found that individual

digit movements of the right and left hand are well represented. Some neurons were specific for a single digit while others were activated by several digits (e.g. right thumb and pinky, but not the index.) Functional overlap was prominent between matched digits of the right and left. Overlap was also prominent between the middle, index, and pinky potentially reflecting correlated motion during natural behavior and biomechanical factors. Digit representations coded for multiple degrees of freedom enabling decoding of 2D thumb movements. These neural representations provided a versatile set of control signals and could be used for a variety of prosthetic applications including the continuous control of individuated finger movements of a virtual avatar, two dimensional cursor control, and the detection of finger flexion movements for the neural control of a virtual piano and typing interface. Further, we found that the relationship between single finger movements and combined movements of multiple fingers and whole hand grasps was frequently complex, but with underlying structure.

Title: Changes in perception of step length size after split-belt walking

Authors: ***C. J. SOMBRIC**[1], G. TORRES-OVIEDO[2];
[1]Dept. of Bioengineering, [2]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Step asymmetry post-stroke significantly limits patients' mobility. It has been proposed that patients' reduced perception of their gait asymmetry contributes to their inability to recover symmetric walking (Wutzke et al. 2015). Thus, there is an interest in understanding if the perception of step asymmetry can be altered. A recent study indicates that split-belt walking, in which legs move at different speeds, changes the perception of asymmetric walking speeds in unimpaired subjects (Vazquez et al. 2015). Here, we hypothesize that the perception of asymmetric step lengths can also be altered after split-belt adaptation. To test this, we investigated subjects' perception of step lengths for each leg before and after split-belt adaptation. Participants (n=10, 25.2±4.3) first learned a spatial map of three distinct, subject-

specific, step length sizes (short, comfortable, and long) by observing their step length and the targeted step size. All visual feedback was displayed with an Oculus Rift and Vizard software. We assessed changes in subjects' perception of their step lengths after two walking conditions: normal walking (n=5) at 1m/s and split-belt walking (n=5) at 1.5 m/s (fast leg) and 0.5 m/s (slow leg). Step length perception before and after walking was evaluated by recording step length accuracy while subjects walked at 1m/s with reduced visual feedback projecting only 35% of the actual step length error. Both groups walked for 810 strides before step length perception was assessed. A catch trial (both legs walk at 1m/s for 10 steps) was introduced during the walking period to identify motor after-effects induced by the split-belt walking condition. A two-way ANOVA with two factors, (1) walking condition and (2) stepping leg, was used to test for difference in motor and/or perception after-effects across groups or legs. We found that subjects in the split-belt group had significant motor ($p=0.007$) and perception ($p=0.001$) after-effects compared to the control group. We also found that perception after-effects were distinct for each leg: the slow leg undershot the stepping target while the fast leg overshot it following split-belt walking. Importantly, all subjects maintained the step size spatial map since there were no differences ($p=0.66$) in stepping accuracy for the different targets tested without visual feedback before walking and after perception after-effects were extinguished. In sum, we found that split-belt walking induces changes in the perception of step lengths. This is important since paradigms like split-belt walking could be used to alter patients' active perception of limb position and improve their awareness of asymmetric stepping.

Title: Intertrial variability of EMG reveals lack of bilateral or inter-joint muscle synergies for walking in unimpaired and post-stroke patients

Authors: *P. A. ITURRALDE, G. TORRES-OVIEDO;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Activation of 'muscle synergies' has been proposed to underlie neural control of movement, and cortical damage is thought to change the structure of these neural commands

(Cheung et al. 2014). To test these hypotheses we identified muscle synergies in unimpaired and post-stroke subjects that were independent from task requirements. We specifically recorded 30 bilateral muscles in 16 chronic post-stroke subjects and 16 age and sex matched controls under two walking conditions imposing distinct movement demands: normal walking vs. split-belt walking, in which legs move at different speeds. We identified potential muscle synergies by computing covariance matrices indicating correlated activity across muscles. Importantly, we dissociated covariations in EMG signals due to task requirements and those due to common neural drive by analyzing 1) rectified and filtered EMG data ('full dataset') and 2) fluctuations in EMG recordings from the mean activity across strides ('intertrial dataset').
We found co-activations between anatomical (22/22 signif. correlations, median r^2=.73), multijoint (119/188, r^2=.30), and bilateral (149/225, r^2=.29) muscles in the full dataset, which have been previously interpreted as anatomical, multisegmental, and bilateral muscle synergies, respectively. However, only anatomical co-activations were observed in the intertrial dataset (22/22, r^2=.36), while the others became much weaker (r^2<=.08). We also found that muscle co-activations between bilateral muscles in the full dataset change across walking conditions to match changes in task constraints (median change in r^2 =.14), whereas muscle co-activations in the intertrial dataset were maintained the same.
Lastly, anatomical muscle co-activations identified in the intertrial dataset of patients were the same (22/22, r^2=.40) as controls and surprisingly symmetric across legs. Conversely, full dataset analysis revealed that stroke patients have less multijoint (94/188, r^2=.38) and bilateral (113/225, r^2=.30) muscle co-activations than controls, suggesting a deficit in patients task performance or reduced task demands (since all patients walked slower than controls).
Taken together these results suggest that only anatomical groups might receive unified neural drive, but correlated activity in muscles across joints and legs (multijoint and bilateral muscle synergies) reflects task demands, rather than shared neural control signals. As such, differences in multijoint and bilateral muscle synergies between patients and controls may represent patients' deficits in task performance or reduced task demands and not clear differences in neural commands.

Title: Deficits in automatic postural responses are related to cerebellar involvement in people with Multiple Sclerosis

Authors: G. GERA[1], B. W. FLING[1], *F. B. HORAK[1,2];
[1]OHSU, Portland, OR; [2]VA Portland Hlth. Care Syst. (VAPORHCS), Portland, OR

Abstract: Introduction: Balance problems are prevalent in people with Multiple Sclerosis (PwMS); however, little is known about the mechanisms behind such deficits. We aimed to investigate ability of PwMS to predictively scale their postural responses to gradually increasing magnitudes of discrete surface perturbations. Given the cerebellum is responsible for predictive scaling or feedforward control of postural responses; we hypothesized that deficits in scaling postural responses to increased perturbation amplitudes will be related to the involvement of cerebellum in PwMS. Methods: Subjects (24MS, 14Control) stood on a force platform that translated backwards in four blocks of predictable increasing amplitudes (3.6, 6.0, 8.4 and 12 cm). Each block consisted of five trials (total of 20 trials). To determine the role of feedforward mechanism, automatic postural responses to displacements was estimated as rate change of center of pressure under each foot before the feedback response could change the postural response. Predictive scaling was estimated by computing the slope of regression between early postural responses and gradually increased perturbation amplitudes. International Cooperative Ataxia Rating Scale (ICARS) was used as a clinical scale to assess the extent of ataxia. Diffusion weighted images (DTI) of brain were also acquired. Radial diffusivity (RD), an indirect neural marker of myelination, of cerebellar peduncles was calculated for each participant. Lower RD is interpreted as being indicative of better white matter tract microstructure. Results: To date, we have analyzed the data of 9 MS and 9 control subjects. Control subjects exhibited better scaling of postural responses to the increasing magnitudes of the postural perturbations than PwMS (Regression coefficients: Control: 0.75±0.38; PwMS: 0.37±0.65). For PwMS, slope of the rate change of center of pressure with respect to the perturbation magnitude was negatively correlated with the ICARS scores (r=-0.65). ICARS scores were also correlated to the radial diffusivity of the cerebellar peduncles (r=0.5). However, the radial diffusivity of cerebellar peduncles was not related to the rate change of center or pressure (Control: 0.12; PwMS: 0.3). Conclusion: Preliminary data suggests that deficits in predictive scaling of postural responses in PwMS seem to be related to the cerebellar involvement as evident by the relationship of ICARS and postural response scaling.

Title: The effect of cognitive dual-task on balance and gait in older men

Authors: *P. CARLSON-KUHTA[1], A. LAIRD[2], M. MANCINI[1], E. S. ORWOLL[3], J. A. LAPIDUS[2], M. EL-GOHARY[4], F. B. HORAK[1,5];
[1]Neurol., [2]Sch. of Publ. Health, Biostatistics & Design Program, [3]Endocrinol., Oregon Hlth. & Sci. Univ., Portland, OR; [4]APDM, Portland, OR; [5]Res., VA Portland Hlth. Care Syst. (VAPORHCS), Portland, OR

Abstract: Background: Activities of daily living (ADL) require balance control, especially during functional movement while performing other attention-demanding tasks. Older people with limited information-processing capacity are often challenged when performing several tasks simultaneously, that require greater attention resources. Moreover, older people who perform poorly under dual-task conditions are at increased risk of falls. We utilized a group of elderly men who are part of the Osteoporotic Fractures in Men (MrOS) cohort, to examine the dual-task impact on gait and balance, using wearable inertial sensors. We hypothesize that the impact of a cognitive challenge would be larger on balance than straight ahead gait in older men.
Methods: Two-hundred seven, elderly men (mean age: 83, range 80-87) completed an

Instrumented Stand and Walk (ISAW) test, wearing inertial sensors (APDM, Portland, OR), added to their routine MrOS study visit at the Portland, OR site. The ISAW protocol consists of: stand quietly for 30 seconds, followed by walking seven meters, 180° turn, and walking back seven meters. The protocol was repeated two times – without and with a dual task of reciting serial subtractions by three's. Standardized response means (SRM) were used to determine relative dual-task effects on objective metrics characterizing balance (postural sway, turning and trunk motion in gait) and gait spatial/temporal metrics. An SRM value of 0.20 represents a small, 0.50 a moderate, and 0.80 a large dual-task response.
Results: Spatial and temporal measures of gait, such as gait speed, gait cycle time, stride length and angle at foot strike or heel off showed a large effect with the dual task compared to single task (SRM>0.8). Dynamic stability during gait, such as double support time also showed a large dual-task effect (SRM>0.8). In contrast, postural sway measures of amplitude, jerkiness, and velocity showed a small dual task cost (SRM<0.3), while sway frequency had a moderate dual task cost (SRM>0.5). Similarly, dual task cost was small when turning (SRM<0.2).
Discussion: We showed that a concurrent cognitive dual task affected spatio-temporal gait parameters more than balance during postural sway, gait or a postural transition, such as turning. This suggests that more attention is required for gait than balance by older men in this task. We plan to divide our participants into fallers and non-fallers (prospectively) to determine if the effect of a concurrent dual task on specific domains of mobility could potentially serve as a biomarker for future falls.

Title: Biofeedback device for gait rehabilitation: a validity test

Authors: *K. A. LEYBA[1], I.-H. KHOO[2], P. MARAYONG[3], V. KRISHNAN[4], O. ROJAS[1], N. BALAGTAS[1];
[2]Electrical Engin., [3]Mechanical and Aerospace Engin., [4]Physical Therapy, [1]California State University, Long Beach, Long Beach, CA

Abstract: Stroke patients exhibiting gait asymmetry require rehabilitation to improve walking and reduce injury from fall. A device, called 'Walk-Even', which consists of force sensor embedded insoles, a wireless module, a microcontroller, and a laser trigger system has been developed which analyzes gait and provides auditory biofeedback to correct gait asymmetry in real-time. To test Walk-Even's accuracy in measuring the key gait parameters, an experiment was conducted on 17 healthy adults ages 18 to 28 to compare the measurements of Walk-Even with a commercial electronic pressure mat, the ProtoKinetics Zeno Walkway (Havertown, PA). During the experiment, participants wore Walk-Even while performing a straight walk at a self-selected pace on Zeno Walkway. Two conditions were tested: normal walking and simulated asymmetrical walking. Asymmetrical walking was simulated by attaching a 7-pound weight on the participant's ankle. Temporal gait parameters, including gait time (the time it takes for a person to complete one walking cycle), swing time (the time when the person's foot is off the ground), and stance time (the time when the person's foot is on the ground) were measured. The asymmetry ratio, defined as one minus the ratio between the stance time of the affected leg to the normal leg, was then calculated. Spatial gait parameters, including step length (the distance from a person's first foot contact to subsequent contact of the opposite foot), stride length (the distance from a person's first foot contact to next contact of the same foot), and average velocity were also determined.
From the experiment, data analysis will show if the correlation between gait time, swing time, stance time, and asymmetry ratio between Walk-Even and Zeno Walkway were good. [Data to be reported]. These results may indicate Walk-Even's ability to provide accurate gait measurements for future experimental use in stroke patient rehabilitation by providing biofeedback. Due to the affordability, portability, and user-friendly interface, Walk-Even could be a possible alternative to expensive commercial devices in analyzing gait asymmetry, and another option in traditional physical therapy treatment to correct gait asymmetry.

Title: The effect of external cues and closed-loop biofeedback on Freezing of Gait in Parkinson's disease

Authors: *M. MANCINI[1], G. HARKER[2], K. SMULDERS[2], J. G. NUTT[2], F. B. HORAK[2]; [1]Neurology, Balance Disorders Lab., Oregon Hlth. and Sci. Univ., Portland, OR; [2]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Background. Accumulating evidence suggests that inadequate integration of sensory information and defective proprioceptive internal maps may underlie abnormal motor control in PD. Interestingly, freezing of gait most frequently occurs during tasks that require control of asymmetric motor tasks, such as turning or gait initiation and depend heavily on integration of proprioceptive information. For these reasons, augmenting somatosensory information with biofeedback during appropriate phases of the gait cycle may improve gait disturbances. Here we compare the effects of open-loop external cues (metronome) and closed-loop tactile biofeedback on freezing of gait (FoG) in Parkinson's disease (PD).
Methods. Twenty subjects with idiopathic PD with FoG (MDS-UPDRS III: 43±11 and new FoG questionnaire score: 18±7) performed a turning task, consisting of turning in place for one minute (changing turning direction after each full turn) while off their levodopa medication. Three inertial sensors were mounted on the posterior trunk and on each shin. Turning was compared across 3 randomized conditions: i) baseline (no cues); ii) turning to the beat of a metronome (control), and iii) turning with phase-dependent tactile biofeedback via light vibration to the wrists every time the ipsilateral foot was in stance phase. For each condition, a Freezing ratio calculated as the power spectral density ratio between high and low frequencies of shin accelerations and the percentage of time spent freezing during the task were measured. This study is in progress and will also examine 20 PD subjects without FoG.
Results. All subjects showed mild-to-moderate FoG during the assessment. At baseline, the Freezing ratio was 2.2±0.4, and it significantly reduced with both the metronome to 0.8±0.2 ($p<0.001$), and tactile-biofeedback conditions to 0.8±0.1 ($p=0.001$; one-way ANOVA $F=6$, $p=0.004$). Similarly, the % time spent freezing in the turning task significantly decreased from

45±5% at baseline to 18±4% in the metronome condition ($p<0.001$) and to 19±4% in the tactile biofeedback condition ($p=0.001$; one-way ANOVA $F=12$, $p=0.001$).
Conclusions. We observed a significant decrease in freezing of gait while turning in both a biofeedback (closed-loop) and externally-cued condition (metronome, open-loop). These preliminary observations suggest that augmenting somatosensory information with a phase-dependent biofeedback system relying on an unobtrusive modality, might be an effective tool in reducing FoG in everyday life.

Title: The modulation of locomotor heading required for obstacle avoidance is altered by the presence of visuospatial neglect.

Authors: *G. ARAVIND, A. LAMONTAGNE;
McGill Univ., Montreal, QC, Canada

Abstract: Introduction: Altered perception of visuospatial information caused by visuospatial neglect (VSN) after a stroke; can lead to an impaired control of locomotor heading especially in response to visual stimuli present in the contralesional side of space. In a virtual reality scenario, we assessed how the presence of VSN influenced the ability of stroke survivors to modulate their heading in response to moving obstacles when walking towards a stationary target. **Methods**: Twenty-six stroke survivors (13 with and 13 without VSN) were instructed to walk towards a centrally-located target, while avoiding a collision with a moving cylinder that approached either ipsilesionally, contralesionally or head-on. Outcomes assessed were related to obstacle avoidance (onset-of-heading change, maximum mediolateral (MaxML) deviation, walking speed and target alignment (heading and head rotation errors with the target). Relationships between aforementioned measures with clinical measures of neglect severity were also examined. **Results**: Collisions with contralesional and head-on obstacles were observed in 75% of

individuals with VSN individuals compared to 38% of individuals free of VSN. In individuals free of VSN, walking towards the same side as the approaching obstacle emerged as a safer strategy while deviating to the side opposite to the obstacle seemed more demanding (e.g. earlier onset-of-heading change, larger MaxML deviations and faster walking speeds) and led to occasional collisions. Individuals with VSN deviated to the ipsilesional side for all obstacle conditions, hence displaying same-side and opposite-side strategies for ipsilesional and contralesional obstacles, respectively. In this group, collisions with the contralesional obstacles were frequent, invariantly observed for the opposite-side strategy, and were associated with large delays in onset of heading reorientation. Individuals with VSN further showed greater delays in the onset-of-heading change, smaller distances from the obstacle and larger errors in alignment with the target at the end of the trial, compared to individuals free of VSN. None of the locomotor outcomes were explained by clinical measures of neglect. **Conclusion**: VSN negatively affects the modulation of the heading in response to moving obstacles while walking, leading to frequent collisions with obstacles approaching from the contralesional side and from head-on. The locomotor strategies adopted by stroke survivors with VSN further resulted in a failure to align with the intended goal. These findings could explain the poor community ambulation abilities commonly reported in individuals with post-stroke VSN.

Title: Changes in dynamic balance and gait during challenging walking conditions in people with multiple sclerosis

Authors: *T. ONUSHKO[1], T. BOERGER[2], J. VAN DEHY[1], B. D. SCHMIT[1];
[1]Biomed. Engin., [2]Physical Therapy, Marquette Univ., Milwaukee, WI

Abstract: People with multiple sclerosis (MS) commonly have impaired balance control and often report that it is the most disruptive symptom of the disease. For example, people with MS have difficulty maintaining their balance when walking in new and unpredictable environments or when transferring their weight. These balance difficulties likely arise due to disorders of the sensory system that lead to inadequate motor responses during balance disturbances. As a result,

people with MS develop compensatory strategies to maintain balance during functional tasks. The purpose of this study is to understand the strategies people with MS use to maintain balance in a challenging walking environment. In this preliminary study, we recruited four people with MS (1 male) and asked them to walk on a treadmill mounted on top of a six-degree of freedom motion base system under 3 conditions: sinusoidal (0.12 Hz) medial-lateral (ML) translation (6 cm), combination of sinusoidal movement (0.12 Hz) in three-degrees of freedom (roll, pitch, yaw; RPY) (4 degrees), and no movement. We measured kinematics as subjects walked at their self-selected speed for 80 seconds for each trial. We analyzed step width, step length, cadence and margin of stability (measure of gait stability) during walking. Data are represented as percent change with respect to the stable walking surface. During the ML translation, MS subjects demonstrated wider (step width: +27.0%), shorter (step length: -3.4%) and faster steps (cadence: +3.1%), compared with unperturbed walking. During the RPY movement, MS subjects also demonstrated wider (step width: +8.1%) and faster steps (cadence: +2.0%), but had longer steps (step length: +4.0%). Margin of stability increased for both movement types, but the increase was greater for the ML translation (+9.0%) compared with the RPY movement (+2.1%). Previous studies have shown that a combination of increased step width and cadence, and decreased step length is a beneficial strategy for controlling balance during increasing frontal plane perturbations, which also increase the margin of stability. Our preliminary data suggest that people with MS have greater difficulty controlling their balance during more challenging walking conditions (i.e. RPY), and may indicate they are at greater risk for falls. This information could be used for rehabilitative interventions aimed at improving balance.

Title: Auto segmentation of physical activities during a Timed-Up-and-Go (TUG) task in patients with Parkinson's Disease using a system of inertial sensors

Authors: ***S. BOGARD**[1], H. NGUYEN[2], K. LEBEL[3], P. BOISSY[3], E. GOUBAULT[2], E. LE[2], N. ROOFIGARI[2], C. DUVAL[2];
[1]Sci. of Physical Activity, Univ. of Quebec At Montreal, Montreal, QC, Canada; [2]Univ. of Quebec at Montreal, Montreal, QC, Canada; [3]Univ. of Sherbrooke, Sherbrooke, QC, Canada

Abstract: INTRODUCTION: Wearable sensors could provide clinicians with access to motor performance of patients with PD as they undergo physical and clinical rehabilitation by analyzing the quality of their movements. However, the data captured by these sensors often have to be manually segmented before analysis could be performed. This process can be time consuming and cumbersome. We recently proposed segmentation algorithms based on peak detection using inertial sensors to automatically segment common activities in daily living by identifying the transition points between tasks. These algorithms were developed using a population of healthy older adult; however PD patients often exhibited altered gaits and movements due to the neurological damages caused by the disease. The aim of this study was to investigate the transferability of these algorithms in segmenting these tasks in patients with PD. **METHOD:** A modified Time-Up-And-Go (TUG) task was used since it comprised of four common daily living activities; *Stand up*, *Walking*, *Turning*, and *Sit down*, all performed in a continuous fashion. Twelve older adults who were diagnosed with early PD (Y&H<=2) were recruited for the study. They performed three trials of a 10 meters TUG task. They were outfitted with 17 inertial sensors covering each body segment. Raw data from sensors were detrended to remove sensor shift, normalized, and band pass filtered in the frequency domain with an optimal frequency to reveal kinematics peaks that correspond to different activities. Segmentation was accomplished by identifying the time of the first minimum or maximum to the right and left of these peaks. Multiple sensors were used to detect the same task transition point to create a redundant system to prevent detection failure due to altered gaits in PD patients. The segmentation times were evaluated by comparing them with the times identified by two independent examiners who visually segmented these tasks. **RESULTS:** The results showed that the two examiners had a variance of 175±106 millisecond (*ms*) during visual segmentation and the automated algorithm had a variance of 317±138 *ms*. This demonstrated that the automation could reliably segment these tasks just as well as the examiners but in less time. This was further reinforced by the fact that, on average, the difference in the transition points identified by the examiners and the algorithm was 466±138 *ms*. The study also demonstrated the need for a system of redundant sensors to robustly adapt to the variability in the pathological gaits and movements in patient with PD which was absent in healthy older adults.

Title: Change in the cutaneous reflexes during walking in patient with chronic ankle instability

Authors: *G. FUTATSUBASHI[1,2], S. SUZUKI[1,3], H. OHTSUKA[4], T. KOMIYAMA[1,5];
[1]Tokyo Gakugei Univ., Tokyo, Japan; [2]Jobu Univ., Gunma, Japan; [3]Kyorin Univ., Tokyo, Japan; [4]Hlth. Sci. Univ. of Hokkaido, Hokkaido, Japan; [5]Chiba Univ., Chiba, Japan

Abstract: Many patients with ankle sprain complain of loss of control of the ankle joint, which may be related to the frequent recurrence of ankle sprains. Ankle instability is usually strongly related to mechanical and functional degeneration, signifying that it may stem from sensorimotor or neuromuscular deficits. Furthermore, cutaneous reflexes and their regulation are also important aspects of sensorimotor control like as walking. We have previously shown that the suppressive middle latency cutaneous reflexes (MLRs: ~70–120 ms) of the peroneus longus muscle (PL) were more pronounced on the injured sides of patients with chronic ankle instability (CAI) than on their uninjured sides or in control subjects during tonic contraction of the test muscles during sitting. However, it remains unknown whether the MLRs of the lower limb muscles during dynamic condition (like as walking) are modified in the patients with CAI. Therefore, the present study investigated the cutaneous reflexes in the subjects with CAI during walking to shed light on the neural mechanisms underlying the regulation of the lower muscles. .
The participants were 10 individuals (8 males and 2 females) who had sustained CAI and age-matched control subjects. Participants were asked to walk on the treadmill at a speed of 4 Km/h. To elicit cutaneous reflex, non-noxious electrical stimulation of the sural nerve at the lateral malleolus was applied during treadmill walking (PT ×2.5, 333 Hz, 5 pulses). EMG signals were recorded from the tibialis anterior (TA), medial gastrocnemius (MG), peroneus longus (PL), vastus lateralis (VL) and biceps femoris (BF). Using the Force sensing resistors (FSRs) data, all responses for all data for each stimulus condition occurring in the same phase of the step cycle. Subsequence analysis was conducted on full-wave rectified and averaged reflexes in 16 equidistant phases of the movement cycle (n = ~20–30 responses per phase).
During treadmill walking, locomotor background muscle activation patterns in CAI were almost the same as those in the control subjects. In PL and BF, phase-dependent modulation of MLR was found in both CAI and control subjects following the sural nerve stimulation, though the degree of modulation were blunted in CAI. On the other hand, in the TA and MG, phase-dependent modulation of MLR was also found in both CAI and control subjects, but there was no significant differences.
These findings suggest that MLR in PL and BF in CAI subjects during walking was modulated, and would be relate to impairment of ankle joint regulation.

Title: Walking during continuous surface movement alters joint kinematics in persons with multiple sclerosis

Authors: *T. F. BOERGER[1], J. VAN DEHY[2], T. ONUSHKO[2], B. D. SCHMIT[2], A. S. HYNGSTROM[1];
[1]Physical Therapy, [2]Biomed. Engin., Marquette Univ., Milwaukee, WI

Abstract: Dynamic balance is believed to be impaired in persons with multiple sclerosis (PwMS), but has not been well described in the literature. Therefore, the purpose of our study was to characterize gait kinematics during continuous, sinusoidal movements of a walking surface. In order to perturb balance during walking, participants walked on a treadmill mounted atop a 6-degree of freedom motion platform (MOOG, INC). Six participants (age range 44-63, 1male/5 females) with MS walked at a self-selected speed during 4 sinusoidal movement conditions which were: no movement, pitch, roll, and roll, pitch, yaw combined. For movement conditions, we determined the maximum movement degree each participate could safely tolerate and perform our testing. Pitch and roll movements were performed at 0.12Hz, and the combined movement at 0.15, 0.16, 0.17Hz respectively. Retroreflective markers were placed on major landmarks to model sagittal plane lower extremity kinematics. We used a 14 camera Optitrak system and sampled the markers at 120 Hz to capture whold body motion. To quantify absolute variability of sagittal plane joint angles, we calculated the step-to-step standard deviation at each 1% of the gait cycle and then averaged each of these values across the gait cycle. Ankle angle variability increased from 2.28±0.76º during no movement to 4.61±1.29º, 3.67±1.02º, and 4.19±1.22º for pitch, roll, and combined respectively. Knee angle variability increased from 2.72±1.00º during no movement to 5.63±2.09º, 2.97±1.05º, and 4.73±1.93º respectively. Hip angle variability increased from 2.02±0.954º during no movement to 4.36±1.40º, 3.29±1.08º, and 3.84±1.48º. These data demonstrate that continuous walking movements require alterations in joint kinematics in PwMS. Therefore, our data suggest that our treadmill movements are more challenging than normal walking in PwMS. In the future, we will implement our movements into a training protocol designed to improve dynamic balance.

Title: Effects of Parkinson's disease on neural preparation and step initiation in unpredictable conditions

Authors: *R. E. POPOV[1], J. GAMACHE[2], J. R. HITT[2], J. T. BOYD[2], J. V. JACOBS[3]; [1]Neurosci. Grad. Program, [2]Univ. of Vermont, Burlington, VT; [3]Liberty Mutual Res. Inst. for Safety, Hopkinton, MA

Abstract: Objective: We sought to determine the effects of Parkinson's disease (PD) on cortical preparation and resulting motor execution during step initiation in predictable and unpredictable conditions.
Methods: Ten subjects with PD and 12 older adults without PD performed forward steps to a target in predictable and unpredictable conditions. All subjects received a warning cue followed by a cue to step two seconds later. In the predictable condition, subjects were instructed to step with a pre-defined leg before trials, and in the unpredictable condition, the instructed swing leg was presented with the cue to step. Scalp EEG was used to derive parameters of contingent negative variation (CNV) and beta event related desynchronization (bERD). Force plates under the subjects' feet were used to derive parameters of the anticipatory postural adjustment (APA). Passive-marker motion capture was used to derive step parameters. Mixed-model ANOVA were used to determine effects of group and condition on cortical preparation, the APA, and the step. Pearson's correlation coefficients were used to correlate clinical measures of PD severity to experimental task variables. Significance was set at 0.05.
Results: No significant differences in cortical preparation were detected between groups. Subjects with PD exhibited significantly less change between the predictable and unpredictable conditions in the number of trials with multiple APAs, largely due to higher values in the predictable condition. Across both conditions, subjects with PD also exhibited delayed time-to-peak APA and swing onset, diminished peak APA amplitudes, and prolonged APA durations as well as lower peak swing-foot velocities and smaller normalized step lengths. More impaired ambulatory capacity derived from the Movement Disorder Society-sponsored revision of the Unified Parkinson's Disease Rating Scale (MDS-UPDRS) significantly correlated with later peak bERD (predictable condition) and APA amplitude onset latencies (unpredictable condition). Larger CNV amplitudes significantly correlated with larger normalized step errors (unpredictable condition) and greater motor symptom severity as recorded by the MDS-UPDRS (predictable

condition).
Conclusions: We confirm past reports of impaired step initiation with PD, which is similarly evident regardless of predictability of swing limb. Delayed cortical and postural preparation related to transitioning of motor state during step initiation associates with clinically impaired ambulatory capacity. Enhanced cortical preparation related to anticipation associates with impaired step accuracy and more severe motor symptoms.

Title: Motor switching during stepping in Parkinson's disease and freezing of gait

Authors: *K. SMULDERS[1], M. MANCINI[1], F. B. HORAK[1,2];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]VA Portland Hlth. Care Systems, Portland, OR

Abstract: Introduction: Freezing of gait (FoG) is the strongest contributor to decreased quality of life in patients with Parkinson's disease (PD). Previous work has shown that FoG is associated with impaired set switching performance on cognitive tasks. Here, we evaluated motor switching in a stepping task in people with PD with and without FoG. We hypothesize that motor switching for step initiation is impaired in PD with FoG compared to PD without FoG.
Methods: Eighteen subjects with PD participated in this study, in their 'OFF' state. Nine subjects had self-reported FoG (Hoehn & Yahr 2, mean MDS-UPDRS-III 36) and 9 did not report FoG (Hoehn & Yahr 2, mean MDS-UPDRS-III 33). Subjects were instructed to take a step forward with their left or right foot depending on the auditory cue 'same' or 'switch', cueing a step with the same leg as in the previous trial or a switch to the contralateral leg. A total of 42 step trials were performed (21 of each condition). Angular velocity signals from inertial sensors placed at the shins were used to detect the instant of foot-off. Reaction time (RT) was calculated as the difference between onset of the auditory cue and the instant of foot-off.

Results: Reaction time between PD with and without FoG did not differ significantly. Contrary to expectation, the reaction times for 'switch' leg trials were faster than in the 'same' leg trials. This effect was similar for PD with and without FoG (no significant FoG x switch effect). In addition, switch costs in trials requiring switching to the most affected and to least affected side were not different. Accuracy on the task was high for both groups (>99%).
Discussion: Results did not support our hypothesis that PD with FoG would have higher motor switching costs for step initiation than non-freezers. In fact, in contrast to consistently reported delays in reaction time when switching between cognitive sets using upper limb responses, we observed *faster* responses when switching leg than when stepping with the same leg. Biomechanical and locomotor mechanisms related to balance control potentially underlie this discrepancy. For example, asymmetry in weight-bearing when returning from a step may be more advantageous to execute a next step with the contralateral leg, thereby masking central set effects. Alternatively, reciprocal pattern generators for locomotion may speed switching of steps between legs.

Title: Alterations in upper and lower extremity kinematics in Parkinson's disease during dual-task conditions in a Two Minute Walk Test

Authors: *A. ROSENFELDT, A. L. PENKO, T. DEY, A. S. BAZYK, M. STREICHER, J. L. ALBERTS;
Cleveland Clin. Fndn., Cleveland, OH

Abstract: Introduction: Dual task (DT) conditions, or the simultaneous performance of two attention demanding activities, results in greater number of falls in those with PD compared to their healthy peers. Characterization of gait dysfunction during DT conditions is needed on a clinical and biomechanical level. The purpose of this study was: 1) To compare the distance covered in an over ground Two Minute Walk Test (2MWT) under single task (ST) and DT

conditions in individuals with PD; 2) To characterize changes in gait parameters observed during ST and DT conditions using a three-dimensional biomechanical gait analysis. Methods: Individuals with idiopathic PD performed the 2MWT on a flat, over ground surface under the following conditions: 1) Over ground walking alone ($2MWT_{ST}$); 2) While performing a cognitive task of Serial 7s ($2MWT_{COG}$); 3) While holding a cup of water ($2MWT_{MOTOR}$). The $2MWT_{ST}$ and $2MWT_{COG}$ were then performed on the Computer Assisted Rehabilitation Environment system, a virtual reality system with a fully integrated three-dimensional motion capture and a self-paced treadmill system. Results: Twenty-three participants completed the study. The mean UPDRS score was 33.0±13.1 with Hoehn and Yahr scores ranging between I-III. There was a significant difference in over ground distance walked between the $2MWT_{ST}$ (518.7 ± 85.2 ft.) and $2MWT_{COG}$ (432.3 ± 98.2 ft.) ($p<0.001$) and between the $2MWT_{ST}$ and $2MWT_{MOTOR}$ (467.7 ± 76.4 ft.) ($p=0.002$). During the $2MWT_{COG}$, individuals displayed a significant decrease in arm swing, velocity, cadence, step length, and a significant increase step width ($p<0.05$). Discussion: Individuals walked a significantly shorter distance during the 2MWT under DT conditions. The difference can be attributed to changes in velocity, cadence, and step length. By identifying gait parameters that are associated with DT losses, therapists may be able to provide more targeted treatments to improve gait performance.

Title: Bipedal hopping reveals evidence of advanced neuromuscular aging among people with mild multiple sclerosis

Authors: *M. C. KIRKLAND, M. B. DOWNER, E. J. B. HOLLOWAY, E. M. WALLACK, E. J. LOCKYER, N. C. M. BUCKLE, C. L. ABBOTT, M. PLOUGHMAN;

Abstract: Measures of walking such as the timed 25 foot walk test (T25FWT) may not be able to detect subtle impairment in lower limb function among people with multiple sclerosis (MS). We examined bipedal hopping to determine to what extent people with mild (Expanded Disease Severity Scale (EDSS) $\leq$3.5) MS would differ compared to age, gender and education-matched controls and elderly participants. We measured lower limb power (e.g. hop length, velocity), consistency (e.g. variability of hop length, time) and symmetry. Participants completed the T25FWT then walked at self-selected speed along an instrumented walkway (4.3m). After a rest, they then hopped using both feet four times along the walkway. We found that although the groups did not differ in self-selected walking speed and all groups scored below the six second cut-off for T25FWT, the Elderly group had significantly shorter hop lengths, more variability and more asymmetry than the Controls. The MS group were not significantly different from the Elderly or Controls in most measures and their values fell between the Control and Elderly groups. Hop length, but not measures of walking predicted EDSS score (R^2=0.38, p=0.02). Bipedal hopping is a potentially useful measure of lower limb neuromuscular performance.

Title: Decreased nonlinear dynamic gait stability in acutely concussed athletes: a longitudinal analysis of dual-task gait

Authors: P. C. FINO, C. W. SWANSON, *L. A. KING;
Neurol., Oregon Hlth. and Sci. Univ. Dept. of Neurol., Portland, OR

Abstract: Dual-task (DT) gait deficits have been reported following concussion. It is unclear whether these DT deficits impact the risk of global destabilizations in everyday life. This ambiguity may be due to the relatively low ecological validity of previous DT paradigms or the use of traditional gait metrics. We examined the effects of several ecologically valid DT paradigms on the local dynamic stability (LDS) of gait following concussion over several weeks. Three tasks were chosen: reading, a congruent head turning task - participants responded to an auditory tone by turning their head towards the cue, and an incongruent head turning task - participants turned their head away from the cue. We hypothesized that individuals with a recent concussion would demonstrate a greater decline in stability with the addition of a DT compared to controls in each condition. Twenty-five college athletes with a recent concussion were tested longitudinally at approximately of 2, 5, 10, 16, 23, 30, 37, 44, and 51 days post-concussion. Twenty-five controls were matched and tested at similar intervals. Participants walked at their self-selected speed for two minutes with no secondary task and with each of the three DT paradigms. The audio cue was delivered randomly to either the left or right ear at inter-stimulus intervals between 2.1 and 3.6 seconds. Protocols and procedures were approved by the Oregon Health & Science University IRB. Data were recorded from lumbar-mounted inertial sensors. Lyapunov exponents calculated from the tri-axial accelerations estimated the LDS. A linear mixed model compared the effects of group, time, task, group*time and group*task interactions on the LDS during gait. A main effect of task was found with the reading task differing from normal gait ($p < 0.001$). No differences among normal, congruent or incongruent head turns was found. A significant group*task interaction was found for the reading tasks only ($p = 0.005$). The reading DT requires suppression of the vestibulo-ocular reflex to maintain visual fixation and elicited significantly less stability in the concussed group. The rate of reading did not differ between concussed and control groups demonstrating that the concussed athletes could perform the reading DT adequately. However, the decreased gait stability suggests less attentional allocation on stability or difficulty integrating the various senses used to maintain stability. This increased instability during a fairly common DT may increase their risk for re-injury post-concussion.

Title: Freezing of gait in Parkinson's disease consists of unique pressure-based gait phase transitions

Authors: *P. MAZZONI[1], D. ZANOTTO[2], F. MAGET[2], B. XU[1], S. AGRAWAL[2];
[1]Dept Neurol, [2]Dept Mech Eng, Columbia Univ., New York, NY

Abstract: Freezing of gait (FOG) is a major debilitating symptom and cause of falls in many patients with Parkinson's disease (PD). FOG consists of sudden interruptions of the gait cycle of highly variable duration. It often does not respond to treatments given on steady basis, like medications, pacing sounds, and patterned visual backgrounds ("open-loop" interventions). We therefore plan to develop "closed-loop" interventions triggered by the onset of FOG episodes. This approach requires real-time detection of FOG onset. We introduce a new method of detection of FOG episodes based on underfoot pressure measured by custom-built instrumented footwear (SoleSound system). This fully portable system can measure temporal and spatial gait parameters and deliver auditory and vibrotactile feedback in response to those parameters. In this work, underfoot pressure data are recorded while a human subject walks freely in a 20-m range. We introduce a new variant of gait phase representation based on the binary on-the-ground/off-the-ground state of the heel and forefoot. We studied such representations of foot pressure patterns during freezing and non-freezing portions periods of walking in patients with PD and FOG. Analysis of gait phase transitions revealed unique reversals of transition directions at the onset of FOG episodes. These transitions were different from those observed during gait initiation, walking, and turning. This finding allowed accurate detection of FOG onset using a look-up table comparison of the present and previous two gait phases. This method is suitable for future implementation of rapid real-time detection of FOG, possibly as quickly as 500 ms after FOG onset. The unique signature of FOG in gait phase space may hold clues to the nature of the gait control abnormality that underlies FOG.

Title: Callosal integrity and dynamic stability of gait in people with parkinsonism

Authors: *C. CURTZE[1], B. W. FLING[1], M. DALE[1], J. G. NUTT[1], F. B. HORAK[1,2]; [1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]VA Portland Hlth. Care Syst. (VAPORHCS), Portland, OR

Abstract: Introduction
People with parkinsonism (PD) are at an increased risk of falls due to instability during walking. Impaired interhemispheric, communication has been suggested as a cause for decline in dynamic gait stability. Here, we studied the association of genu collosal integrity and measures of dynamic gait stability. The 'margin of stability' is a measure of how close a person is to instability, taking the spatio-temporal accuracy of medio-lateral foot placement with respect to the body center of mass into account.
Methods
We recruited 10 subjects with idiopathic PD, 10 subjects with frontal gait disorder, and 8 age-matched healthy controls. All subjects underwent diffusion tensor imaging (DTI) to assess white matter microstructural integrity through the genu of the corpus callosum. Gait was assessed using an instrumented walkway (GAITRite). Margin of stability was calculated as the minimal difference between lateral center of pressure (CoP) and extrapolated center of mass (XcoM) during gait. Subjects performed three trials of 8 meters at a comfortable walking speed.
Results
Significant correlations between genu fiber tract microstructural integrity (FA) and stride width (Spearman's rho -0.82) and margin of stability (Spearman's rho -0.77) were found for the subjects with frontal gait disorders but not for the idiopathic PD or healthy controls. Subjects with frontal gait disorders walked with a wider stride width and a larger margin of stability than subjects with idiopathic PD and healthy controls ($p<0.01$). The margin of stability increased with stride width (Spearman's rho 0.76, $p<0.001$). Coefficient of variation of margin of stability decreased with stride width in the Frontal and PD groups. Trunk displacement in the coronal plan was not different among the groups.
Conclusion
The inability for people with frontal gait disorders to tandem walk is related to mediolateral instability. By assuming a wide stride width, people with frontal gait disorders are more stable and less variable while walking than PD or control subjects with their normal gait width.

Title: Executive function under dual-task conditions forecasts cognitive declines in older adults with mild cognitive impairment

Authors: *A. CLARK[1], C. CRADDOCK[2], R. WEST[2], H. KELLEHER[2], C. M. CULLUM[4], R. ZHANG[4], B. TSENG[3];
[1]Univ. of Texas At Tyler, Tyler, TX; [2]Lab. of Brain Aging & Neuromotor Behavior, [3]Hlth. & Kinesiology, Univ. of Texas at Tyler, Tyler, TX; [4]Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Background: Evidence suggests that older adults become more reliant on cognitive resources to compensate for the structural and functional declines in the brain as a result of natural aging. Moreover, simple motor tasks, such as walking, become more cognitively demanding over time. This paradoxical relationship between diminishing supply of cognitive resources and increasing attentional demand is exacerbated in people with Alzheimer's Disease (AD) and Mild Cognitive Impairment (MCI). The purpose of this study was to investigate the central hypothesis that the cognitive performance and manifestation of motor deficits under dual-task conditions is predictive of cognitive decline throughout adult lifespan.
Methods: Twenty-five middle-aged (MA) adults (7 males, 18 females, age=43±10.73 yrs, education=16±1.91 yrs), 23 older adults (OC)(7 males, 16 females, age 67±6.17 yrs, education=16±2.81 yrs), and 17 people with MCI (8 male, 9 female, age=64±5.24 yrs., education=16±2.00 yrs.) participated. Gait velocity at baseline was measured using a 10-meter walk test. Subjects were then asked to repeat the 10-meter walk under 4 different dual-task (DT) conditions designed to challenge their executive and memory function as they walk (i.e. DT-1: verbal fluency; DT-2: 5-digit span; DT-3: serial-7 subtraction; and DT-4: 3-item delayed recall tests). Gait velocity under each DT condition was recorded. One-way analysis of variance (ANOVA) was used to compare outcome variables across all groups.
Results: Both MA and OC outperformed the MCI group cognitively in DT-1, DT-2, and DT-3. More importantly, MCI patients produced less words per second in DT-1 relative to MA and OC ($p<0.05$). In addition, MCI patients also exhibited a more pronounced gait slowing than MA and OC in DT-4 ($p<0.001$).
Conclusion: These findings suggest that verbal fluency performance as measured by words produced per second under dual-task conditions, where cognitive function is challenged simultaneously when performing a motor (i.e. walking) task, is sensitive in differentiating early MCI patients who may appear cognitively intact. In addition, pronounced gait slowing under

dual-task conditions may also have the potential to serve as a behavioral marker to better identify MCI at its pre-clinical stage.

Title: Educational level preserves cognitive integrity in older adults but not in patients with mild cognitive impairment

Authors: *R. WEST[1], C. CRADDOCK[3], A. CLARK[2], H. KELLEHER[3], H. GADDAM[3], C. M. CULLUM[5], R. ZHANG[6], B. TSENG[4];

Medicine-Cardiology, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Background: Maintaining cognitive vitality at old age remains one of the most challenging endeavors in our rapidly aging society. It has been suggested that higher cognitive reserve (CR) may help maintain cognitive function later in life. However, with age, performance of routine motor tasks becomes more reliant on CR to compensate for the structural and functional declines in the brain. The purpose of this study was to examine the impact of education level on preserving cognitive performance in older adults. We hypothesized that people with higher education level will out-perform their counterparts in the dual-task (DT) tests where cognitive function is challenged simultaneously while performing a motor task (i.e. walking).
Methods: Sixteen patients (7 males, age=64±5, Education=15.9±2.1, BMI=26 ±3) with mild cognitive impairment (MCI), a prodromal stage of Alzheimer's disease (AD), and 23 non-MCI older adults (7 males, age=67±6, Education=15.8±2.9, BMI=27±4) participated. Educational level was documented (years). Gait velocity (m/s) at baseline was measured using a 10-meter walk test. Subjects were then asked to repeat the 10-meter walk under 4 different dual-task (DT) conditions designed to challenge their executive and memory function as they walk (i.e. DT1: verbal fluency; DT2: 5-digit span; DT3: serial-7 subtraction; and DT4: 3-item delayed recall &

sorting tests). Gait velocity under each DT condition was also recorded.
Results: No significant difference was found in educational level and body mass index (BMI) between 2 groups although MCI exhibited more gait slowing (21%) during DT4 than their non-MCI (5%) counterparts (p=<.001). More importantly, a negative relationship was found between educational level and gait slowing under DT4 in non-MCI subjects (r^2=.28, p=.01), indicating less gait slowing in those with more years of education. However, the same relationship was not found in the MCI group (p>.05).
Conclusion: Our findings suggest that years of education plays a protective role in normal cognitive aging as supported by the cognitive reserve theory. Interestingly, the same beneficial effect cannot be applied in the MCI group, suggesting that cognitive decline trumps educational level in MCI disease course.

Title: Effects of long-term administration of the antioxidant resveratrol on age-related motor function deficits

Authors: *S. D. POTDAR, K. SOWA, J. CAVANAUGH;
Pharmaceut. Sciencces, Duquesne Univ., Pittsburgh, PA

Abstract: Aging is associated with a loss of motor co-ordination that results in an increase in number of falls, greater incidence of hip fractures and a general decline in the quality of life of the elderly population. An increase in oxidative stress with aging, resulting in damage to dopaminergic neurons that play a role in controlling motor function, has been implicated in the onset of motor deficits. We hypothesize that antioxidant therapy will be effective in combating motor function loss induced by increase in oxidative stress. One such antioxidant is resveratrol, a phytoalexin found in red wine, grapes and berries. Resveratrol is known for its anti-inflammatory, anti-cancer and neuroprotective properties. Our goal is to elucidate the effects of resveratrol on motor deficits in an animal model of aging. We supplemented the diet of middle-aged (14-16 mo) C57BL/6 male mice with resveratrol (120mg/kg of food). The mice will be administered the diet chronically (6months) and will be tested for motor deficits every 2 months. Although we did not observe a significant improvement in exploratory behavior as measured by

the spontaneous activity test at an early time point (2 months), we postulate that the low bioavailability of resveratrol necessitates its administration for a longer time duration and will be effective in attenuating motor deficits following prolonged supplementation.
In addition to behavior changes, we also plan to elucidate the mechanisms through which resveratrol acts because this has not yet been fully understood. Extracellular protein kinase 1 and 2 (ERK1/2), belonging to the mitogen-activated protein kinases (MAPK) family, are involved in cell proliferation, differentiation, migration, and survival. Natural antioxidants, including resveratrol, have been known to activate these pathways *in vitro*. Therefore, we were therefore interested in testing the effects of resveratrol on these pathways in vivo. We have previously found that resveratrol activated ERK1/2 in the striatum of old mice (22-24mo) compared to young (2-4 mo) old mice following short-term resveratrol administration. We will therefore investigate if a chronic resveratrol diet activates these signaling pathways in the areas of the brain involved in modulating motor function (striatum and ventral tegmental area).

Title: Changes in attentional control and gait in MCI and healthy elderly during Dichotic Listening in dual-tasking

Authors: ***M. M. GORECKA**, M. KLAUSSEN, K. WATERLOO, C. RODRIGUEZ-ARANDA;
Dept. of Psychology, Univ. of Tromsø, Tromso, Norway

Abstract: Dual-task research explores the mechanisms behind fall risk in Alzheimer's disease and other dementias. However, investigations including mild cognitive impairment (MCI) are few. The present dual-task study, uses dichotic listening (DL) during walking to challenge gait and attention in MCI. Different auditory stimuli are presented to each ear. In three conditions, subjects forced their attention towards a specific ear, or freely attended stimuli from any ear. Thus, DL mimics real life situations that require different levels of attention during walking. Execution of DL and walking in a dual-task situation allows to study the interplay between motor control, cognition and perceptual integration in elderly populations with increased risk of

falling. **Aim.** Evaluate the effects of a new dual-task paradigm focusing on control of auditory attention on spatiotemporal gait parameters and cognition in healthy elderly and older people with MCI. **Methods.** 15 MCI subjects (*M* =72,87 years) and 15 age-matched controls, all right-handed. The experiment had four conditions: normal walking baseline and three dual-task DL-conditions: Non-forced (NF), Forced-Right (FR) and Forced-Left (FL). Gait measures of step length, stride length and speed were evaluated with the Optogait©-system. The mean and coefficient of variation (CV) were calculated and used for group comparisons for both feet and per foot to explore laterality effects. ***Statistics***. Mixed model ANOVAs with repeated measures were conducted. ***Results.*** MCI participants showed difficulty in attentional auditory control. In both groups, DL performance affected step and speed and their variability across conditions. All groups had shorter steps, decreased speed and higher variability that gradually become more accentuated from baseline to FL condition. Group differences were present as MCIs had higher variability, shorter steps/strides and were slower than controls. An interaction effect was observed in all groups on the FR condition where elderly and in special, the MCI group, had shorter strides and higher variability on the left foot. ***Conclusion***. Performance on DL during walking affects spatiotemporal parameters of gait in elderly controls and more evidently in MCI individuals. In particular, focusing attention to the right ear seems to disturb the contralateral lower limb. This finding needs to be understood as a disruption of the lateralization of motor control caused by competing sources of information. The use of DL during walking proves to be a useful paradigm to comprehend effects on gait caused by specific attentional constraints.

Title: Higher levels of perceived groove in music improve spatiotemporal parameters of gait during accelerated rhythmic auditory stimulation

Authors: *E. A. READY[1], L. M. J. MCGARRY[2], J. D. HOLMES[3], J. A. GRAHN[2];
[1]Hlth. & Rehabil. Sci., [2]Psychology, [3]Sch. of Occup. Therapy, Univ. of Western Ontario, London, ON, Canada

Abstract: Music-based rhythmic auditory stimulation (RAS) is a cueing technique used in gait rehabilitation, typically involving synchronizing footsteps with the beat in music. The beat rate of the music is generally adapted to be at or slightly faster than the participant's walking pace. The effects of music-based RAS can be enhanced by using 'high groove' music (music that induces the desire to move), which elicits larger and faster strides than low groove music when walking at normal pace. However, RAS outcomes vary significantly across individuals, so other factors clearly remain to be optimized. One potential factor is whether participants are instructed to synchronize to the beat or not. Instructions to synchronize may be detrimental to participants who have difficulty perceiving a beat, resulting in higher cognitive demand, which is known to impair gait. Therefore, we examined how task instructions (synchronized versus 'free' walking) and beat perception abilities influence spatiotemporal parameters of gait when walking to high- and low-groove music. Healthy young adults (n = 37 to date, data collection ongoing) were randomly allocated to either synchronized or free-walking RAS. In both conditions, participants walked back and forth eight times across a sensor walkway to assess baseline gait parameters. Then, participants walked to high- and-low groove music that was adjusted to be 15% faster (beats per minute) than baseline cadence (steps per minute). Finally, participants completed the Beat Alignment Test to measure beat perception ability. Preliminary results indicate that RAS elicited longer, faster and more stable strides, but only when stimuli were high groove. In high groove conditions, stride velocity, cadence, and stride length significantly increased relative to low-groove music. Stride width decreased during high groove conditions, indicating greater gait stability. There also appear to be interactions between groove and synchronized versus free-walking, suggesting the effects of groove may be more prominent during synchronized than during free-walking RAS. Future analyses will investigate the relationship of these factors to beat perception abilities.

Title: Auto detection of daily living activities during a Timed-Up-and-Go (TUG) task in patients with Parkinson's disease using multiple inertial sensors

Authors: *H. P. NGUYEN[1], K. LEBEL[2], P. BOISSY[2], S. BOGARD[3], E. GOUBAULT[3], E. LE[3], N. ROOFIGARI[3], C. DUVAL[3];
[1]Sci. of Physical activity, Univ. of Quebec At Montreal, Montreal, QC, Canada; [2]Univ. of Sherbrooke, Sherbrooke, QC, Canada; [3]Univ. of Quebec at Montreal, Montreal, QC, Canada

Abstract: INTRODUCTION: Recently, much attention has been given to the use of inertial motion sensors for remote monitoring of individuals with limited mobility, particularly in patients with Parkinson's disease (PD). However, the focus has been mostly on the detection of symptoms, not specific activities. Monitoring specific activities will allow us to analyze changes in patients' mobility during physical and clinical rehabilitation by characterizing the quality of their movements. We recently proposed detection algorithms based on peak detection using linear acceleration, angular velocity and angular displacement data from multiple inertial sensors in healthy older adults. Inertial sensors attached to different body segments were use to detect common activities such as: *Stand up*, *Walking*, *Turning*, and *Sit down* during daily living. However, PD patients tend exhibited pathological gaits and movements that are different from healthy adults. The objective of the present study was to test the feasibility and robustness of the recognition algorithm to detect common activities in daily living in patients with PD. **METHOD**: A modified Time-Up-And-Go (TUG) task was used since it comprised of these common activities all performed in a continuous fashion. Twelve older adults who were diagnosed with early PD (Y&H<=2) were recruited for the study. Participants performed three trials of a 5 and 10 meters TUG task. They were outfitted with 17 inertial motion sensors covering each body segment. Raw data from sensors were detrended to remove sensor shift, normalized, and band pass filtered in the frequency domain with an optimal frequency to reveal kinematics peaks that correspond to different activities. Specificity (true positive) and sensitivity (true negative) were used to evaluate the accuracy of the algorithm. **RESULTS**: Using the selected set of sensors, we were able to detect these activities with 100% sensitivity (n=216) during the 10 meters TUG. The specificity was also 100% for all tasks except *Sit down* (specificity=97%). During the 5 meters TUG, sensitivity was 100% for (*Stand up*, *Turning*, *Sit down*) and 99% for *Walking* (n=216). Specificity was 100% for *Sit down* and *Turning* and 97% for *Stand up* and *Walking*. The present study lays the foundation for the development of a comprehensive algorithm to detect activities in more naturalistic activities using *inertial sensors*, in hope of automating the analysis of motor performance within the detected tasks in patients with PD. Furthermore, our study show the need to have task specific sensor to accurately and reliably detect these tasks to minimize failure in population with altered gaits and movements.

Title: Walking reveals compromised neural resource capacity during dual tasking in people with multiple sclerosis

Authors: *M. B. DOWNER[1], M. C. KIRKLAND[1], E. M. WALLACK[1], G. GROVER[2], M. PLOUGHMAN[1];
[1]Fac. of Medicine, Mem. Univ., Recovery and Performance Lab., St. John's, NL, Canada; [2]Sch. of Human Kinetics and Recreation, Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Background: Cognitive-motor interference is prevalent in the everyday lives of people with multiple sclerosis (MS), often causing subtle impairment when attempting to undertake multiple tasks simultaneously (i.e.: Dual Tasking). Recently, MS studies have examined the effects of cognitive-motor interference by analyzing gait parameters, consistently showing a worsening of motor performance when paired with a cognitive component. However, the majority of studies have disregarded the potential cost inflicted on the cognitive task. We examined the effect that dual tasking has on cognitive performance on a mental tracking task (Serial 7's) in people with MS compared to healthy controls. **Methods:** Participant with MS (n=13; mean age ± SD, 43.92 ± 12.93) and age (±3 years), gender and education (±3 years) matched controls (n=10; mean age ± SD, 45.70 ± 12.90; (HC)). All participants performed the validated method of serially subtracting sevens as the cognitive component as both part of the Montreal Cognitive Assessment and later as a dual task while walking. The serial 7's task is a mental tracking task designed to test working memory and information processing abilities. Time elapsed as well as the number of correct/total answers was analyzed from audio records to determine a performance score. An algorithm of Mental Tracking Rate was created to negate the potential influence of a speed-accuracy tradeoff. **Results:** MS participants demonstrated a significant decline (52%), (from 4.15±1.34 correct answers to 2.15±1.99; $p<0.001$) compared to

HC, who did not significantly change between the two conditions (from 3.00±2.11 to 3.30±1.77; p=0.65). MS subjects provided significantly fewer *correct* answers than controls (4.62±3.66 and 10.40±8.45 respectively; $F(1,21)$=4.94, p=0.04). However, MS subjects and controls provided the same number of answers when walking 16m (MS group 6.69±4.03, HC group 11.30±8.12; $F(1,21)$=3.19, p=0.09) and spent the same time completing the task (MS group 39.63s±21.37, HC group 39.51s±13.76; $F(1,21)$<0.001, p=0.99). Mental Tracking Rate (% correct answers/min) correlated strongly with MS-related disability measured using the Expanded Disability Status Scale (EDSS; r(11)=-0.68, p<0.01). **Conclusion:** We propose that compromised mental tracking during walking in people with MS could be related to limited neural resource capacity and could be a potentially useful outcome measure to detect ecologically-valid dual tasking impairments.

Title: Evaluation of locomotor phase modulation after cortical injury in the rodent stroke model

Authors: *K. TUNTEVSKI[1], S. FREEMAN[2], H. HU[3], X. REN[3], S. YAKOVENKO[4]; [1]West Virginia University, Centers For Neurosci., Morgantown, WV; [2]Neurosci., West Virginia Univ. - Centers For Neurosci., Morgantown, WV; [3]Dept. of Physiol. & Pharmacology, Exptl. Stroke Core,, Ctr. for Basic and Translational Stroke Research, West Virginia Univ., Morgantown, WV; [4]Exercise Physiol., West Virginia Univ. Sch. of Med., Morgantown, WV

Abstract: Stroke remains one of the most prevalent causes of mortality and morbidity in the world. The improvement of motor coordination in people with poststroke hemiparesis is one of the primary goals of rehabilitation. The functional reorganization of M1 after brain injury has been described by the idea of cortical vicariation, or the ability of surviving cortex to take over functions of the lesioned parts. This process has been directly studied with ICMS using mostly single electrode mapping techniques in monkeys and in rodents. Yet, the temporal dynamics and

the interplay between surviving neural pathways are poorly understood. The corticospinal dynamics that relies on complex processing in M1 and the integration of pyramidal and other descending signals on the spinal rhythmogenic elements need to be described. Our approach uses rats as an animal model due in part to their low variability in organization and location of M1 compared to higher mammals (e.g. cats and monkeys), and the smooth cortical surface that is well suited for MEA use. We have developed a behavioral task for rats that requires precise foot placement during locomotion on pegs (Tuntevski et al., 2016). Unlike in unrestrained overground locomotion where M1 cell activity is low (Drew et al., 2008), the peg walkway task is expected to require intact M to generated coordinated muscle patterns. Similar to stepping over obstacles in cats (Yakovenko & Drew, 2015), we expect that M1 in rats contributes to the regulation of flexor and extensor phases in the peg walkway task. Here, we tested the outcomes of mild cortical ischemic injury induced by a 60 min middle cerebral arterial occlusion (MCAo). Rats were briefly trained to walk on the walkway instrumented with the array of force sensors. Pegs were configured to produce either symmetric or two types of asymmetric locomotion favoring each side. After a week of recovery following MCAo, rats were performing the behavioral task for food rewards. The poststroke asymmetry in the phase control on the paretic side was measured with the asymmetry index calculated from the slopes in the relationship between stance and cycle duration in both forelimbs. The overstepping induced changes in the slope of the stance phase characteristic even in healthy locomotion, but it revealed injury lateralization in rats with MCAo. The slope of the stance phase characteristic was lower on the paretic side than on the 'healthy' side. This supports the hypothesis that M1 inputs may contribute to the coordination of muscle synergies in peg walking task in rats. Moreover, this method may provide the quantified tracking of precise limb recovery as a function of rehabilitation strategy after stroke.

Title: Effects of cholinergic tone on gait and cognition in Parkinson's disease is the final title for the abstract

Authors: *D. MARTINI, B. W. FLING, M. MANCINI, A. GENDREAU, F. HORAK, J. NUTT;
Neurol., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Recent studies have demonstrated reduced levels of cholinergic tone in people with Parkinson's disease (PD), which has also been shown to be associated with reductions in gait speed and impaired postural control. The aim of the current study is to compare the effects of placebo and donepezil, a cholinesterase inhibitor, on measures of gait and dual-task cost in PD patients in a double-blind, placebo controlled, cross-over randomized clinical trial. Short-latency afferent inhibition (SAI), a physiological index of central cholinergic function, is being collected to determine if deficits in balance and gait correlate with reduced SAI. Finally, the attention network test (ANT) is being administered to determine if changes in gait are mediated by changes in attention. Data collection is ongoing and assessors remain blinded to group assignment. For this abstract, we present data collected from 24 participants with idiopathic PD at the end of their initial segment of the study (either drug or placebo). In addition to the ANT and SAI, we collected measurements of gait speed, percent time in double support, and stride time variability during Single Task (ST) and Dual Task (DT – serial subtraction by 3's) walking. Stride time variability during ST walking was significantly correlated with reduced SAI (rho = .44, p = .03), but not gait speed or double support time. During DT walking, no significant correlations were observed, however increased percent of time in double support (rho = .39, p = 0.06) and decreased gait speed (rho = -.38, p = 0.07) showed a notable association with reduced SAI. The relationships between ANT and SAI were nonsignificant. This preliminary data provides evidence that reduced cholinergic tone in persons with PD is related to impaired gait performance that may not be mediated by attention deficits. Our ongoing data collection will continue to investigate the potential utility of cholinergic manipulation as a strategy for treating balance and gait dysfunction in PD. The findings of this trial are intended to lead to more sharply focused questions about the role of cholinergic neurotransmission in balance and gait and eventually to Phase II B trials to determine clinical utility of cholinergic manipulation to prevent falls and improve mobility.

Title: Goal-directed locomotion in post-stroke unilateral spatial neglect

Authors: ***T. OGOURTSOVA**[1], P. S. ARCHAMBAULT[2], A. LAMONTAGNE[2];
[1]McGill University, Sch. of Physical and Occupati, Montreal, QC, Canada; [2]McGill Univ., Montreal, QC, Canada

Abstract: ***Introduction***: Unilateral spatial neglect (USN), a highly prevalent post-stroke impairment, has been shown to affect the recovery of locomotion. However, our current understanding of goal-directed locomotion control in post-stroke USN is poor and existing literature lacks consensus on the expression of the deficits. Goal-directed reaching accuracy to remembered (i.e. off-line movement), as opposed to actual seen objects (i.e. on-line movement), is also more affected by USN, supporting the hypothesis of the ventral as opposed to the dorsal stream involvement in USN. Whether such distinctions exist for goal-directed walking remains to be explored. The objectives were to examine (1) goal-directed locomotion (mediolateral displacement [MLD] and heading errors [HE]); and (2) direction of deviation of the walking trajectory in subjects with and without USN (USN+ and USN-) and in healthy controls (HC). ***Methods***: Subjects (n=45) performed goal-directed walking trials to actual, remembered and shifting targets located 7 meters away at 0° and 15° right/left while immersed in 3-dimensional virtual reality scene viewed through an NVisor SX60 helmet mounted display. ***Results:*** The endpoint MLD and HE were greater in USN+ than in USN- and HC groups in all conditions. USN+ group showed greater MLD and HEs to left-sided targets, especially under remembered condition, compared to middle and right-sided targets. USN+ group demonstrated a trajectory deviation to the right (non-neglected) side for middle and left targets in all conditions. ***Conclusion***: In support of the ventral stream involvement hypothesis in USN, findings indicate that USN alters goal-directed locomotion to remembered targets, predominantly in the left hemispace. Moreover, results on the rightward deviation of the walking trajectory could help establish a consensus on the expression of USN. Goal-directed locomotion to remembered targets could also serve as a more sensitive assessment of USN than traditional paper and pencil tests.

Title: Physical activity is more strongly related to gait variability while walking in a real-world environment than in a lab-based setting for community-living individuals post-stroke

Authors: *L. A. ZUKOWSKI[1], J. A. FELD[2], A. DREWS[1,3], D. FLETCHER[1,4], C. A. GIULIANI[1,2], P. PLUMMER[1,2];

Abstract: High risk of falling, which is associated with high gait variability, may be contributing to low levels of community participation in stroke survivors. Gait variability is typically measured during undistracted walking in the clinic, and it is not known how gait variability relates to real-world walking and daily physical activity. The purpose of this study was to examine the relationships between amount of physical activity in the community and gait variability assessed in single- and dual-task conditions in the lab and in a real-world setting in adults post-stroke. **METHODS:** Sixteen ambulatory, community-dwelling adults with stroke (mean±SD: 49.9±14.0 years old, 15.8±10.7 months post-stroke) participated. Spatiotemporal gait parameters were recorded during single- and cognitive-motor dual-task walking in a lab and a real-world environment (hospital lobby). Coefficient of variation (CV, %) was calculated for stride length and stride time. Physical activity was recorded using a physical activity monitor worn for two consecutive days. Average walking bout duration (s), maximum walking bout duration (s), and total number of steps taken each day were calculated. Relationships between physical activity measures and gait variability were examined using Spearman's rho correlation coefficients. **RESULTS:** Maximum walking duration was the only variable related to stride time CV during single-task walking in the lab (rho=-0.50, p=0.05). Stride time CV during lab-based dual-task walking was not associated with any physical activity measures. Conversely, there were significant relationships between stride time CV assessed in the hospital lobby (single- and dual-task) and physical activity measures. Average walking duration (rho=-0.51, p=0.04), maximum walking duration (rho=-0.61, p=0.01), and total number of steps taken per day (rho=-0.51, p=0.05) were negatively related to stride time CV during single-task walking in the hospital lobby. Average walking duration was also negatively related to stride time CV during dual-task walking in the hospital lobby (rho=-0.67, p<0.01), notably stronger than the relationship with

single-task walking. None of the physical activity measures were related to stride length CV in any condition. **CONCLUSIONS:** Temporal gait variability during dual-task walking in the real-world is strongly related to amount of community ambulation after stroke, more so than gait variability measured in the lab, even under dual-task conditions. These data suggest that rehabilitation may need to target gait variability in high-distraction settings in order to improve physical activity in community-dwelling stroke survivors.

Title: Intrinsic properties and connectivity of spinal flexor and extensor rhythm generating neurons

Authors: *N. HA, L. YAO, N. A. SHEVTSOVA, K. J. DOUGHERTY;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The hindlimb locomotor central pattern generator (CPG) consists of ventrally located interneurons (INs) within the lumbar region of the spinal cord. Each limb contains a CPG with at least two layers, the rhythm generating (RG) layer and the pattern formation layer. The rhythm generating layer includes flexor RG INs, extensor RG INs, and inhibitory INs that connect and coordinate flexor-extensor RG INs ipsilaterally. Previous studies have proposed a flexor/extensor asymmetry where locomotor rhythmicity results from the activity of the flexor RG INs. The extensor RG INs fire tonically and are driven into bursting mode by the phasic inhibition from the rhythmically active flexor RG INs via inhibitory INs. This then suggests that there are differences in intrinsic excitability, burst generating mechanisms, and/or connectivity between flexor and extensor RG INs. Recently, Shox2 INs have been identified to be one of the cellular components of the rhythm generator for locomotion. Ablating these cells led to a reduction of the locomotor rhythm and no change in the flexor and extensor alternation. The goal of the present study is to determine potential factors contributing to a flexor/extensor asymmetry, focusing on

connectivity and intrinsic properties related to excitability and rhythmogenesis. We performed whole cell patch clamp recordings from identified Shox2 INs in reduced isolated spinal cord preparations from neonatal Shox2:Cre; tdTomato mice. Flexor and extensor RG INs were identified based on fluorescence and their preferred firing during drug-evoked locomotion *in vitro*. Voltage clamp and current clamp protocols were run to study the intrinsic passive and active properties of these cells, including ionic currents linked to cellular rhythmicity. Our data suggest that there are no differences in the cellular excitability between flexor-related Shox2 INs and extensor-related Shox2 INs. Potential rhythmogenic currents including I_h, persistent inward current, and T-type Ca^{2+} current are present in some of these cells. A differential distribution of these currents in the flexor/extensor Shox2 INs likely plays a role in establishing cell rhythmicity during locomotion. In addition to intrinsic properties, dual Shox2 IN recordings show that interconnectivity is scarce but may be preferential within flexor or extensor RG populations. Therefore, connectivity and expression of particular ionic currents in rhythm generating neurons may contribute to flexor-extensor asymmetry.

Title: Intrinsic conductances of neuron types need not vary across animals

Authors: ***C. GUNAY**[1], A. DOLOC-MIHU[2], D. LAMB[3], R. CALABRESE[2];
[1]Sch. of Sci. and Technol., Georgia Gwinnett Col., Lawrenceville, GA; [2]Biol., Emory Univ., Atlanta, GA; [3]Neurol., Univ. of Florida, Gainesville, FL

Abstract: Identified neurons (types) can have intrinsic ionic conductances that vary several fold across different animals, which appear to be compensated by co-regulation of conductances to maintain stereotypical activity. Neuron types could also achieve this by having identical conductances across animals, although this has not been observed. Possibility of having identical conductances is even less likely in systems that exhibit substantial animal to animal variability in activity, such as the well-studied leech (Hirudo sp.) heartbeat central pattern generator network. A dataset of 6 leeches showed individual variations in a complete input-output network composed of firing patterns from all premotor inhibitory interneurons, strengths of their synapses

that impinge onto two bilateral pairs of output motor neurons, and those motor neurons' output firing patterns (Wright and Calabrese 2011, J Neurosci, 31:17555-71). Underlying motor neuron intrinsic conductances were estimated using a computational model that replicates recorded input-output properties. We expanded a previously used multi-objective evolutionary algorithm (MOEA) optimization method (Lamb and Calabrese 2013, PLoS ONE 8(11): e79267) to find the maximal conductance parameters of two Hodgkin-Huxley type, multicompartmental models of heart (HE) motor neurons in the leech ganglia 8 and 12, that match activity profiles recorded for each animal. This allows us to test the hypothesis whether intrinsic conductances necessarily differ across animals. The method failed to find matches to different activity profiles when we used average values of previously reported synaptic strengths. Matches were found only when we considered slight deviations in individual synaptic strengths. The newly found model synaptic strengths for each animal were not statistically different than the average synaptic strengths observed experimentally across animals. However, we have not quantified experimental variance of measured strengths to test whether the same is true on the individual animal level. We are improving our method of estimating synaptic strengths from spike-triggered averaging in voltage clamp recordings to encompass measures of variance (Norris et al 2007, J Neurophys 98:2992-3005). In conclusion, we found that varying intrinsic conductances cannot compensate for extrinsic network connectivity parameters even if they are only slightly wrong. Furthermore, with flexible synaptic strengths, we confirmed our hypothesis that a model neuron with same intrinsic conductances can replicate the substantial activity pattern variances in different animals.

Title: The role of the sodium pump in mouse spinal locomotor network activity

Authors: F. NASCIMENTO, L. D. PICTON, K. T. SILLAR, *G. B. MILES;
Univ. St Andrews, St Andrews, United Kingdom

Abstract: Locomotor rhythm generation must be flexible to adapt motor behaviour to prevailing demands. The Na^+/K^+-ATPase (or sodium pump) influences locomotor networks in *Xenopus* tadpoles (Zhang, Picton, Li, & Sillar, 2015, Sci. Rep. 5,16188) and *Drosophila* larvae (Pulver and Griffith, 2010, Nat. Neurosci. 13:53-9) in an activity dependent manner, but its contribution in equivalent mammalian networks is less well described. We describe a functional role for sodium pumps in murine locomotor networks. Using spinal cords isolated from neonatal mice (postnatal day (P)0-P4), we induced locomotor-related activity pharmacologically (NMDA 5μM, 5-HT 10 μM and DA 50μM) and recorded it through glass suction electrodes attached to lumbar ventral roots (L_1, L_2, L_5). The sodium pump inhibitor, ouabain (1-3μM), increased rhythm frequency and decreased burst amplitude, an effect that was more pronounced in the presence of 50μM DA. The sodium ionophore monensin (10μM) was used to increase intracellular sodium concentration and hence to mimic sodium pump activation. Monensin decreased locomotor burst frequency and disrupted right-left and extensor-flexor phase relationships. We next used dorsal root sensory stimulation in the absence of drugs in order to induce short episodes of more natural locomotor activity. When the interval between evoked episodes was reduced, episodes became shorter and slower. Ouabain (1-3μM) increased the frequency and duration of these episodes whilst monensin (10μM) exerted the opposite effect. These data suggest a possible role for sodium pumps in network self-regulation. Using spinal cord slices from neonatal mice (P2-P15) we performed whole-cell patch-clamp recordings from spinal motoneurons (MNs) and ventral horn interneurons (INs). We observed an ultra-slow afterhyperpolarisation (usAHP) in 40/97 MNs and 15/35 INs of ~5mV amplitude with ~60s duration following high frequency firing. In MNs, this was blocked by ouabain (1-3μM) and TTX (0.5μM), suggesting the usAHP involves a spike dependent increase in sodium pump activation. In MNs with a usAHP, monensin (10μM) caused a ~5mV hyperpolarisation. Perfusion of dopamine (10μM) increased the duration of this pump current by ~60%. Taken together, our data reveal a role for the sodium pump in mammalian spinal locomotor control circuits. Interestingly, this feature is present in some, but not all MNs and INs, suggesting that the functional role of the sodium pump may be restricted to specific neuronal subtypes, as in frog tadpoles (Zhang et al., 2015). The data also highlight the importance of the sodium pump as a spinal target for the neuromodulator DA.

Abstract: Chemical synapses contain a number of diverse proteins, which form the postsynaptic density (PSD), and these are involved in synaptic structure, neurotransmission and signal transduction. PSD-95 is implicated in the formation and maturation of excitatory synapses. PSD-95 regulates the localization of NMDA receptors by means of binding with NMDA receptor subunit 2 (NR2). Rhythmical oro-maxillofacial activities, such as suckling and chewing, are generated in the brainstem, and we showed that NMDA receptors play a critical role in the rhythm and pattern generation and signal transmission around the trigeminal motor nucleus during prenatal and early postnatal development. Here, we immunohistochemically examined the temporal distribution of PSD-95 protein in developing rat brainstem from suckling to the mature chewing stage. There was early emergence of PSD-95 expression in the interneurons located in the medial region of the trigeminal motor nucleus. This observation supports the notion that the central pattern generator for rhythmical jaw movements is located peritrigeminal area.

Title: Spontaneous miniature outward currents are generated by calcium-induced calcium release in putative interneurons of the newt medullary reticular formation

Authors: *D. B. YAEGER, R. GREEN, L. MERLINO, R. RAPPOPORT, E. J. CODDINGTON;
Willamette Univ., Salem, OR

Abstract: Locomotor behavior of vertebrates is controlled by medullary reticulospinal neurons projecting to central pattern generators in the spinal cord.
Although reticulospinal neurons receive descending synaptic inputs from midbrain and forebrain areas, reticulospinal neurons also receive synaptic inputs from local interneurons. The properties of local interneurons in the medullary reticular formation have not been studied in any vertebrate, contributing to a gap in our understanding of how local connections regulate the activity of reticulospinal neurons. Using whole-cell recordings in brain slices made from adult rough-skinned newts (*Taricha granulosa*), we studied the properties of a class of putative interneurons. These interneurons exhibited spontaneous miniature outward currents (SMOCs), and the frequency of events increased with depolarization between approximately -55 and -45 mV. At potentials more depolarized than -45 mV, SMOCs disappeared and a sustained outward K^+ current was activated. SMOCs reversed polarity based on the Nernstian potential for K^+ and were reversibly blocked by tetraethylammonium. Furthermore, SMOCs were blocked when extracellular Ca^{2+} was replaced with cobalt, suggesting that SMOCs were generated by Ca^{2+}-gated K^+ channels in response to Ca^{2+} influx through voltage-gated Ca^{2+} channels. Furthermore, SMOC frequency temporarily increased and then decreased in the presence of caffeine, and gradually decreased in the presence of the Ca^{2+}-ATPase inhibitor cyclopiazonic acid, indicating that SMOCs depended on Ca^{2+} release from intracellular stores. Together these results indicate that SMOCs are generated by Ca^{2+}-induced Ca^{2+} release in putative interneurons. As SMOCs are activated at membrane potentials negative to spike threshold, these results indicate that SMOCs regulate spiking in putative interneurons in the medullary reticular formation.

Title: Characterization of motoneurons and interneurons mediating rolling waves in *Aplysia* locomotor network

Authors: K. YU[1], D.-D. LIU[1], R.-N. JIA[1], Y. LOU[1], Y.-T. ZHENG[1], Y.-N. SU[1], S.-A. CHEN[1], T.-T. CHEN[1], W. YU[1], E. C. CROPPER[2], K. R. WEISS[2], *J. JING[1,2];
[1]Nanjing Univ., Jiangsu, China; [2]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Rolling waves of neural activity are responsible for locomotion in a number of vertebrates and invertebrates. We study neural mechanisms underlying rolling waves in the Aplysia locomotor network. We previously identified a cluster of ~ 20 putative motoneurons on the ventral surface of the pedal ganglion. These neurons send their axons through nerves P1, P7, and P8 to the periphery, i.e., the foot, and exhibited different activity phases following tail nerve stimulation which elicits fictive locomotor programs as monitored by activity in parapedal commissural nerve (PPCN). We also identified interneurons that do not project out to any peripheral nerves.

Here, we use a neuromuscular preparation to demonstrate that stimulating a substantial fraction of this cluster's neurons elicits foot-muscle contraction in a frequency-dependent manner, thus indicating that many of them are motoneurons. After tail nerve stimulation, phasic activity of these motoneurons is associated with rhythmic contraction of the foot muscle and PPCN bursting activity.

We further analyzed the phasic activity of this cluster of motoneurons relative to PPCN bursting activity following tail nerve stimulation. If the phasic activity of a motoneuron precedes the PPCN activity for a full cycle, we define the relative phase as -100%. If the phasic activity of a motoneuron overlaps with PPCN activity, we define the relative phase as 0%. We then recorded nearly all of the neurons in this cluster in single preparations (n = 5). Using the above definitions, we found that the distribution of relative phases of these motoneurons is largely continuous, covering from -100% to 0%. However, we also found that there tend to be more motoneurons at two time periods: -40% to -60% and -10% to +10%, suggesting that activity of motoneurons may also be partially clustered. This implies that rolling movements may also occur in bouts. In addition, we found that motoneurons with similar relative phasing are more likely to be electrically coupled than motoneurons with different relative phasing. Finally, we found that several interneurons show relative phasing of about -69.2%, and that these are usually electrically coupled to motoneurons with slightly delayed relative phasing, e.g., about -57.8%, suggesting that interneurons may provide a driving force for the rolling wave.

In summary, we have demonstrated that a cluster of motoneurons may contribute to the formation of rolling waves in Aplysia. In addition, electrical coupling between specific motoneurons, and between motoneurons and interneurons may be one of the important synaptic mechanisms underlying rolling waves.

Title: Optogenetic analysis of the role of motoneurons in the regulation of locomotor-like activity in the neonatal mouse spinal cord

Authors: M. FALGAIROLLE[1], J. G. PUHL[2], A. PUJALA[3], *M. J. O'DONOVAN[1]; [1]NINDS, NIH, Bethesda, MD; [2]Univ. of Minnesota, St. Paul, MN; [3]Janelia Farms Res. Campus, Ashburn, VA

Abstract: Stimulation of motoneuron axons in an isolated preparation of the neonatal (P0-4) mouse spinal cord can activate the central pattern generator (CPG) for locomotion. To establish if motoneuron firing can influence the CPG during locomotor-like activity evoked by drugs, we generated mice in which either ChannelRhodopsin-2 (ChR2) or Archaerhodopsin-3 (Arch) was expressed in $ChAT^+$ neurons. We used an LED system to illuminate the cord over the lumbar (L1-L6) or more restricted segments. In ChAT-ChR2 mice, a train of light pulses at 1-4 Hz for 10 sec activated locomotor-like activity in the absence of drugs confirming our earlier experiments with ventral root stimulation. Arch-ChAT mice were used to examine the effect of silencing motoneuron firing on the locomotor rhythm recorded from slow ventral root potentials (after low pass filtering the neurograms) and from whole cell recordings from motoneurons. Individual extensor motoneurons were hyperpolarized by 5-20 mV during illumination and their firing was abolished. Firing was easier to suppress in extensor compared to flexor motoneurons, and in the L5/6 roots compared to the L1/2 roots. This appeared to be because the primary rhythmic synaptic drive to flexors is excitatory and that to the extensors is inhibitory. Illumination frequently hyperpolarized extensor motoneurons below the chloride equilibrium potential rendering their inhibitory synaptic drive depolarizing and in phase with flexor activity. Suppression of extensor bursting from L1-L6 did not block the locomotor rhythm or significantly alter the phase of the left/right L1/2 ventral root discharge. When flexor activity could be suppressed, this resulted in transient changes in the phase of the left/right L1/2 ventral root activity and in some preparations the locomotor rhythm was transiently blocked. When the light was turned off, the amplitude of the locomotor bursts and sometimes their frequency was transiently increased for tens of seconds before returning to control levels. We conclude that flexor motoneurons provide feedback to the CPG during drug-induced locomotor-like activity that acts to stabilize the locomotor rhythm. Our findings are consistent with recent work

suggesting that flexor-related neurons are particularly important for genesis of the locomotor rhythm.

Title: Synaptic origin of synchronized bursting in the spinal cord and the role of gap junctions

Authors: ***A. MAHROUS**, S. ELBASIOUNY;
NCBP Dept., Wright State Univ., Dayton, OH

Abstract: Rhythmic patterns of motoneuron activity in the spinal cord represent the basis for generating important motor behaviors such as locomotion and respiration. The cellular and network mechanisms responsible for generating these patterns are still not completely understood. We attempted to study the role of the small conductance calcium-activated potassium channels (SK channels) in generating synchronized bursts in the spinal cord. The synaptic conductances mediating the synchronized bursting were also investigated. In addition, a possible role of gap junctions in synchronizing the activity of motoneurons to generate this behavior was studied. We used the in-vitro sacral cord preparation from adult mice as it allows for different pharmacological manipulations. Synchronized bursting was induced pharmacologically and the motor output was measured both from the ventral roots as well as from single motoneurons. Our results show that SK channels play a major role in initiating and grading synchronized bursts in the spinal cord. We also found that the synaptic pathway involved in generating the synchronized bursting depends on both NMDA and AMPA receptors. Neither the burst characteristics nor the synchrony across different pools were affected by gap junction blockers. Consequently, a role of gap junction in mediating this synchronized bursting behavior is excluded. A common synaptic input to the motor pool is a more likely mechanism for synchrony.

Title: Functional recovery of a developing locomotor network following spinal cord injury

Authors: S. ANAGIANNI, *H. ZHANG;
Ctr. for Neuroregeneration, Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Spinal cord injury in mammals including human is detrimental and can lead to complete loss of function, which is primarily due to the inability of neuronal axons to regenerate and reconnect to their appropriate targets beyond the injury site. In contrast, *Xenopus* tadpoles show tremendous regenerative capability and are able to swim again in a couple of days after spinal cord transection, providing an excellent model to investigate regeneration of spinal neural circuit following injury. Spinal neural circuits controlling rhythmic movements like swimming and walking are called central pattern generators (CPGs). It is still largely unknown how CPG networks recover following injury. Using the spinal cord of *Xenopus* tadpoles we aim to reveal a successful functional recovery at behavioral, network, and cellular levels. *Xenopus* embryos at the time of hatching (2 days old, stage 37/38) were used to perform complete spinal cord transection. After one-day recovery at stage 42, *Xenopus* larval swimming behavior was monitored using high speed video recording, which showed that *Xenopus* tadpoles regained the ability to freely swim, but the speed was lower. CPG network output (ventral root activity) was recorded simultaneously with single neuron whole-cell current-clamp recording in order to explore the recovery of rhythmic motor output following spinalisation and how the properties of injured CPG neurons change during functional recovery. Our results showed that rhythmic motor output was restored beyond the lesion site after complete spinal cord transection, but swimming episode duration was shorter and motor burst frequency was lower. Using neurobiotin-DAB staining, the extent of axonal regeneration of different classes of CPG neurons was also investigated. Understanding basic mechanisms of motor circuit repair after spinal cord injury can be beneficial for further studies on motor circuit regeneration in mammals and possible treatments for spinal cord injuries.

Title: Properties of spinal locomotor circuitry during development in SMN deficient neonatal mice

Authors: *D. L. HIGGIN, J. LOMBARDO, M. HARRINGTON;
Dept. of Biol. Sci., Delaware State Univ., Dover, DE

Abstract: Rhythmic locomotor activity is present in the lumbar spinal cords of neonatal mice as early as the first post-natal day (P0) well before the emergence of walking behavior, but its functional role and the timeline for its functional development is unknown.
Recent work with mouse models of Spinal Muscle Atrophy (SMA) has shown that SMN-deficient motor neurons are impaired in central circuitry and synaptic function; however whether this loss effects rhythmic locomotor activity is unknown. Therefore, the neonates of SMA mouse models present an approach for determining the functional significance and developmental timeline of this early locomotor network maturation in a model where significant motor neuronal loss is expected.
Pharmacological application of Dopamine, NMDA, Serotonin, and Potassium has been shown to elicit locomotor-like activity and bath application in acutely isolated spinal cords from neonatal mice elucidate rhythmic alternating activity in the lumbar section of the spinal cord and contralateral ventral root discharge recordings of drug induced motor neuron activity are readily accomplished by suction electrodes.
We investigated spontaneous and drug induced rhythmic behavior in the lumbar spinal cord and compared control and SMA mice in early post-natal (P0 – P7) preparations, where rhythmicity has been shown to be established. We investigated rhythmicity in the network throughout various segmental levels of the lumbar spinal cord including those higher in the cord which are affected earlier in the course of the disease compared to those lower in the cord that are affected later.

Title: Descending input and its effect on a coordinating network

Authors: *F. CLOTTEN[1], C. R. SMARANDACHE-WELLMANN[2];
[1]Zoological Inst., Univ. of Cologne, Koeln, Germany; [2]Inst. of Zoology, Univ. of Cologne, Cologne, Germany

Abstract: The swimmeret system of the crayfish is an easily accessible model for studying locomotion. The segmental organization of the central nervous system provides the opportunity to elucidate the mechanisms of both, the intersegmental coordination of central pattern generators (CPGs) and the coordination of coupled CPGs within one segment (left-right coordination). The general network properties of the swimmeret system and the coordination of CPGs that underlies this coupled activity were previously investigated in detail. Consequently it is of great interest to understand the effect of descending input from the brain on the coordination of the swimmeret CPGs. Both excitatory and inhibitory command neurons of the swimmeret system were described but no information is available about the input these neurons receive or their neural targets within the swimmeret system.
In this comparative study separated axon bundles in the connectives of the abdominal nerve cord were stimulated electrically. Stimulation induced and terminated rhythmic activity in inactive and active preparations, respectively. Histological identification of the stimulation sides revealed that the locations of the stimulated axon bundles are consistent with previously described locations of excitatory and inhibitory command neurons. In the signal crayfish, *Pacifastacus leniusculus*, electrical stimulations affected both sides of the nervous system in the same manner. Rhythmic activity was initiated or terminated bilaterally to the same extent. In contrast, asymmetric rhythmic activity (i.e. rhythmic activity solely ipsilateral to the stimulated axon bundles) could be induced in the galician crayfish, *Astacus leptodactylus*. In intact crustaceans this behavior is known as a righting response of the swimmeret system due to spatial movements of the animal. Bath application of carbachol, a nicotinic and muscarinic analog of acetylcholine that increases the excitation of the swimmeret system, increased the stimulation effect on the side of the abdominal nerve cord that was contralateral to the stimulation side. This suggests that the ipsilateral or bilateral initiation of swimmeret movements depends on the system's excitation level.

With increasing stimulation frequencies the period of the evoked rhythmic activity decreased and more motor neurons were recruited. These results, in addition with intracellular recordings of motor neurons during sub-threshold stimulations, give evidence that both the swimmeret motor neurons and presynaptic interneurons of the pattern-generating micro-circuits are possible targets of the command neurons within the swimmeret system.

Title: Ultrasound-induced inhibition of neural activity in an invertebrate motoneuron

Authors: *M. NEWHOFF[1], W. LEGON[2], K. A. MESCE[1];
[1]Grad. Program in Neurosci., Univ. of Minnesota, Saint Paul, MN; [2]Physical Med. and Rehabil., Univ. of Minnesota, Minneapolis, MN

Abstract: Ultrasound (US) is a promising noninvasive neuromodulation technology with the potential to confer the high spatial resolution of invasive techniques used to treat a wide range of neurological disorders, including epilepsy and Parkinson's disease. Although researchers have known for several decades that ultrasound is capable of altering neural firing rates, the underlying cellular mechanisms accounting for such changes have remained elusive. Several hypotheses regarding its mode of efficacy include formation of microbubbles (cavitation), generation of heat, and mechanical distortion. To gain a greater understanding of the cellular mechanisms underlying the actions of US, we utilized simultaneous ultrasonic stimulation and single-unit electrophysiological recordings in a well-studied invertebrate model, the medicinal leech *Hirudo verbana*. This preparation provides an especially accessible physiological system in which identified neurons can be studied at the level of their membrane biophysical properties, circuit connections and behavioral roles. One well-studied motoneuron involved in locomotion, the Dorsal Longitudinal Muscle Excitor (DE-3), has one of the largest axons in its nerve root, and thus can be unambiguously detected via extracellular recording. Using ultrasound at a frequency of 960 kHz, we were able to inhibit repeatedly and reversibly the firing rate of DE-3

(N=6), and by 50-100% (N=4). The robust restoration of firing rates argues against the idea that cavitation and its deleterious effects on cells were causal to the US-induced changes observed. Intriguingly, US also rapidly switched tonic DE-3 firing over to a bursting mode in the presence of dopamine, a phenomenon that may have resulted as a consequence of hyperpolarization-activated depolarizing inward currents. Repeated application of US did result in a maximum temperature increase of 2°C, but such fluctuations alone did not affect neuronal firing rates appreciably. We conclude that the effects of US on DE-3 likely involve activation of ion channels mediating hyperpolarizing conductance states. Furthermore, because the neuron that we tested with US was a motoneuron, as opposed to a mechanosensory neuron, we have the opportunity to understand better how US alters a host of ion-channels that are not biologically maximized for mechanical gating (e.g. TRP channels). Pharmacological manipulations in the presence of US are currently being carried out to determine the identity of ion channels affected by US stimulation. By gaining a greater understanding of the mechanisms by which US enacts changes in neural activity, we hope to increase its therapeutic potential.

Title: Synapses between encoders and decoders: understanding a coordinating network

Authors: ***F. BLUMENTHAL**[1], C. R. SMARANDACHE-WELLMANN[2];
[1]Zoological Institute, Animal Physiology, Emmy-Noether Group, Univ. of Cologne, Koeln, Germany; [2]Zoological Institute, Animal Physiology, Emmy-Noether Group, Univ. of Cologne, Cologne, Germany

Abstract: The swimmeret system is an excellent model to understand neural mechanisms of coordination of distributed central pattern generators (CPG). During swimming the four paired swimmerets of the crayfish's abdomen are coordinated in an anteriorly proceeding metachronal wave. Each swimmeret is innervated by neurons from its own module, containing a CPG, these have to be coordinated among each other. The intersegmental coordination of four ipsilateral, anatomically separated CPGs is achieved by three neurons located in each hemisegment forming a coordinating circuit. One ascending (ASC_E) and one descending (DSC) coordinating neuron

encode the information about the status of their home module and project it to the other neighbors. A nonspiking neuron, Commissural Interneuron 1 (ComInt1), decodes this information transmitted by three neighboring coordinating neurons and integrates it into its own CPG. ComInt1 receives these inputs with a gradient of synaptic strength, where the strongest excitatory postsynaptic potential (EPSP) is always elicited by the ASC_E from the posterior neighbor. The anterior DSC elicits a weaker EPSP and the most distant coordinating neuron has the weakest input.
Here we want to investigate if the gradient of synaptic strength is due to the morphology of synaptic contacts. For these experiments, ComInt1 and coordinating neurons were filled with fluorescent dye and the presynaptic boutons of the coordinating neurons on ComInt1 were marked immunohistochemically with Anti-Synapsin. An immunohistochemical labeling of the postsynapses of ComInt1 with PSD-95 was so far not successful.
The axons of the coordinating neurons run dorsally, parallel to the midline through each segment. ComInt1 has its soma in one hemisegment, sends its primary neurite dorsally over the midline to the lateral neuropil on the contralateral side where it forms an electrical synapse with one of the CPG neurons. ComInt1 has one ascending and one descending dendritic branch parallel to the midline and to the axons of the coordinating neurons.
At the midline we identified synapses of the coordinating neurons by colocalized presynaptic boutons with an intracellular stained axon. The colocalizations were dorsally all along and strictly parallel to the midline of the ganglion. These colocalizations do not yet explain the three distinct sizes of EPSPs in ComInt1 but it is a first approach to investigate this morphologically. We will perform more double stainings of two different coordinating neurons and presynaptic boutons as well as triple stainings with ComInt1 to investigate if the areas of colocalization and the number of synapses vary in accordance to the synaptic inputs.

Title: Ionic currents and their influence on rhythm generation and coordination

Authors: *L. SCHLAEGER[1], C. R. SMARANDACHE-WELLMANN[2];
[1]Dept. of Animal Physiol., [2]Inst. of Zoology, Animal Physiology, Emmy-Noether Group, Univ. of Cologne, Cologne, Germany

Abstract: The function of nervous systems is based on the interaction of neuronal networks. These networks are built of neurons with individual activity patterns that together regulate and coordinate complex movements and behavior. To better understand the properties of such networks, we investigate the crayfish swimmeret system. Swimmerets are four pairs of abdominal limbs that move in alternating power- and return strokes in a metachronal wave from posterior to anterior. In each hemiganglion a similar subset of neurons can be found that drives this movement. Each microcircuit is composed of five interneurons forming the rhythm generating circuit, three coordinating neurons, and 70 motor neurons (MN). When the system is active, all of these neurons show membrane potential oscillations but with distinct activity patterns. Despite our good understanding of the cellular components and synaptic contacts among them, the intrinsic mechanisms that enable the individual activity pattern still remain unknown. Therefore we are interested in the ionic currents underlying the similar yet different activity patterns of the neurons and how they influence rhythm generation and coordination between segments.
We performed single electrode current- and voltage-clamp recordings from dendritic aborizations in the isolated abdominal nervous system of the crayfish, *Pacifastacus leniusculus*. To identify and reveal different ionic currents we bath applied selective ion-channel blockers. In this system we did not find any indication of the existence of the hyperpolarizing activated cation current (I_H). This is remarkable since it was shown in other systems to have key importance for generating membrane potential oscillations. This led to further investigations regarding the origin of the neuronal activities. After application of channel blockers against the high voltage activated calcium current I_L (Nifedipine), the transient potassium current I_A (4-AP) or the persistent sodium current I_{NaP} (Riluzole) we could observe an altered ability of the system to produce a steady and coordinated motor rhythm. This led to the conclusion, that the activities of the pattern generating, as well as the coordinating neurons, are dependent on these currents. When analyzing the effect of the channel blockers on input resistances of MNs, Nifedipine had the strongest effect in increasing the resistances. The other blockers did not change the input resistances significantly. However, the amplitude of membrane potential oscillations declined under application of all channel blockers. Resulting, we anticipate a major importance of I_L and a minor relevance of I_{NaP} and I_A for motorneuronal activities.

Title: Differential tuning of neurons in a coordinating circuit

Authors: *A. C. SCHNEIDER[1], F. BLUMENTHAL[2], C. R. SMARANDACHE-WELLMANN[2];
[1]Univ. of Cologne, Koeln, Germany; [2]Inst. of Zoology, Animal Physiology, Emmy-Noether Group, Univ. of Cologne, Cologne, Germany

Abstract: Neural oscillators coordinated to produce meaningful behavior exist in a large variety of animals, ranging from simple locomotor networks to brain oscillations. A model system to study coordination of distributed neural oscillators is the crayfish swimmeret system. Its neurons, especially those for coordination, are identified and their connections characterized.
These neurons drive four pairs of swimmerets in a metachronal wave with 25% phase lag between segments. Each swimmeret is controlled by its own central pattern generator (CPG) located in the corresponding abdominal hemisegment. Necessary and sufficient to coordinate CPGs across segments are three neurons per hemisegment: The ascending (ASC_E) and descending (DSC) coordinating neuron, and the non-spiking Commissural Interneuron 1 (ComInt 1). ASC_E and DSC, driven by the CPG, encode information about their home ganglion's activity state and send it as corollary discharge to the ComInt 1s of the other ganglia. Each action potential of ASC_E and DSC causes a distinct and fast excitatory postsynaptic potential in the target ComInt 1, which integrates the coordinating information in the target CPG.
The 25% phase lag is independent of frequency and strength of swimmeret movements. Therefore, we hypothesized that changes in the system's excitation tune the encoding and decoding properties of the coordinating circuit. We used isolated abdominal nerve cords to record intracellularly from ASC_E, DSC or ComInt 1. Excitation was changed by bath application of different carbachol (cholinergic agonist) or edrophonium chloride (acetylcholine esterase inhibitor) concentrations.
To investigate direct and indirect actions of the drugs we measured input resistance (Rin) and membrane potential of these neurons both in the intact network and chemically isolated. Rin of ASC_E decreased, of DSC increased, and of ComInt 1 did not change with increasing drug concentration. Only when isolated from the network with TTX in low Ca^{2+}/high Mg^{2+} saline drug concentration had the opposite effect on ASC_E's and DSC's Rin, and their membrane

potential depolarized. These opposing effects show that the direct effects of system excitation were usually masked by indirect network effects. ComInt 1 was largely unaffected by changes in excitation. We conclude that the differential direct and indirect effects on the coordinating neurons' tune their encoding properties. As ComInt 1 is not subject to excitation it cannot entirely decode coordinating information but may rather work as hub neuron. Decoding with respect to excitation may then take place in the CPG itself, which is also one source of tuning for the coordinating neurons.

Title: Crossed reflex pathways in freely walking mice

Authors: *O. D. LAFLAMME[1,2], T. AKAY[1,2];
[1]Dalhousie Univ., Halifax, NS, Canada; [2]Atlantic Mobility Action Project, Halifax, NS, Canada

Abstract: The commissural neuronal circuitry, involved in left-right coordination, has been investigated at a cellular and functional level by combining *in vivo* experiments in cats and *in vitro* electrophysiological experiments with mouse genetics. These experiments identified several genetically distinctive commissural pathways and their possible role in transmitting the activity of central pattern generators (CPG) underlying locomotion from one side of the body to the contralateral side. Investigations with the cat unraveled several crossed reflex pathways, but the role of these pathways during walking and their relation to the commissural pathways identified in mice remained unknown. The overall aim of our study is to characterize crossed reflex pathways in mice that would enable connections to be formed between the crossed reflex data from cat experiments and the more recent commissural CPG pathways from mouse experiments. Here, we describe crossed reflex pathways in mice induced either by proprioceptive or cutaneous afferent signals. We chronically implanted nerve stimulation electrodes to activate cutaneous

(Sural nerve) and proprioceptive feedback from flexor (Peroneal nerve) and extensor (Tibial nerve) muscles in fully awake mice during resting and walking on a treadmill. In parallel, electromyogram activities from multiple flexor and extensor muscles of the contralateral leg were recorded to document reflex responses transmitted to the contralateral side of the spinal cord. Electrical stimulation of all three nerves evoked motor responses on the contralateral side of the body in every muscle investigated. All muscles were activated approximately at the same latency, except for the tibialis anterior, which was slightly faster. Moreover, the temporal aspect of this pattern remained similar during resting and walking. The amplitude of flexor and extensor muscle activation in response to sural nerve stimulation was consistently stronger during walking than during resting. However, during proprioceptive nerve stimulation, regardless of whether from flexor or extensor muscle, the extensor muscle response decreased, while flexor activity either slightly increased or remained the same during walking compared to resting. We describe the crossed reflex in mice and show that the amplitude of the flexor and extensor muscle activities, but not the temporal structure of muscle response is modulated during walking compared to resting.

Title: The roles of different potassium currents for action potential propagation

Authors: *N. DAUR, F. NADIM, D. BUCHER;
Dept. of Biol. Sci., NJIT and Rutgers Univ., Newark, NJ

Abstract: Most neurons express multiple types of voltage-gated ion channels in their axons, giving rise to nonlinear membrane behavior beyond simple spike propagation with just fast Na^+ and delayed rectifier K^+ currents. One consequence is spike history-dependent change in conduction velocity that goes far beyond simple refractory effects and can substantially alter the interval structure of repetitive activity. This implies that axonal propagation can potentially influence the temporal code of neural communication.
We have previously described changes in conduction velocity in rhythmically active neurons in the lobster stomatogastric nervous system (Ballo et al., J Neurosci 2012). Spike delay along the

4-5 cm axon of the pyloric dilator (PD) neuron depends on mean activity rate, as repeated bursting hyperpolarizes the axon and increases delay with a time constant of several minutes. This slow time scale increase in delay is accompanied by an increase in delay variability: after several minutes of activity, delay can change by ~30% within a single burst. The slow time scale hyperpolarization depends on activation of a Na^+/K^+ pump, which is balanced by a hyperpolarization-activated current (I_h).
A computer model of the axon shows that the fast time scale variability is due to the effect of changing resting potential on the gating variables of the Na^+ current. Because Na^+ current gating depends on the activation levels of K^+ currents, we explore the contribution of K^+ currents to temporal fidelity. Voltage-clamp recordings of the PD axon reveal delayed rectifier (I_{Kd}) and A-type (I_A) currents, but no calcium-dependent K^+ currents. Complete block of I_{Kd} with TEA results in repetitive firing in response to a single nerve stimulus. In contrast, block of I_A with 4-AP substantially increases spike duration, but does not lead to repetitive firing. I_{Kd} and I_A also have differential effects on temporal fidelity. Partial block of I_{Kd} with low concentrations of TEA has little effect on the variability of conduction delay at the beginning of repeated burst stimulation, but substantially alters it after several minutes of stimulation, when the resting membrane potential is more hyperpolarized. In contrast, partial block of I_A with low concentrations of 4-AP substantially alters variability of delay at the beginning of stimulation, but has little effect after several minutes, ensuing activity-dependent hyperpolarization. Therefore, the contribution of these different K^+ currents differentially depends on the history of spiking activity itself, and may affect different aspects of axonal function. We explore the underlying ionic conductance mechanisms using our axon model.

Title: A coactivated command like neuron modifies the dynamics of motor program articulation.

Authors: *C. G. EVANS[1], K. R. WEISS[2], E. C. CROPPER[2];
[1]Dept. of Neurosci., Mount Sinai Sch. of Med., Ny, NY; [2]Dept. of Neurosci. and Friedman Brain Inst., Mount Sinai Sch. of Med., New York, NY

Abstract: In many invertebrate model systems, it has been shown that multiple command-like neurons are activated to initiate or maintain a specific behavior. In principle this may suggest there is redundancy, or that each command-like neuron has a unique function, contributing to specific parameters of the behavior. Although data in a number of contexts are beginning to favor the latter view, little is known about these individual functions. We address this issue in the well described feeding system of *Aplysia californica*. In *Aplysia*, motor output from the buccal ganglia can drive egestive and ingestive behaviors. A population of about 13 cerebral-buccal interneurons (CBIs) project to the buccal ganglia and are higher-order interneurons that can activate or modulate feeding motor programs. The most extensively characterized is CBI-2. It is activated by chemical (food) and tactile stimuli to the lips and tentacles and strongly and reliably drives motor programs in the buccal ganglia. It will initiate feeding movements in semi intact preparations. When CBI-2 is made to fire repeatedly in bursts at fixed intervals the motor programs gradually convert from initially intermediate to ingestive. We have termed this effect, repetition priming. CBI-3 is also activated by food, and has been found to fire with CBI-2 during protraction in feeding intact-head preparations. When driven to fire with CBI-2, in isolated ganglia, CBI-3 immediately converts an intermediate or egestive program into an ingestive program. In the present study we examine the effect of firing CBI-3 at a physiologically relevant frequency simultaneously with CBI-2 during repetition priming. We show that co-activation of CBI2 and CBI3 results in a faster transition from intermediate to ingestive motor programs than with stimulation of CBI-2 alone. Therefore one of the functions of a co-activated command-like neuron during feeding behavior is to modify the dynamics of motor programs induced by the other.

Title: The spatial topography of cranial motor neuron activity patterns in larval zebrafish revealed by confocal and whole brain light-sheet calcium imaging

Authors: *K. L. MCARTHUR, J. R. FETCHO;
Neurobio. & Behavior, Cornell Univ., Ithaca, NY

Abstract: A neuron's location in the developing neuroepithelium both reflects its ontogenetic history and predicts its functional future. Spatial signaling gradients drive differential gene expression, such that specific neuronal subtypes reliably arise in particular brain locations. Spatial location is further refined by neuronal migrations - including some dramatic repositioning of entire populations and more subtle relative positioning within each population. Ultimately, the location of a neuron's cell body and extensions will determine its access to presynaptic and neuromodulatory inputs - though the relationship between location and connectivity may be more or less flexible for specific synaptic partners. To understand the relationship between location and function in the developing hindbrain, we focus on the facial branchiomotor neurons (FBMNs) in larval zebrafish, a group of cranial motor neurons driving respiration and feeding. These neurons adopt a clear age topography early in development and serve as a general model for the relationship between dorsoventral location, age, and function in cranial motor pools. Further, because these neurons execute an early and dramatic caudal migration in wild type animals (but not in specific mutant lines), we have the opportunity to study the impact of abnormal population positioning on circuit architecture throughout the hindbrain. We mapped FBMN activity patterns in three-dimensional space, using confocal and light sheet imaging of genetically encoding calcium indicators. We found a loose functional topography, where FBMNs exhibiting higher-frequency respiratory bursts (in addition to swim-related activity) are concentrated in the ventrolateral portion of the motor nuclei in wild type larvae. These results are consistent with previous backfill data regarding the location of motor pools known to participate in respiratory behaviors. We also probed for neurons that have correlated activity with FBMNs. This revealed neurons with potential functional relationships to the FBMNs, including other motor neurons and potential presynaptic interneurons. This wild type data provides a basis for comparison to whole-brain activity in mutants, to discover to what extent the spatial structure of hindbrain neuronal activity is altered when a critical motor nucleus is abnormally positioned. Leveraging whole-brain calcium imaging in this way, in this specific group of neurons - when combined with single-cell morphology and electrophysiology - will finally allow us to test hypotheses about the degree to which large-scale circuit architecture depends on proper positioning of neuronal populations.

Title: Imaging neural dynamics governing *Drosophila* limb control during walking and grooming

Authors: *P. RAMDYA;
Caltech, Pasadena, CA

Abstract: Motor control circuits cannot be fully understood without measuring their dynamic activity during behavior. Until now, it has been challenging to image the activity of vertebrate and invertebrate limb coordination circuits due to their inaccessibility. Here, I introduce a preparation that permits 2-photon calcium imaging of neural activity in the ventral nerve cord of tethered, behaving *Drosophila melanogaster*. A dorsal thoracic dissection uncovers neurons that control prothoracic and mesothoracic legs as well as populations of descending and ascending interneurons that pass through the cervical connective. I will demonstrate how this preparation can reveal the dynamics of peripheral sensory neurons, interneurons for inter-leg coordination, neuromodulatory neurons, and motor neurons while animals walk and groom on a spherical treadmill. This approach provides an indispensable tool for uncovering how a relatively compact motor control system can orchestrate complex behaviors.

Title: Anatomical and electrophysiological characterization of WT1-expressing neurons in the mammalian spinal cord.

Authors: F. HAQUE[1], W. ZHANG[2], *S. GOSGNACH[3];
[1]Ctr. for Neurosci, [2]Dept. of Physiol., [3]Ctr. for Neurosci., Univ. of Alberta, Edmonton, AB, Canada

Abstract: The neural network underlying locomotion (i.e. locomotor CPG) in mammals is comprised of interneurons located in the ventromedial aspect of the lumbar spinal cord, and is able to generate rhythmic locomotor-like motor patterns in the absence of sensory input or descending inputs from the brain. Traditional methods of investigating the structure and mechanism of function of this neural circuit have involved identifying and characterizing single component interneurons based on electrophysiological and anatomical criteria. This approach has proven to be extremely low yield due to the large number of interneurons present in the mammalian spinal cord combined with the fact that cells with a similar function are intermingled with other, functionally unrelated, interneurons. Our lab implements a molecular genetic approach to label entire interneuronal populations with a similar genetic lineage and study each genetically-distinct population in order to characterize their anatomical and electrophysiological properties, as well as their potential role in generating locomotor outputs. Recently we have focused on the dI6 population, a group of interneurons that originate in the dorsal region of the developing neural tube, migrate ventromedially, and settle in lamina VIII of the functionally mature spinal cord. dI6 cells can be divided up into at least 3 subsets based on transcription factor expression: WT1+ cells; DMRT3+ cells; and WT1+/DMRT3+ cells. Previous work demonstrated that the DMRT3+ population is primarily inhibitory and have axons that contact both ipsilateral and contralateral motor neurons. Our work investigates the detailed morphology, neurotransmitter phenotype, and electrophysiological properties of the WT1+ and WT1+/DMRT3+ cells. Results indicate that both subsets are primarily GABAergic, and that the axonal projection pattern of WT1+ cells is distinct from that of the DMRT3+ subset. Furthermore, the vast majority of the WT1+ cells are rhythmically active during locomotion suggesting that these cells may be a component of the locomotor CPG.

Title: Partially shared inhibitory and excitatory spinal circuits for withdrawal reflex, scratch and locomotion

Authors: *G. GATTO, M. GOULDING;
Salk Inst. For Biol. Studies, LA Jolla, CA

Abstract: Animals display a highly varied repertoire of motor behaviors that reflect the patterned activity of a limited number of muscles and motor neurons. Rhythmic behaviors, such as walking or breathing, are generated by the activity of neuronal networks, known as central pattern generators (CPGs). Work in turtles has shown a partial overlap of the CPG neurons that are active during locomotion and scratching. To date, these neurons have not been molecularly identified. Using a tripartite intersectional genetic approach, we have investigated the role of specific interneuron populations during reflex responses and locomotion. Spinal ablation of V1 (En1-Cre) and V2a (Chx10-Cre), but not V2b (Gata3-Cre) interneurons in adult mice leads to impaired responses to chloroquine-induced scratch. Among the analyzed mice, ablation of V1 or V2a interneurons causes a strong reduction in the speed of scratching, and in the number of scratch bouts, suggesting that these interneuron populations have an essential role in enabling fast scratch movements. Acute silencing of these neurons, using CNO-activated hM4D receptor, recapitulates the slower velocity during scratching. Interestingly, ablation of V1 or V2a interneurons has already been shown to impair mice performance at high locomotory speeds, implying that scratch and locomotion share the CPG neurons responsible for facilitating fast movements. We also find an impaired response to mechanical stimuli but not noxious-induced paw withdrawal in V1 ablated mice, suggesting that the withdrawal reflex may recruit different interneuron pathways according to the applied stimulus.
Taken together, these data identify two key CPG populations as common elements in the CPG circuits for rhythmic scratch and locomotion. Our data also infer that V2a interneurons might be part of the scratch-rhythm generator, while the V1 interneurons are required for the fine-tuning of the speed. In the future, it will be important to address how these two populations are connected and interact during scratch (a unilateral rhythmic behavior) and locomotion (a bilateral coordination of rhythm).

Title: The effectiveness of treadmill training is enhanced by applying robotic resistance in a rodent model of spinal cord injury

Authors: *C. A. ESTRADA[1], E. J. HINAHON[2], E. RUIZ[3], T. TRAUGHBER, Jr[2], S. VILLANUEVA[1], S. SIROT[1], M. ROBLES[1], R. MARTINEZ[1], D. WON[4], R. DE LEON[2]; [1]Dept. of Biol. Sci., [2]Sch. of Kinesiology and Nutritional Sci., [3]Dept. of Chem. and Biochem., [4]Col. of Engineering, Computer Science, and Technol., Cal State LA, Los Angeles, CA

Abstract: There is evidence that robotic-assisted treadmill training with body weight support did not improve the recovery of stepping patterns after a spinal cord injury (SCI). Applying robotic resistance, however, may be beneficial although, to date, proper controls have not been included in experiments of robotic resistance. We examined the effects of robotic-applied resistive forces in a rodent model of SCI. Forty female Sprague Dawley rats received a severe mid-thoracic spinal cord contusion injury. A baseline test was performed two weeks later, after which treadmill training began. A robotic device was used to apply viscous forces that opposed horizontal or vertical movements of the hindlimbs during treadmill training. One group rats (n=10) was trained with a robotic horizontal force (HF) and another group (n=10) was trained with a vertical force (VF). Control groups consisted of a group of rats receiving treadmill training without robotic resistance (n=10) and a group of untrained rats (n=10). Training was performed for 15 minutes/day, 5 days/week. After 6 weeks of training with robotic resistive forces, improvements in step cycle kinematics were observed based on ankle position data collected by the robotic device. Specifically, training with the HF significantly increased step length and forward displacement by 24% and 16%. Training with VF did not affect step length parameters but significantly improved step height by 26%. Training with VF also significantly increased peak vertical velocity during lift and peak vertical velocity prior to paw contact by 49% and 40% respectively. The percentage of weight bearing steps only improved in the rats trained with VF. No significant changes were observed in untrained controls or in rats that were trained without the resistive forces. These findings suggested for the first time that adding resistive forces enhanced the effectiveness of weight supported treadmill training. HF and VF shaped the step cycle in a direction-dependent manner, but training with the vertical resistance (which has not yet been studied) may be more beneficial than horizontal resistance. These

findings have implications for the use of robotic technology in treadmill training therapies following SCI.

Title: treadmill training with robotic resistance enhances synaptic plasticity in spinal cord injured rats

Authors: *E. RUIZ[1], S. VILLANUEVA[2], C. ESTRADA[2], E. HINAHON[3], T. TRAUGHBER, Jr.[3], S. SIROT[2], M. ROBLES[2], R. MARTINEZ[2], D. WON[4], R. DE LEON[3];

Abstract: There is evidence that applying resistive forces during treadmill training improves the recovery of stepping patterns after a spinal cord injury (SCI). Whether the effects of treadmill training are augmented by the addition of resistive forces augments is not known. The question we asked here was whether adding resistive forces enhanced plasticity in the rat spinal cord more so than treadmill training alone. Forty female Sprague Dawley rats received a severe mid-thoracic spinal cord contusion injury. A baseline test was performed two weeks later, after which treadmill training using a robotic device to apply viscous forces that opposed horizontal or vertical movements of the hind limbs. One group of rats (n=10) was trained with a robotic horizontal force (HF), another group (n=10) was trained with a vertical force (VF), another group was trained (T) without force (n=10) and one group was untrained (UT) (n=10). Training was performed for 15 minutes/day, 5 days/week. After 6 weeks of training, the rats were killed and the spinal cords removed and processed for immunohistochemistry. We performed experiments to quantify biochemical markers for synaptic plasticity, i.e. synatophysin, VGLUT1 and GLYT2, in the ventral horn of the lumbar spinal cord. The expression of synaptophysin was significantly greater after HF training compared to VF and T training ($p<0.05$). No significant differences were found for VGLUT1 and GLYT2 expression in the ventral horn. These preliminary data

suggested that HF training increased the amount of synapses in the lumbar spinal cord more so than other forms of training. The enhanced synaptic plasticity may be associated with the observed beneficial effects of training with horizontal resistance. On-going experiments with VGLUT and GLYT2 expression around labeled motor neurons will provide greater insight into the nature of these synapses. These findings have implications for the use of treadmill exercise therapies following SCI.

Title: The effects of weight supported quadrupedal treadmill training in a rat model of spinal cord injury and metabolic syndrome

Authors: *T. TRAUGHBER, JR[1], E. RUIZ[2], C. ESTRADA[3], E. ARCENA[1], S. VILLANUEVA[3], S. DERIQUITO[1], R. DE LEON[1];

Abstract: Weight supported treadmill training improves walking in individuals with spinal cord injured (SCI). Because it is a form of exercise, it may also reduce the risk factors associated with metabolic syndrome which is prevalent in the SCI population. In this study, we examined the effects of imposing quadrupedal body weight supported treadmill exercise in a rodent model of SCI and metabolic syndrome. Seventeen rats received a severe spinal cord contusion (T10). One day after the contusion, the rats were placed on a high energy diet consisting of 10% fat, 20% sucrose, and 70% normal rodent chow and 40 days later, a low dose of streptozotocin (30 mg/kg, i.p.) was administered. The rats were assigned to a trained (n=8) or non-trained group (n=9). Training consisted of weight supported, quadrupedal treadmill walking (23 cm/s) for 1 hr/day, 5 days/week for 6 weeks. Insulin tolerance tests were performed, hemodynamic measurements were recorded, and heart and hindlimb muscle tissue was harvested after the rats were killed. Based on fasting blood glucose, the high energy diet and STZ treatment was successful in

inducing hyperglycemia (i.e. >140 mg/dL; trained: 202±50 mg/dL; non-trained: 146±29 mg/dL). Fasting blood glucose levels were not significantly different between the groups. However, insulin sensitivity was improved by weight supported, quadrupedal treadmill training based on insulin tolerance test. We found significant differences in glucose levels 45 and 60 min after insulin injection indicating a greater insulin sensitivity in the trained group. No difference in insulin sensitivity was found at baseline. Training also significantly increased tibialis anterior, gastrocnemius and soleus muscle weights by 7%, 20%, 31% respectively indicating the training was effective in activating hindlimb activity in the SCI rats. No significant differences in body mass, heart weight or hemodynamic measurements were found between the groups. These findings suggest that weight supported treadmill exercise training can reduce some metabolic abnormalities that occur after SCI. The mechanism is unclear, but might involve adaptations in leg muscles which result in improved glucose utilization.

Title: A new, simple device for facilitating weight supported overground and treadmill locomotion in spinal cord injured rats

Authors: *S. G. DERIQUITO[1], S. SIROT[2], C. GONZALEZ[1], T. TRAUGHBER, Jr.[1], D. REINKENSMEYER[3], R. DE LEON[1];
[1]Sch. of Kinesiology and Nutritional Sci., [2]Dept. of Biol. Sci., Cal State LA, Los Angeles, CA; [3]Dept. of Mechanical and Aerospace Engin., Univ. of California Irvine, Irvine, CA

Abstract: Previous studies of weight supported training use robotic devices that place the rodents in unnatural bipedal walking conditions. We developed the BART device (Body weight supported, ambulatory, rodent trainer) to train rodents in their more natural, quadrupedal gait (Hamlin et al., J Neurosci Methods.246:134-41, 2015). However, with the BART device only a limited number of steps was possible. We developed circular BART or CBART to exercise both the hindlimbs and forelimbs during weight supported overground and treadmill locomotion. The CBART device consists of a lever arm that hinges on a fulcrum. One advantage of the simple

design is that CBART can be easily constructed using parts obtained from any hardware store. The rat is placed at one end of the arm and is lifted by a weight placed on the other end of the arm. The amount of weight support is controlled by adding more weight or moving the location of the weight on the lever arm. The rats walk along a circular path during overground locomotion because the arm rotates around a vertical axis. We performed preliminary tests of CBART in Sprague Dawley rats that received a severe mid-thoracic spinal cord contusion injury (SCI (n=4) and in normal rats (n=4). Ink was placed on the skin above bony landmarks for the ileum, hip, ankle and metatarsal-phalangeal joint and the limbs were recorded by a small camera placed on the CBART arm. The recorded sequences were analyzed on a computer using MATLAB software that was developed in-house. After two weeks of training, all the rats learned to perform the overground locomotor task while attached to CBART with and without weight support provided. The effect of adding weight support was to decrease step length by 21% and increase hip-ankle-toe angle by 10%, consistent with our previous studies. During quadrupedal treadmill locomotion, CBART was effective in quantifying differences between poor and good stepping spinally contused rats. For example, hindlimb step length was significantly greater in good steppers compared to poor steppers (4.25±1.2 vs 0.56±0.5 mm). Ongoing analyses is being performed that will provide more details of kinematic characteristics. These preliminary data suggested that the CBART device facilitated quadrupedal overground and treadmill locomotion. Moreover, CBART is simple, inexpensive and easy to construct. These results suggested that the CBART device will be a useful tool for studying more natural forms of locomotion in SCI rats.

Title: New therapeutic strategy to treat spasticity by targetting KCC2 after spinal cord injury

Authors: S. LIABEUF[1], L. STUHL GOURMAND[1], P. BOULENGUEZ[1], F. GACKIERE[1], A. VIALLAT LIEUTAUD[1], R. MANCUSO[1], L. VINAY[1], *F. BROCARD[2];
[1]CNRS, AMU, Marseille, France; [2]CNRS, Marseille, France

Abstract: In healthy adults, activation of γ-aminobutyric acidA (GABAA) and glycine receptors inhibits neurons as a result of low intracellular chloride concentration, which is maintained by the potassium-chloride cotransporter KCC2. A reduction of KCC2 expression or function is involved in the pathogenesis of several neurological disorders including spasticity following spinal cord injury (SCI). Given the critical role of KCC2 in regulating the strength and robustness of inhibition, identifying tools that may increase KCC2 function and hence restore endogenous inhibition in pathological conditions is of particular importance. The screening of a library of marketed drugs enabled to identify a family of compounds that are able to activate KCC2 function and reduce spasticity after spinal cord injury. We showed that the prochlorperazine, a member of this family, tested in vitro on the isolated neonatal rat spinal cord, was able to hyperpolarize the chloride equilibrium potential in motoneurons and strengthen the reciprocal inhibition, after neonatal spinal cord transection. We then showed that the prochorperazine was able to reduce spasticity after SCI *in vivo* in adult rats. This effect was blocked by pharmacological blockade of KCC2 using intrathecal injection of DIOA. Acute prochlorperazine injection *in vivo* increased the plasmalemal expression of KCC2 in the ventral horn, as revealed by means of immunohistochemistry. These data confirm that targeting KCC2 represents a valuable therapeutic strategy to reduce spasticity after SCI.

Title: Forelimb rehabilitation after mild cervical injury

Authors: *E. COLLYER, K. KADOYA, P. LU, M. TUSZYNSKI;
UCSD, LA Jolla, CA

Abstract: Spinal cord injury (SCI) is a devastating condition. The specific deficits that result from injury depend on the level and severity of the injury. One major challenge for SCI repair is

to restore voluntary movement, especially hand function, after cervical injury. Rehabilitative training, alone or in combination with pro-regenerative interventions, has substantial potential to improve functional outcomes after SCI. One useful model for evaluating functional recovery in the forelimb after SCI is the C4 bilateral dorsal column lesion (DCL). This injury model removes the vast majority of corticospinal inputs onto the forelimb motor pool and creates a severe deficit in grasping behaviour, eliminating the ability of rats to retrieve food pellet rewards on a Montoya staircase task (Wang et al J Neurosci. 2011). The latter study used the Listed hooded rat, an outbred rat strain. Many studies using cell transplantation utilize inbred rat strains, such as the Fischer 344 rat. To investigate the utility of the C4 bilateral DCL model for assessing functional outcomes, we performed C4 DCL in this rat strain. Notably, the same injury model in the Fischer 344 rat resulted in only a mild deficit on pellet retrieval: from a pre-operative baseline of 17 $\pm$ 0.5 pellets, these animals exhibited a drop in the number of pellets eaten to 2 $\pm$ 0.3 when tested 7 day post-lesion. However, they spontaneously recovered to retrieval of 7 $\pm$ 0.3 pellets by 42 days post-lesion. Thus different rat strains can yield different behavioral outcomes, likely due to strain-related differences in the importance of other axonal systems in forelimb control, including the rubrospinal projection. To develop a lesion model that resulted in persistent forelimb deficits and was sensitive to rehabilitation effects, we performed bilateral C4 DCL (to remove the CST) plus right dorsal quadrant lesions (to remove the rubrospinal projection) in Fischer 344 rats. This lesion resulted in persistent deficits in right forelimb food pellet retrieval (0 pellets at 7 days to 2$\pm$0.3 pellets at 70 days). Notably, rehabilitation significantly improved the mean number of retrieved pellets on week 9 post-lesion from 1.6 $\pm$ 0.7 pellets/session in lesioned, non-rehabilitated rats to 4.6 $\pm$ 0.3 pellets/session in injured, rehabilitated rats ($P<0.05$, RM ANOVA). On anatomical analysis, lesions were consistent in size and extent. This cervical lesion model therefore offers the benefit of exhibiting a benefit from rehabilitation on the Fischer 344 rat strain. We will now test whether the combination of neural stem cell grafts and rehabilitation provide synergistic benefits in functional outcomes.

Title: Changes in inter- and intra-limb coordination following locomotor training in people with spinal cord injury

Authors: *R. N. MALIK, K. PAUHL, T. LAM;
ICORD, Vancouver, BC, Canada

Abstract: Background: In individuals with motor-incomplete spinal cord injury (m-iSCI), the ability to functionally ambulate is reduced, partly due to the skilled walking requirements in our everyday lives. The ability to modify gait patterns for skilled walking requires appropriate intra- and inter-limb coordination. Following SCI, coordination within a limb (intra-limb coordination) and the coordination between limbs (inter-limb coordination) can be impaired, which may contribute to the reduced ambulatory capacity among individuals with SCI. The aim of this project was to determine whether intra- and inter-limb coordination can be improved following body weight supported treadmill training with a velocity-dependent resistance applied to the lower limbs and whether improvements in coordination are related to improvements in functional walking capacity.
Methods: Individuals with chronic m-iSCI were randomly assigned to body weight support treadmill training (BWSTT) with Lokomat-applied resistance (Loko-R) or to conventional Lokomat assisted BWSTT (Control). Training sessions lasted 45 minutes, 3 times a week for 3 months. Before (baseline) and after (post-training) training, lower limb joint kinematics were recorded while participants walked on a treadmill with body weight support at their comfortable and fastest speed. Motion capture markers were used to determine, hip, knee and ankle angles during walking. Joint angles were used to determine overall range of motion and intra- and inter-limb coordination. Over-ground skilled waking capacity, measured by the Spinal Cord Injury Functional Ambulation Profile (SCI-FAP), walking speed (10-meter walk test), and endurance (6-minute walk test) were also measured at baseline and post-training.
Results: Following training individuals in the Loko-R group tended to have greater joint range of motion during gait compared to the Control group, and also tended to show improvements in lower limb coordination. The Loko-R group also showed greater improvements in over-ground skilled walking capacity compared to the control group.
Conclusion: Lower limb coordination can be improved by BWSTT with Lokomat-applied resistance. This data suggests that skilled walking capacity, range of motion and lower limb coordination could potentially be used to show improvements in motor control following SCI.

Engineering, Psychology and Neurosci., [6]Ctr. for Neuroengineering, Duke Univ., Durham, NC

Abstract: A complete spinal cord Injury interrupts bidirectional communication between the subject's brain and body. The lesion level, severity and time since the spinal cord damage determine both the degree of sensorimotor impairment and the recovery prognosis. In the case of chronic paraplegic patients, diagnosed clinically with a complete lesion, or ASIA A (no sensory nor motor functions below the level of the injury), chances of spontaneous or induced clinical recovery are considered negligible. Here, we describe clinical results of a 24 month training protocol, based on a non-invasive closed loop brain machine interfaces, integrated with physical rehabilitation. A total of 7 SCI patients (6 ASIA A, 1 ASIA B) were followed. Patients were trained to brain control both virtual avatars in a simulated world and robotic gait trainers, using both a body-weight support system on a treadmill (Lokomat) and a custom-built exoskeleton. In addition, patients received continuous visual and tactile feedback. The latter was delivered, via a haptic display, applied to forearm skin. Tactile feedback was given in synchrony with the steps of the virtual or robotic actuators. Overall, we observed sensory improvements in all 7 of our patients, considering the perception of fine touch, pain and proprioception. Moreover, significant motor improvement, involving multiple myotomes below the level of lesion, was documented by

clinical evaluation (ASIA measurement) and validated via surface EMGs. Overall, 6 out of 7 patient had their ASIA rank updated (1 subject moved from ASIA B to ASIA C, 4 subjects moved from A to C and 1 subject moved from A to B). We propose that a long term training with closed-loop brain machine interfaces, combined with routine aided walking, may become a new rehabilitative therapy for chronic SCI patients.

Title: Repetitive exposure to intermittent hypoxia enhances overground walking in persons with chronic incomplete spinal cord injury

Authors: ***D. M. PETERS**, H. B. HAYES, M. C. OAKLEY, R. T. HAVRANEK, R. D. TRUMBOWER;
Emory Univ., Atlanta, GA

Abstract: Improving overground walking is a highly valued goal for persons with incomplete spinal cord injury (iSCI). Repetitive exposure to short bouts of low oxygen (acute intermittent hypoxia, AIH) is a non-invasive therapy that induces locomotor recovery in rodent models and humans with iSCI. Recently, we showed that 5 consecutive days of AIH alone or with walking practice increases walking ability in persons with chronic iSCI. Despite these exciting findings, little is known about the potential long-term beneficial effects or the impact of more frequent exposures of AIH on walking recovery in persons with chronic (>1 year) iSCI. The purpose of this study was to investigate the effects of prolonged exposures to AIH on overground walking speed and endurance in persons with chronic iSCI. We hypothesize that repetitive exposures (5 times/week for 2 weeks) to modest bouts of low oxygen will enhance and prolong walking recovery in persons with chronic iSCI.
Utilizing a double-blind, counterbalanced, crossover study, four persons with iSCI (AIS D) received AIH (FIO_2 = 0.09) or normoxia (FIO_2 = 0.21) consisting of 15 episodes of 1.5 min AIH/normoxia alternated with 1 min normoxia, followed by 30 min overground walking practice. We assessed walking speed and endurance using the 10-meter and 6-minute walk tests

at baseline, treatment days 5 and 10, and at four follow-ups (out to 3.5 weeks post-treatment). Measurements of spasticity, incidences of autonomic dysreflexia and systemic hypertension were also assessed to confirm that repeat exposures to mild bouts of AIH elicits benefits without meaningful maladaptive plasticity in persons with iSCI.
AIH + walking increased overground walking speed (0.18 ± 0.02 m/s) and distance (78.1 ± 30.1 m) more than normoxia + walking (speed: -0.01 ± 0.03 m/s, endurance: -16.9 ± 27.4 m). After AIH + walking, 4 of 4 subjects exceeded the minimal clinically important difference (MCID) for walking speed (≥0.13 m/s) and 3 of 4 subjects exceeded the MCID for walking endurance (≥50 m) relative to baseline, which persisted up to 3.5 weeks in 3 subjects. AIH was well-tolerated with no increase in spasticity, no episodes of autonomic dysreflexia, and low systemic hypertension incidence rate.
Consistent with our hypotheses, AIH appears to be a safe and effective treatment strategy to enhance walking recovery in persons with chronic iSCI. When coupled with walking practice, AIH elicits prolonged improvements in overground walking speed and endurance, making AIH an attractive combinatorial adjuvant to iSCI rehabilitation. Harnessing AIH-induced plasticity to promote functional recovery may lead to safer and more efficient community walking in persons with iSCI.

Title: Robot assisted rehabilitation paired with subthreshold optogenetic stimulation of motor cortex below bregma enriches cortical representation of trunk muscles in complete spinal transected adult rats

Authors: *K. A. SCHMIDT, S. F. GISZTER;
Drexel Univ., Philadelphia, PA

Abstract: Due to altered sensory afferents and motor efferents, a complete T9/T10 spinal cord injury (SCI) in rats leads to reorganization of sensori-motor cortex. Neonatally transected (NTX) rats can be trained to take weight supported steps on a treadmill with the assistance of a body weight supporting robot. Robot/treadmill trained NTX rats undergo an additional cortical reorganization compared to untrained NTX rats such that the center of gravity (COG) of trunk motor areas shifts caudally, and a greater representation of trunk muscle segments below the sight of injury appear. Because this cortical reorganization is coupled with an improvement in locomotor activity in NTX rats, we asked if promoting plasticity in the trunk motor cortex below bregma using subthreshold optogenetic stimulation would affect cortical reorganization and functional changes in adult transected (ATX) rats.
Using viral delivery, we introduced Channelrhodopsin (ChR2) or a control fluorophore (EYFP) targeted to pyramidal cells of the sensorimotor cortex below bregma. With robotic assistance, some ATX rats were trained to walk on a treadmill as described above while receiving continuous 470nm light stimulation. Three groups of robot trained rats were prepared: ATX with ChR2 (ATX-ChR2, current N=6), ATX-ChR2 rats also with AAV5-BDNF injected into the lumbar spinal cord to induce hindlimb alternation (ATX-ChR2/BDNF, current N=4), and a control group (ATX-EYFP, current N=6). A cage rest group (ATX-ChR2-CR, current N=5) received constant light stimulation 20mins/day for five weeks. After five weeks, rats underwent a terminal intracortical microstimulation (ICMS) map.
A significant caudal shift in trunk representation COG was observed in robot trained ChR2 rats but not in CR rats ($p<0.05$ Wilcoxon rank-sum test). Both ChR2 robot trained groups showed significantly more information by entropy calculations in regions of cortex below bregma compared to controls ($p<0.05$ ANOVA with LSD post hoc comparison). A significant increase in lumbar trunk representation was observed in ChR2-BDNF treated rats compared to EYFP rats ($p<0.05$ Wilcoxon rank-sum test). The ChR2-BDNF group also showed more information by entropy calculations from muscles located below the site of injury, and had higher cumulative pairwise mutual information than other groups. These results show that, when paired with robot assisted rehabilitation training, optogenetic subthreshold excitation can enrich cortical trunk representation below bregma and may lead to improved functional outcome in ATX rats.

Title: Safety and feasibility of a pragmatic approach for augmenting fine motor training with transcranial direct current stimulation in persons with tetraplegia

Authors: *J. A. IDDINGS, S. M. CALLAHAN, E. C. FIELD-FOTE;
Crawford Res. Inst., Shepherd Ctr., Atlanta, GA

Abstract: Objectives: Restoration of upper extremity (UE) motor function is often cited as the primary rehabilitation priority among individuals with tetraplegia. Direct modulation of cortical excitability with a single session of transcranial direct current stimulation (tDCS) has been shown to improve UE function in persons with tetraplegia. However, the functional effects of a multi-session course of tDCS have not been evaluated in persons with tetraplegia using a pragmatic approach designed to closely mirror traditional UE rehabilitation. The goal of this pilot study was to determine whether tDCS was a safe and feasible adjunct to standard fine motor training (FMT) sessions in the clinical setting.
Methods: Two participants with subacute (≤ 3 months post-injury) and two participants with chronic (≥ 6 months post-injury) cervical spinal cord injury were recruited for this pilot study. Following a one week control wash-in consisting of two 1 hour sessions of FMT alone, tDCS was applied as an adjunct to inpatient/outpatient FMT for three weeks. FMT was specifically tailored to reflect the individual recovery goals of each participant. UE strength (manual muscle testing, dynamometry), sensation (Semmes-Weinstein Monofilament Test) and function (Graded Redefined Assessment of Strength, Sensibility and Prehension - GRASSP) were measured prior to the intervention (baseline), following the control wash-in (FMT) and after the three weeks of combined cortical stimulation and training (tDCS + FMT). One subacute participant also participated in a follow-up evaluation three weeks after the conclusion of tDCS + FMT.
Results: Cortical stimulation was well-tolerated by all participants with only one subject reporting a mild headache the evening after the first tDCS session. Function of the UE stimulated by tDCS improved during the study for all participants (1-4 point improvement in GRASSP quantitative total score). However, based on this small sample of subjects it is not possible to determine whether these improvements were related to cortical stimulation, as similar rates of functional and sensory gains were observed during both the control wash-in and combined cortical stimulation and training. Interestingly, the individual who participated in follow-up displayed greater functional improvements in the stimulated UE than the unstimulated UE at final evaluation.
Conclusions: This pilot study demonstrates that tDCS is a safe adjunct to FMT that is feasible for application in the clinical setting. Future studies should directly compare the multi-session effects of FMT alone vs. tDCS + FMT to determine the effectiveness of augmenting FMT with tDCS in the clinical setting.

Title: Comparative effects of non-pharmacological interventions for lower extremity spasticity in persons with spinal cord injury - a pilot study

Authors: *S. ESTES, J. IDDINGS, A. HOLZWARTH, E. SANDLER, E. FIELD-FOTE; Spinal Cord Injury, Shepherd Center/Crawford Res. Inst., Atlanta, GA

Abstract: Purpose: Individuals with a spinal cord injury (SCI) often experience involuntary, reflex evoked muscle activity and stiffness associated with spasticity. While pharmacological treatments are the most often used approach to alleviate this spasticity, these treatments often have deleterious side effects. Physical therapeutic interventions offer an alternative treatment for the reduction of spasticity. However, while many different interventions have been studied, a systematic comparison of these approaches has not previously been completed. The purpose of this study was to compare four non-pharmacological interventions to assess their efficacy for spasticity reduction. Methods: Participants were individuals (n=10) with chronic SCI (≥ 1 year) who exhibited hyperreflexic responses to stretch of the quadriceps. The degree of quadriceps spasticity was objectively quantified using the pendulum test before and at two time points after (immediate and delayed: 45 min) each of 4 different physical therapeutic interventions: stretching, cyclic passive movement (treadmill-based robotic gait orthosis), transcutaneous spinal cord stimulation (tcSCS), and transcranial direct current stimulation (tDCS). A fifth intervention (peripheral stimulation, PS), consisting of a brief ramp up and down of stimulation at the knee and ankle, served as the sham control condition. A minimum 48 hour washout period was utilized between interventions. In addition to the pendulum test, electromyographic (EMG) recordings of the quadriceps, hamstrings, tibialis anterior, and soleus muscle activity were used to verify the presence of the stretch response and identify the onset of stretch-evoked muscle activation. Results: There was a significant reduction in quadriceps spasticity, as indicated by an increase in pendulum angle, for all interventions when compared to the sham control. Moreover, the decrease in spasticity from each intervention persisted for at least 45 minutes. While there was no single intervention that was significantly more effective at reducing spasticity, tcSCS showed a trend towards having a greater persistence in the reduction of spasticity than other interventions. Discussion and Conclusions: These preliminary findings indicate that single sessions of each physical therapeutic intervention can function as feasible short-term treatments for spasticity. While these findings suggest that physical therapeutic interventions may

supplement or replace standard antispastic medications, future studies should directly compare the antispastic effects of these physical therapeutic interventions to those of the antispastic medications.

Title: Leveraging activity and guidance to promote sprouting of direct connections between corticospinal tract axons and spinal motoneurons in PlexinA1 knockout mice.

Authors: *J. KALAMBOGIAS[1,2], Z. GU[3], Y. YOSHIDA[3], J. MARTIN[1,2];
[1]Biol., The Grad. Center, City Univ. of New York, New York, NY; [2]Physiology, Pharmacol. and Neurosci., Sophie Davis Biomed. Education, CUNY Sch. of Med., The City College of New York, NY; [3]Div. of Developmental Biol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: The corticospinal tract (CST) is critical for skilled and voluntary movements. Damage to the CST after stroke or SCI results in motor impairments. Most injuries are incomplete and promoting spared CST connections after injury is an important strategy for CST repair. In rodents, CST connections are made primarily with contralateral spinal interneurons. In many monkey species and humans, the CST makes mostly contralateral and some ipsilateral projections to spinal cord interneurons and, importantly, motoneurons. Thus rodent models fail to capture some of the key features of the CST in humans. Mice with conditional forebrain deletion of the gene for Plexin A1 (PlexA1KO), have an abundance of direct connections between the CST and motoneurons, as well as ipsilateral descending projections in white matter territories similar to primates and humans (Gu et al, submitted; Kalambogias et al; SFN abstracts 2015), making this mouse potentially an important model to study CST repair. The effect of gene deletion on CST connections is attributable to eliminating axon repulsion and maintenance of exuberant projections during development due to loss of CST PlexinA1-Semaphorin6D signaling. Here we used this novel mouse model with a CST that shares key features of the human CST to determine if M1 electrical stimulation, which we have shown in rats promotes CST sprouting, can be used to establish more corticomotoneuronal (CM) connections and

stronger M1 to muscle throughput. We assayed for CM connections using M1 stimulus-triggered averaging and confocal microscopy. To promote activity-dependent sprouting, we chronically stimulated M1 unilaterally for 10 days (6 hours/day; Brus-Ramer et al 2007). In adult uninjured PlexA1 KO mice, anterograde tracing revealed increased CST axon length and varicosities within cervical motor pools in stimulated compared to non-stimulated mice. Stimulation also increased projections to the intermediate zone and, generally, to the ipsilateral side. Morphological analyses are in progress to determine if there were similar changes in putative CST synapses on motoneurons and interneurons. The anatomical changes were paralleled by a substantially increased capacity for M1 to activate forelimb muscles. Our findings show that activity-dependent sprouting takes advantage of the reduced repulsive effects of PlexinA1-Sema6D signaling to increase CM connections, as well as interneuron connections and ipsilateral CST projections. That CST neuron activation can lead to the formation of new CM connections in this model further suggests that PlexinA1-Sema6D signaling is important in the maturity in specifying CST connections.

Title: Effects of different rehabilitative locomotor trainings on the innervation of lumbar motoneurons in adult rats with complete spinal cord transection.

Authors: *H. BRAS[1], M.-C. MORIN, Jr[2], O. ALLUIN[4], M.-P. COTÉ[5], S. ROSSIGNOL[6], F. BROCARD[3];
[1]CNRS, Marseille Cedex 05, France; [2]INT, [3]CNRS, AMU, Marseille, France; [4]CNRS UMR 7287, AMU, Marseille, France; [5]Drexel university, Philadelphia, PA; [6]Faculté de medecine, Montreal, QC, Canada

Abstract: More than 250,000 traumatic spinal cord injuries are reported every year worldwide, causing paralysis of the lower limbs in 53 % of the cases. Locomotor training has been shown to be efficacious in the progression of neurologic rehabilitation. It is founded on the principle of activity dependent plasticity but the understanding of its mechanisms remains poorly investigated. In Wistar female adult rats with complete spinal cord transection (SCT), we

compared the effect of 3 different types of locomotor training on the innervation of lumbar motoneurons (MNs). The training procedures, which started one week after SCT and lasted 10 weeks, were as follows: 1) Passive training of bicycling exercise (BE rats, Coté et al., 2014); 2) Imposed treadmill training with perineal stimulation (PS rats, Alluin et al. 2015); 3) Combination of spontaneous moving in enriched environment, treadmill training and physiotherapy, completed after 8 weeks by 5-HT_2 agonists treatment (UOS rats, Bras et al., 2013). By means of immunocytochemistry we analyzed: 1) Occurence of cholinergic (VACHT) and glutamatergic (VGLUT1) excitatory inputs. 2) Occurrence of inhibitory GABA and Glycine inputs (VGAT). 3) Density of P-boutons (GAD65, pre-synaptic inhibition) on primary sensory afferents (VGLUT1). More than 450 MNs with similar diameters were selected in L3-L4 lumbar segments. In intact rats, VGLUT1 and VACHT axon terminals were large boutons (5 μm2), sparsely distributed on the MN membrane (3 and 5 per 100 μm). VGLUT1 received a mean number of 1.6 p-boutons. VGAT terminals were smaller boutons (2.4 μm2), 7 times more numerous than VGLUT1. In BE rats, a significantly increase of the size of VGLUT1 terminals suggested an increased excitability of MNs in absence of changes in the density and size of VACHT and VGAT terminals as well as p-boutons. In PS rats the density of VGLUT1 and the size of VACHT boutons significantly decreased whereas the size of VGAT terminals and p-boutons were significantly reduced, suggesting a decrease of both excitatory and inhibitory innervations. In UOS rats, a significant increase of the size of cholinergic excitatory inputs as well as VGAT inhibitory inputs, together with an increased density of the p-boutons, suggested a reinforcement of both excitation and inhibition. In sum, different training procedures of SCT rats result in specific changes of the innervation of lumbar MNs. This results show that sub-lesional lumbar premotor interneurons are able of adaptive plastic changes of their innervation to adjust the balance between excitation and inhibition and adapt to alterations of the integrative properties of MNs occurring after SCI.

Title: Gait kinematic analysis in people with incomplete spinal cord injury after arm and leg cycling training

Authors: *R. ZHOU[1], L. ALVARADO[1], O. SHAW[3], R. OGILVIE[1], S. CHONG[1], V. MUSHAHWAR[1,2];
[1]Ctr. for Neurosci., [2]Div. of Physical Med. & Rehabil., Univ. of Alberta, Edmonton, AB, Canada; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: The goal of this project is to develop an intervention for improving walking after incomplete spinal cord injury (iSCI). Arm activity can significantly modulate the performance of the legs in various types of rhythmic locomotor activities including walking and cycling, which are generated by a common spinal network. Despite this knowledge, current rehabilitation interventions for improving walking do not actively involve the arms.
Therefore, we proposed the combined use of arm and leg cycling in a 12-week training paradigm for people with iSCI to improve ambulation. Thirteen volunteers with chronic iSCI were divided in 2 groups: arm & leg cycling (A&L) group and leg only cycling (Leg) group as control. We investigated: 1) the role of arms in the improvement of walking; and 2) the transfer of the effects of recumbent cycling to upright walking.
There was no significant difference between the two groups in walking speed or walking distance at the pre-training stage. Compared to pre-training, the 10-meter walking speed test showed significant improvements of 0.10 to 0.62 m/s in the A&L group, and 0.02 to 0.21 m/s in the Leg group. The A&L group improved significantly more in normalized speed change than the Leg group ($p=0.03$). Similarly, the 6-minute walking distance test showed post-training improvements of 29.83 to 292.84 m in the A&L group, and -7.04 to 61.09 m in the Leg group, although the difference in improvements between the two groups was not significant ($p=0.38$). Spatiotemporal kinematic parameters were measured (i.e. double support, step length, swing time and stance time) to evaluate the quality of over-ground walking. Participants were instructed to walk on a 6-m long track at self-selected speeds before and after training. After training, the A&L group showed significant improvements in most of the measures, whereas the Leg group only had significantly faster self-selected walking speed after training. Hip-knee cyclograms illustrated the angular excursions of the two joints within each gait cycle. Significantly higher cycle consistency of the hip-knee joint movement ($p=0.016$) and larger area within the cyclogram ($p=0.042$) were found. Furthermore, the stronger side in the A&L group had a significant increase in the consistency coefficient of 0.06 ± 0.02, but no significance in consistency was found in the Leg group.
This study suggests that non-gait-specific neurorehabilitation techniques could be translated into improved ambulation. More importantly, the findings provide strong support for active engagement of the arms in lower limb rehabilitation for more effective restoration of leg function.

Title: The effect of trans-spinal static magnetic field stimulation on the corticospinal excitability of upper limb muscles

Authors: *K. NAKAGAWA[1,2], K. NAKAZAWA[1];
[1]Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan; [2]JSPS Res. Fellow, Tokyo, Japan

Abstract: Neuromodulation techniques to spinal neural circuits can be applied to enhance rehabilitation for individuals with spinal cord injury patients (Herman et al. 2002; Harkeme et al. 2011). To date, some techniques such as transcutaneous spinal direct current stimulation (Lamy et al. 2012) or repetitive trans-spinal magnetic stimulation (Gerasimenko et al. 2010) have been utilized to non-invasively modulate spinal neural activity. Recently, transcranial static magnetic field stimulation (tSMS) has been demonstrated to modulate cortical function as one of the most non-invasive and painless neuromodulation tools (Oliviero et al. 2011; 2015). In the present study, we investigated the effect of tSMS applied over the spinal cord on the corticospinal excitability for testing a potential new technique to modulate spinal neural activity. To obtain static magnetic field, we utilized a cylindrical neodymium magnet (50 mm × 30 mm) with a magnetic intensity at the surface of the magnet of 0.46 T. We applied tSMS and sham stimulation with putting the magnet or non-magnetic steel cylinder over the cutaneous surface of the neck (C8 level) for 15 minutes to healthy subjects. Motor evoked potentials (MEPs) were recorded from muscles (target: first digital interosseous (FDI)) in right upper limb by single transcranial magnetic stimulation (TMS) of the left motor cortex. MEPs were recorded before, during and after tSMS and sham stimulation. All subjects participated in two experimental conditions (tSMS and sham stimulation) on separate days. The experiments were performed in a double-blinded design. Results showed 20~30% reduction of the MEPs on average during and after tSMS. Two-way repeated ANOVA showed a significant main effect of condition (tSMS and sham). It indicated that the corticospinal excitability in upper limb muscles was decreased by the tSMS compared to sham stimulation. This result suggests that tSMS is able to be a future neuromodulation tool for individuals with spinal cord injury.

Title: Characterization of stimulation-evoked muscle activity via intrapsinal microstimulation in a swine model

Authors: *J. S. CALVERT, P. J. GRAHN, A. A. MENDEZ, K. E. BENNET, I. A. LAVROV, K. H. LEE, J. L. LUJAN;
Mayo Clin., Rochester, MN

Abstract: Introduction: Chronically paralyzed spinal cord injured (SCI) patients have shown the ability to generate voluntary step-like movements via electrical spinal stimulation. Intraspinal microstimulation (ISMS) is a technique which has shown promise in restoring motor function by activating specific muscle groups while minimizing fatigue. We have developed a large animal swine model of spinal stimulation to take advantage of the anatomical similarities between human and swine spinal cords and to facilitate the development of spinal cord stimulation technologies. However, the intervertebral and intraspinal locations of motor pools that drive muscle activity responsible for limb function need to be elucidated before this model can be used to develop technologies for functional restoration. Therefore, we set out to characterize these motor-evoked responses using ISMS to create a functional atlas of spinal-evoked responses by recording muscle activity in the hind limbs of swine.
Methods: Swine (n=6 female) hind limb flexion, extension, abduction, and adduction movements were evoked using intraspinal stimulation (50 Hz, 2 s, 200 μA) at different depths, separated by 250 microns, and following a dorsoventral implantation trajectory. During stimulation, electrical activity from the biceps femoris, gastrocnemius, gluteus medius, gracilis, tibialis anterior, and soleus muscles was recorded using intramuscular electromyography (EMG). Spatial mapping of muscle activation was achieved by co-registering subject-specific post-mortem magnetic resonance imaging (MRI), computed tomography (CT) scans, and stereotactic electrode coordinates in a single coordinate system.
Results: As the electrode was advanced into ventrally-located motor regions of the spinal cord, the motor-evoked muscle responses varied, typically displaying an increasing response as the electrode approached the ventral limit of the trajectory. A functional atlas of the swine spinal cord was established via co-registration of the CT and MRI scans across stimulation parameters and across animals.

Conclusions: This functional atlas established will permit targeted stimulation of specific hind limb muscles via stereotactic delivery of intraspinal electrodes for targeted activation of hind limb muscles in chronic SCI models. This work will be used to evaluate responses in a chronic model of SCI, which can be used to optimize clinical stimulation techniques.

Title: Chronic theta burst electrical stimulation of rat motor cortex promotes CST outgrowth and M1-to-muscle connection strength

Authors: *A. AMER[1,2], G. SHAKAROV[3], Y. SOLIMAN[3], J. MARTIN[3,2,1];
[1]Ctr. of Discovery and Innovation of CCNY, New York, NY; [2]Biology/Neuroscience, The Grad. Ctr. at CUNY, New York, NY; [3]Physiol. Pharmacol. and Neurosci., Sophie Davis Sch. of Biomed. Education/CUNY Sch. of Med., New York, NY

Abstract: SCI interrupts connections between the brain and spinal cord. An important strategy for promoting motor function after SCI is to promote sprouting of the spared axons of descending motor pathways. We focused on the corticospinal tract (CST), which is essential for skilled voluntary movements. We showed that electrical stimulation of the motor cortex (M1) to activate CST neurons enhances CST outgrowth and promotes motor recovery. We recently showed that combined chronic M1 and trans-spinal direct current stimulation (tsDCS), 30 minutes/day for 10 days, results in robust CST outgrowth and motor recovery after pyramidal tract lesion (Song et al., 2016). In that study we used intermittent theta burst stimulation (iTBS), which has the same pulse pattern as the commonly-used magnetic neuromodulatory stimulation in humans for producing corticospinal system plasticity. Electrical iTBS in rats produced strong short-term enhancement of evoked muscle activation. Importantly, only 30 minutes of daily stimulation was effective in producing durable, functional plasticity. The goal of the present

study is to determine the differential contributions of iTBS M1 stimulation and and tsDC on CST outgrowth and M1-to-muscle connection strength in rats. Chronic stimulation, between day 10 and day 20 after unilateral pyramidal tract lesion (PTX), was delivered for 30 minutes daily. We examined 4 animal groups: injury only; injury+tsDC; injury+iTBS; injury+combined iTBS and tsDC. Cervical DC stimulation was cathodal and was applied using skin electrodes (trans-spinal). To date, we have analyzed the effects of iTBS only. The contributions of spinal DC is in progress. iTBS produced significant CST sprouting into the ipsilateral (denervated) intermediate zone and motor pool compared with the injury-only animal group. We assayed M1-to-muscle connection strength by constructing muscle response recruitment curves that show the increase in muscle evoked responses to progressively larger amplitude M1 stimulation. Compared with injury only, iTBS substantially enhanced the muscle response recruitment curve. This enhancement was paralleled with an expansion of the ipsilateral cortical motor map of the impaired/denervated wrist and elbow. Our findings show that a remarkably brief daily period of iTBS of M1 is capable of producing robust CST axonal outgrowth and stronger M1-to-muscle connections. This suggests that M1 neuromodulatory approaches commonly used in humans could produce structural plasticity in the spinal cord and further informs activity-based therapies for promoting function after injury.

Title: Delayed treatment of forelimb flexor muscles with an AAV encoding human Neurotrophin-3 normalizes muscle afferent connectivity, treats abnormal proprioceptive reflexes, reduces forelimb spasms, and improves walking after bilateral corticospinal tract injury in rats

Authors: *L. D. MOON[1], T. H. HUTSON[2], S. B. MCMAHON[1], C. KATHE[1];
[1]King's Col. London, London, United Kingdom; [2]Div. of Brain Sci., Imperial Col. London, London, United Kingdom

Abstract: CNS injury often causes spasticity and disability. We now show that bilateral transection of the corticospinal (CST) tracts in the pyramids causes flexor spasms in the forelimbs, hindlimbs and tail that are easily quantified from movies of freely moving rats in the open field. Fortnightly H-reflex testing confirmed that naïve rats show rate-dependent depression of a monosynaptic reflex of a flexor forelimb muscle whereas rats with bilateral pyramidotomy exhibit less rate-dependent depression (i.e., hyper-reflexia). Polysynaptic reflexes between antagonist muscles were increased after CST injury, which may cause co-contraction. Corticospinal tract injury slightly reduced grip strength and caused mild forepaw hypersensitivity (Von Frey). Walking was impaired on a horizontal ladder with irregularly spaced rungs.
Injection of AAV1 encoding human prepro neurotrophin-3 (NT3) unilaterally into forelimb flexor muscles reduced all these signs of spasticity (relative to AAV1-GFP). Intramuscular NT3 progressively reduced forelimb flexor spasms in the open field and normalized proprioceptive monosynaptic H-reflexes of a flexor forelimb muscle. This is consistent with expression of TrkC receptors in proprioceptive muscle afferents. NT3 also normalized polysynaptic reflexes to muscles supplied by the ulnar nerve but only those involving afferents from injected muscles (e.g., synergist flexor muscles and not antagonist extensor muscles). NT3 normalised the pattern of excitatory synapse-like boutons from primary afferents upon motor neurons. NT3 also normalized the pattern of vGAT+ boutons on vGluT1+ afferents, indicating that pre-synaptic inhibition may have been restored. NT3 also normalized the level of the KCC2 ion transporter in motor neuron membranes, which may indicate more-normal neuromuscular excitability. Finally, NT3 was transported in afferents from injected muscles to the DRG. RNAseq of cervical DRG identified mRNAs and miRNAs whose levels were dysregulated by CST injury but were normalized by NT3 treatment. Finally, NT3 treatment did not cause cutaneous hypersensitivity (pain). Thus, whereas existing therapies for spasticity are symptomatic, NT3 treats many underlying causes of spasticity as well as its symptoms.
These findings are exciting because (1) we administered NT3 in a clinically relevant time frame and by a straightforward route. (2) Recombinant NT3 is safe and well-tolerated in five Phase I and II clinical trials (unlike NGF). (3) The world's first gene therapy (Glybera) involves i.m. injection of an AAV1 encoding a different transgene, which paves the way for NT3 as a therapy for CNS injury.

Title: The effects of robotic gait training on seated balance and postural control for individuals with a complete spinal cord injury

Authors: *A. M. M. WILLIAMS[1,2], A. E. CHISHOLM[1,2], C. CHAN[3], T. LAM[1,2];

Abstract: Background: Postural control is the ability to maintain or restore a state of balance during any posture or activity. It involves the coordination of the trunk, lower and upper limbs, and head along with inputs from multiple sensory systems. Many people with a spinal cord injury (SCI) at or above the level of T6 experience impaired postural control while seated due to a loss of innervation of the trunk muscles. Improving seated postural control is particularly important in SCI wheelchair users because it increases independence with activities of daily living, facilitates functional mobility, and enhances quality of life. Robotic exoskeletons facilitate gait training for those with neurological impairments, but it remains unknown how they engage postural muscles to control balance during walking. If training with robotics challenges dynamic postural control, secondary benefits of training may include the transfer of improved postural control to seated balance activities. The purpose of this study is to examine changes in seated balance control in people with motor-complete SCI after gait training with robotic exoskeletons.
Methods: Individuals with motor-complete SCI at or above the level of T6 (n= 4) were randomly assigned to complete 3 training phases with robotic exoskeleton gait devices, either Ekso-Lokomat-Ekso or Lokomat-Ekso-Lokomat. Each phase involves 10 sessions completed over 3 weeks with up to 45 minutes of walking per session. During these sessions, we focus on increasing comfortable walking speed. We evaluate seated balance control before and after each training phase. The center of pressure (COP) variability during eyes open (EO) and eyes closed (EC) conditions, and total distance during a limit of stability (LOS) test is calculated from a forceplate.
Results: Subject 1 reduced COP sway after phase 1 Ekso-training (EO= 3.17 to 1.66mm, EC= 4.23 to 3.48 mm). COP sway increased to 2.48mm during EO and remained at 3.47mm for EC after phase 2 Lokomat-training. LOS total distance was 323 mm at baseline, 385mm after phase 1, and 319mm after phase 2. Subject 2 is currently in phase 2. After Ekso-training in phase 1, Subject 2 reduced COP sway (EO= 4.36 to 3.09mm, EC= 6.96 to 4.23mm) and improved LOS

total distance from 194.6mm at baseline to 217.6mm after phase 1. Subject 3 and 4 are currently in phase 1.
Conclusions: Our preliminary findings show that gait training with robotics may improve seated balance control following SCI. This work will be important to understand how balance control mechanisms are challenged during gait training with robotics.

Title: The effects of acute intermittent hypoxia on diaphragm activation and respiratory function in an individual with spinal cord injury

Authors: *E. J. FOX[1,3], A. D'ALESSANDRO[3], T. SUTOR[1], A. KERWIN[4], H. WEISS[3], G. JACOBS[3], K. MAHER[3], M. HOEFNAGEL[3], G. S. MITCHELL[2], D. D. FULLER[2];
[2]Physical Therapy, [1]Univ. of Florida, Gainesville, FL; [3]Brooks Rehabil., Jacksonville, FL; [4]UF Hlth. Shands Jacksonville, Jacksonville, FL

Abstract: Background: Individuals with cervical spinal cord injuries (SCIs) often have severe respiratory impairments and require ventilatory support. Rhythmic diaphragm activation via intramuscularly placed wires (i.e. “pacing”) is a relatively new approach for sustaining ventilation after acute SCI, and the intramuscular wires also enable recording of diaphragm electrical activity. Acute, intermittent exposure to moderate (and safe) levels of hypoxia (IH) is a therapeutic approach that can trigger spinal neuroplasticity and increases in respiratory and somatic motor output in both animals and humans with SCI. However, the direct impact of acute IH on diaphragm activation has never been examined in a person with SCI. In addition, the potential for IH to modulate respiratory function has not been explored in individuals with severe respiratory impairment after SCI. Accordingly, the purpose of this case report is to describe the effects of IH on respiratory function and diaphragm activation in an adult with SCI and dependence on diaphragm pacing. Methods: A 46 year-old male with complete C5 SCI (AIS A)

completed eight, 1-minute bouts of IH. Each bout consisted of breathing a mildly hypoxic gas mixture (10-15% oxygen) through a face mask, interspersed with 1-minute periods of room air breathing. Blood oxygen saturation was monitored. Maximal expiratory and inspiratory pressures as well as diaphragm electromyograms were recorded prior to and 45-minutes after completion of IH. Diaphragm muscle activation was quantified based on the peak amplitudes of activation recorded during a maximal inspiratory effort. Results: During the bouts of IH, blood oxygen saturation decreased from 96 to 86% for brief intervals and then rebounded. This response is consistent with prior reports of IH in adults with SCIs. Following eight bouts of IH, maximal expiratory pressure increased 45% from 11.5 to 16.7 cmH20, while maximal inspiratory pressure increased 18% from 22.3 to 26.3 cmH20. Peak amplitude of diaphragm electromyograms recorded from intramuscular wires increased 6%. Conclusions and Discussion: The outcomes demonstrate that acute IH is feasible and potentially beneficial in individuals with severe SCIs and dependence on diaphragm pacing. The increased respiratory pressures and diaphragm activation following IH are consistent with facilitation of respiratory synaptic pathways, as demonstrated in numerous animal studies. To our knowledge this is the first time IH has been applied to an individual with a diaphragm pacer and severe respiratory impairment. The outcomes suggest great therapeutic potential of IH to trigger plasticity and motor recovery in severe cases of SCI.

Title: Deep brain stimulation of the mesencephalic locomotor region in incomplete spinal cord injury in rats

Authors: *A.-S. HOFER[1], M. P. SCHNEIDER[1], A. K. ENGMANN[1], A. C. MOSBERGER[1], L. C. BACHMANN[2], N. RUSSI[1], S. IMOBERSTEG[1], H. KASPER[1], M. E. SCHWAB[1]; [1]Brain Res. Inst., Univ. and ETH Zurich, Zurich, Switzerland; [2]The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Incomplete spinal cord injury, characterized by sparing of some fibers and parts of tracts still connecting the brain with the spinal cord caudal to the lesion, affects millions of people worldwide. Loss of motor control and locomotion is common, also in patients who retain some degree of leg muscle innervation. A small group of neurons in the pedunculopontine and cuneiform nuclei of the midbrain tegmentum, the mesencephalic locomotor region (MLR), are well known to initiate and control locomotion in the spinal cord predominantly indirectly via ipsi- and contralateral reticulospinal tracts. Electrical deep brain stimulation (DBS) of the MLR using the brain´s intrinsic motor command circuits was shown to be a novel treatment strategy to induce recovery of locomotor functions in rats with subtotal spinal cord lesions. In order to investigate the long-term effects of DBS of the MLR on hindlimb motor function and cortical control, we stereotactically implanted DBS electrodes unilaterally into the MLR of rats, which afterwards received extensive thoracic spinal cord injuries. Detailed functional analyses of joint movements and limb kinematics during overground locomotion with (DBS-ON) and without stimulation (DBS-OFF) were performed. MLR-DBS acutely enables close to normal locomotion in rats with functional deficits resembling those observed in patients able to stand, but with very limited walking abilities. MLR-DBS enhances particularly speed and frequency of hindlimb movements during walking as well as under gravity-released conditions during wading and swimming. Importantly, rats avoid clashing into walls or obstacles, suggesting that cortical control is preserved at low and medium intensities during acute stimulation. The long-term functional and anatomical effects of DBS of the MLR are currently under investigation. MLR-DBS may represent a novel strategy not only to acutely awake locomotor activity, but also to train severely locomotor impaired patients to permanently reach a higher level of functionality.

Title: Exercise modulates sensory processing through chloride homeostasis after SCI.

Authors: *G. CARON, S. CHOYKE, B. DUFFY, J. WILSON, M.-P. COTE;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Spinal Cord Injury (SCI) undeniably decreases the amount of activity performed by an individual. Activity-based therapies are part of comprehensive rehabilitation strategies, but the mechanisms underlying the observed functional improvement after SCI remains poorly understood. Normal $GABA_A$ receptor function is critically dependent on chloride homeostasis, which is largely determined by the relative expression of two chloride transporters, the outward-rectifying KCC2 and the inwardly-directed NKCC1. SCI decreases KCC2/NKCC1 ratio in dorsal horn neurons and lumbar motoneurons with a consequent increase in intracellular Cl^-. This disruption in chloride homeostasis after SCI leads to neuropathic pain and hyperreflexia/spasticity. We have showed that chloride homeostasis can be restored by physical activity with consequent improvement in reflex modulation and also decrease hyperreflexia. The regulation of chloride homeostasis is not only involved in the regulation of motor output, but is also involved in sensory processing. A notable exception to chloride transporters expression takes place in primary afferents neurons. Because KCC2 is not expressed in primary afferents neurons located in DRGs, chloride levels remain high and $GABA_A$ receptors activation induce a primary afferents depolarization (PAD). Here, we explore the role of NKCC1 expression level on the level of presynaptic inhibition after SCI and the beneficial effects of physical activity on its recovery. NKCC1 expression will be quantified using PCR and Western blot analysis of L3-L5 DRGs and will be correlated to the level of presynaptic inhibition measured as dorsal root potentials in step-trained rats and untrained rats. Our results suggest that SCI decreases NKCC1 expression in DRG neurons associated with a decrease in presynaptic inhibition. Step-training returned NKCC1 levels and improved presynaptic inhibition without increasing neuropathic pain. Differential results obtained from proprioceptive and nociceptive afferents will be presented.

Abstract: Neural interfaces enable reading from and writing into the peripheral nervous system (PNS). Their stimulation capabilities have opened opportunities to restore lost sensation and alleviate motor deficits. However, incomplete characterisation of the long-term usability and bio-integration of intra-neural electrodes has restricted their clinical applications. Here, we conducted a longitudinal assessment of the stability, functionality, and biocompatibility of polyimide-based intra-neural electrodes that were inserted in the rat sciatic nerve of healthy or spinal cord injured rats for up to six months. Regular neurophysiological assessments demonstrated the ability to recruit extensor and flexor muscles of the ankle selectively throughout the experiments with electrical stimulation properties stabilizing three to four weeks after the implantation. The time course of these adaptations coincided with the progressive development of a fibrotic capsule around the electrodes. Despite this foreign body reaction, the selectivity remained stable over the following months. These functional properties supported the development of control algorithms that modulated the forces produced by ankle extensor and flexor muscles with high precision. We exploited this selectivity in a rat model of severe spinal cord injury to develop hybrid neuromodulation strategies combining peripheral and epidural electrical stimulations applied over lumbar segments. Continuous epidural electrical stimulation (EES) is known to enable locomotion of paralyzed rats. The additional, closed-loop control of peripheral nerve stimulation allowed the selective and graded tuning of key gait features, which enabled the rats to walk overground and climb staircase despite the interruption of brain input. This complementary EES-PNS neuromodulation therapy opens up novel opportunities to enable and restore motor control after neurological disorders.

Title: Exposure to acute intermittent hypoxia enhances upper extremity function in individuals with spinal cord injury

Authors: *M. S. SANDHU, B. AFSHARIPOUR, G. RASOOL, W. Z. RYMER;
Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Most spinal cord injuries (SCIs) are incomplete, however spontaneous plasticity, mediated via the spared spinal pathways is insufficient to restore normal function. One approach to augment plasticity in spinal networks is via intermittent brief exposure to mild hypoxia (also known as acute intermittent hypoxia or AIH). AIH induces rapid neuroplasticity, and has been shown to enhance volitional lower limb function in persons with incomplete SCI. Whether AIH induced neuroplasticity is equally prevalent in spinal motor pathways regulating upper limb musculature is not known. Accordingly, in ongoing studies we are testing the hypothesis that AIH will augment upper limb neuromotor function in humans. In two sets of experiments, we quantified the effect of a single session of AIH (15, 90-second episodes of 10% oxygen) on arm and hand function. First, we measured isometric flexion force at the elbow during maximal voluntary contraction (MVC) in three subjects (2 able-bodied, and 1 incomplete cervical SCI). Muscle activity from the biceps brachii was also recorded using a 128 channel high density EMG grid. The root mean square (RMS) value for each channel was calculated to generate muscle activity maps. MVC was done before, immediately after, and 60-minutes post-AIH. Sham normoxia trials were done one week later in the same individuals. We found that isometric MVC at the elbow increased by 45±5% in the two able bodied individuals, and by 30% in the SCI subject, at 60 minutes post-AIH. This increase in strength correlated with increased activation of biceps brachii. Average RMS value increased from 198±11uV to 350±3uV, and from 351uV to 392uV following AIH, in the healthy subjects and SCI patient, respectively. Sham AIH resulted in no change. In the second set of pilot experiments, we are quantifying the time-course of outcome improvement and decay following a single session of AIH on grip and pinch strength. A baseline assessment was made before administration of AIH, immediately after AIH, and every 30 minutes for up to 5 hours in three individuals with SCI. We found that the mean grip strength increased by 26±4% at 60 minutes post AIH, and the effect of AIH persisted for up to 3 hours. In comparison, there was a 5±3% change after normoxia in the same individuals after sham AIH.

These preliminary observations demonstrate the potential of AIH to enhance motor strength and upper limb function in persons with chronic incomplete SCI.

Title: Functional map of intraspinal microstimulation in the lumbar spinal cord of non-human primates

Authors: ***A. TOOSSI**[1], D. G. EVERAERT[2], S. I. PERLMUTTER[4], V. K. MUSHAHWAR[3]; [1]Ctr. For Neuroscience, Univ. of Alberta, Edmonton, AB, Canada; [2]Div. of Physical Med. and Rehabil., [3]Div. of Physical Med. and Rehabil. and Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [4]Washington Natl. Primate Res. Ctr. and Dept. of Physiol. and Biophysics, Univ. of Washington, Seattle, WA

Abstract: **Introduction:** The overall goal of this study is to prepare intraspinal microstimulation (ISMS) for testing in humans. ISMS is an electrical stimulation method developed in our lab for restoring standing and walking after spinal cord injury. It involves the implantation of arrays of penetrating electrodes in the lumbosacral spinal cord and the passing of minute electrical currents to activate networks of motoneuronal pools that evoke coordinated leg movements. Results from animal studies suggested that ISMS may produce better functional outcomes than clinically available interventions, and justified its translation to humans. The functional organization of the motoneuronal networks targeted by ISMS is well studied in cats; however, it is not directly known for humans. Yet, this information is necessary in order to translate ISMS from cats to humans. Therefore, as an intermediate step, this study focused on mapping the ISMS targets in non-human primates.

Methods and Results: Experiments were conducted in three rhesus monkeys under pentobarbital anesthesia. A laminectomy was performed to expose the lumbosacral enlargement, and the ventral horns were mapped by stimulation through a microelectrode. The stimulation parameters were: 50 Hz frequency, 0.5s long pulse trains, 200μs pulse width and amplitudes ranging from 10μA to 100μA. The electrode was mounted in a micromanipulator and moved in steps of 0.5mm, 0.5mm and 2mm, in the mediolateral, dorsoventral and rostrocaudal directions, respectively. The animal's leg ipsilateral to the side of spinal cord stimulation was suspended to allow visualization of the evoked movements. At each location, leg movement and stimulation threshold were documented and at selected locations, kinematics, force and EMG signals were also recorded. In three animals, a total of 117, 218 and 112 locations were stimulated in a 35.3 ± 1.2 mm long region of the lumbosacral enlargement. Of those, 43.4 ± 5.1% resulted in movement production. The majority of these responses had stimulation thresholds ≤10μA. The functional organization of the motoneuronal pools obtained in these experiments was consistent between animals and similar to that of cats.
Conclusions: The overall functional organization of the ISMS targets is similar in the lumbar spinal cords of cats and rhesus monkeys. Therefore, we anticipate that the functional map in humans will be similar to that of the monkeys and cats. These findings will guide the target locations for the first exploratory testing of ISMS in humans.

Title: Postural control in individuals with complete paralysis using non-invasive spinal cord stimulation

Authors: *D. SAYENKO[1], R. EDGERTON[2], Y. GERASIMENKO[2,3];
[1]Dept. of Integrative Biol. and Physiol., [2]Integrative Biol. and Physioloy, Univ. of California Los Angeles, Los Angeles, CA; [3]Pavlov Inst. of Physiol., St. Petersburg, Russian Federation

Abstract: Previous findings demonstrated that epidural stimulation over the lumbosacral spinal cord can activate the spinal neural networks in individuals with severe spinal cord injury (SCI), and facilitate standing. Given that one of the results using epidural stimulation was recovery of standing, the overall objective of this study was to determine the effects of painless transcutaneous electrical spinal cord stimulation, or painless enabling motor control (pcEmc) combined with motor task-specific therapeutic activity during standing on the neurophysiological, clinical, and functional outcomes in individuals with a severe SCI. Thus far, we evaluated the acute and cumulated effects of pcEmc and standing in five participants with chronic motor and sensory complete SCI. Without spinal cord stimulation, full assistance during standing was required in all participants. In fact, they were able to maintain upright posture only because of the trainers' assistance at the knees and hips, and because of extensive bearing on their arms. The combination of stimulation features most critical for facilitating effective standing with pcEmc were: a) both distal and proximal leg muscles must be activated, with predominant activation of extensors; b) the stimulation intensity should be sufficient to evoke motor threshold responses in non-weight-bearing condition; c) frequencies between 10 to 20 Hz should be used. These features of pcEmc applied at multiple low thoracic and lumbosacral levels required the least amount of assistance to support the participants. Some periods of self-generated standing occurred within the first training session. Three participants regained the ability to stand in the presence of stimulation, without assistance applied to the knees or hips while there was only light contact with the finger tip on a handlebar. In summary, our results demonstrate the feasibility and effectiveness of transcutaneous electrical spinal cord stimulation as a means to regain dynamic standing ability even after complete paralysis. As with the invasive epidural stimulation approach, there can be an effective reawakening of relatively dormant spinal networks that can relearn how to stand. Such non-invasive intervention could be a viable clinical approach for functional recovery after paralysis of different severity among a broad SCI population.

Title: Plasticity of spinal rhythm generating interneurons after spinal cord injury

Authors: S. BIBU, N. HA, L. YAO, *K. J. DOUGHERTY;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Neural circuitry generating rhythm and pattern components of locomotion is located in the thoracolumbar spinal cord. Although this locomotor circuitry is not fully understood, most spinal cord injury (SCI) occurs above it so it may be harnessed for improving motor function after SCI. The SCI-induced loss of voluntary control is likely due to both a reduction in descending controls and spinal plasticity, involving alterations in network excitability and/or defects in neural processing. Locomotor rhythm generating interneurons (INs) are an obvious entry point for studying SCI and treatment. However, there is little information regarding the effects of SCI on these neurons or their connections, both afferent and efferent. Elucidating the alterations to these funtional circuits, following SCI, will enhance our understanding of the beneficial as well as the maladaptive plasticity that occurs in the spinal cord. The resultant insights will provide pathways for a more targeted and refined approach to treatment. The main objective of the present study is to identify targets for enhancing locomotor function, focusing on Shox2 rhythm generating INs. Complete thoracic spinal transections were performed on adult Shox2cre;Rosa26tdTomato mice. Whole cell patch clamp recordings targeted Shox2 INs in spinal slices from uninjured and chronic SCI adult mice. Shox2 INs displayed a wide reportoire of firing properties which can be linked to underlying voltage-gated currents. There were no major differences in excitability properties between control and SCI Shox2 INs. A fraction of Shox2 INs from both uninjured and SCI mice showed plateau properties, persistant inward currents, and displayed spontaneous bursting properties which were enhanced in the presence of serotonin. Additionally, a subset of Shox2 INs displayed monosynaptic excitatory postsynaptic potentials in response to low threshold afferent fiber stimulation. Current focus is on how the fidelity of afferent-evoked responses in Shox2 INs changes post-injury. In summary, the intrinsic properties of adult Shox2 INs are relatively resilient to SCI-induced plasticity, leaving them as robust targets for post-injury therapies.

Title: Endpoint variability during overground walking in persons with chronic incomplete spinal cord injury

Authors: *W. SOHN, A. Q. TAN, D. PETERS, Y. THIBAUDIER, R. TRUMBOWER; Rehabil. Med. and Physical Therapy, Emory Univ., Atlanta, GA

Abstract: Incomplete spinal cord injury (iSCI) disrupts spinal neural pathways that contribute to sensorimotor deficits in the lower limb. In persons with iSCI, the resulting impairments decrease functional walking ability as their foot trajectory is often irregular, jerky, and variable from step-to-step. Gait variability is a relevant marker of gait instability (e.g., fall risk) and cortical control given the inverse association between variability and stability during walking. Therefore, we propose that evaluating the variability in endpoint foot kinematics during overground walking may elucidate the relationship between endpoint variability and walking recovery in persons with chronic iSCI.

The purpose of this study was to evaluate the effect of cadence and auditory cues on endpoint variability in persons with chronic iSCI during overground walking as compared to age-matched able-bodied (AB) persons with and without assistive device (AD). We hypothesized that persons with iSCI will exhibit greater variability in step-to-step endpoint foot-trajectory, as well as, greater endpoint variability with decreasing cadence as compared to AB during overground walking. To test our hypotheses, chronic iSCI participants and their age-matched AB controls were asked to walk at self-selected (SS), cadence-matched self-selected (SSmet), and fast cadence (Fmet) using an audible metronome. AB participants also walked at iSCI-matched cadences with AD. We measured kinematics of overground walking using motion analyses. We quantified variability of endpoint foot-trajectory during overground walking by computing the mean spatial density of metatarsophalangeal (MTP) marker in the sagittal plane during swing phase of gait.

Consistent with our hypotheses, we observed that the spatial path of the MTP in persons with iSCI was more variable than matched AB subjects at all cadences (SS, SSmet, Fmet). We also found that endpoint variability decreased at faster cadences in iSCI participants. However, the use of a metronome reduced variability, suggesting that walking variability can be regulated by walking cadence and auditory cues in persons with iSCI. Furthermore, in AB participants we

observed that walking with AD resulted in greater endpoint variability compared to no AD. These preliminary results suggest that training persons with iSCI subjects to walk at faster cadences or with auditory cues may improve gait stability by reducing endpoint gait variability and subsequently lead to improved walking ability after iSCI.

Title: Topographic anatomy and skeletopy of white swine spine and spinal cord: establishing a targeting atlas for spinal cord neuromodulation in a large animal model.

Authors: *A. A. MENDEZ, J. CALVERT, R. ISLAM, P. J. GRAHN, K. E. BENNET, K. H. LEE, I. A. LAVROV;
Mayo Clin., Rochester, MN

Abstract: Background: Electrical stimulation of the spinal cord has emerged as a possible therapeutic to restore volitional motor control. However, the mechanisms by which stimulation restores function are not well-understood. To this end, we previously established a large animal swine model of spinal cord stimulation to allow development of stimulation technologies that can be rapidly translated to the clinic. However, there still remains lack of information on the variability of spine and spinal cord anatomy for this model. Additionally, to date, no correlation has been established for the relative locations of anatomical structures for successful implementation of this large animal model for spinal cord neuromodulation.
Methods: Adult white swine were used for this work. MRI and CT scans were performed on live, anesthetized animals. Image fusion was performed manually using anatomical landmarks within both CT and MR images. Next, anatomical measurements were performed as follows: (1) landmarks were established along the facet joints, transverse processes, anterior and posterior portions of the vertebral laminas, as well as dorsal spinal cord rootlets, (2) distances between these landmarks were measured, and (3) dimensions were arithmetically compared and averaged

across subjects. To reduce variability, three operators conducted anatomical measurements of vertebras, dorsal roots, rootlets and spinal cord diameter at each spinal level. Finally, histological sections in transverse plane of the spinal cord were carried out and were correlated to the appropriate spinal segment.
Results: Spine and spinal cord anatomy varied across animals. Ratios for vertebral bone size, segment length and distances within spine and spinal cord landmarks were established for appropriate navigation within the pig lumbar spine when compared to empirical navigation. Observed correlations between vertebra length, spinal segment length, and rootlets entry, allows location of spinal cord segments based on bone landmarks. Correlation between histological data and imaging scans with anatomical landmarks and dimensions provides a single high-resolution coordinate system across tested animals.
Conclusions: This work represents our first attempt to establish precise anatomy of swine spine and spinal cord that will allow target selection based on anatomical structures and will provide precise stereotactic delivery of electrodes for targeted electrical investigation of spinal structures.

Title: Layer-specific dynamics of sensorimotor cortex during motor learning

Authors: *P. GAO;
Physiol. and Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: Recent studies have shown that motor learning is accompanied by enhancement of synaptic strength and synaptogenesis in the sensorimotor cortex. Functional reorganization of local circuit activity in primary somatosensory (S1) and primary motor (M1) cortices is believed to support changes associated with motor learning. While characterization of functional changes at distinct cortical layers (e.g. layers II/III and V) is focus of extensive studies, an investigation that links these changes with synaptic molecular machinery has been elusive. In this study, I investigated the time-dependent relationship between the learning and consolidation of a motor task and the expression of protein kinase M zeta (PKMζ) and postsynaptic density protein 95

(PSD-95), two molecular factors key for synaptic plasticity and remodeling, in layers II/III and V of the sensorimotor cortex.
My results showed that PKMζ expression level increased significantly on layer II/III of S1 and layers II/III and layer V of M1 during late stages of a skilled reaching task and sustained to be higher with extended training. In contrast, PSD-95 showed an increased level of clustering size in M1 layer V during the early stages of learning that was not sustained with extended training. My studies suggest that the increase of PKMζ may participate in the long-term storage of well-learned motor skills, whereas the PSD-95 dependent structural modification of synapses may mainly contribute to the acquisition of new motor skills.

Title: Direct synaptic input to spinal neurons from corticospinal and putative Ia axons during development

Authors: *S. FUKUDA[1], H. MAEDA[1], T. OHNO[1], H. KAMEDA[1], N. MURABE[1], N. ISOO[1], H. MIZUKAMI[2], K. OZAWA[2,3], M. SAKURAI[1];

Abstract: Spinal motoneurons (MNs) received direct inputs from Ia fibers, however, not from corticospinal (CS) axons in adult rodents. In this study, we succeed in making transverse slice of spinal cord in good health from 2nd to 4th weeks rodents and found the monosynaptic connections from putative Ia afferent and CS axons to MN by the stimulation of the dorsal column. Using cervical cord slices prepared from rodent 2nd weeks after birth, a stimulating electrode was placed in the ventralmost part or in the middle part of the dorsal column where the CS tract (CST) or putative Ia afferents are located (Yoshida et al. 2006) respectively. Whole cell recordings were made from two groups of MNs retrogradely labelled with fluorescent cholera toxin B subunit injected into forelimb muscles or pectralis major muscle. When we recorded responses with fixed latencies and same time course in ACSF containing high concentrations of divalent cations (7 mM Ca2+, 3 mM Mg2+), we judged those responses to be monosynaptic EPSCs. To more selectively stimulate CS axons we employed optogenetic stimulation by

injecting an adeno-associated virus vector encoding channelrhodopsin-2 (ChR2) into the sensorimotor cortex on P0 animals. After recording we observed close contacts between CS axons and MNs with a confocal microscope. Monosynaptic EPSCs were recorded from forelimb MNs by stimulation of the CST or the middle part of the dorsal column. The latency of putative Ia afferents-evoked monosynaptic EPSCs was 2.7 ± 0.2 ms, which is in good agreement with previous reports. This latency was significantly shorter (about half) than the CST-evoked monosynaptic EPSCs (4.9 ± 0.2 ms). The amplitude of Ia-evoked EPSCs was larger than CST-evoked EPSCs. These Ia-induced EPSCs showed significantly clearer paired-pulse depression than CST-induced EPSCs. Thus the electrode placed in middle part of the dorsal column stimulated Ia afferent axons. Any monosynaptic EPSCs were not recorded from pectralis major MNs by stimulation of the CST, but EPSC frequencies increased by repetitive (10 ms interval, 10 times) stimulation in normal ACSF. Pectralis major MNs received direct input from Ia afferent fibers, however, received only polysynaptic inputs from CS axons. Optogenetic stimulation evoked monosynaptic EPSCs in forelimb MNs. We showed close contacts between these forelimb MNs and CS axons labelled with the ChR2 (9.4 ± 4.2 per MN). Almost half of these contacts (55.3%) colocalized with PSD-95 in their partner dendrites. It is intriguing that these results are analogous to the connection pattern seen in adult primates. We found the connection with putative Ia afferent and spinal neuron in rodent > 4th weeks after birth.

Title: The effects of aging on the axon initial segment and electrical properties of spinal motoneurones in the C57BL/6J mouse.

Authors: S. GOLTASH, M. H. JAKOBSEN, J. LEHNHOFF, K. P. DIMINTIYANOVA, L. GROENDAHL, *C. F. MEEHAN;
Univ. of Copenhagen, Kobenhavn N, Denmark

Abstract: Our previous investigations in a mouse model of Amyotrophic Lateral Sclerosis (ALS) found differences related to action potentials and axon initial segments (AIS) at symptom

onset (Jørgensen et al 2015 SFN abstract). How mouse motoneurones age normally however, is unknown. Therefore, we conducted a series of experiments in male C57BL/6J mice at 100, 300-400 and 600-750 days old. Rotorod scores significantly declined with age ($P<0.0001$, n= 41 mice), confirming a decline in motor function. Intracellular recording was then performed in 18 mice (6 at 100 days old, 6 at 300-400 days old and 6 at 600-750 days old). Somatic action potentials had significantly lower amplitudes in 600-750 day old mice compared to 100 day old mice ($P<0.0001$). Consistent with this, we observed a significantly reduced rate of rise of somatic action potentials in 600-750 day old mice ($P<0.005$). The rate of fall was also significantly slower in 600-750 day old mice compared to 100 day old mice ($P<0.005$). Consequently, the action potential width at 2/3 amplitude was significantly wider in 600-750 day old mice than both the 100 and 300-400 day old mice. The rate of rise of the IS component of action potentials was not significantly different at any age. Post-spike after-hyperpolarization (AHP) amplitudes were significantly larger at 300-400 days compared to 100 days ($P<0.05$) but not significantly so at 600-750 days. Compared to 100 day old mice, AHP durations were significantly shorter at 300-400 days old ($P<0.05$) but returned to the 100 day old levels at 600-750 days old. These changes appeared not to influence the current-frequency slopes which were not significantly different between groups. Immunohistochemistry was performed on 6 mice at 300-400 days old and 7 at 600-750 days to label AISs and motoneurones with antibodies against Ankyrin G and ChAT respectively. AISs were slightly shorter (approx. 4 %, $P<0.05$) and wider (12%, $P<0.0001$) in the aged mice. In four 600-750 day old mice the nodes of Ranvier of motor axons in the ventral roots were labeled with antibodies against KV1.2, Caspr and voltage-gated sodium channels. In these mice a clear breakdown of the juxtaparanode-paranodal boundary was evident compared with 4 younger mice. Conclusions: While the changes in AHPs mirror that which has been observed in humans with ALS and our recordings in mouse ALS models, the changes related to amplitude/rate of rise of action potentials, and structural changes at the AIS however are directly opposite to what we have observed in symptomatic ALS mice. Our results therefore suggest that changes related to sodium channels that we previously observed at disease onset in ALS mice do not represent a normal or accelerated aging.

Title: Acute intermittent hypoxia reduces rate-dependent depression of the H-reflex

Authors: *N. P. PHAGU[1], M. CATEGE[1], I. C. SOLOMON[2], W. F. COLLINS, III[1];
[1]Neurobio. and Behavior, [2]Physiol. and Biophysics, Stony Brook Univ., Stony Brook, NY

Abstract: Acute intermittent hypoxia (AIH) produces a robust increase in inspiratory motor output that continues after cessation of the hypoxia. Although referred to as respiratory long-term facilitation (LTF), this AIH-induced neural plasticity is not limited to respiratory motor outputs and may have widespread effects on somatic motor systems. The aim of the present study was to assess the effect of AIH on the monosynaptic H-reflex, an electrophysiological correlate of the myotactic stretch reflex, with particular focus on possible changes in H-reflex rate-dependent depression (RDD). Experiments were conducted on urethane-anesthetized (1.4 g/kg), spontaneously breathing adult female Sprague Dawley rats (250-300g). The left hind limb was secured with the ankle in a flexed position and platinum needle electrodes were inserted percutaneously along the medial aspect of the distal Achilles tendon (2-3 mm separation) for stimulation of the posterior branch of the tibial nerve. H-reflex EMG responses were recorded using fine stainless steel wires inserted into the dorsal metatarsal region (active electrode) and the tip of the fifth digit (reference electrode) of the ipsilateral hind paw. To elicit the H-reflex, the tibial nerve was stimulated throughout the experiment using trains of 15 stimuli (0.2 ms pulse duration; 2-3x H-reflex threshold; 10 Hz) delivered every 50 seconds (0.02 Hz). H-reflex RDD was estimated within each stimulus train by calculating the ratio of H-reflex amplitudes (15th response (10 Hz) / 1st response (0.02 Hz)). Diaphragm EMG activity was simultaneously acquired to assess AIH-induced respiratory LTF. Following at least 30 minutes of baseline recording, rats were exposed to a single bout AIH protocol consisting of three five-minute episodes of hypoxia (10% O_2; 90% N_2) separated by five-minute exposures to room air after which data acquisition continued for at least 90 minutes. Prior to AIH, rats exhibited H-reflex RDD of 30 - 70% (i.e., amplitude ratio 0.7 - 0.3, respectively). Following AIH, up to a 30% reduction in H-reflex RDD was detected, and this reduction persisted for up to 90 minutes. The reduced H-reflex RDD following AIH was due to less H-reflex amplitude depression at 10Hz, and no change in H-reflex amplitude at 0.02 Hz was observed. These results indicate that AIH exposure can enhance active monosynaptic spinal segmental reflexes and thereby contribute to AIH-induced motor plasticity.

Title: Neurosteroid alfaxalone fails to alteration excitatory synaptic transmission to rat hypoglossal motor neurons

Authors: *P. P. THAKRE, M. C. BELLINGHAM;
Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia

Abstract: Alfaxalone is widely used in veterinary anaesthesia; however, neuromotor excitation during anaesthesia limits its use in laboratory rodents. Prior work has shown that alfaxalone suppresses inhibitory synaptic transmission to hypoglossal motoneurons (HMNs) via activation of cannabinoid receptor-1 (CB_R-1) and transient receptor potential (TRP) channels. However, the effect of alfaxalone on excitatory synaptic transmission has not been established. We evaluated effects of alfaxalone on excitatory neurotransmission to HMNs and the presence of TRPM4 channels and CB_R-1 receptors by immunohistochemical localization. Whole-cell patch-clamp recordings were made from HMNs in 300μm-thick transverse brainstem slices from 7-14 days-old Wistar rats after sodium pentobarbitone anaesthesia. Spontaneous excitatory postsynaptic currents (EPSCs) were recorded as inward currents at holding potential of -60mV using CsCl-based internal solution and in the presence of strychnine-HCl (20μM). Alfaxalone was bath applied at 3μM concentration. Alfaxalone failed to significantly alter the spontaneous EPSC frequency, amplitude, half-width and rise-time. Immunohistochemical studies showed that both TRPM4 channel and CB_R-1 receptor proteins are widely expressed on HMNs, confirming the modulation of inhibitory transmission to HMNs. Our results suggest that alfaxalone produces hyperactivity of motor neurons by reducing inhibitory but not excitatory transmission. The failure of alfaxalone to modulate excitatory neurotransmission and the presence of TRPM4 and CB_R-1 proteins on HMNs indicate that alfaxalone-induced hyperactivity and hence, neuromotor excitation during anaesthesia, is primarily governed by its effect on inhibitory transmission, which can possibly be reduced by TRPM4 and CB_R-1 antagonists.

Title: The modulatory effects of caffeine on the intrinsic properties of spinal lateral motoneurons: evidence for its dependence on adenosine A1-dopamine D1 receptor heteromers

Authors: *M. S. RIVERA OLIVER[1], Y. ALVAREZ-BAGNAROL[2], C. AYALA-SANTIAGO[4], E. MORENO[5], G. SEALE[3], L. PEREZ-PORTOCARRERO[2], O. ACEVEDO-ARUS[2], V. CASADO[5], S. FERRE[6], M. DIAZ-RIOS[2];

Inst. of Hlth., Baltimore, MD

Abstract: Caffeine is a known non-selective adenosine receptor antagonist whose actions include multiple sites within the brain, mostly by binding to adenosine A1 and A2A receptors (A1R and A2AR). It produces similar behavioral effects as other classical psychostimulants including increased motor activation, arousal, and having reinforcing effects related to indirect dopaminergic mechanisms that depend on heteromerization of A1R and A2AR receptors with dopamine D1 and D2 receptors (D1R and D2R) in the striatum, respectively. We recently performed extracellular recordings of ventral nerves from the lumbar cord of mice in the presence of serotonin (5-HT), NMDA and dopamine (DA), which are known to elicit locomotor activity in mammals, and showed that caffeine stimulates motor activity by blocking A1R, by potentiating the ability of dopamine to activate D1R. Also, perforated patch clamp recordings in lumbar cord slices showed that the effects of caffeine are specifically targeted at modulating the intrinsic membrane properties of spinal lateral motoneurons (MNs). We then investigated if these properties of caffeine depended on the existence of A1R-D1R heteromers within spinal MNs. Thus, we proceeded to assess the presence of A1R-D1R complexes within spinal lateral MNs

using electrophysiological and histological techniques. Basal concentrations of DA or NMDA perfusion in the presence of synaptic blockers of inhibitory and excitatory neurotransmission depolarized the membrane potential of most MNs reversibly. The addition of caffeine, in the presence of DA or NMDA, significantly depolarized the membrane potential, decreased the action potential after-hyperpolarization (AHP) and increased the firing frequency by 90% of the recorded MNs. Also, we were able to support our theory that caffeine exerts its neuromodulatory effects on the spinal lateral MNs via A1R-D1R heteromers when the perfusion of an A1R agonist before a D1R agonist completely blocked the modulatory effects of the D1R agonist. Finally, potential A1R-D1R heteromer in MNs were localized anatomically through immunohistochemistry and with the use of a proximity ligation assay using antibodies directed toward the A1R and the D1R. Our experiments suggest that the primary target for the neuromodulatory effects of caffeine in the lumbar region of the spinal cord are the lateral MNs and that the excitatory effects produced by caffeine onto this neuronal population is dependent on A1R-D1R heteromers.

Title: Synaptic strength and plasticity differ within the axial motor neuron pool in larval zebrafish

Authors: *W.-C. WANG, P. BREHM;
OHSU, Vollum Inst., Portland, OR

Abstract: The ability to perform movements with variable intensities allows animals to interact properly with the surrounding environment. Movement intensities are governed by activation of different types of motor neurons and muscles. Although many studies have been done on the recruitment pattern of motor neurons and muscles when generating forces of different amplitudes and speeds, there is a lack of systematic examination of synaptic properties at the neuromuscular junction between different types of motor neurons and muscles. In larval zebrafish, axial motor neurons in the spinal cord are arranged with a dorsoventral gradient. Ventrally located, smaller and more excitable motor neurons are activated during slow swimming, while dorsally located, larger and less excitable motor neurons are only recruited at fast swimming or escape. Compared to recruitment patterns during swimming, less is known about how the activity pattern of these motor neurons is translated into muscle contraction. More specifically, is there also a systematic difference in synaptic strength and plasticity for outputs of different motor neurons?
We performed whole cell patch recordings on connected motor neuron and skeletal muscle cell pairs to examine end plate currents (EPCs) elicited by firing the motor neuron. We found that when firing the motor neuron at low frequencies, EPCs elicited by secondary motor neurons (SMNs) in either fast or slow muscles were less reliable, as well as smaller and more variable in amplitude compared with primary motor neuron (PMN) elicited EPCs in fast muscles. The larger SMN EPCs were sufficient to elicit an action potential in the fast muscle but smaller ones were subthreshold. In response to firing the SMN at high frequencies, a potentiation in EPC amplitude was seen during the high frequency firing and persisted for several seconds to a couple minutes after switching to low frequency firing. This short term plasticity was different from PMNs, where EPCs showed an initial depression in response to high frequency PMN firing. The differences in amplitude, variability, and plasticity of SMN and PMN outputs were further confirmed by using high-speed video recording to examine muscle contraction elicited by firing a single motor neuron. The kinetics of potentiation during high frequency motor neuron firing was modified by internal EGTA concentrations, suggesting a calcium dependent process. Our findings suggest a significant difference in motor output from motor neurons that were previously demonstrated to be involved in swimming at different intensities and reveal the importance of synaptic transmission properties at the neuromuscular junction in motor control.

Title: Non-reciprocal effects of KCNQ/Kv7 channel modulation on the excitability of spinal motoneurons in mouse neonates

Authors: *J. LOMBARDO, M. A. HARRINGTON;
Delaware State Univ., Dover, DE

Abstract: Motoneurons (MNs) are referred to as the 'final common pathway' because they represent the final arbitrers of the neuro-motor transformation. They perform this task by integrating the information from incoming inputs into trains of action potentials, thus their passive and active membrane properties, also referred to as intrinsic excitability, constitute a central component of this neuro-motor transformation. The voltage threshold of spinal MNs in particular appears to be preferentially targeted in regulating their output. Indeed, it is modulated acutely during fictive locomotion but also persistently after physical training, operant conditioning, weight bearing, and spinalization. Recently, the inhibition of KCNQ/Kv7 channels has been shown to modulate the voltage threshold of hippocampal and cortical neurons. These channels form a slow non-inactivating K^+ current, also known as the M-current, which activates in the sub-threshold range of membrane potentials and regulates different aspects of neuronal excitability. These channels may be important modulators of excitability in MNs as well. A mutation in the KCNQ2 channel subunit has initially been implicated in myokymia, a form of involuntary, repetitive muscle contraction, resulting from the hyper-activity of the motor units. Electrophysiological recordings have confirmed the presence of a slow, non-inactivating, K^+ current sensitive to both muscarinic receptor-mediated inhibition and KCNQ/Kv7 channel blockers in turtle MNs, and immunohistochemical studies have also confirmed the presence of KCNQ2 channel subunits in the somata, axonal initial segment and nodes of Ranvier of rat MNs. Finally, recordings from rat sciatic nerves demonstrated that KCNQ/Kv7 channels underlie the slow K^+ current at nodes of Ranvier and affect axonal conduction velocity. Although these initial findings highlighted the importance of KCNQ/Kv7 channels in spinal MNs, the function that these channels play in the neuro-motor transformation, and in the regulation of MN voltage threshold is unclear. To increase our understanding of the function of KCNQ/Kv7 channels in regulating the intrinsic excitability of spinal MNs, we have investigated the impact of modulators of KCNQ/Kv7 channels in spinal MNs whole-cell patch-clamp recordings obtained from acute neonatal mouse spinal cord slices. Using a combination of electrophysiological recordings and computational modelling, we demonstrate that KCNQ/Kv7 channel modulators contribute to the alteration of the axosomatic spinal MN excitability, even though the up- and down-modulation of their activity has non-reciprocal effects.

Title: The location of neurons innervating the triceps brachii muscle of the pigeon as revealed by the retrograde transporter of the cholera toxin B subunit

Authors: *J. PARK[1], J. CHO[1], T.-K. LEE[1], I. KIM[1], J. AHN[2], K. SEO[3], M.-H. WON[1]; [1]Kangwon Natl. Univ., Chuncheon, Korea, Republic of; [2]Hallym Univ., Chuncheon, Korea, Republic of; [3]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Many researchers have investigated the anatomical organization of the motor neurons which control behavioral output in mammals using various techniques. However, the anatomical distribution of motor neurons in the avian brain is still not fully elucidated. The purpose of this study was to finely determine the localization of the neurons innervating the triceps brachii muscle in the pigeon. The study was carried out in a total of 6 pigeons. The cholera toxin B subunit (CTB) was employed as a retrograde tracer to determine the location of the neurons of the triceps brachii muscle in the telencephalon of the pigeon following intramuscular injection. The animals were sacrificed at 14 days after intramuscular injection with CTB. We found that labelled neurons with CTB were located contralaterally in the nucleus basalis of the frontal telencephalon. This study shows that CTB is easily taken up by nerve terminals which are located in the triceps brachii muscle of the pigeon and motor neurons in the contralateral nucleus basalis may be closely associated with the movement of triceps brachii muscle.

Title: A novel mutation in the VCP gene identified by analysis of sporadic amyotrophic lateral scrlerosis in Japan

Authors: *H. SAKAMOTO[1], M. HIRANO[1,2], S. UENO[1], C. ISONO[1], M. NISHIDA[1], K. SAIGOH[2], Y. NAKAMURA[1], S. KUSUNOKI[2];
[1]Dept. Neurology, Kindai Univ. Sakai Hosp., Sakai, Osaka, Japan; [2]Neurol., Kindai Univ. Fac. of Med., Osakasayama, Osaka, Japan

Abstract: Background: Most cases of amyotrophic lateral sclerosis (ALS) are sporadic, but 5% to 10% are familial (FALS). Recent reports demonstrated that more than 10% of patients with sporadic ALS (SALS) have mutations in genes causative for FALS, suggesting a genetic-based pathomechanism in such cases. Mutations in the *VCP* gene encoding valosin-containing protein (VCP) cause inclusion body myopathy with Paget's disease of the bone and frontotemporal dementia (IBMPFD) and ALS. A recent study from China failed to identify any mutations in this gene in 324 patients with SALS. Methods: We sequenced the *VCP* gene in 90 Japanese patients with SALS. We constructed plasmid vectors expressing GFP-fused wild-type and mutant VCP, transiently transfected them separately in neuroblastoma SH-SY5Y cells, and treated the cells with an oxidative stress inducer, l-buthionine sulfoximine (BSO). BSO is an inhibitor of synthesis of the free-radical scavenger glutathione. Results: We found a novel *VCP* mutation, p.Arg487His in a patient (patient 1). He had progressive bulbar signs and weakness with severe amyotrophy of all four limbs from the age of 61 yr. Deep tendon reflexes were diminished, but extensor plantar reflexes were present. He required a percutaneous endoscopic gastrostomy (PEG) tube and artificial ventilation through a tracheostomy tube at the age of 66. Higher functions and personality were apparently normal until the age of 69. His personality was mildly changed with decreased attention after the age of 70. He had an elder brother (patient 2) with dementia, which was later found to be frontotemporal dementia with parkinsonism. Parkinsonism is occasionally found in patients with *VCP* mutations. Unfortunately, he had already died, and no DNA or further detailed clinical information was available. Fibroblasts from patient 1 was susceptible to BSO-induced oxidative stress. Transient expression of the newly identified mutant as well as of known mutants also rendered SH-SY5Y neuroblastoma cells vulnerable to oxidative stress.
Discussion and Conclusion: The presence of the mutation in the Japanese population extends the geographic region for involvement of the *VCP* gene in sporadic ALS to East Asia. In addition,

our findings suggest the involvement of oxidative stress in the pathomechanism of VCP-related ALS.

Title: Structural and functional correlates of variation in neuronal numbers in the locus coeruleus of zebrafish imaged with multiphoton and high-speed light sheet microscopy

Authors: M. J. FARRAR[1,2], *K. E. KOLKMAN[1], J. R. FETCHO[1];
[1]Cornell Univ., Ithaca, NY; [2]Messiah Col., Mechanicsburg, PA

Abstract: Norepinephrine (NE), a neuromodulator found throughout the CNS, acts by altering target neuron excitability and synaptic plasticity. Activity in the locus coeruleus (LC), a major source of NE in the brain, is associated with alertness, attention, and memory processing. Zebrafish are an ideal model organism in which to study the role of the LC in physiology and pathology due to the ease of creating transgenic models, transparency in the larval stage, and small size of the LC nucleus. Using a *Tg:ET-VMAT GFP* line confirmed by antibody staining, we examined zebrafish larvae at 5 days post fertilization using 2PEF microscopy. In agreement with previous studies, LC neuron cell counts ranged between 10 and 20 bilaterally, with a mean of 15. This variation–as much as 100%– is not unique to zebrafish.
To study the correlation between LC number and neurite projections, we performed single-cell electroporations in the *Tg:ET-VMAT GFP* line. Using 3-D Sholl analysis, we found no systematic differences in projection density proximal to the soma of individual neurons between fish with few and many LC neurons.
To explore whether neurite density in target areas distal to the soma is correlated with LC neuron count, we used CRISPR/Cas9-mediated knock-in to create a transgenic line (*NET:mCFP*) with a membrane-targeted CFP under the endogenous NE transporter (NET) promoter, allowing us to reveal all NE projections with high fidelity. We examined the optic tectum and the spinal cord since NE projections in these areas are predominantly from the LC. We found a positive correlation (n = 5 fish) between LC number and neurite density.

We investigated the activity of LC neurons by creating a transgenic line expressing nuclear localized GCamp6f (*NET: H2B-GCamp6f*). To achieve high-speed bilateral imaging of neuronal activity, we custom-built a high-speed light sheet microscope (based on Ahrens et al., 2013) that allowed for whole brain imaging at several brains a second. We imaged spontaneous activity in the LC neurons in intact larvae as well as ones with hindbrain spinal-projecting neurons backfilled with Calcium Green dextran to allow correlation of LC activity with activity of identified descending neuronal populations. Correlated activity was observed between LC neurons and cells associated with swimming behavior including putative MiV2 and 3 neurons as well as neurons in the nucleus of the MLF. The average activity of individual neurons in the LC was negatively correlated with LC neuron count (n = 9 fish). These findings suggest that fish with fewer LC neurons may maintain physiological NE levels at lower projection density by a compensatory increase in the activity of individual cells.

Title: Emergent properties in the cortex-wide dynamics during motor learning

Authors: ***H. MAKINO**, C. REN, A. KIM, N. KONDAPANENI, T. KOMIYAMA; UCSD, La Jolla, CA

Abstract: Learning involves brain-wide transformation of operation dynamics. However, our understandings of basic principles governing learning-dependent changes in macroscopic dynamics are poor. Here we chronically monitored cortex-wide activity of the mouse brain using wide-field calcium imaging while the mouse learned a motor task over two weeks. Distinct cortical modules were extracted from activity patterns using methods based on independent component analysis. Across these modules, we found that motor learning alters the speed, direction and robustness of the signal propagation. Over learning, activity of the cortical modules reached its peak faster and their sequential activity became temporally more compressed. Moreover, a second stream of activity flow emerged from anterior regions of the cortex during learning. Lastly, in activity space where each dimension corresponds to activity of individual cortical modules, trial-by-trial variability was reduced along behaviorally relevant axes after learning. These results reveal newly emergent properties of the macroscopic cortical dynamics during motor learning.

Title: Axotomized neurons in recovery of premotor network function following ischemic stroke

Authors: *N. JACOBS[1], S. T. CARMICHAEL[2];
[1]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA; [2]Neurol., UCLA, Los Angeles, CA

Abstract: Ischemic stroke causes major neurological deficits affecting millions of individuals worldwide each year. Neurorehabilitation is the primary therapeutic option for stroke recovery. During early recovery period (days to weeks) surviving peri-infarct tissue in cortex exhibits axonal sprouting and network reorganization. Axotomized neurons recovering from the recent loss of downstream targets could play a crucial role in guiding this network reorganization and re-establishing function with compensatory network architectures. Rapid intracellular injury signals such as early calcium waves and mitogen-activated protein kinase signalling effectors in axotomized cells may allow them to act as early responders. The potential for axotomized

neurons to act at the leading edge of stroke recovery was probed using viral expression of GCaMP6s for network dynamics in premotor cortex and turbo-RFP for retrograde labeling of pre-motor cortex cells with axonal projections into targeted stroke site at forelimb M1 cortex. A photo-thrombic (PT) stroke model was used. Network function was assessed at baseline, +1, +7, and +21 days post-stroke using two-photon microscopy of calcium transients in mice performing a simple walk-left walk-right cued motor task. Preparatory motor coding of neural trajectories (Li et al., 2016) and the relative information content of axotomized vs non-axotomized cells was assessed. Analysis of this data is ongoing.

Abstract: The midbrain cephalomotor neurons in primate interstitial nucleus of Cajal convert pulse of neural discharge encoding head velocity to steady state response characterizing head position, hence serving as the neural integrator keeping the head steady in desired orientation. It is hypothesized that impairment in the neural integrator or its feedback might cause abnormal twisting, turning, and oscillations of the head characterizing a debilitating movement disorder called cervical dystonia. We tested this hypothesis by analyzing the single-unit activity of the eye only, head only, and eye-head neurons in midbrain Interstitial Nucleus of Cajal (INC) in response to eye and head movements during stereotaxic surgeries aimed to treat cervical dystonia. The control group, the eye only neurons, sustained their activity during eccentric vertical gaze holding. However, there was a rapid exponential decline in the discharge of the head only INC neurons, suggesting impairment in the neural integration of head movements. We then measured the activity of eye-head neurons, predicting that the deficit localized within the

neural integrator will cause decay in the responses of eye-head neurons during eyes as well as head movements. On the contrary, if the impairment is in the head movement feedback, then the eye-head combined neurons will sustain activity during gaze holding, but the activity of the same neuron will decline during head holding. The results suggested impairment in head movement feedback. Our experiments, therefore, supported the hypothesis that impaired feedback, for example, cerebellar or basal ganglia manifest in dystonia by affecting the function of head neural integrator.

Title: Catalepsy-induced typical and atypical antipsychotics is regulated by L-NOARG and Fos B expression

Authors: *J. C. SILVA[1], S. C. G. PRIETO[1], E. A. DEL BEL[2], M. B. ECHEVERRY[1]; [1]Univ. Federal Do ABC, Sao Bernardo Do Campo, Brazil; [2]MEF-Physiology, Univ. de São Paulo, Ribeirão Preto, Brazil

Abstract: *Introduction:* The Nitric Oxide (NO) is an atypical neurotransmitter synthesized from L-arginine by the nitric oxide synthase (NOS). The NO has been implicated in various neural process like synaptic plasticity, on modulating neurotransmitters, neurotoxicity and some gene expression, like *fos* family. Furthermore, the systemic administration of NOS inhibitors has shown similar motor effects to antipsychotics treatment. Therefore, the goal of this study was to investigate if the tolerance to the cataleptic effect induce by the NOS inhibitor is related to the FosB protein modulation. *Methods:* C57BL male mice (n = 5-8/group) The animals received L-NOARG 15 mg/Kg on 1, 3 and 5 day 30 min before to haloperidol 1 mg/Kg, clozapine 20 mg/Kg or olanzapine 15 mg/Kg administration. They were then challenged once per day for 5 days with antipsychotics or vehicle. *Behavioral test*: Catalepsy test was evaluated 120 min after

of antipsychotic administration. *Immunohistochemistry*: Was used the primary antibody FosB (1:1000 sc-7203, Santa Cruz Biotechnology). The striatum was divided into 4 quadrants for the analyze Dorsolateral (DL), Dorsomedial (DM), Ventrolateral (VL) and nuclei accumbens (NAc). The NAc quadrant was subdivide in Core and Shell region. *Statistical analyses*: The data were analyzed with ANOVA one-way or repetitive measures followed by Duncan's post hoc test. *Results: Subchronic treatment with* both, antipsychotic and NOS inhibitor showed effect in the treatment, haloperidol [$F_{(3,18)}$= 11.700; P = 0.002], olanzapine [$F_{(3,18)}$= 7.160; P = 0.009] and clozapine group [$F_{(3,18)}$= 25.146; P < 0.001], with decreased cataleptic effect on last day in atypical antipsychotics groups (P < 0.05). The olanzapine group presented an increase in FosB protein expression in the shell region [$F_{(4,11)}$= 8.919; P = 0.003]. However, when was given in combination with NOS inhibitor increased FosB protein expression in all striatum (P < 0.05). On the other hand, with clozapine treatment was observed decreased expression in the dorso-lateral [$F_{(3,11)}$= 94.420; P < 0.001] and dorso-medial striatum [$F_{(3,11)}$= 32.931; P < 0.001]. But, subchronic treatment of clozapine with NOS inhibitor decreased the expression of FosB protein in all striatum (P < 0.05). *Conclusions:* The antipsychotics induced extrapyramidal symptoms regulating intracellular mechanism as a FosB protein expression in the striatal regions. In addition, a co-treatment with NOS inhibitor decreased the cataleptic effect induced by olanzapine or clozapine. Therefore, the Nitric Oxide could be an important regulator in the motor alterations produced by neuroleptics.

Title: Low-dimensional population dynamics converge to a cyclical attractor over the course of a motor program

Authors: *A. BRUNO[1], M. D. HUMPHRIES[2], W. N. FROST[3];
[1]Univ. California San Diego, San Diego, CA; [2]Fac. of Life Sci., Univ. of Manchester, Manchester, United Kingdom; [3]Cell Biol. & Anat., Rosalind Franklin Univ. Of Med. and Sci., North Chicago, IL

Abstract: Neural control of motor behavior arises from the mass action of neuron populations. While individual neuron activity can correlate with specific aspects of movement, a parsimonious theory of motor control may require unravelling the underlying system embodied by a population. For example, rotational dynamics during movement initiation have been observed in neural populations in motor cortex of nonhuman primates. Similarly, theoretical accounts suggest neural populations generating repetitive ongoing movements embody cyclical attractors. To determine the extent to which low-dimensional rotational dynamics persist in a less constrained, ongoing motor program, we investigated the dynamical structure of the neural population implementing the locomotion motor program in the pedal ganglion of Aplysia californica. We obtained multi-neuron datasets of the rhythmic motor program using large-scale optical recording with a fast voltage sensitive dye. We discovered that the sustained low-dimensional, rotational dynamics of the locomotion motor program are directly implemented by a cyclical attractor network.
We found that the neural population in the pedal ganglion met the necessary and sufficient conditions for a cyclical attractor. Evoking the locomotion program caused population activity to rapidly settle into a low-dimensional, slowly decaying periodic orbit. Repeatedly evoking the program within each animal caused the population activity to converge on the same low-dimensional manifold. Periodic dynamics were highly consistent across animals, indicating that a common underlying dynamical system generated the heterogeneous spike patterns. Spontaneous perturbations of the population dynamics predominantly returned to the attractor. Finally, to show that the cyclical attractor manifold is the motor program, we were able to decode specific firing of the neck-projecting motor-neurons directly from the low-dimensional dynamics. Collectively, our results support the hypothesis that repetitive movement is directly generated by the neural implementation of a cyclical attractor. Inherent in these findings is the notion that population activity, and not specifics of single neuron firing, are key to motor control. Such discovery of the overlying principles governing the dynamics in neural systems may mark the beginning of a more global understanding of brain function.

Title: Decreased volume of gray matter in different regions and their correlation with motor impairment in Huntington's disease by magnetic resonance imaging

Authors: *A. CAMPOS-ROMO[1,2], V. GÁLVEZ[2,3], G. RAMÍREZ-GARCÍA[2], J. FERNANDEZ-RUIZ[4];
[2]Unidad Periférica de Neurociencias, Facultad de Medicina UNAM/INNN, [1]UNAM, Distrito Federal, Mexico; [3]Inst. de Neuroetología, Univ. Veracruzana, Xalapa, Mexico; [4]Lab. de Neuropsicología, Dept. de Fisiología, Facultad de Medicina, Univ. Nacional Autónoma de México, Distrito Federal, Mexico

Abstract: Introduction: The striatum, a fundamental component of the basal ganglia is the main structure compromised in Huntington's disease (HD). However, it is still unknown if degeneration in other brain regions could also contribute to the major motor signs in HD patients at the early stages of the disease. **Objective:** Analyze, using voxel based morphometry (VBM), if degeneration in areas other than the striatum are linked to the major motor impairments in HD patients. **Method:** Twenty-two incipient molecular diagnosed HD patients, and 22 control subjects matched by sex and age, participated in this study. Patients were evaluated with the Unified Huntington's Disease Rating Scale (UHDRS). Structural T1 magnetic resonance images were acquired on a 3T scanner and used to obtain the volume of gray matter of each participant. **Results:** VBM analysis showed a significant negative correlation between the left insula, the culmen of the right cerebellum, the right cerebellar dentate, the right posterior cerebellum and bilateral cingulate gyrus with the motor UHDRS scale. In addition, as expected, regions such as caudate, putamen, sensorimotor and premotor cortices also correlated significantly with the motor scale (Figure). **Conclusion:** These results show that the motor alterations at the beginning of Huntington's disease does not exclusively correlate with basal ganglia degeneration, but thee motor deficits also correlate with damage in other brain regions involved in the control of movement, such as the cerebellum.

Title: Changes in the intrinsic physiology of premotor neurons as a result of auditory experience in the HVC of juvenile songbirds

Authors: *M. T. ROSS[1], D. FLORES[2], R. BERTRAM[2], F. JOHNSON[1], R. HYSON[1];
[1]Neurosci., [2]Mathematics, Florida State Univ., Tallahassee, FL

Abstract: These experiments explore how auditory experience shapes the intrinsic physiology of premotor neurons during the developmental process of vocal learning in zebra finches. The learned vocalizations of songbirds are acquired over sensory and sensorimotor stages during development and require exposure to a tutor's song pattern. The cortical premotor nucleus HVC (not an acronym) is critical to the encoding and production of learned vocalizations in that proper functioning of HVC is required for the acquisition of song during sensory learning and for the proper timing of the adult vocal pattern (Roberts et al. 2012, Long et al. 2010). It is known that the HVC undergoes network level physiological changes during development (Day et al. 2013) and that learning drives changes in synaptic turnover, density, and morphology (Roberts et al. 2010, Peng et al. 2012), however it is unknown how the physiology of individual HVC neurons changes during learning and development. We have previously developed and tested kinetic models of adult HVC neurons and determined the role of several key ion channels in shaping their intrinsic physiology (Daou et al. 2013). This project explores how the intrinsic physiology of HVC neurons change over sensory and sensorimotor stages of learning in juvenile finches and explores the role that auditory experience has in shaping their intrinsic physiology. Using patch clamp electrophysiology, we recorded from distinct classes of HVC neurons across developmental learning stages and characterized the changes in their physiology. The results show changes in specific firing properties across stages of learning, such as a reduced rectifying response to hyperpolarizing currents in HVC_X projection neurons in juveniles compared to adults. We then developed biomathematical models in order to better characterize the neurons' physiology and predict changes in specific ion channel expression patterns. To explore whether learning was driving these changes in physiology, we performed patch clamp electrophysiology in the HVC of juvenile finches in a variety of tutor exposure conditions and compared their physiology to those who had normal tutor exposure. The results suggest that sensory learning does drive changes in the intrinsic physiology of HVC neurons. This would indicate that vocal motor encoding in songbirds not only requires changes in synaptic connectivity, but also changes in the intrinsic physiology of neurons through the alteration of ion channel expression patterns. These results give an improved understanding of the mechanisms of plasticity that the nervous system uses to encode new information or behaviors.

Title: Electrophysiological properties of neurons of the female zebra finch song nucleus and comparision with males

Authors: *D. FLORES[1], D. SHAUGHNESSY[2], F. JOHNSON[2], R. L. HYSON[2], R. BERTRAM[3];
[2]Program in Neurosci., [3]Dept. of Mathematics, [1]Florida State Univ., Tallahassee, FL

Abstract: Male zebra finches learn to sing by forming an auditory memory of song (listening to a tutor bird, typically its father) then using the memory as an internal reference to guide motor learning of a facsimile. In contrast, although female zebra finches form auditory memories of song, they don't sing. This striking behavioral difference is reflected in differences in the structure of the neural song system. Nucleus HVC (proper name), which plays a central role in both auditory and motor learning in males, is larger in males than in non-singing females. One possibility is that the smaller female HVC supports auditory, but not motor, learning. We performed an electrophysiological study of the properties of neurons from the female HVC, using the whole-cell patch technique to determine which types of ion channels contribute to the electrical behavior of the neurons. Differences in shape and duration of action potentials between female and male HVC projecting neurons suggest a distinction among sodium and potassium channels in these cells. This analysis was facilitated by the use of mathematical modeling, as we have done in a prior study of male HVC neurons. The behavior and characteristics of the projection neurons and interneurons of the female HVC were compared with those of male HVC neurons, again using modeling to facilitate the comparison. Finally, the dynamic clamp technique, which allows one to apply a model ionic conductance to a real cell, was used to determine how the addition or subtraction of an ionic conductance can make the electrical activity of the female neurons more like those of the male. Overall, we find consistent differences between male and female HVC neurons, both in the magnitude of channel conductances and in their kinetics.

Title: A brainstem efference copy model for the control of singing in zebra finch

Authors: *D. GALVIS[1], R. L. HYSON[2], F. JOHNSON[2], R. BERTRAM[2];
[1]Mathematics Dept., [2]Program in Neurosci., Florida State Univ., Tallahassee, FL

Abstract: The cortical nucleus HVC (proper name) is largely responsible for the neural control of the learned song in the male zebra finch. Our lab has previously shown that bilateral medial ablations of the HVC produce variations in the sequencing of syllables in a bird's motif, while lateral ablations result in omitted syllables. These data suggest distinct roles for the medial and lateral portions of the HVC in the neural control of song. The centrality of the HVC in the timing of syllables was established earlier in studies showing that cooling the HVC uniformly stretched song syllable and gaps across multiple timescales (Long & Fee 2008). We present a computational neural network model that can account for the effects of medial and lateral ablations as well as the effects of temperature on patterned neural activity that controls song syllable timing and duration. A previous computational model assumed a role for brainstem feedback in the production of syllable sequencing while using synfire chains to control individual syllables (Gibb et al. 2009). We propose a modified brainstem efference copy model which explains medial and lateral ablations in terms of selective knockout of chains from within the medial HVC and lateral HVC representations of the network. "Medial ablation" within the model results in non-random atypical syllable sequences which can account for the transition patterns seen in the experimental data. "Lateral ablation" within the model results in syllable omissions and truncation of the song sequence. As with the experimental data, ablations within the model do not result in partial syllable production. This model unifies various theories regarding the role of HVC in the production of birdsong and is the first model that can explain the effects of targeted HVC ablations.

Abstract: Zebra finches (*Taeniopygia guttata)* exhibit a dramatic, binary sex difference in behavior. Males learn to produce a song, whereas female zebra finches do not. However, both sexes form auditory memories of songs, which are encoded in part by the cortical nucleus HVC (proper name). In males, HVC also directs the motor production of the learned song. For over 30 years, the absence of singing by female zebra finches has been attributed to the smaller size of female HVC (Nottebohm & Arnold 1976) and, in particular, the apparent anatomical disconnect between HVC and the vocal-motor nucleus RA (robust nucleus of the arcopallium; Konishi & Akutagawa 1985, Williams & Nottebohm 1985). We revisited HVC connectivity in female zebra finches, applying newly developed surgical and visualization techniques. Dye injections into female HVC showed male-like connectivity, with efferent outputs from HVC to RA and Area X (of the avian striatum), as well as afferent inputs from NIf (nucleus interfacialis) and Uva (nucleus uvaeformis). Although female HVC is smaller than in males, the sexes share similar extrinsic HVC connectivity. Thus, the absence of singing by females is not due to the lack of an efferent connection from HVC to the vocal-motor nucleus RA.

Title: Role of alpha-synuclein in Area X of adult male zebra finches: implications for acoustic variability in birdsong

Authors: *S. J. MUNGER, C. A. MEDINA, L. Y. SO, K. B. CHURCH, J. L. RITTER, J. E. MILLER;

Abstract: Abnormal accumulation of alpha-synuclein is a key finding in the brains of individuals with Parkinson's Disease (PD). Rodent models have been developed to examine how alpha-synuclein protein expression is related to limb motor symptoms of PD through the use of transgenic mice and Adeno-Associated Viruses (AAV) targeted at dopaminergic pathways in rodents. Emerging evidence from these rodent models indicates that vocal changes precede the limb motor symptoms and could potentially be used for an earlier diagnosis of PD. These models, however, rely upon interpretation of vocal signals whose underlying neural circuits are not well-characterized. By contrast, the zebra finch (*Taeniopygia guttata)* songbird model has identified brain nuclei dedicated to vocal learning and on-going song maintenance. Experimental manipulations in these vocal control regions can be directly correlated with changes in song. To understand the role of alpha-synuclein in birdsong and to establish a model for the Parkinsonian vocal deficits, we characterized baseline levels of alpha-synuclein across non-singing and social-context dependent singing states, i.e. when an adult male sings alone (undirected song-UD) versus to a female (directed song-FD). Western blot analysis showed down-regulation in singing birds of alpha-synuclein protein in Area X, a song-dedicated sub-region of the basal ganglia. To establish the zebra finch as a genetic PD model, an alpha-synuclein overexpressing AAV was injected into Area X and compared to a Green Fluorescent Protein (GFP) control virus. Immunohistochemical analysis showed that unilateral injections of the alpha-synuclein AAV into an Area X hemisphere resulted in higher levels of the protein compared to the control virus-injected side. Bilateral injections into Area X were done with either alpha-synuclein or GFP control virus with song recorded pre and post-injection over three months. We hypothesized that alpha-synuclein overexpression would decrease the level of acoustic variability in the bird's UD and FD songs. Birds that received alpha-synuclein virus showed subtle changes in acoustic

features of song syllables. On-going work is investigating the impact of alpha-synuclein overexpression on dopaminergic pathways within Area X as they relate to the occurrence of vocal deficits in humans.

Title: Behavioral regulation of dopamine biomarkers in Area X of adult male zebra finch songbirds

Authors: *L. Y. SO, S. J. MUNGER, J. E. MILLER;
Dept of Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Dopamine (DA) is an important neuromodulator of motor control across vertebrate species, and under neuropathological conditions, the loss of DA in the basal ganglia leads to Parkinson's Disease (PD). Vocal deficits associated with PD include monotonous voice, decreased loudness, and articulatory problems; however, the link between the loss of DA and vocal modulation is not well-understood. In rodent and songbird models, 6-hydroxydopamine (6-OHDA), a neurotoxin that causes dopaminergic cell death, has been used to study the effects of DA loss on vocalizations. Zebra finch (*Taeniopygia guttata)* songbirds are vocal learners and have similar dopaminergic pathways as in the human brain making them an advantageous model to study the role of DA in vocalizations. The zebra finch songbird model has been used to characterize the role of DA in modulating neuronal firing patterns in Area X when the bird is singing by himself (undirected, UD) or to a female (directed, FD). In the current study, we investigated whether the vocal behavior of the zebra finch (non-singing vs. UD/FD) regulates the protein expression of different biomarkers associated with dopaminergic activity in Area X, including tyrosine hydroxylase (TH), an enzyme required for DA biosynthesis. Two hours following the non-singing (NS) or singing states, a key time-point used to examine song-related changes in gene expression, the brain was extracted and Area X tissue biopsied for Western blotting. We hypothesized that TH levels in Area X would be higher during singing versus NS as well as higher in FD than UD due to previous studies sampling DA metabolites and given the rewarding nature of FD courtship behavior. TH levels were differentially regulated in Area X across NS and singing states and may be regulated by the amount of song and social-context (UD

vs. FD). On-going experiments are investigating protein expression patterns in NS and singing states for DA receptors and other biomarkers in Area X. Future work will examine how 6-OHDA-induced DA depletion in Area X affects DA biomarkers in different vocally-driven behavioral states. The goal is to understand the neurobiological mechanisms whereby DA contributes to normal vocal behavior and the consequences of DA loss as noted in PD.

Title: Formation of hierarchical network of vocalizations in songbird groups

Authors: *A. L. VYSSOTSKI[1], V. N. ANISIMOV[2], A. V. LATANOV[2], R. H. R. HAHNLOSER[1];
[1]Inst. of Neuroinformatics, Univ. of Zurich and ETH Zurich, Zurich, Switzerland; [2]Fac. of Biol., Moscow State Univ., Moscow, Russian Federation

Abstract: Vocalizations are an essential part of social interactions in birds. They have important biological functions in coordinating activity of group members. In the previous study (SfN 2013, 549.10) using back-attached ultra-miniature sound/acceleration logger (Anisimov et al., Nat. Meth. 2014) we recorded vocalizations in groups of freely moving laboratory-housed zebra finches and have found that communication networks in zebra finch groups have a stable hierarchical structure.
The networks formed and strengthen over the course of several days in newly created groups (from animals that never have been in contact with each other), where the strengthening was manifested in faster and more reliable call-call responses. Singing behaviors differed between individuals. Some animals tended to sing together whereas others avoided that tendency. Introduction of the female strongly decreased the number of songs produced by males and changed the hierarchy of their call interactions within the entire group. After female removal the original hierarchy recovered in most cases.

However, a sudden creation of a group from unfamiliar birds is probably a rare event in the wild where stable communities of flocking birds take place. Thus, we decided to verify the dynamics of vocal interactions in a group formed from familiar birds that we temporarily separated before recording sessions. We recorded vocalizations in a group formed by four adult brothers from the same clutch (216-220 days-post-hatch) and their father (1049 dph at the beginning of the group recording session). Animals were separated from each other about 150 days before recording, but were kept in cages together with other birds. Forty days before the communal recording session animals were placed in individual sound isolation chambers for song recording and habituation to the backpack weight.
After placing animals in the communal recording chamber their hierarchical network of vocalizations was established within the first 2.5 hours and was very robust during the following week. The most intensive vocal interactions were observed on the first day. Whereas only 4 from 12 unfamiliar birds demonstrated pairwise co-singing (33%), all siblings (n = 4) sang in stable pairs (100%). The father always lead vocalizations of the group in spite of the smallest number of calls produced. Presumably, an important factor contributing to fast formation of a hierarchical network of call interactions is familiarity of animals. And, we speculate that zebra finches do not forget their relatives even after long separation and that memorization and recognition might be facilitated by song similarity.

Title: HVC controls song timing by synchronizing the activation of multiple respiratory motor systems

Authors: *C. M. URBANO[1], J. M. MÉNDEZ[2], B. G. COOPER[1];
[1]Dept. of Psychology, Texas Christian Univ., Fort Worth, TX; [2]Dept. of Physics and Astronomy, Minnesota State Univ., Mankato, MN

Abstract: Birdsong, like human speech, is a vocal behavior that requires the formation of long-term auditory memory. Vocal reproduction of the memorized acoustic model requires that birds

precisely coordinate the activation of respiratory and vocal organ motor systems. In both juvenile and adult songbirds, ablation or inactivation of HVC (proper name) neural activity disrupts temporal features of song. Consistent with the role of respiration in controlling song tempo, we have previously demonstrated that HVC contributes to song respiratory production in adult male Bengalese finches (*Lonchura striata domestica*, Urbano & Cooper, 2015). Here we further explored these findings by recording subsyringeal air sac pressure and syringeal (avian vocal organ) electromyographic activity in singing birds prior to, during, and following recovery from HVC inactivation. Dialysis probes were implanted into either left or right HVC in adult male Bengalese finches (N=5), allowing for reversible suppression of neural activity (muscimol, 1.5 mg/mL). In all animals, mean air sac pressure and initial (10 ms) slope of song-related expiratory pulses (EPs) dropped significantly during HVC inactivation and recovered (Amplitude: $F(2,8) = 12.8$, $p = 0.003$; Slope: $F(2,8) = 15.3$, $p = 0.002$). Subsyringeal air pressure is driven by the combined activation of expiratory muscles (*m. obliquus externus abdominis*) and syringeal adductor muscles (*m. tracheobronchialis dorsalis*, dTB). To investigate the mechanism underlying the reduced air pressure amplitude and slope, the onset time of dTB activity (n=3) or expiratory muscle activation (n = 1) relative to EP onset was measured. During baseline song, dTB activity preceded song EP onset by 5-20 ms and expiratory muscle activation preceded EP onset by 10-15 ms. During right HVC inactivation, left (n=1) and right (n=2) dTB activity was delayed by ~10 ms in a subset of syllables with activation occurring atypically after EP onset. In contrast, we did not observe a similar temporal delay in activation of expiratory muscles, but did observe a decrease in activation amplitude. However, unilateral HVC inactivation did not affect air pressure amplitude, slope, or the timing of dTB activity during the production of learned contact calls. These results suggest that song degradation after HVC lesion or inactivation is linked to temporal changes in dTB activity and reduced activation of expiratory muscles. Therefore, HVC controls song timing by synchronizing diverse motor systems required to reproduce respiratory patterns that generate sequential, learned vocalizations.

Title: Imaging neural representations of learned vocalizations in the basal ganglia

Authors: *J. SINGH ALVARADO[1], M. G. KEARNEY[1], R. MOONEY[2];
[1]Neurobio., Duke Univ., Durham, NC; [2]Neurobio., Duke, Durham, NC

Abstract: The basal ganglia (BG) plays a key role in coordination and execution of complex behaviors. Songbirds represent a tractable experimental platform for studying the mechanisms by which BG neuronal ensembles encode, drive, and modify behavior. Indeed, song learning and production is orchestrated by a specialized network of anatomically discrete brain nuclei including the BG homologue Area X. The dedicated nature of this system provides a rare opportunity in which BG population activity can be directly linked to a readily quantifiable behavior such as song. To investigate neural representations of song we performed deep brain calcium imaging of Area X neurons with a miniature head mounted 1 photon microscope. In initial experiments we used a nonspecific viral approach to pan-neuronally label all cell types in songbird BG with the genetically encoded calcium indicator, GCaMP6s. Calcium signals from single neurons revealed neural signatures of vocal initiation and termination, as well as stereotyped activity during song. Area X contains intermixed neuronal cell types including medium spiny neurons (MSNs), pallidal neurons (GPi- and GPe-like neurons). As MSNs are hypothesized to be a critical site of plasticity underlying learning, we sought to selectively monitor their activity during singing. We employed a CaMKII promoter-based strategy to virally label cells whose size is consistent with MSNs and confirmed that viral expression of the reporter construct co-localized with an MSN marker (DARPP-32). In vivo imaging of genetically identified MSNs during singing demonstrated distributed sequential activity throughout the song motif. Longitudinal measurements from identified BG neurons have the potential to describe the fundamental neural changes that enable the acquisition and maintenance of a complex vocal behavior.

Title: Songbird basal ganglia enable context-dependent motor skill adaptation

Authors: *L. Y. TIAN, M. S. BRAINARD;
UCSF, San Francisco, CA

Abstract: Adaptive behavior depends on the ability to flexibly organize individual actions, or gestures, into sequences. Crucial to the optimal performance of action sequences is the ability to vary how an individual gesture is executed, depending on which sequence it is embedded in (i.e. its sequential “context"). An example is coarticulation in speech, where a given gesture, or phoneme, can be executed with different articulator (e.g. lip) positions depending on its sequential context (e.g. what word it is in) in order to enable smooth transitions between the phonemes that make up each word. Here we investigate the neural substrates that underlie context-dependent modification of individual motor gestures in Bengalese finch song. Bengalese finch song consists of sequences of syllables that are variably ordered from rendition-to-rendition, such that the same syllable can be sung in different sequential contexts. We found that we could use aversive reinforcement to train birds to modify the same syllable differentially in different contexts. Moreover, the expression of such context-dependent modifications depended on the anterior forebrain pathway (AFP), a basal ganglia-pallial circuit important for song plasticity. Specifically, pharmacological inactivation of the output nucleus of the AFP blocked the full expression of modifications that were sequence-dependent (resulting from differential training in different contexts), but not modifications that were sequence-independent (resulting from the same training in all contexts). Our results indicate that the AFP integrates information about sequential context and learning signals in order to enable adaptive, context-dependent modifications of syllables. More broadly, we suggest that other forms of context-dependent motor adaptation, for which neural substrates are unclear, might similarly depend on basal ganglia circuits.

Title: Development of a representation of self-generated vocal behavior in songbird vocal motor cortex

Authors: *R. C. YUAN, S. W. BOTTJER;
USC, Los Angeles, CA

Abstract: Similar to speech acquisition in infants, vocal learning in juvenile zebra finches entails a process of sensorimotor integration in which auditory feedback of self-produced vocalizations guides refinement of variable immature vocal sounds into stereotyped adult patterns. In zebra finches, the output of this sensorimotor processing is conveyed to RA, a region of motor cortex that drives vocal output. Neurons in RA of adult zebra finches demonstrate greater response strength to playback of the bird's own song than to playback of conspecific songs. However, little is known about how the responsivity of RA neurons in juveniles engaged in sensorimotor learning compares to that in adults: do neurons in juvenile RA also demonstrate greater selectivity for the bird's own vocalizations? Alternatively, juvenile RA neurons may maintain broad responsivity to all possible motor outputs, thereby facilitating exploration of variable vocalizations during learning. We investigated this question by making extracellular recordings in RA of anesthetized juvenile (40-48 dph) and adult (> 90 dph) male zebra finches and testing the neural response to playback of each bird's own song (OWN) against playback of a mirror reverse of each bird's own song (REV), juvenile and adult conspecific songs (CON), and the adult tutor song. Single neurons in RA of juvenile birds were broadly responsive: 82% of recorded neurons demonstrated a significant increase in mean firing rate during playback of two or more song stimuli. Across all recordings, response strength to playback of each juvenile song (OWN, REV, juvenile CON) was greater than the response to the adult tutor song ($n = 41$ units; $p < .05$). However, response strength did not vary among playback of juvenile song stimuli. This pattern of results suggests that neurons in RA of juvenile birds prefer acoustic features inherent to immature juvenile vocalizations over adult vocal patterns, but do not prefer the bird's own song over other immature vocal sounds. In contrast to juveniles, neurons in RA of adults demonstrated greater response strength to playback of OWN compared to all other stimuli – including the acoustically similar tutor song ($n = 31$ units; $p < .05$). Moreover, the magnitude of selectivity for OWN over tutor song was greater in adults than in juveniles ($p < .01$). These results indicate that RA neurons respond to playback of various juvenile vocal sounds during early learning but develop a strong preference for the bird's own vocalizations by the end of sensorimotor development. This pattern suggests that selectivity of RA neurons may be shaped more by auditory feedback of self-produced sounds than by auditory experience with the tutor song.

Title: Distributed mechanism of song timing generation

Authors: *K. HAMAGUCHI[1], M. TANAKA[2], R. MOONEY[2];
[1]Kyoto Univ., Kyoto, Japan; [2]Duke Univ., Durham, NC

Abstract: Timing control is a fundamental aspect of precise motor control. Birdsong is an elaborate and stereotyped vocal behavior controlled with millisecond precision. Various lines of evidence support the hypothesis that song premotor neurons located in a telencephalic nucleus (HVC) form a synaptic chain to generate song tempo. On the other hand, vocalization also depends on the brainstem circuits that involve the control of respiratory, expiratory rhythms and muscles in syrinx. How the forebrain and brainstem interact to produce temporally precise and reproducible behaviors is not well understood. Here we combine physiological, dynamical and computational methods to show that song tempo is the product of a distributed and recurrent synaptic network spanning the forebrain and brainstem. Using a miniature Peltier device, we found that focally manipulating the temperature of HVC exerted nearly identical effects on song tempo and activity propagation through a recurrent, distributed network that contains HVC as one of its elements. In contrast, cooling HVC exerted three to four fold greater effect on activity propagation locally within HVC than it did on song tempo. Moreover, focally manipulating temperature at a thalamic node in the recurrent network also altered song tempo, and these effects could not be attributed to thermal effects on HVC. Finally, intracellular recordings in singing birds reveal that different HVC premotor cells, which generate sparse and sequential action potential activity during singing, receive high frequency and synchronous patterns of depolarizing postsynaptic potentials, a synaptic feature that is inconsistent with simple local chain models studied so far. We confirmed that a simple distributed chain model can account for the temperature sensitivity and synchronous synaptic activity underlying the sparse sequential action potential activity. These findings indicate that precisely timed neural activity critical to the

regulation of song tempo arises from a distributed, recurrent network rather than through a localized mechanism.

Title: Sleep may promote maintenance of stable motor performance in songbirds

Authors: *S. MOORMAN, W. A. LIBERTI, III, L. N. PERKINS, B. H. PRICE, T. J. GARDNER;
Biol., Boston Univ., Boston, MA

Abstract: Zebra finch males sing a single, stereotyped song, hundreds of times per day, and this song is produced with remarkable precision for a bird's entire adult life. It is not known how a neural network can maintain this stable behavior on timescales of months or years. A premotor brain region called HVC (used as a proper name) is crucially important for song production: Lesions or perturbations of normal activity in HVC during song learning prevent the juvenile from learning to sing (Roberts, Gobes, et al., 2012), and during adulthood disturb song performance (Williams et al., 1992; Long & Fee, 2008; Wang et al., 2008; Basista et al., 2014). Cells in HVC that project to downstream brain regions (motor cortex, basal ganglia and a secondary auditory brain region) show extremely stereotyped activity patterns during singing: they burst sparsely, precisely aligned to an exact position in the song (Hahnloser et al., 2002; Markowitz, Liberti, et al., 2015). When the bird is awake and not singing, these cells are rarely active. However, it has been observed that spontaneous replay of sequences of neural activity occur in the song system throughout sleep (Dave & Margoliash, 2000; Chi et al., 2003; Hahnloser et al., 2006; Crandall et al., 2007; Shank & Margoliash, 2009; Moorman, Gobes, et al., 2015). We hypothesized that sleep might be important for the maintenance of behavioral stability of song. To study activity of HVC projection neurons during natural sleep, we used a genetically encoded calcium indicator in conjunction with head-fixed fluorescence microscopy. Here, we demonstrate that sleep-related activity of HVC projection neurons differs from daytime

singing. The statistical structure of spontaneous activity in sleep is more variable than during singing: the temporal correlations between cells are less stereotyped, and the duration distribution of sleep replay events is broad. We propose that noisy spontaneous activity in sleep might be integral to maintaining stable motor patterns on a long timescale, by promoting variability in the song motor program that serves as a substrate for adaptive plasticity during singing. In support of this, we observe that projection neurons in the song motor system change their firing patterns over intervals of sleep, and that the stereotypy of HVC projection neuron firing shows a circadian cycle during undirected singing. This daily variation in the song motor program is paralleled by small but detectable overnight changes in song acoustical structure and song variance. These variations raise the possibility that novel firing patterns generated through noisy sleep processes can be selectively reinforced during subsequent days of singing.

Title: Bird song syllable decoding from neural activity

Authors: *V. GILJA[1], W. JIANG[1], T. PAILLA[1], E. ARNEODO[2], T. GENTNER[3];
[1]Electrical & Computer Eng., [2]Biocircuits Inst., [3]Psychology, UCSD, La Jolla, CA

Abstract: Songbirds, just like humans, learn to produce complex vocal sequences to communicate. Their rich vocal output results from the interaction between the brain and a vocal organ that is very similar to that of humans. For these reasons, songbirds represent an ideal animal model to study the general mechanisms underlying complex, learned motor behavior. Insights gained on how birdsong is represented in higher brain areas and how those neural representations are related to motor movements are particularly desirable if we are to understand the human speech production system and to develop a human speech neuroprosthesis.
We present a discrete neural decoder that predicts different syllables of a zebra finch listening to its own song. Previous research has demonstrated that neural activity in the bird's HVC and RA is similar during listening and singing its own song. Therefore, a high-performance decoder for these auditory stimuli is likely to translate to a high-performance decoder for singing activity.

Using spiking rates from multiple neuronal units as features and a linear discriminant analysis (LDA) classifier, we identify a separability in neural space for the 7 distinct syllables of the bird song.
We compute syllable classification performance using 10-fold cross-validation and perform a grid search over window length, bin size and window onset. We achieve a peak syllable classification accuracy of 41±3% (mean +/- s.e.m; chance level is 14%). We observe a trend of increasing performance with larger window length and bin size. As we might expect, we find a tendency for higher performance with window onset close to stimulus onset. However, and more interestingly, we have found that neural spiking rates prior to stimulus onset encode information about the subsequent syllable. This seemingly acausal effect could suggest that the bird anticipates syllables of its own song before hearing them.
These initial analyses suggest that bird song syllables can be decoded from neural activity collected at the recording site. The decoding models described here do not utilize dynamical structure present in the behavior and likely to be present in the recorded neural activity. Future work will explore these dynamics and their relationship to auditory feedback and volitional motor control.

Title: Identification of a neural circuit that carries viscerosensory feedback to forebrain song control nuclei

Authors: A. PERLEGOS[1], A. PERKES[1], J. MENDEZ[2], F. GOLLER[2], *M. F. SCHMIDT[1]; [1]Univ. of Pennsylvania, Philadelphia, PA; [2]Univ. of Utah, Salt Lake City, UT

Abstract: The central role of respiration during song production in birds requires delicate coordination with syringeal motor systems. Sensory feedback mechanisms must play a critical role in achieving this coordination, and input from air sac receptors in the vocal-respiratory periphery is likely to have an immediate influence on song output. This sensory information is relayed by the vagus nerve to the tractus solitarius (nTS), and could reach the forebrain song control system through projections to the inspiration related nucleus parambigualis (PAm) in the medulla which then projects to HVC via the thalamic nucleus Uvaeformis (Uva).

We report physiological evidence for the existence of this neural pathway through which viscerosensory feedback information from the respiratory brainstem can be relayed to HVC. We used short (100 ms) air pressure pulses delivered directly to the air sacs of anesthetized male zebra finches (*Taeniopygia guttata*) while recording neural activity in PAm, Uva and HVC. We recorded from PAm at 14 sites in 3 birds. Of 28 isolated single units, 18 showed short latency responses to the pressure stimulus irrespective of the phase of the respiratory cycle. We then recorded extracellular activity in HVC across 118 recording sites in 12 birds. Of the 276 units, 77 units (28%) showed a significant response to air sac stimulation with an average latency of 35 ms. To test whether viscerosensory information reaches HVC via Uva, we also recorded from antidromically identified HVC-projecting neurons in Uva. These neurons (N = 2 sites) responded vigorously to air sac stimulation without showing any significant responses to other sensory stimuli (somatosensory or visual). In one bird, we were able to record simultaneously in HVC and Uva. Thalamic responses always preceded those observed in HVC, suggesting that viscerosensory information flows from Uva to HVC. To test this directly, we inactivated Uva while recording in HVC. Preliminary data from one bird show that such inactivation completely eliminates responses in HVC. Taken together, these experiments indicate that HVC, a crucial region for song motor control, receives direct viscerosensory information from the vocal-respiratory apparatus, which could provide online feedback during singing.

Title: Rules for context and order in the songbird HVC.

Authors: ***W. A. LIBERTI, III**[1], E. SPENCER[1], D. P. LEMAN[1], N. PERKINS[1], D. C. LIBERTI[1], J. E. MARKOWITZ[3], T. J. GARDNER[2];

Abstract: Motor actions can involve a hierarchical organization with simple or complex rules governing the sequential ordering of elementary motor units (Markowitz, 2013). However, the neural underpinnings of the serial ordering of behavior remains largely unknown. In one of the simplest cases of learned vocal-motor behavior, a male zebra finch learns to sing a single, stereotyped song. This song contains acoustic 'motifs' that are remarkably stereotyped, and on this level, the neural correlates of the behavior have been extensively studied. However, on a slightly larger time-scale of the full song performance 'bout', song is also structured: there is a well defined start, and end of song, and in the middle zebra finches can sing a variable number of motifs, and occasionally insert variations in the syllable sequence. The songbird premotor nucleus HVC is a promising place to search for 'bout-level' coding, because the nucleus is known to be involved with both the initiation and timing of song (Long, 2008; Hahnloser, 2002), and stimulation of HVC during singing can terminate, restart, or rearrange song syntax (Wang, 2008). In a closely related species, the bengalese finch, one class of neurons in HVC that project to the basal ganglia (HVC_X) displays context-dependent activity correlated to syllable repetition and transition. (Fujimoto, 2011). To date, higher order context encoding beyond the syllable level has yet to be described in zebra finches. Using cell-type specific genetically encoded calcium indicators and custom ultralight miniature head-mounted microscopes, we describe the firing patterns of excitatory projection neurons in the premotor cortical area HVC over days and weeks in the awake behaving finch. Our data reveals that calcium activity in some projections neurons in HVC correspond reliably with simple bout-level features such as song start, song termination, and motif number within a bout.
The finding that zebra finch projection neurons in HVC correlate with features of the bout-level structure will allow for the study of motor sequence organization in a particularly controlled setting, and may provide insight into the neural basis of how complex, sequential behaviors are assembled from more elementary, discrete components.

Title: *In vivo* recording of song nuclei in free moving canaries

Authors: L. TROST[1], *M. L. GAHR[2], A. TER MAAT[2];
[1]Behavioural Neurobio., [2]Max Planck Inst. For Ornithology, Seewiesen, Germany

Abstract: Singing in male canaries is plastic and strongly influenced by seasonally determined levels of hormones [1, 2]. Recordings from anesthetized male canaries have revealed that photoperiodic status influences the selectivity of HVC neurons for the bird's own song [3, 4]. Testosterone implanted female canaries produce complex songs that are structurally similar to the song of reproductively active males [5]. In particular, male songs and testosterone-induced female songs are successions of repeated motor units, unlike the commonly studied zebra finches. We have succeeded in obtaining stable (multi-)unit recordings from the song nuclei RA and HVC in free moving male canaries. Up to 8 days of continuous recordings were analyzed with respect to spike activity and local field potentials. Regular firing RA units were active before calls and song syllables, including those that were part of high-frequency trills. HVC, neurons were found whose activity preceded calls and song syllables. Playback of bird's own song during surgery showed that multiunit HVC activity followed the syllable onsets, whereas it preceded the syllables during active singing. Comparison of the song related activity of HVC-neurons among male and female canaries and among canaries and zebra finches will inform about the generality of motor coding.

Title: High frequency vocalizations of the Black Jacobin, a neotropical hummingbird

Authors: *C. R. OLSON[1], M. FERNÁNDEZ-VARGARS[2], C. V. PORTFORS[2], C. V. MELLO[3];
[1]Dept. of Physiol., Midwestern Univ., Glendale, AZ; [2]Washington State Univ. Vancouver, Vancouver, WA; [3]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Hummingbirds represent a relatively recent order of vocal learning birds that have radiated into a variety of ecological niches in the Americas. Vocal learning is well represented, possibly occurring in all nine generally recognized hummingbird lineages. Here we describe the vocal behavior of Black Jacobins (*Florisuga fusca*), a representative species from the Topaz clade, recently proposed to be a sister to all other hummingbird lineages. Black Jacobins occur in the Atlantic Forest of Brazil, where they are one of the most abundant hummingbird species. Vocalizations were recorded in and around established feeders at the Museu de Biologia Mello Leitão in Santa Teresa, Espírito Santo, Brazil. We used a multichannel Avisoft recorder system with microphones capable of recording vocal signals with energy in the sonic and ultrasonic ranges. The most common vocalization was a rapid sequence of three repeats occurring over ~0.3 s., with a fundamental frequency (FF) of 12-14 KHz and strong harmonics as high as 80 KHz. A power spectrum revealed equivalent energies in the fundamental and first harmonic, and decaying energy in the upper harmonics. These triplets occurred in a number of conditions, including in flight and close to the feeders, during in flight antagonistic interactions with conspecifics, as well as when birds were perched alone away from the feeders. These vocalizations contained significant spectro-temporal complexity, consisting or rapid and periodic frequency modulations alternating with shorter unmodulated segments. There was suggestion of individual variation, which could implicate learning and the presence of cortical vocal circuitry, but further proof would require recording isolated individuals and histological study of brain circuitry. A second, call-like vocalization type occurred rarely and consisted of a downward frequency modulated utterance that occurred over ~0.02 s, at intervals of 0.5-5 s and a FF of ~10 KHz. It occurred only when birds were perched and were guarding nearby feeders. No

vocalizations were noted below 10 KHz. The frequency range for these vocalizations is remarkable in that it is above the upper limit of both the hearing and vocal frequency range thought to be present in birds in general. Tropical forests present unique acoustic challenges, including complex canopy structure and noisy environments from a diverse assemblage of species. The high frequency of Jacobin vocalizations may represent a frequency shift to better allow effective and exclusive acoustic communication in a noisy environment with a broad diversity of other hummingbird species.

Title: Androgens in the anterior forebrain pathway maintain song stereotypy in adult male canaries

Authors: *B. A. ALWARD, G. F. BALL;
Psychology, Univ. of Maryland At Col. Park, College Park, MD

Abstract: Optimal performance of social behaviors requires they be coordinated appropriately to the environmental context. During breeding contexts, male songbirds tend to produce a stable, stereotyped song that facilitates them effectively attracting a mate or repelling a competitor, while outside of breeding contexts when birds are altering their songs it becomes more variable. This is especially prevalent in open-ended vocal learners like male canaries (*Serinus canaria*), which as adults undergo enhanced song variability during the non-breeding season, but produce a highly stereotyped song during the breeding season to attract a mate. The mechanisms controlling context-dependent changes in adaptive behavioral variability are unclear. Androgens have been shown to significantly reduce vocal variability and are high during the breeding season when song is stereotyped, but low during the non-breeding season when song is highly variable. We housed male canaries on short days (SD) to simulate non-breeding conditions. Then, we used flutamide to bilaterally block androgen receptors (AR) in the lateral magnocellular nucleus of the anterior nidopallium (LMAN), a cortical-like brain region of the song control system that is known as a vocal variability generator. Immediately following

surgery birds were placed on long days (LD) to simulate the breeding season. We recorded song while birds were housed on SD and LD. Blocking AR in LMAN caused a significant increase in the acoustic variability of song and this was paralleled by a substantial increase in the acoustic variability of syllables. The results of blocking AR in LMAN are in contrast to our previous results showing that blocking AR in HVC, a sensorimotor region involved in song production, caused increased syllable usage variability and syllable sequence variability, while not affecting syllable acoustic variability. However, blocking AR in the robust nucleus of the arcopallium, a premotor brain region, leads to increased syllable acoustic variability, similarly to the current results of AR blockade in LMAN. Indeed, LMAN projects directly to RA and it is via this pathway that LMAN is thought to "inject" variability into the song control system. These results suggest AR in LMAN are important to controlling vocal variability and highlight the pleiotropic nature of steroid hormones in controlling complex social behaviors such as birdsong.

Title: Social context modulates the expression of sequence learning in adult Bengalese finch song.

Authors: *S. SHIN, M. BRAINARD;
Physiol., UCSF, San Francisco, CA

Abstract: Male songbirds sing a more variable 'exploratory' song when they sing alone (undirected song) than when they sing to female (directed song). Undirected song is also associated with an elevated level of neural activity and neural variability within the avian anterior forebrain pathway (AFP) an avian cortico-basal ganglia analog that is crucial for normal song learning and adult song plasticity. Together, these results suggest that undirected song may

reflect a 'practice' state in which there is elevated motor exploration important for learning, while directed song reflects a 'performance' state, in which the AFP is disengaged and the current best version of song (instantiated in more primary motor structures) is produced. Consistent with this model, recently learned changes to the acoustic structure of individual syllables of adult song are partially 'reversed' when either the AFP is inactivated, or when males sing directed song (Andalman and Fee, 2009; Warren et al. 2011, Ali et al. 2013). Here, we tested whether directed song similarly modulates the expression of recently learned changes to a hierarchically distinct aspect of adult song structure: the sequencing of discrete syllables of the bird's song. We used differential reinforcement to drive changes to syllable sequencing during undirected song in adult male Bengalese finches (as in Warren at al. 2012). We then tested the effect of introducing a female, to elicit directed song, on the statistics of syllable sequencing. We found that during directed song, there was a consistent reversion of sequence learning back towards the initial baseline state. The magnitude of this reversion was correlated with the intensity of directed song, as evaluated by the concurrent effect on the variability of syllable acoustic structure. Moreover, we found that inactivation of LMAN, the outflow nucleus of the AFP, caused a similar reversion of sequence learning. These data indicate that the expression of sequence learning is subject to strong modulation by social context and suggest that this influence is mediated in part by avian basal ganglia circuitry.

Title: Dopamine neurons encode performance error in singing birds

Authors: *V. GADAGKAR[1], P. A. PUZEREY[2], R. CHEN[2], E. BAIRD-DANIEL[2], A. FARHANG[2], J. H. GOLDBERG[2];
[1]Neurobio. and Behavior, [2]Cornell Univ., Ithaca, NY

Abstract: In reinforcement learning an animal learns through trial and error to select those actions that maximize reward. Dopamine neurons in the ventral tegmental area (VTA) mediate reinforcement by signaling reward prediction error: they are activated by better-than-predicted reward outcomes and suppressed by worse-than-predicted ones. Yet it remains unclear if dopaminergic error signals apply to behaviors such as speech or playing an instrument that are not learned for primary rewards but are instead learned by matching performance to internal goals. Songbirds use auditory feedback to learn their song, and have a dopaminergic projection from VTA to Area X, a striatal nucleus required for song learning. To test if dopamine encodes error during internally-guided performance evaluation, we recorded zebra finch VTA neurons as we induced perceived auditory error in specific song syllables using distorted auditory feedback. Here we show that a subset of VTA neurons, including those antidromically identified as projecting to Area X, encode performance error. They are suppressed after distorted syllables, consistent with a worse-than-predicted outcome, and are activated at the precise moment of the song when a predicted distortion did not occur, consistent with a better-than-predicted outcome. Error-encoding VTA neurons are a homogenous group that exhibit slow, tonic, irregular discharge similar to mammalian dopamine neurons. Yet they are intermingled with other VTA neurons that exhibit heterogeneous firing patterns, do not encode performance error, and are modulated by movement. Together, these findings identify how auditory error signals reach vocal motor circuits and, more broadly, demonstrate that principles of dopaminergic prediction error can generalize to behaviors that are not learned for primary rewards but are instead learned by comparing performance outcomes to internal goals.

Title: Effect of performance error size on motor correction dynamics in birdsong learning

Authors: *D. LIPKIND[1], A. T. ZAI[2], M. BATTAGLIA[2], R. H. R. HAHNLOSER[2];
[1]Dept Psychology, Hunter Col., New York, NY; [2]Inst. of Neuroinformatics, Univ. of Zurich, Zurich, Switzerland

Abstract: Adjusting motor performance to match a sensory target is crucial for the acquisition of many learned behaviors, such as speech, music, and sports. This process is commonly studied in humans and animals by inducing prediction errors via manipulation of sensory feedback. However, the mechanisms underlying learning the consequences of one's actions (and thus minimizing sensory prediction errors) are likely to be distinct from those underlying matching one's actions to a desired target (i.e., minimizing performance errors). We tested how performance errors are corrected during vocal learning in zebra finches (*Taeniopygia guttata*), by directly manipulating young birds' learning targets, without interfering with sensory feedback. We exposed birds to playbacks of an artificially designed tutor song, and once it was learned, switched the training to an altered tutor song, containing a pitch shifted version of one syllable type. We continuously recorded the birds' vocal output and tracked the developmental trajectory of individual syllables, as the birds adjusted their imitation of the first song to resemble the second song. We varied the size of the induced pitch shift across experimental groups, thus inducing larger or smaller performance errors. We found that error size had a profound effect on observed error correction trajectories. Small (one semitone) errors lead to slow and sometimes partial correction trajectories, while larger (two semitone) errors lead to abrupt and full corrections. However, further increasing error size to four semitones resulted in lack of any corrective pitch shifts towards the target. Instead, the target syllable was generated from scratch and incorporated into the song bout to replace an existing syllable. These results indicate that error size plays a crucial role in determining the assignments between individual motor actions (song syllables) and their corresponding learning targets.

Title: A midbrain-basal ganglia circuit is critical to externally and internally reinforced vocal learning.

Authors: *E. HISEY, M. KEARNEY, R. MOONEY;
Neurobio., Duke Univ., Durham, NC

Abstract: Humans rely on both external and internal reinforcement to learn a variety of motor skills, from learning a video game to playing a musical instrument. Midbrain dopamine-releasing neurons that innervate the basal ganglia (BG) are known to play a key role in externally reinforced forms of learning in vertebrates. In contrast, the role of dopamine in internally reinforced forms of learning remains relatively poorly understood, due in part to the challenge of describing internally reinforced forms of learning in rodents or non-human primates. Songbirds provide a powerful model in which to explore the roles that dopamine signaling plays in internally and externally reinforced learning: as juveniles, they learn to copy a tutor song in a process that is internally reinforced; as adults, they can learn to shift the fundamental frequency (i.e., pitch) of a syllable that is targeted in a contingent manner with noise, a form of externally reinforced learning; and the pitch of the targeted syllable will return to baseline values when noise is discontinued, a process that is internally reinforced. Here we used an intersectional genetic method to ablate midbrain dopaminergic cells (VTA_X cells) that project to Area X, a region of the BG specialized for vocal learning. Though both juvenile copying and adult pitch learning were severely impaired following VTA_X cell ablation, adult recovery of baseline pitch was unaffected. In another set of experiments, we found that infusing dopamine receptor type 1 (D1R) antagonists into Area X also impaired juvenile copying and adult pitch learning, but did not affect adult recovery. These observations support the idea that D1R-mediated signaling from the VTA to Area X may be critical to learning a new motor program, but not to recovering a previously learned vocal pattern. Finally, we found that pitch-contingent optogenetic stimulation of VTA_X terminals in Area X was sufficient to reinforce lasting shifts in syllable pitch. These findings indicate that VTA_X cells and the D1Rs they activate in the BG are necessary to both internally and externally reinforced forms of learning, and that performance-contingent activation of VTA_X terminals is sufficient to reinforce learned vocal behavior.

Title: A circuit for conveying vocal timing signals to an auditory nucleus in the songbird

Authors: *M. TANAKA, R. MOONEY;
Neurobio., Duke Univ., Durham, NC

Abstract: An influential idea is that the integration of vocal motor signals with auditory feedback gives rise to error signals useful for vocal learning. The circuits that mediate sensorimotor integration important to the generation of error signals and vocal learning await elucidation. We sought to address this issue by examining the circuit that links a premotor nucleus important to song timing (i.e., HVC) to an auditory forebrain nucleus (i.e., Avalanche, or Av) in adult male zebra finches. We previously reported that this motor to auditory projection is required for song learning as well as song degradation after deafening, suggesting that it plays a role in auditory feedback-dependent vocal learning and plasticity (Hisey et al., SfN Neuroscience 2014: 565.14). To elucidate the signal that the HVC to Av projection conveys, we performed whole cell patch-clamp recordings from HVC-Av neurons in brain slices and examined their inputs using electrical and optogenetic stimulation methods. Stimulation of HVC neurons that project to a motor region (i.e., RA), which collectively encode song timing information, induced monosynaptic excitatory currents in most HVC-Av neurons. In contrast, stimulation of HVC neurons that project to a basal ganglia region (i.e., Area X) failed to elicit monosynaptic excitatory currents in any HVC-Av neuron. Moreover, stimulation of axon terminals from auditory cortical regions including Av and the nucleus interfacialis (NIf) failed to induce monosynaptic excitatory currents in HVC-Av neurons, but did evoke monosynaptic excitation in the other projection neuron types in HVC. Tracer injections showed that Av neurons project to the ventral part of the intermediate arcopallium (AIV), which contains neurons that are sensitive to perturbations of vocalization-related auditory feedback and that target midbrain dopaminergic neurons implicated in error correction (Mandelblat-Cerf et al., 2014, eLIFE 3:e02152). These results suggest that the HVC-Av projection conveys song timing information to the auditory system, which could be important to the generation of error signals in downstream auditory regions.

Title: The diversity of Bengalese finch song syntax and the role of auditory feedback in its complexity

Authors: S. SURENDRALAL[1], K. E. BOUCHARD[2], M. S. BRAINARD[3], *D. Z. JIN[1]; [1]Dept Physics, Pennsylvania State Univ., University Pk, PA; [2]Computat. Res. Div., Lawrence Berkeley Natl. Lab., Berkeley, CA; [3]Univ. of California at San Francisco, San Francisco, CA

Abstract: Songs of the Bengalese finch consist of variable sequences of discrete syllables. The syllable sequences follow probabilistic rules, and can be accurately described by statistical models, in particular, the partially observable Markov model (POMM) [1]. POMM is a probabilistic state transition model, with each state associated with a syllable. A syllable can be associated with multiple states. This "many-to-one mapping" from the states to the syllables distinguishes POMM from a simple Markov model, in which each syllable is associated with a single state. The number of states required for each syllable can be used to characterize the complexity of Bengalese finch songs. Using a novel method for deriving POMM from observed syllable sequences [2], we constructed the syntax of a number of Bengalese finches. We excluded syllable repetitions since these were addressed elsewhere [3]. We find diverse state transition structures, ranging from simple to complex. While some structures are composed of segments of deterministic transitions with occasional branches, others allow branching from every state. Hence there is no prototypical syntax for Bengalese finch songs. Statistical analysis shows that most songs are beyond Markov models, requiring 2 to 3 extra states for some syllables. Deafening reduces such complexity, simplifying the song syntax into Markov models in most birds. The complexity persists in others. These observations suggest that auditory feedback can induce complexity in the Bengalese finch song syntax. There are also contributions from intrinsic factors other than the auditory feedback. We suggest that the Bengalese finch song syntax is encoded in the interplay between auditory feedback and the intrinsic song generating circuitry.

Title: Auditory error-signals and song destabilization in zebra finch learning and song maintenance

Authors: *N. PERKINS[1], J. MARKOWITZ[3], J. SHEN[1], D. SEMU[1], W. A. LIBERTI, III[1], D. C. LIBERTI[4], T. J. GARDNER[2];
[2]Dept. of Biol., [1]Boston Univ., Boston, MA; [3]Dept. of Neurobio., Harvard Med. Sch., Boston, MA; [4]Boston Med. Ctr., Boston, MA

Abstract: During development, zebra finches learn a distinct stereotyped song, which they are then able to consistently perform hundreds of times a day over many years. The long-term performance of this complex, learned behavior depends on auditory feedback for maintenance. Conditional aversive auditory feedback (CAAF) results in short-term adaptive plasticity of the acoustic structure of song. This externally reinforced sensory-motor learning may be related to the self-evaluation between motor performance and a sensory representations that guides normal song learning and maintenance (Leonardo & Konishi, 1999; Tumer & Brainard, 2007; Andalman & Fee, 2007). The auditory area called HVC shelf is known to be responsive to AAF (Hamaguchi et al., 2014) and provides inputs to AIV, a region that potentially drives dopamine signaling in VTA (Mandelblat-Cert et al., 2014), closing a loop from auditory circuits to a potential reinforcement signal that impacts multiple song motor nuclei as well as the song-related basal ganglia (area X).
This pathway may be critical for identifying sensory errors and modulating vocal performance adaptively. To date, there is little known about how vocal performance errors are encoded in the HVC shelf, and what role they play in song adaptation seen under CAAF. In this study, we use fiber photometry to record neural activity via genetically-encoded calcium indicators (GECIs) from identified projection neuron types in HVC and HVC shelf. AAF is probabilistically presented at a specific point in the song, triggered based on a custom low-latency syllable detector. Using a GECI targeting subpopulations of projection neurons in HVC, we are able to disambiguate CAAF responses arising in HVC shelf from potential adaptation of motor related signals in HVC. This work both expands fiber photometry methods enabling optical interfacing with specific brain regions and develops our understanding of how sensory error signals are used in maintenance and modification of learned, complex motor behaviors.

Title: The link between anxious behaviors and habenular mast cells in social inequity-conditioned rats

Authors: ***H. LEE**, T. JUNG, W. KIM, J. NOH;
Dankook Univ., Suji-Gu, Yongin-Si, Gyeonggi-Do, Korea, Republic of

Abstract: Social equity reduces physiological reactivity to stressors, while social inequity causes emotional distress. Mast cells are immune cells that are found in the brain and affect neuronal system and emotional behavior, independent of the animal's immune status. To determine the role of neuro-immunity in emotional behaviors, we observed the brain mast cells and the anxiety-like behaviors of rats exposed to electrical foot-shock distress with different social environment. There were no differences in body weight and sucrose preference among all assigned rats. The fear memories were augmented in shock-exposed rats with nonshock- or shock- exposed conspecifics compared to solitarily shock-exposed rats. After fear conditioning, shock-exposed rats with nonshock-exposed conspecifics showed intensified anxiety-like behaviors. Importantly, we found the increase of habenular mast cell numbers in intensified anxiogenic groups. The number of mast cells in lateral habenula had a significant correlation with initial decreasing rate of anxiety-like behaviors. Taken together, present study demonstrates that social inequity induces anxiety-related emotional alteration and mast cell changes in the habenula. It provides evidences for the affective behavioral importance of mast cell links in social stress and suggests the functional role of habenular mast cells for helping to relieve a social stress caused exaggerated biopsychological responses. Title: Microglia actively recruit inflammatory monocytes to the brain to promote anxiety-like behavior with Repeated Social Defeat.

Authors: *M. D. WEBER, C. SAWICKI, D. B. MCKIM, J. P. GODBOUT, J. F. SHERIDAN; Ohio State Univ., Columbus, OH

Abstract: Neuroinflammation affects mood, cognition, and behavior and is linked with the etiology of psychiatric disorders, including anxiety and depression. Repeated social defeat (RSD) is a murine stress model that recapitulates many of the immune and behavioral outcomes of stress. For instance, RSD activates fear/stress neurocircuitry, accompanied by microglial activation, increased pro-inflammatory signaling and the promotion of anxiety. We have reported that a key part of RSD-induced anxiety is the trafficking of inflammatory Ly6C^{hi} monocytes from the bone marrow to fear and threat appraisal center of the brain. We hypothesize that the site-specific trafficking of Ly6C^{hi} monocytes to the brain is caused by active recruitment directed by resident microglia. To address this, we used the colony-stimulating factor (CSF)-1 antagonist, PLX5622, to eliminate microglia and determined their role in RSD induced macrophage recruitment to the brain and the induction of anxiety. In these experiments C57/BL6 mice were feed control or PLX5622 diet for 14 days and remained on diet with exposure to RSD. We first confirmed that mice feed the PLX5622 diet had a 99% reduction in brain microglia by cell flow cytometry, histology, and mRNA analyses. PLX5622 intervention alone, however, had no effect on myeloid cells in the bone marrow or in circulation. In addition, PLX5622 intervention and the elimination of resident microglia had no effect on stress-dependent increase in myelopoiesis in bone marrow and enhanced accumulation of Ly6C^{hi} monocytes in circulation. PLX5622 intervention did not affect the stress induced up regulation of vasculature adhesion molecules (ICAM and VCAM) but blocked vascular expression of IL-1 receptor. Importantly, microglia elimination abrogated the recruitment of Ly6C^{hi} monocytes to the brain with stress. This blockade was associated with attenuated neuroinflammatory signaling with stress (reduced IL-1β, CCL2, CCR2, IL-6, TNFα). Moreover, microglia elimination and the absence of inflammatory monocytes prevented the induction of anxiety-like behavior with stress. Taken

together, these data indicate that repeated social defeat activates microglia, which selectively recruit inflammatory monocytes to the brain that augment neuroinflammatory signaling and promote anxiety-like behavior.

Title: Resveratrol suppresses neuroinflammation in the experimental paradigm of ASD

Authors: *R. BHANDARI[1,2], A. KUHAD, 160014[3];
[1]Panjab Univ., Chandigarh, India; [2]Pharmacol., [3]Univ. Inst. of Pharmaceut. Sci., Chandigarh, India

Abstract: Objective: Neuronal dysfunction caused by neuroinflammation triggered by the stimulation of matrix metalloproteinases and the subsequent release of pro-inflammatory cytokines, as a result of oxidative stress and mitochondrial dysfunction, is one of the probable mechanisms involved in the pathogenesis of autism spectrum disorders (ASD). The aim of the present study was to explore the ameliorative potential of resveratrol on neuroinflammation in the experimental paradigm of neuroinflammatory model of ASD in rats. **Method:** 1M Propanoic acid (PPA)(4µl) was infused over 10 minutes into the anterior portion of the lateral ventricle to induce ASD like symptoms in rats. Resveratrol (5, 10 and 15 mg/kg) was administered starting from the 2nd day of the surgery and continued upto 28th day. Rats were tested for various behavioural paradigms such as social interaction, stereotypy, locomotor activity, anxiety, novelty, depression, spatial learning, memory, repetitive and pervasive behaviour between the 7th day and 28th day. In addition, biochemical tests for oxidative stress, mitochondrial complexes, TNF-alpha and MMP-9 were also assessed. **Results:** Treatment with resveratrol for

four weeks restored, significantly and dose dependently, all the neurological, sensory, behavioural, biochemical and molecular deficits in PPA induced autistic phenotype in rats. **Conclusion**: The major finding of the study is that resveratrol restored the core and associated symptoms of autistic phenotype by suppressing oxidative-nitrosative stress, mitochondrial dysfunction, TNF-alpha and MMP-9 expression in PPA induced ASD in rats. Therefore, resveratrol might serve as an adjunct potential therapeutic agent for amelioration of neurobehavioural and biochemical deficits associated with autism spectrum disorders. ***Keywords:*** Autism spectrum disorders (ASD), resveratrol, neurobehavioural, oxido-nitrosative stress, TNF-alpha, MMP-9

Title: Physical versus psychological stress-induced inflammation: a putative role of estrogen in stress susceptibility

Authors: *J. E. FINNELL, C. M. LOMBARD, C. M. MOFFITT, S. K. WOOD; Pharmacology, Physiology, and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Physical exposure to or witnessing social stressors is known to result in the development of depression, which has been associated with elevated peripheral and central inflammation. While women are more susceptible to developing depression than men, the mechanism by which this occurs is unknown. A major system implicated in depression is dysregulation in the locus coreuleus (LC)-norepinephrine (NE) system. Inflammation and estrogen have both been shown to increase NE release from the LC, suggesting a mechanism of increased stress sensitivity in females. Therefore, we utilized a model of social defeat stress to determine differences in stress-induced inflammation between (1) physical (defeated intruder) vs. psychologically stressed (witness) male rats, (2) female intact vs. ovarectomized (OVX) witness rats, and (3) peripheral vs. central responses to social defeat or witness stress in males and females. Male Sprague Dawley rats were randomly assigned into control, intruder or witness

groups. Female Sprague Dawley rats were assigned into control/witness and intact /OVX groups. Intruders were placed into the home cage of a novel Long Evans retired breeder (resident) for 15 mins on 5 consecutive days. Each intruder was paired with a witness, which was placed behind a plexi-glass partition in the resident cage for the duration of the intruder defeat exposure. 4 days after the 5th stress/control exposure, a sucrose preference test was administered and 24 hrs later all stressed rats were re-exposed to the defeat environment in the absence of the resident (15 mins) followed immediately by plasma/tissue collection. Bio-plex analysis of circulating cytokines indicated moderate increases in cytokine expression in male intruders, while male witnesses did not differ from controls. The cytokine response of both intact and OVX female witnesses was significantly elevated from controls, although baseline inflammation was greater in OVX controls. Analysis of sucrose preference indicated that only intact female witnesses exhibited anhedonia. These data indicate that females, regardless of intact or OVX exhibit a more sensitized peripheral inflammatory response to witnessing social stress as compared to males. However, anhedonia was only observed in intact females suggesting that this depressive-like behavior is not driven by peripheral inflammation. Alternatively, ongoing studies are assessing whether intra-LC inflammation contributes to the depressive-like responses in intact females. Furthermore, this enhanced behavioral sensitivity may be reliant upon the effects of estrogen in the stress sensitive LC. Support: 15SDG22430017 and P20GM103641

Title: Antiinflammatory role of perivascular macrophages in a model of depression induced by stress in rats

Authors: *A. SAYD[1,3,2], K. MACDOWELL[2,3], D. MARTIN-HERNANDEZ[2,3], J. CASO[2,3], A. VARGAS[2], J. LEZA[2,3], J. MADRIGAL[2,3], L. ORIO[2], B. GARCIA-BUENO[2,3];
[1]pharmacology, [2]Complutense Univ. of Madrid, Madrid, Spain; [3]Cibersam, Madrid, Spain

Abstract: Perivascular macrophages (PVM) are hematopoyetic cells that migrate to the brain perivascular space modulating the interactions between the immune and central nervous systems (CNS). Previously, their depletion with the icv administration of the pro-apoptotic drug clodronate encapsulated in liposomes increased the vascular production of the proinflammatory prostaglandin PGE_2, the release of ACTH, corticosterone and fever, induced by the intravenous administration of Lipopolysaccharide. Further studies also demonstrated a decrease in the synthesis of the antiinflammatory prostaglandin 15d-PGJ_2. With this background, we decide to explore the mechanisms involved in the anti-inflammatory profile of PVM by depleting them in a model of depression induced by chronic mild stress (CMS) exposure in rats. Our results showed an increase of cytokines TNFα, IL-1 and IL-6 at mRNA levels in the prefrontal cortex of the groups where the PVM were depleted, as well as in the protein levels of nuclear factor NF-κB, the enzymes proinflammatory iNOS, COX-2 and m-PGES-1 and their product PGE_2. A concomitant decrease of the 15d-PGJ_2 mediator was also observed. In addition we also checked whether the depletion of PVMs could regulate the expression of molecules implicated in the leukocyte traffic and infiltration in the CNS in our CMS model. Thus the mRNA levels of the chemokines MCP-1, fractalkine and the adhesion molecule VCAM appeared increased in the animals without PVMs. In summary our results could suggest a potential anti-inflammatory role for PVMs in a depression model chronic stress-induced as CMS.

Title: The influence of stress and inflammation on amyloid-beta production.

Authors: *M. J. EIMERBRINK[1], J. WHITE[1], J. PETERMAN[1], R. PENDRY[1], C. HAGEN[1], H. MOORE[1], M. CHUMLEY[2], G. BOEHM[1];

Abstract: The connection between inflammation and various disease pathologies is strongly confirmed in the existing literature, as is the connection between stress and immune function. Here we present data from a series of studies designed to examine the relationship between stress, inflammation, and amyloid-beta production. First we examined how two different stressors, repeated social defeat and social isolation, influence the pro-inflammatory cytokine response to lipopolysaccharide (LPS). Results from this study provide evidence that both paradigms are capable of increasing the inflammatory response to LPS. Additionally, we found that stress can increase expression of the pro-inflammatory primer, high mobility group box 1 (HMGB1). Following this, we studied the effect of stress on inflammation-induced amyloid-beta production in a non-transgenic model, using C57BL6/J mice. After completion of a stress protocol, animals were treated with either LPS or saline once per day for seven consecutive days. Results show that the treatment with LPS increases expression of amyloid-beta in the hippocampus, and that stress exacerbates LPS-induced expression of hippocampal amyloid-beta. We also show that LPS-induced elevations in hippocampal amyloid-beta are sufficient to induce cognitive deficits in a contextual fear conditioning paradigm. Taken together, our results support the hypothesis that stress and inflammation can interact to increase amyloid-beta production.

Abstract: Background: Genome scale comparison of mononuclear cell transcriptional engagement following a common trigger of delivery, allows an unbiased window into differential systemic immune alterations during the triggering of postpartum depression. Methods: Reproductive steroid hormones and blood mononuclear transcriptional signature immediately following delivery were compared between mothers developing a depressive episode and those who remained unaffected upon prospective follow up. Results: Bioinformatic analyses demonstrated altered immune - inflammatory activation among mothers developing a depressive episode. Differently expressed transcripts enriched Pathways supporting altered mononuclear cell activation accompanying the development of a depressive episode. Reproductive hormones did not show significant differences among depressed mothers. Discussion: Genome scale expression changes immediately following delivery implicate altered mononuclear cell immune activation among mothers developing a depressive episode upon long term follow. Immune activation may be mechanistically involved in depression pathogenesis through neural - immune signaling. Title: Electrophysiological alterations of synaptic inputs converging on area CA3 the hippocampus in a model of prenatal infection.

Authors: *C. SOTO[1], E. GÁLVAN[2];
[1]Farmacobiología, [2]CINVESTAV, Sede Sur, Mexico, Mexico

Abstract: Maternal infections during pregnancy have been identified as a risk factor for the development of neurological and psychiatric disorders in the progeny; a condition that is mimicked by prenatal exposure of rats to lipopolysaccharide (LPS). In this model, the resultant offspring will experience impaired learning and psychotic-like behaviors. Thus, we explored the changes in the synaptic strength of glutamatergic inputs converging on area CA3 of the hippocampus as well as the interneuron-mediated inhibition of animals exposed to prenatal infection (LPS administration on gestational days 15 and 16, 100 μg/Kg). A histological analysis revealed a structural disorganization of the dentate granule cell layer and pyramidal cell layer of the hippocampus of animals prenatally exposed to LPS. The strength of the glutamatergic inputs, assessed by mean of input-output curves (I-O curves), indicate an increase in the excitability ratio of the perforant path to dentate granule cells (PP-DG) synapse and the PP-CA3 pyramidal cells (PP-CA3) synapse. The increased excitability was also found in the mossy fiber-CA3 synapse (MF-CA3). Paired-pulse protocols were used to unmask changes in the interneuron-mediated inhibition and short-term synaptic enhancement of these synapses. Compared to control, the PP-DG, PP-CA3, and MF-CA3 synapses exhibited a decreased index of depression. Conversely, the three synaptic inputs exhibited an increased index of facilitation. These electrophysiological alterations indicate an imbalance in the inhibition/excitation ratio as a consequence of the exposure to LPS. As the synaptic interactions between DG and area CA3 take part in the transfer of the somatosensorial information arriving from the entorhinal cortex, the synaptic imbalance observed in this study, may represent the mechanistic basis underlying the cognitive impairment triggered by prenatal infections.

Title: Effects of sleep deprivation on gut microbiota in *Drosophila* menlanogaster

Authors: *Y. ORTIZ-CASTELLNO[1], N. RODRIGUEZ-GOMEZ[2], J. F. RUIZ[2], M. G. DOMINGUEZ-BELLO[3], C. LEUCIANO-MONTALVO[2], J. L. AGOSTO-RIVERA[2];

[1]Biol., Univ. of Puerto Rico At Rio Piedras, Caguas, PR; [2]Biol., Univ. of Puerto Rico At Rio Piedras, San Juan, PR; [3]Med., New York Univ. Langone Med. Ctr., New York, NY

Abstract: Sleep loss are common in today's society. Sleep deprivation can have serious consequences on health affecting cardiovascular, immune and the central nervous system (CNS), among others. Interestingly, sleep difficulties have also been associated with intestinal microbiota dysbiosis and changes in protein expression of the CNS. Early classical experiments transferring cerebrospinal fluid (CSF) from sleep-deprived animals into rested non-deprived animals established that the homeostatic control of sleep involved the accumulation of sleep-inducing substances. Later studies identified fragments of bacterial cell wall products called muramyl peptides (MPs) as important sleep-inducing substances. Although it was known that MPs could be produced by phagocytosis of gram-negative and gram-positive bacteria, whether the bacterial source came from opportunistic infections, endogenous bacteria or contamination has been the subject of a long-standing debate and speculation. Here we take advantage of the sequencing tools available in our genomic era and the Drosophila melanogaster, to shine a light into this issue. We show for the first time that: 1) sleep deprivation leads to a global decrease in the number of gut microbes and alters the relative abundance of specific bacterial strains and; 2) these changes depend on the translational repressor *Pumilio* since knock-down of this gene prevent these alterations; 3) rearing the fruit flies with broad-spectrum antibiotics produced a decrease in total sleep. Taken together, these results indicate that gut microbes are affected by sleep deprivation and may play a role in sleep homeostasis. Given the alarming increases in the prevalence of chronic sleep deprivation and related disorders in our society and the accessibility of gut microbes, our findings could provide the basis for both diagnostic tools for sleep conditions as well as novel treatments.

Title: Acute stress induces a protracted priming of amygdalar microglia: a role for the alarmin HMGB1, CD200R and NLRP3

Authors: *M. G. FRANK, R. M. BARRIENTOS, L. K. FONKEN, L. R. WATKINS, S. F. MAIER;
Univ. of Colorado, Boulder, CO

Abstract: Stress sensitizes the neuroinflammatory as well as the microglial pro-inflammatory response to subsequent immune challenges. Much of this prior work has focused, in large part, on hippocampal microglia. Recent evidence suggests that the amygdala is particularly sensitive to the pro-inflammatory effects of stress, however, it is unknown whether stress primes the pro-inflammatory response of amygdalar microglia to subsequent immune challenges. To address this question, we examined the effects of acute stress on amygdalar microglia activation markers in vivo as well as the pro-inflammatory response of isolated amygdalar microglia ex vivo. Male Sprague-Dawley rats were exposed to inescapable tailshock (IS; 100 shocks, 1.6 mA, 5 sec ITI) or served as home cage controls (HCC). 8 days post-IS exposure, amygdala was dissected and microglia immunophenotype was characterized using real time RT-PCR. In addition, protein levels of the alarmin HMGB1 were measured. In the amygdala, we found that IS increased HMGB1 protein and mRNA, NLRP3 mRNA and NFKBIA mRNA, but decreased mRNA levels of CD200R and MHCII. In addition, IS increased the expression of the microglia inhibitory ligands CD200 and CX3CL1. Notably, the ratio of CX3CR1 to CX3CL1 (1.09) in IS subjects did not significantly differ from HCC (1.22). However, exposure to IS induced a profound downward shift in the ratio of CD200R to CD200 (3.91) compared to HCC (13.28). Importantly, IS exposure failed to affect pro-inflammatory cytokine (IL-1 beta, TNFa and IL-6) expression suggesting that stress primes rather than activates amygdalar microglia. To test this notion, microglia were isolated from amygdala 8 days after exposure to IS using a Percoll density gradient. Amygdalar microglia were then treated with LPS (0, 1, 10 and 100 ng/ml) for 2h ex vivo and pro-inflammatory cytokine expression measured. Prior exposure to IS potentiated the pro-inflammatory cytokine (IL-1 beta, TNFa) response of amygdalar microglia indicating that IS primes amygdalar microglia to subsequent immune challenges. The present results suggest that acute stress induces a protracted priming of amygdalar microglia. Further, these priming effects may be the result of stress-induced dis-inhibition of microglia through down-regulation of the microglial inhibitory receptor CD200R.

Title: Mononuclear cell transcriptional reactivity following first methylphenidate challenge among drug naïve children with Attention Deficit and Hyperactivity Disorder

Authors: *R. SEGMAN[1], T. GOLTSER DUBNER[1], A. MELTZER[2], G. BODENHEIMER[2], A. SHARON[2], R. GIESSER[2], L. KALMAN[2], A. SHALEV[2], L. CANETTI[1], E. GALILI[2]; [1]Hadassah Univ. Hosp., Jerusalem, Israel; [2]The Herman-Danna Div. of Pediatric Psychiatry, Dept. of Psychiatry, Hadassah - Hebrew Univ. Med. Ctr., Jerusalem, Israel

Abstract: Background: Exposure to stimulant drugs has been increasing in recent years among children and adolescents, during critical periods of brain development. Understanding their mechanism of action, or long term molecular effects, is hindered by lack of access to relevant brain cells in humans. Methods: Children diagnosed with Attention Deficit Hyperactivity Disorder (ADHD) underwent a computerized assessment of their clinical response to an initial methylphenidate trial. Quantitative changes in continuous computerized performance measures was compared between the baseline drug naïve state and peak methylphenidate effect, and correlated with simultaneous mononuclear cell genome scale transcriptional reactivity. Results: Transcriptional changes following methylphenidate exposure among children demonstrating a concomitant prospectively documented clinical response, point to predictive clinical drug response biomarkers, as well as implicate potentially relevant mechanistic drug targets. Conclusions: Prospectively documented systemic transcriptional reactivity following initial methylphenidate exposure among previously drug naïve children diagnosed with ADHD, may offer a surrogate venue offering insight into molecular pathways of methylphenidate action. This work was supported by an Israel Ministry of Health Chief Scientist grant and the Herman Dana Foundation.

Title: The antioxidant nuclear factor Nrf2 pathway dysregulation and its modulation by antidepressants in chronic mild stress rats

Authors: *D. MARTÍN HERNÁNDEZ[1,2], Á. GONZÁLEZ BRIS[1,2], A. SAYD GABÁN[1,2], K. MACDOWELL MATA[1,2], B. GARCÍA BUENO[1,2], J. MUÑOZ MADRIGAL[1,2], J. LEZA CERRO[1,2], J. CASO FERNÁNDEZ[1,2];
[1]Pharmacol., Complutense Univ. of Madrid, Madrid, Spain; [2]CIBERSAM, Madrid, Spain

Abstract: *Introduction:* patients with major depression who are otherwise medically healthy have activated inflammatory pathways. It has been described that depression is not only escorted by inflammation but also by induction of multiple oxidative/nitrosative stress pathways. Nevertheless, there are finely regulated mechanisms involved in preserving cells from damage, such as the nuclear factor Nrf2.
Aims: to explore in a depression-like model the Nrf2 pathway in the prefrontal cortex (PFC) and the hippocampus of rats and to analyze which classic antidepressants affect the antioxidant activity of the Nrf2 pathway.
Methods: male Wistar rats were exposed to chronic mild stress (CMS) and some of them were treated with desipramine, escitalopram or duloxetine. We studied the expression in the PFC and hippocampus of upstream and downstream elements of the Nrf2 pathway and the oxidative damage induced by the CMS.
Results: after exposure to a CMS protocol, in the PFC, there is an inhibition of upstream and downstream elements of the Nrf2 pathway. Moreover, antidepressant treatments, particularly desipramine and duloxetine, are able to recover some of these elements and to reduce the oxidative damage induced by the depression model. In the hippocampus however, Nrf2 pathways are not that affected and antidepressants do not have many actions.
Conclusions: Nrf2 pathway is differentially regulated by antidepressants in the PFC and hippocampus. The Nrf2 pathway is involved in the oxidative/nitrosative damage detected in the PFC after CMS exposure. However, it seems that Nrf2 is not very involved in the effects caused by the CMS in the hippocampus.

Abstract: Social stressors and bacterial endotoxins known to elicit anxiety- and depressive-like behaviours in mice increase pro-inflammatory cytokines in stress-sensitive brain regions and disturb microbial communities in the gastrointestinal tract. Appreciable evidence indicates that interventions that target the gut microbiome may modulate peripheral and brain cytokines and come to affect neurochemical processes and behaviour. The aim of the current study was to examine whether promoting a healthy gut microbiota via a probiotic treatment would prevent variations of the pro-inflammatory cytokines interleukin (IL)-1β, IL-6, and tumor necrosis factor (TNF)-α in the prefrontal cortex (PFC) elicited by a social stressor or an immune challenge. CD-1 male mice received a probiotic mixture (*L. helveticus* and *B. longum*; 1 x 10^9 colony forming units/day) or a placebo daily for 3 weeks. A subset of mice then experienced an acute (15 min) or a chronic (15 min on each of 10 consecutive days) social defeat stressor or their respective control conditions whereas another subset received an intraperitoneal injection of the bacterial endotoxin lipopolysaccharide (LPS; 10 μg) or a saline solution (*n*=10/group). Locomotor activity was monitored for 90 minutes following the stressor or immune challenges after which blood and brain tissue from the PFC were collected for the determination of plasma corticosterone levels and gene expression of pro-inflammatory cytokines, respectively. Elevations of plasma corticosterone levels and of prefrontal IL-6 mRNA expression elicited by the social stressors and LPS were not prevented by the 3-week probiotic treatment. Curiously, IL-1β expression in the PFC was altered only when the social stressors or LPS were administered to probiotic-treated mice. These results suggest that gut microbial influences on brain inflammatory activation elicited by stressor or endotoxin challenges might be cytokine-specific.

Title: Sympathetic nervous system contributes to enhanced corticosterone levels following chronic stress.

Authors: *A. KULP[1], S. LOWRANCE[2], E. FUSCO[2], H. KENNEDY[2], M. RUSS[2], N. ASHCHERKIN[2], A. PARKER[2], J. JOHNSON[2];
[1]Biomed. Sci., [2]Neurosci., Kent State Univ., Kent, OH

Abstract: Exposure to chronic stress often elevates basal circulating glucocorticoids during the circadian nadir and leads to exaggerated glucocorticoid production following exposure to subsequent stressors. While glucocorticoid production is primarily mediated by the hypothalamic-pituitary-adrenal (HPA) axis, there is evidence that the sympathetic nervous system (SNS) can affect diurnal glucocorticoid production by direct actions at the adrenal gland. Experiments here were designed to examine the role of the HPA and SNS in enhancing corticosterone production following chronic stress. Rats were exposed to a four-day stress paradigm or control conditions then exposed to acute restraint stress on the fifth day to examine corticosterone and ACTH responses. Repeated stressor exposure resulted in a small increase in corticosterone, but not ACTH, during the circadian nadir, and also resulted in exaggerated corticosterone production 5, 10, and 20 min following restraint stress. While circulating ACTH levels increased after 5 min of restraint, levels were not greater in chronic stress animals compared to controls until following 20 min. Administration of astressin (a CRH antagonist) prior to restraint stress significantly reduced ACTH responses but did not prevent the sensitized corticosterone response in chronic stress animals. In contrast, administration of chlorisondamine (a ganglionic blocker) returned basal corticosterone levels in chronic stress animals to normal levels and reduced early corticosterone production following restraint (up to 10 min) but did not block the exaggerated corticosterone response in chronic stress animals at 20min. These data indicate that increased SNS tone contributes to elevated basal and rapid glucocorticoid production following chronic stress, but HPA responses likely mediate peak corticosterone responses to stressors of longer duration. Future studies are aimed to investigate the role brain cytokines play in the over-activation of the SNS following chronic stress and to use Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) techniques to activate major control regions for sympathetic output such as the rostral ventrolateral medulla and measure glucocorticoid production.

Title: Corticosterone pre-treatment sensitises microglial inflammatory responses: non-classical neuroimmune actions

Authors: *J. LIU[1], S. MUSTAFA[2,3], M. R. HUTCHINSON[1,3];
[1]Sch. of Medicine/ Discipline of Physiol., [2]Sch. of Medicine/ Discipline of Pharmacol., The Univ. of Adelaide, Adelaide, Australia; [3]Australian Res. Council Ctr. of Excellence for Nanoscale BioPhotonics, Adelaide, Australia

Abstract: Corticosterone (CORT), the predominant end product of the hypothalamus pituitary adrenal axis in mice, is a stress response hormone which is classically anti-inflammatory. Recent evidence has shown that CORT can mediate the neuroimmune sensitisation effects of stress in mice, which could contribute to the neuroimmune involvement in stress-related disorders. This study investigates the conditions in which CORT can prime the immune system, by measuring the effects of CORT pre-treatment on BV2 mouse microglia-like cells and RAW264.7 mouse macrophage-like cells on subsequent immune responses to Lipopolysaccharide (LPS) exposure in vitro.Results from this current study demonstrated both anti- and pro-inflammatory actions of CORT. CORT was anti-inflammatory in all measures at a high physiological dose (500nM). Low-dose (50nM) CORT however increased IL-1β conversion and release in BV2 but not RAW264.7 cells, only after removal of CORT pre-treatment before addition of LPS. This sensitisation was not found in IL-6 responses to the same dose of LPS. Low-dose CORT also increased nuclear translocation of NF-κB p65, a pro-inflammatory transcriptional factor, while retaining the ramified morphology of BV2 cells during LPS treatment. These results suggest that mild elevations in CORT, a common occurrence in stress-related disorders such as depression, causes selective adaptations in microglia to over-respond to a second immune challenge in a non-classical manner, thus partially explaining both pro- and anti-inflammatory effects of CORT reported in the literature. CORT-induced mRNA expression changes in the Toll-like receptor 4, inflammasome, and steroid receptor pathways in response to LPS administration will be explored, to further explain the mechanisms behind this selective sensitisation in BV2 cells.

Abstract: The prevalence of inflammatory diseases is increasing in modern urban societies. Inflammation increases risk of stress-related pathology; consequently, immunoregulatory or anti-inflammatory approaches may protect against negative stress-related outcomes. To test this hypothesis, we immunized (3 x weekly immunizations) adult male mice with a heat-killed preparation of the immunoregulatory bacterium, *Mycobacterium vaccae* (NCTC 11659), or vehicle and then evaluated gut microbiome and defensive behavioral responses during exposure to the chronic subordinate colony housing (CSC) model of chronic psychosocial stress, as well as immunologic responses and anxiety-like behavioral responses following the CSC procedure. Briefly, CSC exposure consisted of co-housing four subordinate mice with one dominant resident mouse for a period of 19 days. Subordinate mice were moved to the cage of a new, dominant male aggressor on days 8 and 15. Single housed mice were used as controls. We show that stress disrupts the homeostatic relationship between the microbiota and the host, resulting in exaggerated inflammation, as assessed by histological damage to the colon, stress-induced exaggeration of dextran sulfate sodium-induced colitis (a murine model of inflammatory bowel disease) and increased release of interferon-γ and interleukin-6 from freshly isolated mesenteric lymph node cells stimulated with anti-CD3 antibody in vitro. Repeated immunization with a heat-killed preparation of *M. vaccae* reduced subordinate, flight, and avoiding behavioral responses to a dominant aggressor in a murine model of chronic psychosocial stress when tested 1-2 wk following the final immunization. Furthermore, immunization with *M. vaccae* prevented stress-induced spontaneous colitis and, in stressed mice, induced anxiolytic or fear-reducing effects as measured on the elevated plus-maze, despite stress-induced gut microbiota changes characteristic of gut infection and colitis. Immunization with *M. vaccae* also prevented stress-induced aggravation of colitis in a model of inflammatory bowel disease. Depletion of regulatory T cells negated protective effects of immunization with *M. vaccae* on stress-induced colitis and anxiety-like or fear behaviors. Consistent with long-term effects of *M. vaccae* immunization on neural systems implicated in control of emotional behavior, immunization with *M. vaccae* increased tryptophan hydroxylase 2 mRNA expression in the dorsal raphe nucleus, regardless of prior stress exposure. These data provide a framework for developing microbiome- and immunoregulation- based strategies for prevention of stress-related pathologies.

Title: The affect of repeated stress exposure on microglial phagocytosis

Authors: *D. F. BARNARD, J. D. JOHNSON;
Kent State Univ., Kent, OH

Abstract: Microglia are the innate immune cell within the central nervous system. They are highly motile, phagocytic cells that actively scan their microenvironment and are capable of releasing various signaling molecules including inflammatory cytokines (e.g. IL-1, TNF-alpha, and IL-6) that are potent inducers of both behavioral and physiological processes. Recent studies have indicated that stress has profound impacts on microglia morphology, density, proliferation, and activation state, which implicate their role in certain pathologies. Our lab has previously shown that exposure to chronic stress induces anhedonic behavioral responses in Fischer rats approximately 5-days after stressor onset. To examine the activation state of microglia at this time, rats were exposed to a four-day chronic mild stress protocol. Twenty-four hours after the last stressor rats were euthanized and microglia isolated from the hippocampus were placed in culture with or without further stimulation. After 4h in culture basal IL-1, TNF-alpha, and IL-6 protein production were not altered in microglia collected from stressed animals compared to microglia collected from controls. Interestingly, after LPS stimulation IL-1 production was attenuated in microglia collected from stressed animals while there were no changes in the production of TNF-alpha or IL-6. Current studies are examining the effect of stress on phagocytosis, an important function of microglia in clearing debris from the brain such as amyloid-beta, by incubated microglia with latex beads coated with fluorescently-labeled rabbit IgG. Prior research has suggested that chronic stress induces microglia to transition from a surveillance state to a more active state characterized by increase in microglial activation marker Iba-1. Here, we report no increase in basal IL-1 production following 5-days of stressor exposure and a suppression in IL-1 production following LPS challenge.

Title: Repeated social defeat stress shifts peripheral immune function in rats: potential impact on basolateral amygdala neurons

Authors: *S. MUNSHI, J. A. ROSENKRANZ;
Rosalind Franklin Univ. of Med. & Sci., North Chicago, IL

Abstract: Psychological stress can induce depression and anxiety, and numerous studies suggest involvement of the immune system in these effects. The amygdala is sensitive to stress and may be an intermediary in the link between immune function and depression and anxiety. Repeated social defeat stress (RSDS) is a powerful model of social stress with known impact on immune function. The peripheral immune system includes pro-inflammatory and anti-inflammatory aspects that, as a whole, may exert very different influences on behavior. The aim of this study is to (1) determine the effect of RSDS on the balance between pro-inflammatory and anti-inflammatory aspects of peripheral immune function, and (2) determine if a shift in this balance causes a change in amygdala function. Adult male Sprague Dawley rats underwent RSDS by exposure to the resident-intruder model using unfamiliar aggressor Long Evans rats for five consecutive days, or control handling. After three days the following were evaluated: (a) peripheral circulating T-cell counts and their intracellular cytokine profile (Th1, Th2) by flow-cytometry, (b) pro- and anti-inflammatory serum cytokine levels by ELISA, and (c) anxiety-like behavior in the open field test (OFT). RSDS decreased the frequency of CD4+ T-cells with no changes in that of the CD8+ T-cells. Frequency of CD4+ T-cells positive for the Th2-like cytokine was reduced without any alteration in those of the CD8+ T-cells. Additionally, RSDS caused changes in many different serum cytokines. OFT showed that RSDS induced an increase in anxiety-like behavior. To test whether a pro-inflammatory state can induce a change in the amygdala physiology, *in vivo* extracellular electrophysiological recordings of the basolateral amygdala (BLA) were performed in a different set of rats that underwent peripheral immune challenge with interleukin-1β. Interleukin-1β caused a trend of a time-dependent alteration of the evoked local field potential as well as alteration of the spontaneous neuronal firing-rate in the BLA. Taken together, these data suggest that RSDS shifts immune balance, and that a shift in immune balance impacts BLA neuronal activity. This could contribute to the effects of RSDS on

anxiety behavior. The results have implications in understanding how chronic stress might alter BLA physiology by recruitment of the peripheral immune system.

Title: Selective inhibition of soluble tumor necrosis factor in a rodent model of depression with increased inflammation: a potential approach to treating treatment resistant depression

Authors: *L. N. EIDSON[1], C. J. BARNUM[1], B. DUKE[1], Y. YANG[1], J. CHANG[1], S. D. KELLY[1], M. E. S. RODRIGUES[1], A. H. MILLER[1], R. J. TESI[2], M. G. TANSEY[1]; [1]Emory Univ., Atlanta, GA; [2]FPRT bio, Scranton, PA

Abstract: Approximately 7 million of the 20+ million sufferers of Major Depressive Disorder (MDD) do not respond to classical anti-depressant treatment termed treatment resistant depression (TRD). Sickness behavior and depression share multiple characteristics, suggesting that inflammation may contribute to a depressive phenotype. Indeed, cytokines, most notably tumor necrosis factor (TNF), are elevated in depressed patients, and a recent trial demonstrated that a subset of TRD patients with elevated levels of inflammatory c-reactive protein (CRP) improve following treatment with infliximab, a non-selective TNF antagonist. Unfortunately, commercially available non-selective TNF antagonists have an unacceptable safety profile; including increased risk of immunosuppression and demyelinating neurologic disease due to action at both soluble TNF (solTNF) and transmembrane TNF (tmTNF). While solTNF drives chronic inflammatory disease, tmTNF facilitates innate immunity to infection and myelination. Here we tested whether administration of a novel, brain permeable, selective inhibitor of solTNF, XPro1595, attenuates depressive- and anxiety-like behaviors and inflammation in a mouse model of depression. Adolescent male and female C57BL/6 mice were bred in house and subjected to chronic psychological stress for 15 consecutive days (P35 - P50) then tested for a depressive-like phenotype (sociability and sucrose preference). Mice were then subject to an additional 15 consecutive days of stress while receiving XPro1595 (10 mg/kg; sc) or vehicle (saline) treatment every third day, and then retested for a depressive- and anxiety-like phenotype (sociability, sucrose preference, and open field). Plasma inflammation was measured every 2 weeks during

stress testing, and hippocampus and prefrontal cortex were collected at end-point to measure peripheral and central inflammation. Our data indicate that chronic adolescent stress induces depressive-like behavior that can be ameliorated by solTNF antagonism using XPro1595. Sexual dimorphisms exist in several measures, and solTNF inhibition in the absence of stress induces abnormal social behavior. Together, these data will lend insight into how to select a target population for sequestration of solTNF by XPro1595 to improve quality of life for individuals suffering from TRD. [Funding by 1R43MH105048-01].

Title: Asthma during adolescence contributes to adult anxiety behavioral and neurobiological phenotype

Authors: *J. I. CAULFIELD[1,2,3], M. J. CARUSO[1,3], R. A. BOURNE[1], S. A. CAVIGELLI[1,2,3]; [1]Biobehavioral Hlth., [2]Grad. Program in Neuroscience, Huck Inst. for Life Sci., [3]Ctr. for Brain, Behavior, and Cognition, The Pennsylvania State Univ., University Park, PA

Abstract: Adolescence is a developmental period sensitive to perturbations that can affect adult neuronal and behavioral processes associated with internalizing disorders, like anxiety and depression. Asthma is a common chronic health challenge during adolescence, affecting 9% of U.S. adolescents, and often comorbid with anxiety and depression. However, little is known about the neurobehavioral impacts of this chronic adolescent challenge. Microglia, the resident immune cells of the brain, become activated in response to peripheral insult, and their over-activation has been implicated in neuropsychiatric disorder development. The mechanism

underlying the comorbidity of asthma and internalizing disorders, and the involvement of microglia in this relationship, has not been established. The present study implemented a mouse model of chronic adolescent asthma to investigate the physiological properties that underlie the connection between asthma and anxiety, as well as the potential involvement of microglia. Three experimental groups, consisting of male and female BALB/c mice, were designed to examine the components of an asthma attack: (1) "Airway inflammation" via repeated house dust mite extract (HDM) exposure; (2) "Labored breathing" via methacholine (MCH) exposure; and (3) "Airway inflammation and Labored breathing" via both HDM and MCH exposure. As adults, MCH animals demonstrated an anxious phenotype, spending 30% less time on open arms of the elevated plus maze compared to non-MCH animals. These mice also had decreased serotonin transporter gene expression in the brainstem, which is consistent with findings supporting low serotonin transporter activity as a risk for developing anxiety. Additionally, MCH animals demonstrated elevated serotonin receptor 1a, mineralocorticoid, and Cd11b expression in the hippocampus compared to non-MCH mice (Cd11b expression indicates microglia activation). HDM-exposed mice exhibited 50% less basal circulating corticosterone levels compared to controls. Preliminary results for hippocampal gene expression of Cd11b revealed a sex difference in HDM-MCH animals, with females exhibiting higher levels. The results of the present experiment indicate that clinical symptoms of chronic asthma, particularly labored breathing, during adolescence lead to increased adult anxiety-related behavior and brain function.

Title: Hippocampal gene networks associated with anxiety- and depression-related behavior caused by adolescent asthma symptoms in male BALB/cJ mice

Authors: *M. J. CARUSO[1], H. M. KAMENS[2], W. J. HORTON[3], R. A. BOURNE[4], A. AUGUST[7], L. C. KLEIN[1], R. H. BONNEAU[5], T. CRAIG[6], S. A. CAVIGELLI[1]; [1]Biobehavioral Hlth., Pennsylvania State Univ., State College, PA; [2]Biobehavioral Hlth., Pennsylvania State Univ., State College PA, PA; [3]Animal Sci., [4]Biol., Pennsylvania State Univ., State College, PA; [5]Microbiology and Immunology; Pediatrics, [6]Med. & Pediatrics; Allergy, Asthma & Immunol., Pennsylvania State Univ., Hershey, PA; [7]Microbiology and Immunol., Cornell Univ., Ithaca, NY

Abstract: Asthma is a stressful chronic disease with high prevalence among adolescents. Moreover, increased rates of internalizing disorders are reported in humans with asthma. The current study aimed to identify alterations in adult anxiety- and depression-like behaviors, glucocorticoid production, and hippocampal gene transcription resulting from symptoms of adolescent allergic asthma. To mimic adolescent allergic asthma symptoms, we exposed male BALB/cJ mice to inhaled house dust mite extract to stimulate lung inflammation, and/or to inhaled methacholine to stimulate bronchoconstriction. Basal glucocorticoid and proinflammatory cytokine production and anxiety- and depression-like behavior were measured in adulthood. Hippocampal gene expression was then measured using RNA sequencing. Transcriptional data were analyzed for asthma-induced changes by: (1) differential gene expression, and (2) gene co-expression using Weighted Gene Co-expression Network Analyses (WGCNA). Adolescent bronchoconstriction caused increased adult anxiety- and depression-like behavior (less time on open arms of elevated plus maze and increased immobility in forced swim test) compared to animals that did not experience bronchoconstriction. Bronchoconstriction was also associated with altered neuroendocrine function as indicated by a reduction in basal glucocorticoid levels. Alternatively, mice that experienced airway inflammation had elevated proinflammatory cytokine levels, but there was no difference in basal glucocorticoid production, anxiety- or depression-like behavior. Bronchoconstriction-induced behavioral changes were accompanied by transcriptional enrichment of mechanistic target of rapamycin (mTOR) signaling pathways in the hippocampus. Prior research indicates that mTOR signaling is involved in regulation of protein translation and synaptogenesis. WGCNA revealed a module of co-expressed genes whose expression profile was associated with both anxiety-like behavior and experimentally-induced bronchoconstriction. *Rictor*, an essential subunit of mTOR protein complex 2 (mTORC2), was identified as an important regulator of gene expression in this module. Neuronal mTORC2 regulates dendritic morphology and synaptic function. Results suggest that anxiety-related behavior that results from adolescent bronchoconstriction is associated with aberrant hippocampal mTOR signaling. These findings raise the possibility that aberrant hippocampal synaptic plasticity, associated with mTOR signaling, contributes to increased anxiety-related behavior observed after repeated bronchoconstriction during development.

Title: Early life stress activates glial cells in the hippocampus but attenuates cytokine secretion in response to an immune challenge in rat pups

Authors: L. SAAVEDRA - PIMENTEL[1], B. FENTON - NAVARRO[3], *L. TORNER[2];
[1]Ctr. de investigacion Biomedica de Michoacan, [2]Inst. Mexicano Del Seguro Social, Morelia, Mexico; [3]Facultad de ciencias medicas y biologicas, Univ. Michoacana de San Nicolas de Hidalgo, Morelia, Mexico

Abstract: Early life stress (ELS) affects permanently the development of the central nervous system (CNS) and increases the vulnerability to develop psychological disorders such as anxiety and depression in adulthood. These diseases are accompanied by inflammatory processes in the brain. Plus, exposure to infections during early stages sensitizes the neuroimmune system and increases the risk to develop psychopathology. Recently we showed that maternal separation (MS) activates microglial cells and induces the expression of IL-1β in the hippocampus. However it is not known how ELS affects the response of the neuroimmune system to an immune challenge. Therefore we studied the effect of MS followed by the administration of lipopolysaccharide (LPS) on the morphology of microglial cells and astrocytes in CA3 region and the Hilus of the hippocampus and on cytokine release at postnatal day (PN) 15. Male Sprague Dawley rat pups were subjected to MS (3h/day, PN1 to PN14) or remained undisturbed at the mother´s nest (Control). LPS (1mg/Kg bw) or vehicle was administered on PD14 to half of each group and they were subjected to the open field (OF) test 1h later. Some groups were sacrificed on PD15 for histological analyses. Other groups of pups were sacrificed 90 min after LPS injection (PN14) and the blood samples and hippocampi were collected. LPS treatment reduced the locomotion of control and MS pups in the OF test 1h later and reduced their body weight gain 24h later. LPS - induced Corticosterone levels were similar in both Control and MS groups. MS induced a mild decrease, but LPS alone or combined with MS reduced more the total number of microglial cells. Activation of microglial cells was observed in hippocampal CA3 and hilus of MS - Veh, it was increased in control - LPS, and was highest in MS - LPS pups. Astrocyte density was reduced in SM - Veh, Control - LPS and reduction was maximal in SM - LPS pups in CA3 area and hilus. In contrast, LPS induced an increased secretion of plasmatic IL-1β, TNFα, IL-6, and of hippocampal IL-1b. However, MS imposed an attenuation of the

cytokine response to LPS in the periphery and reduced IL-1 β protein levels in the hippocampus. We conclude that although the neuroimmune cells are highly activated by MS and LPS, stress induces the attenuation of the hippocampal and peripheral cytokine response by an unidentified mechanism. Title: Paternal stress programming by epigenetic crosstalk: Brain-specific changes in the histone code via sperm microRNA

Authors: *J. CHAN, N. LEU, N. V. BHANU, B. A. GARCIA, T. L. BALE;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Parental exposures to environmental insults such as stress, diet, drugs or toxins have been linked with increased risk of neuropsychiatric disease in subsequent generations. Whereas the mechanisms by which maternal insults can impact fetal neurodevelopment have been widely investigated, how the paternal environment impacts future offspring health is not well understood. Rodent models, where males do not participate in offspring rearing, provide an exciting model for examining the unique epigenetic germ cell contribution to offspring development. Recent studies have shown that paternal exposure to a variety of perturbations can impact offspring behavior and physiology, and have identified changes in histone modifications, DNA methylation, and/or small non-coding RNAs in sperm as potential mechanisms of transmission. We have developed a paternal stress model in which offspring exhibit significantly blunted stress reactivity – a feature of many neuropsychiatric disorders. Mechanistically, we identified 9 microRNA (miRs) increased in paternal sperm following stress exposure. Zygote microinjection of these miRs recapitulated the blunted stress phenotype, providing evidence for a

functional role for sperm miRs. Interestingly, RNA-seq analyses of the adult hypothalamus from zygote-microinjected offspring revealed dramatic transcriptional repression, suggesting an upstream epigenetic repressive mechanism that is developmentally programmed by paternal stress. However, how paternal experiences program lasting changes in the offspring brain and what these changes are is not known. Using single-cell amplification, we found that sperm-derived miRs can regulate maternal mRNA stores in the zygote, and may direct developmental programming by targeting expression of epigenetic regulators. Indeed, RNA-seq analyses of embryonic day 12.5 brains demonstrate a robust, brain-specific reprogramming in the zygote-microinjected embryos that include shifts in expression of many chromatin modifiers. Histone mass spectrometry of these embryonic brains confirm altered abundances of several histone post translational modifications, suggesting sperm miRs can alter the histone code that regulates offspring neurodevelopment. Ongoing studies examine the maintenance and mechanistic contribution of developmentally altered histone marks to the adult hypothalamic phenotype. These studies confer the importance of paternal experiences in influencing offspring health, and offer an exciting and novel epigenetic mechanism by which the male germ cell can reprogram offspring brain development. Title: Regulation of male risk and female resilience to neurodevelopmental disorders by placental H3K27me3

Authors: ***T. L. BALE**[1], C. O'DONNELL[2], B. NUGENT[2];
[1]Dept Animal Biol, [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Many neurodevelopmental disorders are more prevalent in boys than girls. In our mouse model of early prenatal stress (EPS), stress exposure during the first week of gestation imparts long-term neurodevelopmental programming deficits in male offspring resulting in hypersensitivity to stress, cognitive impairments, and alterations in metabolic programming. The placenta, a fetally-derived organ reflecting fetal sex chromosome complement, acts as an arbitrator between the mother and fetus, providing necessary factors for early fetal neurodevelopment. Thus, sex differences in placental function may dramatically influence sex bias in vulnerability to prenatal insults. We previously identified the X-linked, stress sensitive, nutrient sensor O-linked-N-acetylglucosamine (OGT) as a placental biomarker of prenatal stress. OGT escapes X-inactivation in the placenta, providing females with two copies and males with one copy. Placental-specific reduction of OGT recapitulates the neurodevelopmental and metabolic impairments associated with EPS exposure. As OGT is known to modify several epigenetic regulators associated with histone methylation, we hypothesized that sex differences in OGT mediate sex differences in histone methylation and promote sex-specific programs of gene expression. Using ChIP-Seq, biochemistry, and RNA-Seq in mouse placentas with trophoblast-specific OGT reduction, we found that OGT determines genome-wide sex differences in H3K27me3 and gene expression in placental trophoblasts. Further, RNA-Seq of the embryonic hypothalamus revealed that reducing OGT copy number in the female placenta masculinized the expression of key genes associated with hypothalamic development and function in the female brain, suggesting that placental OGT contributes to sex differences in brain development. Females have far more H3K27me3 in placental trophoblasts than males, thus we hypothesize that female-biased epigenetic repression protects females from prenatal insults such as EPS. To test this hypothesis, we reduced H3K27me3 in female placentas to male-like levels using trophoblast-specific genetic manipulations of the H3K27me2/3 methyltransferase, EZH2. We predict that females with decreased placental EZH2 will be vulnerable to the effects of EPS, and display sensitized HPA axis function, metabolic deficiencies, and cognitive impairments in adulthood. These studies, aimed at elucidating the basic biological differences between male and female developmental programs, will bring us closer to fully understanding the etiology of sex-biased neurodevelopmental disorders.

Title: Prenatal stress alters exosome microRNA content and delivery to the developing brain

Authors: *B. M. NUGENT, T. L. BALE;
Dept. of Biomed. Sci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Understanding how prenatal stress alters the fetal milieu is important for identifying mechanisms involved in perturbations of brain programming, which are often associated with neurodevelopmental disorders. In our well-established mouse model, male offspring exposed to early prenatal stress (EPS) have altered hypothalamic pituitary axis (HPA) programming, resulting in increased stress sensitivity and dysregulation in hypothalamic metabolism, similar to endophenotypes identified in boys with autism and men with early-onset schizophrenia. Importantly, our EPS protocol occurs during the first week of gestation, prior to brain development and thus likely alters programming of peripheral tissues in addition to altering neurodevelopmental processes. Previously, our lab found that gene sets important for endo- and exosomal cellular processes are down regulated in the male placenta in response to EPS, suggesting that EPS alters fetal exosome signaling. Exosomes are small vesicles secreted locally and into the bloodstream by most tissues. Exosomes transfer proteins, microRNAs, and other signaling factors between cells and tissues as a means of short and long-distance communication. Importantly, exosomes cross the blood-brain barrier in adults, but their potential to enter and participate in the programming of the developing brain has not been explored. To determine if EPS alters exosome signaling from peripheral tissues to the brain, we are using near infrared whole-animal imaging and confocal microscopy of fluorescently-labeled exosomes in brain tissue sections to track the destination(s) and cellular localization of peripheral exosomes. In addition, microRNAs from control and EPS-exposed fetal serum exosomes were quantified by small RNA-Seq. Concurrently, we performed RNA-Seq on mRNA from hypothalamic punches from the same fetuses used for exosomal microRNA analysis and used bioinformatic approaches to determine if predicted microRNA targets were altered in the brain. Robust changes in exosomal microRNA cargo following EPS that corresponded to changes in hypothalamic gene expression were detected, particularly in male fetuses. To determine if EPS-altered peripheral exosomes contribute to neurodevelopmental programming, we collected exosomes from EPS exposed neonates and cross-injected them into control animals. We predict that injection of EPS-related exosomes recapitulates aspects of EPS exposure in control neonatal mice.

Title: Peripubertal stress reprograms the paraventricular nucleus transcriptome and disrupts HPA axis responsiveness only during pregnancy.

Authors: K. E. MORRISON[1], *C. N. EPPERSON[2], T. L. BALE[1];
[1]Dept. of Biomed. Sci., Univ. of Pennsylvania, Philadelphia, PA; [2]Psychiatry, Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: Adverse childhood experiences, including those during the puberty transition, are one of the greatest predictors for affective disorder presentation for women. As the puberty transition is marked by hormonal changes and ensuing reorganization of the brain and periphery, it may represent a window of vulnerability for adversity to result in long-term reprogramming. Periods of hormonal flux in the female lifespan, including pregnancy and postpartum, exacerbate the risk for affective disturbances and promote hypothalamic-pituitary-adrenal (HPA) axis dysregulation, a key feature of affective disorders. However, little is understood as to how stress experienced during the pubertal transition alters ongoing brain maturation and its interaction with the hormonal changes that occur during pregnancy. We hypothesized that stress during peripuberty, a time of dynamic hormonal change, would enact reprogramming that would interact with a later period of hormonal change, pregnancy, to elicit dysregulated HPA axis responsiveness. Female mice were exposed to chronic stress from postnatal days 21-34, and we examined endpoints in adults related to stress pathway regulation. Corticosterone release following acute restraint stress was assessed prior to pregnancy, during pregnancy, and postpartum. Peripubertal stress resulted in a blunted corticosterone response only during pregnancy. This suggests that HPA programming by peripubertal stress intersects with the state of pregnancy to uncover dysregulation. To investigate the mechanisms by which peripubertal stress interacts with

pregnancy to produce this outcome, we examined peripheral and central regulators of the HPA axis. There was no effect of peripubertal stress on peripheral regulators, including relevant gene expression in the pituitary, adrenal, and placenta, during pregnancy. Transcriptomic analysis of the paraventricular nucleus of the hypothalamus (PVN) during pregnancy via RNA-sequencing revealed a long-term reprogramming of gene expression by peripubertal stress, including widespread changes in immediate early gene expression and their target genes, suggesting the involvement of an upstream epigenetic mechanism. Effects of peripubertal stress on histone marks in the PVN during peripuberty and pregnancy were examined. To understand how pregnancy unmasks HPA axis dysregulation, we conducted pharmacological manipulation of allopregnanolone availability within the PVN. Together, these studies confirm that the pubertal transition is a time of susceptibility for stress to enact central reprogramming and HPA axis dysregulation, particularly during later periods of hormonal flux.

Title: Characterization of resting state network topography in newborn infants at high and low risk of developing neurodevelopment disorders

Authors: *J. CIARRUSTA, J. O'MUIRCHEARTAIGH, R. DIMITROVA, I. POTE, L. CORDERO-GRANDE, A. PRICE, E. HUGHES, J. KANGAS, E. PERRY, D. BATALLE, J. HAJNAL, T. ARICHI, D. MURPHY, G. MCALONAN;

Abstract: Family history of psychiatric conditions can be a significant risk factor for developing Neurodevelopmental Disorders (NDD). MRI studies of brain networks from older patients with NDD reveal subtle alterations in ‘resting-state’ networks, however it is unknown whether such abnormalities are already present at birth. We piloted the use of a multiband (MB) excitation sequence to improve temporal resolution and characterization of high frequency activity of fMRI data in neonates. 10 low risk (LR)(43 weeks) and 6 high risk (HR)(44 weeks) were recruited as

part of the EU-AIMS Brain Imaging in Babies project. HR categorization was based on family history of psychiatric conditions (autism, ADHD and maternal MDD). fMRI data were acquired with a Philips 3T Achieva scanner and a multi-slice echo planar Imaging (15min, resolution 2mm) with multiband (MB) excitation (MB factor 9; TR 0.37s). Data pre-processing was performed using FSL. Single subject data sets were denoised following independent component analysis (ICA) to identify motion, MB and physiological artefact components. Data was warped into an age-appropriate template space, and concatenated group ICA was performed with a dimensionality of 25. Group means and differences were then identified using a general linear model (controlling for age) and the dual regression method. Group ICA identified a rich repertoire of resting state networks across subjects, which was consistent with those described in the literature. There was no significant difference between the LR and HR subjects in any of the identified resting state networks (see figure 1). At this time, we did not identify a significant difference in their spatial representation when comparing infants at HR and LR of developing NDD. However this was a small exploratory sample and was not powered to reveal subtle differences between groups in network architecture. Recruitment of a larger cohort is on-going and we hope the rich temporal and spatial information available using this method may promote understanding about the early pathophysiology of neurodevelopmental disorders.

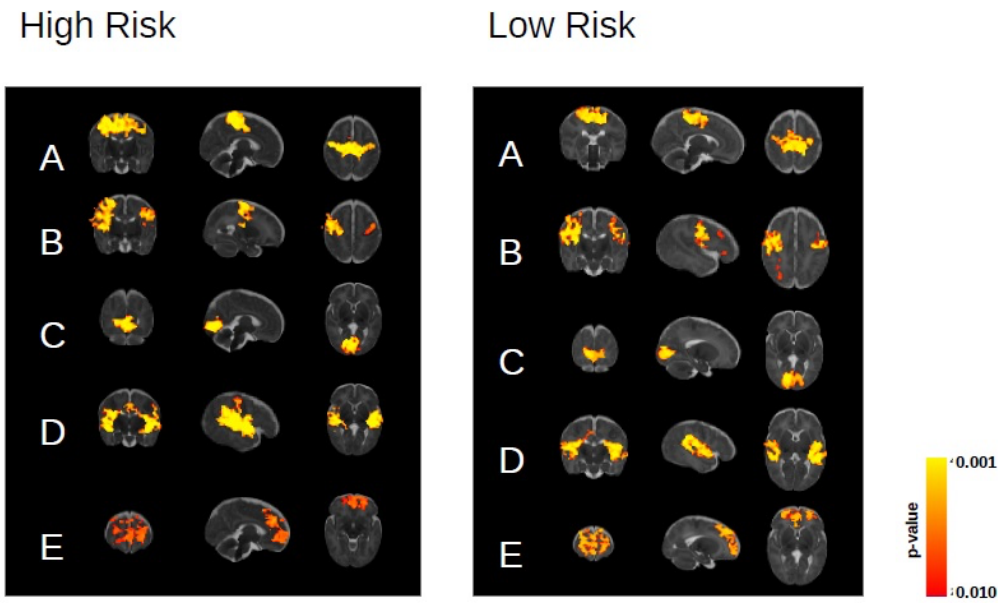

Figure 1. Neonatal Resting State Network
Coronal, sagittal and transverse views of resting state networks overlaid on a neonatal brain template (41 weeks) for low risk and high risk subjects at a threshold of $p<0.01$ (corrected). Representative networks were observed in the somatosensory region (A), motor cortex (B), visual cortex (C), auditory cortex (D) and prefrontal cortex (E).

Title: Chronic stress during adolescence experienced by parents can increase risk for autism spectrum disorder in offspring: a proposed animal model.

Authors: *G. BOERO[1], M. PISU[3], F. BIGGIO[2], M. SERRA[2];
[1]Dept. of Life and Enviromental Science, Section of Neurosci., Univ. of Cagliari, Monserrato, Italy; [2]Univ. of Cagliari, Cagliari, Italy; [3]CNR, Inst. of Neurosci., Cagliari, Italy

Abstract: Adverse life experiences during critical periods for CNS development may cause epigenetic changes that alter hormones pattern and receptors expression that impact brain circuits. These modifications have been associated with increased risk for autism in offspring; for instance, women exposed to childhood abuse experience were more likely to have sons with autism spectrum disorder (ASD) than women unexposed (Roberts et al., 2013). The aim of this research was to characterize a naturalistic animal model of ASD. We tested if the exposure parents to a chronic mild stress during adolescence (social isolation from weaning) could reproduce some ASD symptoms in the subsequent generation. Offspring of socially isolated rats shown a decrease in plasma oxytocin levels, a peptide that plays a crucial role in social behavior that has been shown to be altered in ASD patients. In agreement, in the resident-intruder test these rats spent more time in cage exploration and self-grooming activity rather than in the interaction with the intruder animal. Moreover, offspring of socially isolated parents showed behavioral inflexibility in the Morris water maze test during the probe trial as demonstrated by an increase in the time spent in target zone (i.e. the latency to escape from this quadrant searching platform elsewhere inside the arena). Conversely, learning and spatial memory was not affected; in agreement hippocampal BDNF levels were increased in offspring of socially isolated rats. Furthermore, these animals showed an increase of plasma corticosterone and ACTH levels, suggesting an increase of HPA axis basal activity; nevertheless, this increase was not related to an anxiety-like behavior in the elevated plus maze test. Social deficit, behavioral perseveration, HPA hyperactivity, low oxytocin and high BDNF levels are peculiar characteristics of some established genetic models of autism and ASD patients. Thus, offspring of socially isolated animals meets the attribute of face validity for ASD animal model. The advantage of this model

could be to allow the study of molecular mechanisms underlying ASD, without genetic modifications that could trigger cell adaptation mechanisms and lead to changes in other brain circuits, not involved in pathology. Title: Experimental and clinical findings on the hypothalamus-pituitary-adrenal axis. Stress as a risk factor for neuro-psychopathologies

Authors: *E. H. UMEOKA[1], C. W. BAES[1], L. D. GODOY[2], N. C. B. BARROCA[2], M. S. S. UMEOKA[2], J. ANTUNES-RODRIGUES[2], N. GARCIA-CAIRASCO[2], M. F. JURUENA[1,3,4]; [1]Neurosci. and Behavioral Sci., Ribeirão Preto Sch. of Med. - Univ. of São Paulo, Ribeirao Preto, Brazil; [2]Physiol., Ribeirão Preto Sch. of Med. - Univ. of São Paulo, Ribeirão Preto, Brazil; [3]Inst. of Psychiatry, Psychology and Neurosciences, King's Col. London, London, United Kingdom; [4]Royal Society and Acad. of Med. Sci., London, United Kingdom

Abstract: Here we present our experimental and clinical findings, on the HPA axis function and its association with epilepsy and depression.
It is also known that dysregulation of the HPA axis might lead to stress-sensitive epilepsy. We tested the effects of stress on seizure susceptibility on the Wistar Audiogenic Rats (WAR), a

strain susceptible to sound-induced seizures, which show HPA axis hyperactivity. Adult WARs exposed to 1-hour of stress prior to each sound-induced seizure, in a 20-seizures protocol, expressed significant ($p<0.05$) higher seizure severity and lower latency for tonic seizure than non-stressed WARs. Administration of Gluco-and Mineralocorticoid receptors (GR and MR) antagonists, 0.5 hour before the stress, blocked the effects of stress.
Disturbance in the HPA axis is associated with worse outcomes, treatment-resistance, relapse and cognitive deficits in epileptic as well as depressive (MDD) and bipolar (BD) patients. Experimentally, we assessed early-life stress (ELS) effects on HPA axis function and its association with depressive-like behavior. Wistar rats were stressed from P1 to P21 or kept undisturbed; plasma corticosterone levels were significantly ($p<0.01$) higher in stressed rats than in controls at P3, P14 and P21 indicating no habituation to the protocol. At P90, rats that underwent ELS showed an anhedonic profile identified by a significant ($p<0.05$) decrease in sucrose consumption.
Clinically, patients were diagnosed with BD (n=18) or MDD (n=8) through the International Neuropsychiatric Interview; scores ≥16 in Hamilton Depression Rating Scale were included. When these patients, were submitted to HPA axis challenges with placebo, MR agonist and MR antagonist, administrated at 22:00, their plasma cortisol response, at 09:00 (next day), did not differ from healthy subjects, regardless of patients' ELS history. Post-hoc analyses indicated that BD patients show significant ($p<0.05$) lower cortisol levels than MDD patients after Placebo or MR agonist administration. But cortisol from DB patients was significantly ($p<0.01$) higher after MR antagonist treatment than placebo. In the other hand, cortisol levels of MDD patients were significantly ($p<0.05$) lower after MR agonist treatment than Placebo.
Pre-clinical experiment mimicking these challenges, in a more controlled condition, did not detect effects of ELS on pharmacologically-induced HPA axis response later in life. Furthermore, the cortisol response cannot discriminate patients with or without ELS history but support differential psychiatry diagnose between MDD and BD. Moreover, MR dysregulation plays an important role into Bipolar Depressive physiopathology.

Title: Additive genetic risk for Autism Spectrum Disorder relates to altered functional connectivity

Authors: *K. E. LAWRENCE[1], L. M. HERNANDEZ[1], J. D. RUDIE[1], S. Y. BOOKHEIMER[1], P. LEVITT[2], D. H. GESCHWIND[1], M. DAPRETTO[1];
[1]UCLA, Los Angeles, CA; [2]USC, Los Angeles, CA

Abstract: Autism spectrum disorder (ASD) is a heritable neurodevelopmental disorder that is diagnosed on the basis of impairments in social communication, as well as the presence of repetitive behaviors and restricted interests. Recent findings suggest that the majority of ASD's heritability is explained by the cumulative influence of many common genetic variants, underscoring the importance of studying the impact of such variants on the brain. Prior studies have found that ASD-associated common genetic variants, or single nucleotide polymorphisms (SNPs), relate to decreased long-range connectivity as measured by diffusion tensor imaging and functional magnetic resonance imaging (fMRI) in humans. However, all ASD neuroimaging studies to date have focused on SNPs in single genes despite clear evidence that ASD is related to SNPs across a multitude of genes.

To address this gap in the literature, we investigated how SNPs across multiple genes cumulatively relate to functional connectivity in children and adolescents with and without ASD. Specifically, we created a linearly additive genetic risk score based on subjects' genotypes in a total of seven SNPs across three genes which have been consistently linked to ASD (*CNTNAP2*: rs7794745, rs2710102. *MET*: rs1858830. *OXTR*: rs2254298, rs237887, rs1042778, rs53576). We then related this additive risk score to resting-state functional connectivity as measured by fMRI within two seed-based networks previously found to display atypical connectivity in ASD: the default mode network (DMN) and the salience network (SN). Results were prethresholded in FSL with a mask of within-network connectivity and thresholded at $Z>2.0$, cluster-corrected for multiple comparisons ($p<.05$). The typically-developing (TD) group (n=31) and the ASD group (n=37) did not significantly differ in number of risk alleles, and there was no main effect of diagnosis or risk score on the potential confounds of age, IQ, or mean relative motion.

Within the DMN, higher genetic risk related to decreased connectivity of the medial prefrontal cortex (mPFC) in the ASD group, but increased angular gyrus connectivity in the TD group. Within the SN, greater aggregate risk was related to diminished connectivity of the mPFC in ASD, but greater connectivity of lateral and medial frontal regions in typical development. Our results suggest that common genetic variants associated with ASD additively impact the connectivity of networks related to social cognition (the DMN) and the identification of and response to salient stimuli (the SN). Furthermore, the relationship between genetic risk and connectivity may vary as a function of diagnosis.

Title: Early life stress induced effects on hippocampal neurogenesis and HPA axis are not related to metabolic risk in mature rats; implications in diabetes and depression comorbidity

Authors: R. RUIZ[1], E. PINEDA[1], A. ROQUE[1], *N. LAJUD[2];
[1]Inst. mexicano del Seguro Social, Morelia, Mexico; [2]Inst. Mexicano del Seguro Social, Morelia, Mexico

Abstract: Obesity, depression and aging have all been linked to abnormal functioning of the hypothalamic-pituitary-adrenal (HPA) axis. Furthermore, health problems associated with aging might cause both weight gain and depression or anxiety. Early environmental influences are emerging as contributors to the development of both depression and metabolic disease. In rodents, early-life stress (ELS) decreases hippocampal neurogenesis and causes a deregulation of the HPA axis. Periodic maternal separation (MS) is a rodent model of ELS that affects hippocampal neurogenesis and increases HPA axis activity, this alterations are related depressive like behavior and mild metabolic inbalance in juveniles; however, the interaction between MS and aging induced metabolic alterations has not been studied. Therefore the aim of the study was to test the hypothesis that MS increases age-induced effects on hippocampal neurogenesis and metabolic risk. To test this, Sprague Dawley male rats were subjected to MS during the first two weeks of life (3 hours/day form P1-P14). We evaluated depressive-like behavior in the FST and anxiety-like behavior in the elevated plus maze (EPM) at 10 months of age. Animals were catheterized in the jugular vein and let to recover for one week. We evaluated glucose tolerance and determined the concentration of glucose, triglycerides, cholesterol, CORT and insulin. Rats were intracardialy perfused, brains were dissected and we performed an immunostaining against the immature neurons marker doublecortin (DCX). We estimated the number and density of labeled cells by stereology. MS animals showed a passive coping strategy in the FST without affecting anxiety-like behavior in the EPM. The glucose tolerance test showed that both MS and CONT animals have impaired glucose regulation. We observed no significant differences when comparing other metabolic parameters. However, MS decreased the density (cel No/mm^3) and number of DCX+ cells in the hippocampal neurogenic niche, without causing differences in the volume. In conclusion, our results suggest that metabolic alterations induced by age did not correlate with the effects of MS on hippocampal neurogenesis.

Title: Excess glucocorticoid exposure during early life lead to changes in serotonergic function and increased risk of mood disorder in the adult male

Authors: *M. J. BONESSI, K. C. PAGE;
Biol., Bucknell Univ., Lewisburg, PA

Abstract: It is now widely recognized that exposure to an adverse environment during prenatal development can have lasting effects on an individual's physiology and risk of disease. Maternal stress, and thus exposure to excess glucocorticoid during pregnancy, has been associated with emotional and cognitive deficits in early life. Given their potent actions during development, excess glucocorticoids may represent a common pathway by which poor environmental conditions are signaled from the mother to the fetus triggering persistent changes in the offspring's growth and organ function. Our study was designed to examine the impact of prenatal exposure to a clinical antenatal steroid, Dexamethasone (Dex), and its effects on behavior and cortical expression of key pre- and postsynaptic proteins of adult male rats. Pregnant rat dams were injected once daily with Dex (sc 150ug/kg/day) from gestation-day 14 through 19. Control dams were injected with vehicle. At 120 days, the adult male offspring were tested using the elevated-plus maze (EPM) and the light-dark box to evaluate anxiety-like behavior in both control and Dex-exposed animals. At 150 days, the frontal cortex was rapidly dissected and frozen using liquid nitrogen. Real-time PCR was used to measure the relative levels of mRNA expression for serotonin receptors 5HT1A, 5HT1B, and 5HT2A as well as for key presynaptic proteins involved in vesicle release, synaptotagmin and SNAP-25. Using the EPM, a significant difference was detected between the control and Dex-exposed adult males in the ratio of open arm entries to total arm entries ($p= 0.031$). A significant difference was also observed between the control and Dex- exposed males when the amount of time spent in the open arms was compared to total time on the apparatus ($p= 0.018$). The light-dark box test, which also measures anxiety-like behavior, revealed that Dex-treated animals were more likely to cross to the dark side ($p=0.05$). Moreover, a significant increase in cortical mRNA expression was detected for the serotonin receptors 5HT1A ($p \leq 0.05$) and 5HT2A ($p < 0.05$). The mRNA levels for the 5HT1B receptor, synaptotagmin and SNAP -25 were not significantly changed in the cortex of the Dex-exposed adult males compared to controls. These data support the claim that epigenetic changes during early development lead to genetic programming effects that

persist throughout life. More specifically, prenatal exposure to glucocorticoid during critical periods of brain development disturbs serotonergic function and increases the risk for mood disorders in adult male offspring.

Title: Is acute or chronic juvenile stress a risk factor for PTSD in adulthood?

Authors: *L. CHABY[1], I. LIBERZON[2];
[1]Psychiatry, Liberzon Lab., [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Many factors are suggested to contribute to resilience and susceptibility to post-traumatic stress disorder (PTSD), a chronic, debilitating disorder that can develop after exposure to a traumatic event. Exposure to trauma in childhood has been identified as a key risk factor for PTSD, but animal studies suggest that exposure to stress during the juvenile life stage can both increase stress responsivity and enhance functioning under future stress. We tested the hypothesis that adult rats exposed to chronic stress during juvenile development exhibit exacerbated responses to an animal model of PTSD, single prolonged stress, compared to adult rats reared without stress. We evaluated the lasting effects of both acute and chronic stress in juvenile development on PTSD specific end-points. We report that juvenile stress exposure affects aspects of fear learning and memory, and discuss effects of juvenile stress on morphological traits.

Title: Neural correlates of sensory hyporesponsiveness in toddlers at high risk for autism spectrum disorder

Authors: *D. M. SIMON[1], C. R. DAMIANO[2], T. G. WOYNAROSKI[1], L. V. IBANEZ[3], M. MURIAS[2], W. L. STONE[3], M. T. WALLACE[1], C. J. CASCIO[1];

Abstract: Altered patterns of sensory responsiveness are frequently reported in individuals with autism spectrum disorder (ASD), and are hypothesized to contribute to the development of higher order social and behavioral deficits. Younger siblings of individuals with ASD are at a greatly elevated risk of future diagnosis, and patterns of reduced sensory responsiveness have been shown to emerge early in their development. Previous research has not characterized how patterns of neural activity in these high risk children relate to profiles of sensory responsiveness. Using high density electroencephalography (EEG) we investigated the neural correlates of parent reported sensory responsiveness in 18 month old siblings of individuals with ASD. We found that sensory hyporesponsiveness was associated with relatively increased left frontal alpha power and absolute increased left frontal theta power. Functional connectivity was increased to right frontal regions, decreased to left frontal regions, and broadly elevated in temporal and occipital regions in participants with high levels of hyporesponsiveness. Complementary measures of EEG signal complexity indicated hyporesponsiveness was associated with less complex neural signals. Multiple measures of neural activity thus corresponded with sensory hyporesponsiveness

in toddlers at high risk for ASD. We conclude that concurrent measurement of neural signal features holds promise for early identification of profiles of sensory responsiveness in young children at risk for ASD and improved targeting of interventions.

Title: Sphingosine 1 phosphate 3 receptors in the medial prefrontal cortex promote resilience to social defeat

Authors: ***B. CORBETT**[1], N. SOTUYO[2], J. PEARSON-LEARY[2], S. LUZ[2], S. BHATNAGAR[2];
[1]Abramson Res. Ctr., [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Repeated exposure to stress promotes depressive- and anxiety-like behaviors in animals and the development of psychiatric disorders in humans, including depression and posttraumatic stress disorder. However, not all stressed individuals go on to develop psychiatric disorders. That is, some individuals are resilient to the effects of stress and others are vulnerable to its effects. In a paradigm of chronic social defeat in rats, we have identified subpopulations that are resilient or vulnerable to the neuroendocrine, prodepressive, and anxiogenic effects of defeat. Rats that exhibit a short defeat latency (SL) following placement in the cage of an aggressive resident rat are vulnerable to the effects of stress whereas rats that exhibit longer defeat latencies (LL) are resilient to the effects of stress. SL rats display increased depressive-like and anxiety-like behaviors compared to LL rats. However, the mechanisms underlying stress resilience and vulnerability remain unclear. We used a targeted PCR array approach to identify novel neural substrates underlying resilience and vulnerability. We found that the expression of sphingosine-1-phosphate receptor 3 (S1PR3) was increased in the medial prefrontal cortex (mPFC) of LL rats. S1PR3 is a G-protein-coupled receptor (GPCR) that reduces inflammation and, as an S1PR, has the ability to reduce neuronal activity through G_i coupling and activation of G-protein-coupled inwardly rectifying potassium channels. The mPFC regulates the stress response and affective-like behaviors, is highly susceptible to stress, and is dysfunctional in

stress-related affective disorders. We used a viral vector to overexpress S1PR3 in the mPFC of rats and found that S1PR3 overexpression increased defeat latency and decreased depressive-like and anxiety-like behavior compared to controls. Conversely, virally mediated S1PR3 knockdown decreased defeat latency and increased depressive-like behavior. Similar to LL rats, rats overexpressing S1PR3 in the mPFC displayed facilitated adrenocorticotropic hormone (ACTH) production during restraint compared to controls. S1PR3 knockdown rats displayed attenuated ACTH production during restraint compared to controls. Preliminary results indicate that pharmacological activation or overexpression of S1PR3 in the mPFC decreased neuronal activity and inflammation markers. We propose that S1PR3s in the mPFC promote resilience to stress by altering activity in the mPFC and within its extended network and/or by decreasing inflammation. We conclude that the S1PR3 is a novel receptor that promotes behaviors and neuroendocrine responses characteristic of resilient individuals.

Title: Early life sleep restriction induces behavioral and cognitive impairments in Sprauge Dawely rats

Authors: *F. ATROOZ[1], H. LIU[2], S. SALIM[2];
[1]Pharmacol. and Pharmaceut. Sci., [2]Pharmacol. and Pharmaceut. sciences, Univ. of Houston, Houston, TX

Abstract: Adequate sleep during early life is considered essential for normal brain function. In fact, sleep loss or sleep disturbances in children are associated with development of later life mood disorders. Thus, while negative effects of early life sleep deprivation are well known, information regarding repeated sleep restriction (RSR) during early life (childhood and adolescence) on behavioral and cognitive function is limited. Also, information regarding mechanisms by which RSR during early life causes behavioral and cognitive impairments are also not fully understood. In this study, two groups of Sprague Dawley rats (12 per group) were utilized, control group and RSR group. Rats, at postnatal day (PND) 18 were subjected to RSR

for 14 days (6 hours/day) using Pinnacle automated sleep deprivation system. This apparatus is a cylindrical cage with rotating arms that gently disturb the rats constantly interrupting their sleep. Behavioral tests (anxiety-like behavior, depression-like behavior) and cognitive tests (short-term and long-term learning memory function) were performed at PND 32, 60 and 90. Our results show that rats in the RSR group exhibited anxiety like behavior at PND 32 and 60 but not at PND 90 time point, as compared to the control group. Interestingly, RSR rats did not exhibit depression-like behavior at PND 30 or 60 but developed depression-like behavior at PND 90, as indicated by increased immobility time in forced swim test compared to control group. Furthermore, rats in the RSR group showed learning impairment at PND 60 as revealed by radial arm water maze test. On the other hand, RSR rats showed no impairment in short or long term memory at any time point. In conclusion, early life repeated sleep restriction promotes anxiety-like behavior early in life (PND 30 and 60) which in later life transforms into depression-like behavior (PND 90). Cognitive impairment also was evident at PND 60 suggesting later onset of cognitive dysfunction in Sprague-Dawley rats.

Title: A face only a mother could love: intergenerational trauma exposure reduces male attractiveness to potential mates.

Authors: *S. ALTMANN, J. M. KAN, R. RICHARDSON;
Psychology, The Univ. of New South Wales, Unsw Sydney, Australia

Abstract: The fact that some members of our species are more attractive to the opposite sex than others is well known. However, other than the obvious candidates such as genetics, the factors that determine “attractiveness” remain elusive. The current research used a rodent model to examine this generally understudied, but clinically relevant question, and assessed whether exposure to trauma, either within one’s one life, or intergenerationally, can impact male attractiveness in adulthood. To assess this question male rats were either exposed to Maternal

Separation (MS), a well-validated early life stressor during infancy, or were born to mothers who had experienced MS with their previous litter. Control females were then tested in a mate preference task, wherein she was given 4 trials in which she could choose between two adult males contained within small wire cages, either a control male and a directly-stressed male, or a control male and a male born to a previously stressed mother. The results showed that while females do not discriminate between control males and directly-stressed males, they do discriminate between control males and males born to a previously stressed mother, spending significantly less time across trials in the side of the test arena containing the male born to a previously-stressed mother, and investigating the wire cage in which that male was held significantly less. These results show that an individual's intergenerational exposure to stress may be even more important than their own history of trauma in determining social outcomes such as the ability to attract a mate.

Title: Paternal line transgenerational effects of early experiences.

Authors: *E. L. KINNALLY, S. J. MARTINEZ, J. P. CAPITANIO;
Psychology, UC Davis, Davis, CA

Abstract: It has recently become clear that the effects of early life experiences may not be limited to the exposed generation, but can sometimes influence mental and physical health in the next generation. The mechanisms of transmission are often social in nature, but recent evidence suggests that germ line mechanisms may play a role. We compared the transgenerational effects

of maternal and paternal line early life nursery rearing (NR) on anxiety and health-related traits in two generations of rhesus macaques, including infants that did not have social access to parents because they were cross-fostered to new mothers and social groups. Offspring and grand-offspring (N=340) of NR and CONTROL reared individuals were observed for temperamental nervousness, immune cell counts, and plasma cortisol response to challenge. Paternal NR was associated with greater nervousness and lower immune cell counts in male and female infants ($F(3, 316) = 3.906$, $p = .009$, partial eta2 = .036). This effect persisted into the third generation through the paternal line ($F(3, 316) = 6.298$, $p < .001$, partial eta2 = .056). Maternal-line NR effects were not observed. Germ line mechanisms may be involved, as paternal NR effects were observed in the absence of social contact between parents and cross-fostered offspring. This study suggests that stress-related traits may be "inherited" across generations in primates, and points to non-social mechanisms of inheritance.

Title: Iterative somatic transmission of emotional behavioral abnormalities across generations

Authors: *R. J. CHEN[1], E. MITCHELL[2], S. L. KLEIN[2], J. GAL TOTH[2], P. BERGIN[2], M. TOTH[2];
[1]Neurosci. Grad. Program, Weill Cornell Grad. Sch. of Med. Sci., New York, NY; [2]Dept. of Pharmacol., Weill Cornell Med. Col., New York, NY

Abstract: Though inheritance has traditionally been associated with the Mendelian transmission of genetic information from parents to offspring in allele-dependent manners, it has been shown that progeny can inherit parental behavioral traits through non-genetic mechanisms. While gametic transmission is accepted as a non-Mendelian means of multigenerational inheritance, we show that there is a somatic maternal mechanism for propagation of behavioral abnormalities that is maintained by an iterative process across generations. Studies show that infection and chronic low-grade inflammation during pregnancy increase the risk of psychiatric disorders in

the offspring. Maternal immune dysregulation may be transmitted to the fetus through the placenta past the blood brain barrier, and we present evidence suggesting the maintenance of a multigenerational transmission of abnormal emotional behaviors through a maternal immunological mechanism arising from a deficit in serotonin 1A receptor (5HT1AR). Specifically, our 5HT1AR heterozygote and null mice show increased innate anxiety and reduced motivation, and we show that these behavioral traits are passed up to the F3 offspring iteratively, one generation at a time, through non-gametic means. 5HT1AR is expressed on hematopoietic cells, and so we assessed the immune profiles of multiple generations of offspring and show alterations in their immune profiles. Right after birth, 5HT1AR-deficient mice and their F1 and F2 offspring all exhibit neutrophilia and monocytosis. Furthermore, this peripheral inflammation is accompanied by neutrophil/monocyte transmigration into brain parenchyma, suggesting brain immune activation. We believe brain and peripheral inflammation together explain the behavioral phenotype and accompanying neuronal epigenetic changes observed in adulthood. Also consistent with early life immune activation is the later developing autoimmune-like phenotype, characterized by increased total IgG level, anemia, lymphyocytopenia, and thrombocytopenia. Since maternal autoimmunity increases the risk for offspring immune activation and psychopathology, such mechanisms may explain the iterative nature of mother-to-offspring behavioral transmission. These results suggest that 5HT1AR may play an integral role in immune homeostasis, and that lower than normal 5HT1AR levels seen in a population of anxiety and depression patients may contribute to the psychopathology via low-grade sterile inflammations. Furthermore, our work here shows that multigenerational transmission is not limited to gametic mechanisms, but can occur iteratively through a somatic mechanism.

Title: Paraquat exposure *In utero* alters gene expression patterns in neonate c57bl6 pup microglia and astrocytes post exposure

Authors: *C. WALDEN, S. PANDEY, P. W. HALCROW, D. GUO, A. M. FLODEN, J. E. OHM;
Univ. of North Dakota, Grand Forks, ND

Abstract: Neural disease is a prevalent upcoming concern with the age of onset fast approaching in the population of the United States. The etiology of many neural diseases is unclear and may have links to environmental influences. Epidemiological studies indicate a higher risk for brain cancers for children of pesticide exposed parents and increased risk of neurodegenerative disease in adults residing in high exposure regions. Similar to the Barker Hypothesis we propose that early stress events lead to lasting epigenetic changes that predispose an individual to later onset of disease. To evaluate the impact of stressors in early development we utilized an in utero exposure model of c57bl6 mice exposed to the herbicide paraquat, or control saline, for six weeks over the gestational period. Paraquat is a model toxicant in the study of parkinsonian like symptoms in c57bl6 mice and is known to produce reactive oxygen species through inhibition of mitochondrial function. Adult mice were evaluated for impact of paraquat with histological staining of glial fibrillary acidic protein (GFAP) to measure reactive gliosis. Adult mice treated with paraquat exhibit marked increases in the levels of GFAP compared to controls indicating a reactive response to paraquat treatment. Neonatal pups were collected and astrocytes and microglia were cultured for two weeks removed from paraquat exposure, at which point RNA and DNA were collected from each respective population. RNA sequencing determined a limited number of genes that generally increase in gene expression. Ontological analysis indicate cell to cell interactions as well as developmental processes in these cells are largely impacted. The results of this study indicate that the exposure of mothers to paraquat provides an altered in utero environment changing gene expression in a persistent manner in the offspring. These changes may result in long term ramifications in the function and onset of disease in the central nervous system.

Title: Revealing of hormetic dose of ethanol for white rats

Authors: *L. GOBECHIA-DAVLIANIDZE;
I.Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia

Abstract: Hormesis is a known biological phenomenon by which the body reaches a biologically positive results after the action of stress factors of different nature. It is known that receiving low doses of ethanol in human being is associated with positive events - reduced risk of cardiovascular disease, slowing the aging process and others. The aim of our study was to identify hormetic dose of ethanol for pregnant rats and after that to conduct research on their offsprings - whether or not they manifest any improvement or disorders in the processes of learning and memory (compared with the control animals). In the first series of experiments, testing of intact females held in the multi-way maze. The number of committed errors and time spent on the passage of the maze were registered. Within a 7-day testing sessions all animals reached an automatism in maze passage). Thereafter, the female rat together with male for 5 days was placed in the box. Then on already pregnant rat, we try to reveal the hormetic dose of ethanol - 21 days the rats injected (i/p) with different doses of ethanol (95% alcohol in doses ranging from 0.01 to 0.1 ml /100g). Each doses were tested on 5 rats. In all cases (the ethanol was diluted in 1 ml of the distillate). Performing of maze test was checked in 30 minutes after the administration of ethanol. The most pronounced behavioral manifestation of hormetic effect (acceleration of motility) was revealed at a dose of 0.025 mg / 100g. Administration of 1 ml saline (control animals) caused no change in performing of maze test. Thus it can be said that the hormetic effect of ethanol on rats may be observed at a dose of 0.025 mg / 100g. In the next series of experiments we want to clarify if administration of hormetic dose of ethanol during the pregnancy will cause any physiological (including learning and memory processes and/or morphological changes in offsprings. **Acknowledgement:** The study was supported by the Shota Rustaveli National Science Foundation.

Title: Activation of proto-oncogene c-fos in non-auditory structures of the rats´ brain under stimulation with environmental noise

Authors: D. FERNANDEZ-QUEZADA[1], D. MORAN-TORRES[1], S. LUQUIN[1], J. GARCÍA-ESTRADA[2], Y. RUVALCABA-DELGADILLO[1], *J. H. FERNANDO[1];
[1]Univ. de Guadalajara, Guadalajara, Mexico; [2]Ctr. de Investigación Biomédica de Occidente, Guadalajara, Mexico

Abstract: Backgroung: Noise is an inarticulate auditive stimulus that often becomes annoying. Pollution by environmental noise has increased in parallel with development of human activities (airway, railway, roads and the traffic). In general, the effects of noise on central nervous system may be classified as auditory and non-auditory. Most of the non auditory effects involve the stress HHA regulatory system. Then, it is expected that central structures mediating stress responses could change its activity patterns under noise exposure. Objective: In this experiment, we exposed adult male rats to a noisy environment and immunohistochemically evaluated c-fos changes over the main central structures mediatin stress response. **Material and methods:** 25 male wistar rats were subjected to a rats´ audiogram-fitted adaptation of a noisy environment and sacrificed at different time points as follows: 0 (n=5), 2h (n=5), 6h (n=5), 12h (n=5) and 24h (n=5). Immunohistochemistry against c-fos was performed on 70µm slices belonging to the entire brain. **Results:** We found differential patterns of c-fos expression depending on region analyzed and time of exposure. Then, our results support the idea that noise exposure produce stress-like effects by activating some non-auditory structures involved in stress regulation.

Title: Post traumatic stress disorder is not associated with increased sympathetic activity in US veterans

Authors: *Y. HABER[1,2,4], K. MIGDAL[4], K. BREWER[4], J. SERRADOR[3,4], H. CHANDLER[4]; [1]Newark, NJ; [3]Physiol. and Neurosci., [2]Rutgers Univ., Newark, NJ; [4]War Related Illness and Injury Study Ctr., East Orange, NJ

Abstract: Posttraumatic stress disorder (PTSD) is defined as an anxiety disorder provoked by an event that evokes extreme fear, helplessness, or horror such as an accident, physical or emotional abuse or combat. The Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) identifies three clusters of symptoms that comprise PTSD: intrusive thoughts and re-experiencing of the trauma in dreams and nightmares, avoidance of circumstances of the trauma and a persistent hyperarousal state often including hypervigilance and an exaggerated startle response. It has been assumed that due to hyperarousal contributes to increased sympathetic activity in patients with PTSD. This makes logical sense since sympathetic activity is associated with a fight or flight response. However there is little data that has directly examined sympathetic activity in this population. The goal of this work was to determine if peripheral sympathetic activity was elevated in a group of Veterans with and without PTSD. Thirty Four US Veterans that were participating in studies to examine their autonomic function were classified as having PTSD by a score of 37 or greater on the PCL. Based on this 20 of the 34 would be classified as having PTSD. Non-invasive measures of sympathetic activity were obtained from beat by beat heart rate and blood pressure variance as well as heart rate and blood pressure. There was no difference in resting heart rate (Ctrl: 72.0±11.2 vs PTSD: 70.2±9.7 bpm) or mean arterial blood pressure (Ctrl: 95.4±12.8 vs PTSD: 93.7±10.6 mmHg). Examining heart rate variance there was no difference in low frequency normalized power, indicative of cardiac sympathetic activity (Ctrl: 51.4±25.4 vs PTSD: 56.2±24.0%). Similarly there was no difference in low frequency blood pressure power, indicative of peripheral vascular sympathetic activity (Ctrl: 61.9±33.6 vs PTSD: 54.4±34.9 $mmHg^2$). Performing linear regressions there were no significant correlation between PCL score and any of the parameters. These data suggest that Veterans with PTSD may not demonstrate increased sympathetic activity. However, this was done on a small group of Veterans so confirming in a larger group would be essential. We also plan to look at whether Veterans who specifically demonstrate symptoms of hyperarousal tend to have increased sympathetic activity compared to those with avoidance characteristics. This work was supported by the War Related Illness and Injury Study Center within the Department of Veteran Affairs.

Title: Autonomous Driving - measuring cognitive load via functional near infrared spectroscopy (fNIRS) for complex simulated and in-situ driving scenarios

Authors: *S. BALTERS[1], S. SIBI[2], J. WENDY[2], M. STEINERT[1];
[1]Engin. Design and Materials, Norwegian Univ. of Sci. and Technol., Trondheim, Norway; [2]Ctr. for Design Res., Stanford Univ., Palo Alto, CA

Abstract: Grounded and guided by the fundamentals in affective neuroscience and framed by the human-computer interaction (HCI) paradigm of affective computing, we call for the emergence of affective engineering as a key contributor to future product and system design and development. In an engineering context, we aim to quantitatively measure situational variables that allow us to control for (emotional) behavior responses; that is, we seek to use physiology sensors to "read" the human in critical human-machine interaction scenarios. With the particular focus on (simulated) autonomous driving scenarios, the Center for Design Research at Stanford University and the Department of Engineering Design and Materials at the Norwegian University of Science and Technology aim to address this challenge in a series of joint experiments. As the number of automation features in a car rises, the potential need for the driver to rapidly assess and resume control of the car increases. Simultaneously, the possibility for the driver to pursue secondary activities also emerges. Thus, in order to safely transfer control to the driver, it is vital to incorporate the driver's attentional, physiological, and mental state - one potential way is by using physiology sensors. In a first experiment, we use functional near infrared spectroscopy (fNIRS) in order to measure cognitive load during simulated autonomous driving including simple lane change maneuvers. The main arising challenge is to select/develop a suitable mathematical model for measuring cognitive load for in situ "chaotic" and "noisy" driving scenarios. Since the experimental task differs tremendously from clean laboratory experiments with highly isolated and controlled tasks (such as finger tapping or n-back task), applying proposed cognitive load algorithms that assume a constant response at trigger onset, such as statistical parametric mapping (SPM), are questionable. The ultimate aim is to build the scientific foundation for in situ cognitive load measures in order to design and engineer safe driving in the future.

Title: Effects of intraperitoneal injections of thc on bold signal using functional magnetic resonance imaging in awake rats

Authors: *D. MADULARU[1], P. KULKARNI[2], C. F. FERRIS[2];
[1]Psychiatry, McGill Univ., Verdun, QC, Canada; [2]Psychology, Northeastern Univ., Boston, MA

Abstract: Cannabis is one of the most frequently used illicit drugs worldwide, and has been banned in the United States and Canada since the early 1900s. A recent United Nations report places cannabis at the top of the 2010 illicit drug use list, at an estimated prevalence of 2-5% (120-220 million users), followed by opioids (0.8%), opiates (0.5%) and cocaine (0.4%). Although it has been suggested that the marijuana plant includes over 400 chemical entities of which 60 are cannabinoids, the most studied are Δ-9-tetrahydrocannabinol (Δ^9-THC), cannabidiol (CBD) and cannabinol (CBN); Δ9-THC has been identified to be the main psychoactive agent in cannabis. In addition to the recreational use, cannabis has been widely used to address a series medical conditions, through its anti-emetic, analgesic and appetite-modulating effects.
The purpose of the present study is to assess the effects of three doses (0.1, 1 and 10 mg/kg) of THC on brain activation using fMRI in awake rats. Although more than 170 regions of interest have been assessed, emphasis has been placed on areas rich in CB1 receptors, such as the hippocampus, hypothalamus and prefrontal formations. Overall, the low dose shows increased BOLD activation in a number of areas (ventral and dorsal striatum, basal amygdala, ventral CA1 and ventral pallidum) compared to vehicle. Interestingly, the BOLD activation in response to the low dose was also increased compared to the medium and high doses, although in some regions it follows a U-shaped pattern (i.e. temporal cortex).
These findings offer insight into brain networks activated by THC, providing the first evidence of brain-wide “fingerprinting” of BOLD activity in response to different doses of THC. The results are discussed in the context of pain networks and beyond.

Title: Hemodynamic alteration of cerebral cortex of mouse after chronic cranial window surgery

Authors: *H. PARK[1,2], C. HEO[1], N. YU[2], M. SUH[1,2,3];
[1]Ctr. for Neurosci. Imaging Res. (CNIR), Inst. For Basic Sci. (IBS), Suwon-City, Korea, Republic of; [2]Dept. of Biol. Sci., [3]Dept. of Biomed. Engin., Sungkyunkwan Univ., Suwon-City, Korea, Republic of

Abstract: In brain imaging study, cranial window surgical processes are necessary to get an access to the animal's brain. The invasive surgical procedures would evoke neuroinflammatory mechanism. In particular, drilling and opening skull bone can induce mild traumatic brain injury. Our understanding of how invasive cranial window surgery affects neuronal and hemodynamic responses is very limited. Using cranial window with the soft, flexible, transparent, and biocompatible silicone-based polydimethylsiloxane (PDMS) (Heo et al, 2016, submitted), we investigated the effect of cranial window surgergical procedure on cerebral hemodynamics and its' timecourse. C57bl/6 mice were utilized. Following 2 hours, 14 days, 28days, 32days of surgery, we recorded cerebral blood volume (CBV) changes by whisker stimulation (C2 area) with the intrinsic signal optical imaging. Also we measured cerebral blood flow (CBF) with Laser Doppler Flowmetry. We found that the animals immediately after 2 hours of cranial window surgery have smaller CBV changes than the animals 14days, 28days, 32days post cranial window surgery. The maximum CBV changes was the largest in animals 32days post cranial window surgery. In immunohistochemical studies, we found that the expression level of GFAP of astrocyte and microglial activation is different among the animals of each group. Our study suggests that the cranial window surgical procedure can significantly affect the integrity of neuronal network even though no apparent cellular damages were found. In order to get normal brain hemodynamics, we need to wait at least 28 days post cranial window surgery.

Title: Rapid changes in spontaneous neural activity are associated with hemodynamic fluctuations during different cortical states

Authors: M. BRUYNS-HAYLETT[1], R. SLACK[2], P. PATEL[2], B. GOUDE[2], S. HARRIS[2], L. BOORMAN[2], J. BERWICK[2], *M. JONES[2];
[1]Univ. of Reading, Reading, United Kingdom; [2]Univ. Sheffield, Sheffield, United Kingdom

Abstract: Spontaneous fluctuations in Blood Oxygen Level Dependent (BOLD) functional Magnetic Resonance Imaging (MRI) signals are used to infer functional connectivity. However, the implicit assumption that spontaneous fluctuations in blood oxygenation are related to the underlying spontaneous activity has only been investigated in a small number of studies. For instance, we previously made concurrent 2-dimensional optical imaging spectroscopy (2D-OIS) measurements of spontaneous cortical hemodynamics and multi-laminar electrophysiological measurements of spontaneous cortical activity in urethane anaesthetised rodents (Bruyns-Haylett et al., 2013). We demonstrated that rapid changes in spontaneous activity were associated with hemodynamics that were similar to those elicited by sensory stimuli thus suggesting an association between spontaneous activity and hemodynamic fluctuations. However, it is well known that rodents anaesthetised with urethane move between different states of anaesthetic depth (e.g. Friedberg et al., 1999) which are commensurate with states of quiescence and arousal in awake behaving animals (e.g. Castro Alamancos 2004). Previous studies have suggested that stimulus evoked neurovascular responses may differ in these different states (Jones et al., 2008) but as Bruyns-Haylett et al., (2013) neglected to classify data into these states, whether 'spontaneous' neurovascular responses are preserved during different cortical states is uncertain. Thus information that could aid the interpretation of resting state data in different states of wakefulness was lost. Fortuitously, a recent analysis methodology developed in our laboratory (Slack et al., 2016) allows such data to be sorted into 2 different 'anaesthetics depths' or 'cortical states' based on ongoing fluctuations in LFP. As such, the current investigation takes similar concurrent measurements of cortical hemodynamics and ongoing activity as Bruyns-Haylett et al., (2013) but classifies data into different cortical states before investigating the relationship between rapid spontaneous activity and the accompanying hemodynamics. As previously reported, we find that changes in cortical state themselves are accompanied by slow increases or decreases in total haemoglobin concentration and blood oxygen saturation (Jones et al., 2008, Slack et al., 2016). In both cortical states rapid increases in spontaneous activity are

accompanied by hemodynamics resembling those elicited by sensory stimuli suggesting that spontaneous activity elicits hemodynmic changes despite differences in wakefulness.

Title: Sex differences in inter-hemispheric connectivity during global-local processing

Authors: ***T. HARRIS**, B. PLETZER;
Psychology, Univ. Salzburg, Salzburg, Austria

Abstract: Global-local processing is traditionally studied with hierarchical stimuli, e.g. a large global letter made up of small local letters (Navon paradigm). Participants are asked to identify targets either at any level (divided attention condition) or at a pre-specified level (selected attention condition). Performance is characterized by faster responses to global than to local targets (global advantage effect). Previous studies demonstrated a right-lateralization for global and left-lateralization for local targets. It is presumed that lateralization of brain functions are related to the inhibitory influence of a dominant on the non-dominant hemisphere. However, inter-hemispheric connectivity (IC) has previously not been investigated for global-local processing. Furthermore, we were previously able to demonstrate sex differences in the global advantage effect (stronger global advantage in men during selected attention) and the lateralization of BOLD-response to global and local level (stronger lateralization in women). Whether these differences result from sex differences in IC has not been investigated. 86 men and 41 naturally cycling women in their luteal phase completed a Navon paradigm, modulating attention condition (divided vs. selected) during functional MRI. Most prominent activations to both global and local level were observed bilaterally in the occipital lobe with stronger left lateralization for local and stronger right lateralization for global targets. The individual subject maxima were selected as ROIs for psycho-physiologic interaction (PPI) analyses with ROIs for analyses of global targets in the right-hemisphere and ROIs for analysis of local targets in the left hemisphere. In the divided attention condition, the results demonstrate negative IC of the right occipital lobe to the left occipital lobe for global targets. For local targets, a negative intra-

hemispheric connectivity from occipital to parietal areas was observed within the left hemisphere. These results were not modulated by sex. For the selected attention condition, however, negative IC from right to left occipital areas was only confirmed in men. Women, on the other hand, showed stronger intra-hemispheric connectivity with more anterior areas. For the first time, the global advantage effect during global-local processing and right-lateralization for global targets is demonstrated and may arise from the inhibitory influence of the right on the left hemisphere. Furthermore, sex differences in the global advantage effect and lateralization patterns during global-local processing may arise from sex differences in these IC patterns.

Title: Effect of temperature on FAD and NADH-derived signals and neurometabolic coupling in brain slices

Authors: *B. A. IBRAHIM[1,2], H. WANG[1,2], B. BUCCI[1,2], K. PAUL[1,2], D. A. LLANO[1,2]; [1]Beckman Inst., Urbana, IL; [2]Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Therapeutic hypothermia has long been used as a method to protect the brain from ischemic insults, though the impact of temperature on brain metabolism and neurometabolic coupling is not well understood. Therefore, we examined the effect of temperature on brain metabolism using FAD and NADH auto-fluorescence metabolic signals and electrical field potentials from brain slices prepared from adult mice. We found that basal FAD signals are inversely proportional to temperature while basal NADH signals had a biphasic profile such that the signals decreased with increasing temperature from 13^{o}C to 21^{o}C (Phase I) then increased with increasing the temperature above 25^{o}C (Phase II). Different brain regions showed the same profile for FAD and NADH signals, but the hippocampus had the highest signal intensities for

both. Calculated redox ratio followed the FAD profile suggesting that the redox ratio changes with temperature are likely driven by FAD signals. In auditory thalamocortical slices, electrical stimulation of the subcortical white matter produced a biphasic profile with temperature; the magnitude of both FAD and NADH deviations from baseline were largest around 21-25^{o}C, and diminished at higher and lower temperatures. Additionally, SR95531 (gabazine) was used to elicit spontaneous paroxysmal events, and the link between field potentials and metabolic fluorescence signals was compared at different temperatures. Similar to the evoked responses, the magnitude of the spontaneous FAD and NADH signals adopted a biphasic profile with the temperature. Extracellular recording of spontaneous activity showed that local field potential signal amplitude was strongly coupled to FAD and NADH signal amplitude at temperatures from 13-25^{o}C, but deviations were seen at higher temperatures, such that field potential amplitude was retained to higher temperatures than the fluorescent metabolic signals. These results indicate the strong impact of temperature on brain metabolism which in turn affects neuronal activity and that neurometabolic coupling may show temperature dependence, which has potential implications for therapeutic modulation of brain temperature. In addition, the similarity between temperature-induced biphasic profile of NADH baseline and the metabolic signals coupled with evoked synaptic activity could possibly indicate that glycolysis and the TCA cycle are the most temperature affected metabolic processes.

Title: Characterization of the hemodynamic response function across human cerebral cortex

Authors: *J. KIM, A. TAYLOR, D. RESS;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: In functional magnetic resonance imaging (fMRI) experiments, use is made of the hemodynamic response function (HRF), the stereotypical vascular response evoked by brief (<4 s) neural activation. Use of the HRF to evaluate neurovascular function as a clinical tool is appealing, but there are two main challenges to such clinical applications. First, we need a method to evoke the HRF broadly across the brain, and measure the response specifically in parenchymal gray matter. Second, clinical use of the HRF will require a better understanding of its variability across brain regions and subjects. Here, we present a simple stimulus paradigm to evoke the HRF across the majority of cerebral cortex. The results provide guidance for linear analysis of fMRI data, and more importantly, create a potentially highly attractive clinical tool. **Methods**: A 2-s duration audiovisual stimulus was combined with a fast-paced task to evoke the HRF, and this was repeated ~85 times per session in 8 subjects with a 30-s inter-stimulus interval. FMRI (SMS excitation, 1.5-s/volume) with high spatial resolution (2-mm voxels) was used to focus measurements specifically on the gray matter. Our computational model was used to predict underlying CBF and $CMRO_2$ responses. **Results**: Mean amplitudes of the positive HRFs varied substantially across the cortical surface (Fig A), and from subject-to-subject. ~75% of cortex responded with significant HRFs. ~78% of active cortex exhibited positive HRFs (solid curves); the remainder showed inverted HRFs (dashed curves). However, after a parcellation and normalization procedure, the spatial pattern of the HRF amplitudes was found to be remarkably similar across subjects. The time-to-peak of the initial positive lobe of the HRF showed less subject-to-subject variability, and was relatively stable across the cortical surface (Fig B). **Conclusion**: This method provides a means to quantify neurovascular function across the majority of the brain, with great potential clinical utility to diagnose and monitor the treatment of vascular brain pathologies.

Title: Laterality Index plot of NIRS data indicates the brain activation laterality for calculation test and for Kraepelin performance test

Authors: *H. EDA[1], M. YAMAZAKI[2], N. OKAMOTO[3], Y. KURODA[4];
[1]Grad. Sch. For GPI, Hamamatsu-Shi, Japan; [2]Daito Bunka Univ., Higashimatsuyama, Japan; [3]Ritsumeikan Univ., Kyoto, Japan; [4]Kyoto Univ. of Educ., Kyoto, Japan

Abstract: Introduction
Near infrared spectroscopy (NIRS) calculates hemoglobin parameters, such as changes in oxygenated hemoglobin (oxyHb) and deoxygenated hemoglobin (deoxyHb), assuming the modified Lambert-Beer's law. Laterality Index (LI) is one of the smart ideas for NIRS application to brain study. LI is calculated as (LT-RT) / (LT+RT), where LT is the activation of the left and RT Right. The LI has been popular for language research, measuring Broca's area. We measure forehead by NIRS system, and calculate Laterality indexes. The purpose of this study is to discuss the possibility of the LI plot of NIRS for cognitive research.
Methods
Subjects were required to perform 2 tests. One was a calculation test. Two numbers were appearing on the screen for 4 seconds, such as 62+59. The subject calculated, and typed the answer by ten-key. This was repeated for 50 times. The other was Kraepelin performance test for 5 minutes. We used the NIRS system (Spectratech, Inc., Japan) having 16 Source-Detector pairs (16 channels). The picture shows the area of 16 channels. Channel 1 to 7 were located on the right side, and channel 10 to 16 were located on the left side. We calculated seven Laterality indexes with oxyHb; LI1 (ch16-ch1), LI2 (ch14-ch2), LI3 (ch15-ch3), LI4 (ch13-ch4), LI5 (ch11-ch5), LI6 (ch12-ch6), LI7 (ch10-ch7). These indexes were plotted.
Results
LI plot of 2-digit calculation test and Kraepelin performance test were clearly different. For 2-digit calculation task, LI7 (ch10-ch7) was positive. For Kraepelin performance test, LI1 (ch16-ch1) was positive.
Conclusion
There are many reports on the forehead activation, using NIRS. But the discussion is confused, because we have few functional magnetic resonance images of frontal area. We calculated Laterality Indexes from NIRS multiple channel data. LI plot includes many indexes, and this clearly shows brain activation laterality. This plot can be applied to cognitive research. We know

the laterality pattern according the task and the pattern change before and after the task. This opens the new perspective of educational research.

Title: Cutaneous electrical stimulation of the neck accesses vagal projections: fMRI evidence in humans

Authors: *E. FRANGOS[1,2], B. R. KOMISARUK[1];
[1]Dept. of Psychology, Rutgers The State Univ. of New Jersey, Newark, NJ; [2]Natl. Ctr. for Complementary and Integrative Hlth., NIH, Bethesda, MD

Abstract: While direct stimulation of the vagus nerve via implanted electrodes is currently used as a treatment for refractory epilepsy and depression, recent developments in non-invasive approaches have demonstrated similar beneficial effects. The purpose of the present study was to ascertain whether afferent vagal projections can be accessed non-invasively by transcutaneous electrical stimulation of the antero-lateral surface of the neck, which overlies the course of the vagus nerve. Methods: Thirteen healthy subjects underwent 2 fMRI scans in one session. Each participant experienced transcutaneous electrical stimulation of the right postero-lateral surface of the neck during scan #1 (control condition, sternocleidomastoid stimulation: "SCM") and stimulation of the right antero-lateral surface of the neck during scan #2 (experimental condition, non-invasive vagus nerve stimulation: "nVNS"). The duration of stimulation was 2min for each condition, and was followed by a 15min post-stimulation period to assess possible persistent effects of the stimulation. Mean group effects were analyzed to determine whether nVNS activated classical vagal projections to the brainstem and forebrain, compared to baseline and SCM stimulation. Results: Compared to baseline and control (SCM) stimulation, nVNS significantly activated primary vagal projections including the nucleus of the solitary tract (primary central relay of vagal afferents), parabrachial area, primary sensory cortex, and insula. Regions of the basal ganglia and frontal cortex were also significantly activated. Deactivations were found in the hippocampus, visual cortex, and spinal trigeminal nucleus. During the post-nVNS period, there was initially regional deactivation, approximately 5min later some of the brain regions increased in activity (e.g., hypothalamus), followed by deactivation at the end of the post-nVNS period. Brainstem activations during the post-nVNS period were found within the substantia nigra, ventral tegmental area, raphe nuclei, and periaqueductal gray. Conclusion: The present findings provide evidence in humans that cervical vagal afferents can be accessed non-invasively via transcutaneous electrical stimulation of the antero-lateral surface of the neck (nVNS), which overlies the course of the nerve. These findings suggest an alternative and feasible method of stimulating vagal afferents.

Title: Vascular architecture with CLARITY suggests that contrast-enhanced high-resolution fMRI is dominated by microvessel dilation

Authors: *A. J. POPLAWSKY[1], H. FUKUDA[1], B.-M. KANG[2,3], J. KIM[2], K. CHUNG[5], M. SUH[2,3], S.-G. KIM[2,3,4];
[1]Radiology, Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci., Suwon, Korea, Republic of; [3]Biomed. Engin., [4]Biol. Sci., Sungkyunkwan Univ., Suwon, Korea, Republic of; [5]Chem. Engin., MIT, Cambridge, MA

Abstract: Introduction: Functional magnetic resonance imaging (fMRI) measures the hemodynamic response to neuronal activity, but more evidence is needed to understand how far the high-resolution fMRI response spreads relative to the evoked neuronal activity. The olfactory bulb is an ideal model system to study this issue because synapses localized to a single layer can be preferentially evoked by a selective stimulation. We previously showed that fMRI signal increases due to lateral olfactory tract (LOT) stimulation are highly localized to the evoked synapses in the external plexiform layer (EPL); but it is unknown whether dilation of local microvessels is the dominating source of our fMRI measurements.
Methods: In α-chloralose anesthetized rats, LOT was stimulated in a block design experiment (-200 μA, 200 μs pulse duration, 40 Hz, ~1 min stimulus duration, 4 min interstimulus interval); and high-resolution (55 x 55 x 500 μm^3) blood volume-weighted fMRI responses were measured at 9.4 T. Line profiles from 330-μm thick slabs that orthogonally transected the bulb layers were obtained and the full width at half maximum (FWHM) of the evoked fMRI peaks due to LOT stimulation were measured. In a different rat, blood vessels were stained with DyLight594 Tomato lectin (Vector Laboratories, DL-1177) and the anatomical vascular architecture of EPL

was imaged by 3D CLARITY. The FWHM data were compared to the vessel diameters, lengths and volumes calculated by volumetric analysis of the CLARITY images.
Results: The mean FWHM of the fMRI peaks was 347 ± 102 μm (mean ± SD, n = 30 peaks from 5 rats, 3 slices each rat, 2 peaks each slice), where the mean anatomical thickness of EPL at these lines was 265 ± 65 μm. The fMRI spatial spread beyond the anatomical thickness of EPL was estimated by a least squares linear regression analysis. The regression intercept (± SE), which approximates this spread, was 106 ± 65 μm ($r^2 = 0.34$, $p < 0.001$, $df = 28$). With CLARITY, microvessels that had diameters <12 μm accounted for the majority of the total vascular volume (65.8%) present in EPL and had an average length of 54.8 ± 41.2 μm (± SD, n = 398 vessel segments).
Conclusions: Our preliminary results indicate that the LOT-evoked fMRI signal spreads ~100 μm from the evoked layer EPL (~50 μm on each leg of the fMRI response peaks). This spread coincides with the mean length of microvessels (~50 μm), the predominate vascular compartment in EPL.

Title: Can we capture lateralization of brain activities with EEG and/or NIRS?

Authors: *M. YAMAZAKI[1], H. EDA[2], N. OKAMOTO[3], Y. KURODA[4];
[1]Daito Bunka Univ., Saitama, Japan; [2]Grad. school for GPI, Hamamatsu, Japan; [3]Ritsumeikan Univ., Kyoto, Japan; [4]Kyoto Univ. of Educ., Kyoto, Japan

Abstract: Introduction
Near infrared spectroscopy (NIRS) calculates the changes in hemoglobin parameters. NIRS is widely used in brain science, psychology and clinical field to evaluate the brain activations because of its easy operation compared to other brain measurement systems. Purpose of this study is to validate the methods capturing the brain activities by simultaneous EEG and NIRS recording during Kraepelin test and 2-digit addition calculation task.
Methods
University students (average, 22 years old) from Mathematics Educational division were recruited as subjects. We conducted EEG and NIRS recording simultaneously during two types

of calculation tasks. One of the calculation tasks was Kraepelin test and the other was 2- digit addition test. NIRS : We used NIRS system (Spectratech, Inc., Japan) having 16 channels and put the sensors on the forehead. Laterality Indexes (LI) were calculated as (Left-Right) / (Left+Right) with the changes in oxygenated hemoglobin by NIRS system.EEG : We attached 10 scalp EEG electrodes (Fp1,Fp2, F3,F4,Fz,Cz,T3, T4, O1 and O2)on the head according to 10-20 system and recorded EEG data using polymate II AP216 (TEAC Corp., Japan). Time-frequency analysis was applied to EEG data to evaluate Fm theta wave activity.

Results

During the Kraepelin task EEG began showing Fm theta activities 40 seconds after started the task. These Fm theta activities showed maximum power (μV2) over the Fz electrodes and it also showed slightly higher power on the left side (F3) compared to the right side (F4). NIRS showed oxyHb elevation immediately after started the task. NIRS LI on lateral frontal channel which corresponded with F3 EEG position showed always positive. During the 2-digit addition task EEG showed no clear tendency however subtraction of theta band power by time frequency analysis showed obvious left predominant activities. All of NIRS LIs showed always positive.

Conclusion

This study showed that there were difference of the brain activities between 2-digit calculation task and Kraepelin task. These differences may need to be considered in the educational research. Combined with several measuring modalities give us additional information because the timing of the hemodynamic activation in NIRS differs from the neural activities in EEG.

Title: Portal vein shunts in c57bl/6j mice and strains derived from it - serious implications to neuroscience research.

Authors: *K. LEHTIMÄKI, J. PUOLIVÄLI, T. HUHTALA, T. HEIKKINEN, A. SHATILLO, A. NURMI, P. SWEENEY;
Charles River Discovery, Kuopio, Finland

Abstract: Here we report our findings on portal vein shunts (PS) in naïve C57Bl/6J mice. This confirms and extends the study by Cudalbu et al. 2013 which showed that large portion of C57Bl/6J mice and strains derived from it suffer from this devastating anatomical defect. While

this anomaly must have numerous so far uncharacterized manifestations in affected mice, hyperammonemia is one of the most theoretically obvious. Due to absent portal venous uptake, several substances are not delivered to liver for processing. In the case of excess ammonia in the CNS, astrocyte specific glutamine synthethase detoxifies ammonia to glutamine (GLN) and increase of it is reliably detectable by proton MR spectroscopy (1H-MRS) *in vivo*. Our results confirm seriously altered brain metabolic profile, and extend seen *in vivo* effects everything from altered bodyweight and brain volumes to defective liver enzymes, different brain FDG-PET readouts and affected behavior. Our material consisted 119 five weeks old male C57Bl/6J mice from which total of 11 mice (9.2%) were diagnosed with portal vein shunt using high GLN levels in 1H-MRS study at 11.7T field strength. Body weight matched control group with normal GLN levels was established and all study mice went through the MR angiography that confirmed the absence of normal portal circulation in all high GLN mice. Brain volumes were longitudinally assessed at 5, 8, 12 and 16 weeks and PS mice had consistently higher brain volumes. PS mice gained more weight from early phase of the study and showed behavioral alterations in the rotarod and open-field. FDG-PET signal was significantly increased in the PS animals suggesting longer bioavailability of FDG due to defective hepatic circulation. Blood clinical chemistry showed defective liver enzymes, AST and ALT at group level, but with overlap in individuals which rejects this test as a diagnostic tool. Similarly as ammonia, bile acids are supposed to be delivered back to liver through portal vein, and we observed up to 50-fold increase in serum/plasma total bile acids in PS mice with not even close overlap between the groups. Our laboratory has performed vast amount (>10000) of 1H-MRS scans in pure C57Bl/6J and transgenic mouse strains derived from it. After meta-analysis of data, 10% seems valid estimate on pure C57Bl/6J that we have obtained. Worst transgenic cohorts with C57Bl/6J background have been shown close to 50% prevalence of PS. Together these results show that pure C57Bl/6J mice and strains derived from it should be used with extreme care, preferably only after screening out the mice with PS. We propose plasma/serum total bile acids as affordable and widely available screening method for portal shunts in mice.

Abstract: Introduction: Aging is related to changes in brain structure and function, which may lead to cognitive declines, as well as physical and behavioral changes. Physical activity may have an important role in cognitive and physical health during the aging process. Objective: To evaluate Tai Chi and water aerobics training effects in an fMRI and gait laboratory examinations. Methods: A total of 16 elders (age> 60) from 2 independent groups, 8 Tai Chi (TC) and 8 Water Aerobics (WA) were matched by gender, years of education and age. Participants filled questionnaires, were examined in the gait laboratory (subjects underwent the anthropometric measurements protocol requested by Vicon® system for carrying out the three dimensional examination of gait) and were scanned in a 3.0T Siemmens MRI equipment during an fMRI Stroop Word-Color Task. Results: The TC group seamed to need a smaller amplitude range of the main joints during gait, performing the walk task in a more centered way, and maybe with smaller energy expenditure than the WA group; the TC group maintained joints closer to a neutral position during the entire step cycle than the WA group. Functional magnetic resonance imaging results showed smaller activation in attention areas in the TC when compared to the WA, confirming the smaller cognitive load during the Stroop Word Color Task in the TC group. Conclusion: Tai Chi may help practitioners to develop a more centered movement related to the body axis, a more neutral use of joints, more gravity-related embodiement and a more effective use of attentional systems compared with Water Aerobics.

Title: Investigating the role of cortical temperature in neurovascular function and the mechanisms underpinning the anti-epileptic effects of focal cerebral cooling.

Authors: *L. W. BOORMAN[1], S. HARRIS[1], A. KENNERLEY[1], P. REDGRAVE[1], C. MARTIN[1], T. H. SCHWARTZ[2], J. BERWICK[1];
[1]Univ. Sheffield, Sheffield, United Kingdom; [2]Neurolog. Surgery, Weill Cornell Med. Col., New York, NY

Abstract: Understanding how changes in cortical temperature affect neurovascular function is relevant to the calibration, development, and interpretation, of existing and novel functional neuroimaging techniques, and can offer insights into neurological disease progression and prevention. Here, we address this issue by employing a novel multi-modal methodology that allows the examination of cortical temperature, tissue oxygenation and blood flow concurrently with laminar electrophysiology and spatial measures of hemoglobin concentration. Multi-modal measures were assessed in the whisker barrel cortex of the urethane-anesthetized rat during sensory stimulation, (16s, 5Hz, 1.2mA), hypercapnia challenge (5 and 10%) and recurrent acute neocortical seizures induced by infusion of 4-aminopyridine (4-AP, 15mM, 1µl). Significant increases ($p < 0.01$) in cortical temperature were observed during sensory stimulation (0.19 ± 0.02^{o}C), 5% hypercapnia (0.89 ± 0.11^{o}C), 10% hypercapnia (1.46 ± 0.19^{o}C), and recurrent seizures (1.78 ± 0.08^{o}C). Cortical temperature increases between conditions were significantly different ($p < 0.05$) with the exception of 10% hypercapnia and the ictal condition ($p = 0.36$). Hypercapnic challenges induced a dose dependent increase in cerebral hemodynamics and decrease in spontaneous neuronal activity, and changes in cerebral metabolic rate. Uncoupling between cerebral blood flow (CBF) and total hemoglobin concentration (Hbt) was seen during the return to baseline at higher levels of hypercapnia and during seizure activity. Complex changes in cortical tissue oxygenation were also observed during seizure initiation and propagation. Interestingly, increases in cortical temperature were more closely coupled to increases in Hbt than CBF, possibly due to inflow of core-temperature blood and increased capillary hyperemia. On-going research involves cortical superfusion of temperature-controlled saline to actively manipulate cortical temperature and examine the role of thermoregulation in neurovascular coupling and the therapeutic benefits of cortical cooling in neocortical epilepsy. Our results have important implications for pre-clinical functional neuroimaging methods in health and disease, and elucidate the role of cortical temperature in the maintenance of normal neurovascular function.

Title: Intravenous methylphenidate reduces local functional connectivity density in the Thalamus: An fMRI study

Authors: S. B. DEMIRAL[1], D. TOMASI[1], C. WIERS[1], E. SHOKRI-KOJORI[1], G.-J. WANG[1], *N. D. VOLKOW[2];
[1]NIH/NIAAA, Bethesda, MD; [2]NIH/NIDA, Bethesda, MD

Abstract: Recent functional magnetic resonance imaging (fMRI) studies (Farr et al., 2014; Mueller et al., 2014) showed that the oral administration of methylphenidate (MPH), a dopamine agonist, induced contrastive effects on resting state brain functional connectivity. For instance connectivity within thalamus-dorsal attention networks increased, while connectivity in striato-thalamo-cortical networks decreased. Given the incomplete understanding of the potential effects of MPH on human brain function, and its increasing importance in the treatment of ADHD and similar neurological diseases (Rubia et al., 2009), this study aimed to examine, for the first time, the impact MPH (0.5 mg/kg, iv) on local functional connectivity density (lfcd), a connectivity measure emphasizing the similarities between neighboring voxel activations (Tomasi & Volkow, 2010). In a controlled single-blinded settings, we ran a resting state fMRI study in cannabis abusers (n=13) and in healthy controls (n=16) after iv placebo and on a separate day after iv MPH. Standard fMRI preprocessing routines were applied including motion correction and scrubbing (Power et al., 2014), global signal was taken out, and 6mm smoothing, lfcd threshold was set to 0.6. Our results show that, compared to placebo (PL), MPH decreased lfcd in the Thalamus (total n=29, uncorrected cluster-level p-value 0.002 as found in a t-test using PL-MPH contrast including all subjects). We were not able to find any interaction between PL/MPH administration and cannabis/healthy groups in a 2X2 flexible factorial analysis, using drug administration as within subject factor, and group as a between subject factor. We argue that MPH is potentially minimizing the similarity of the activation patterns between the neighboring voxels in the thalamus thus changing the sub-regional specificity and pace-making routines in cortico-thalamo-cortical loops. Overall, our results indicate that iv MPH has similar effects as oral MPH, and that its influence on lfcd is most pronounced in the thalamus.

Title: Attenuation of descending and limbic pain modulatory activities during offset analgesia in chronic pain patients: a functional magnetic resonance imaging study

Authors: ***S. ZHANG**, E. IKEDA, T. LI, H. KOBINATA, T. OTA, K. MAKITA, J. KURATA; Anesthesiol., Tokyo Med. and Dent. Univ., Tokyo, Japan

Abstract: Chronification of pain potentially involves pathological modification of the descending pain inhibitory system (DPIS). We examined cerebral substrates of such modification by functional magnetic resonance imaging (fMRI) and a thermal stimulation paradigm causing offset analgesia (OA), an endogenous pain inhibition characterized by a disproportionately large reduction in pain perception after a small decrease in thermal pain stimulus. [Method] We recruited 17 chronic pain patients (CP) and age-gender-matched 17 healthy control subjects (HC). We recorded their psychophysical variables including PainDETECT questionnaire (PD-Q), Short-Form McGill Pain Questionnaire (MPQ), Pain Catastrophizing Scale (PCS) and Beck Depression Inventory (BDI). We gave a mixture of peudorandom thermal pain stimulation paradigm, including 3 blocks of OA and 6 other sham blocks, on the left volar forearm of a subject while obtaining whole-brain fMRI on a 3.0 Tesla scanner. We used a thermal stimulator (Medoc, Israel) with a 3 cm-diameter probe and digital continuous recorder of pain ratings between 0 and 10. The OA block consisted of a series of 5-s 46ºC (T1), 5-s 47ºC (T2), and 20-s 46ºC stimuli (T3), between 32ºC-rest conditions. The sham blocks consisted of three 30-s 46ºC stimuli and three 10-s stimuli with T1+T2 only. Functional images were compared between the groups with fixed-effects general linear model analysis at a threshold of uncorrected $p < 0.00001$ by BrainVoyager QX (BrainInnovation, Netherlands). [Results] During OA, we observed a rapid, disproportionate decrease of pain rating on T3 in both groups. Although the magnitudes of OA were comparable, the pain rating was approximately 30% slower in CP than in HS. During OA, the CP showed deactivation at the bilateral medial prefrontal cortex (mPFC), left posterior cingulate cortex (PCC), right dorsolateral prefrontal cortex (DLPFC), right hippocampus, and right amygdala, while the HC showed stationary or positive activation in those areas. On the other hand, bilateral fusiform gyri showed stationary activation in CP but activated robustly in HC. The blood oxygenation level-dependent amplitudes at the maximal OA response of CP was negatively correlated with MPQ at the PCC, positively correlated with PD-Q at the mPFC, positively correlated with PCS and BDI at the right amygdala ($p<0.05$). [Conclusion] In CP, deactivations at the mPFC, PCC, and DLPFC might represent dysfunction of the DPIS; and those at the subcortical limbic system might be associated with negative emotions. Dysfunction of both the cortical and limbic pain modulatory systems might possibly contribute to the cerebral mechanisms of pain chronification.

Title: Soft cranial window development for longitudinal cellular dynamic monitoring

Authors: ***C. HEO**, H. PARK, S.-G. KIM, M. SUH;
Sung Kyun Kwan Univ., Suwon City, Kyeonggi-Do, Korea, Republic of

Abstract: To approach neural tissue to investigate brain function, stable and accessible cranial window is needed for living animal. We developed the new type of cranial window in comparable clarity and stability with conventional glass type window. Big advantage of our soft window is that the window provides multi-site penetration with multiple times by a glass pipette or electrode without causing fluid leakages. The silicon-based soft cover material has sufficient physical properties for penetration by retaining high elastic, flexible, transparent, and biocompatible features. This window can be simply fabricated in laboratory and also easily tailored to any size or shape to cover desired brain area of rat and mouse. We have succeed the longitudinal two-photon imaging for microglial observation before and after chemicals injection into the cortex. In addition, this system allows awake two-photon imaging over 1 hour while the animal was running over treadmill. The soft cranial window showed long term (>3 months) solidity for real-time optical image and electrophysiological recording. Our window technique can provide the new flat form to study various longitudinal and real-time neuroscientific approaches for investigation of dynamic brain function.

Title: Test-retest reproducibility of cerebral blood flow during a sustained attention task

Authors: *F. N. YANG[1,3,2], S. XU[1,4,2], J. DETRE[1,2], H. RAO[1,4,2];
[1]Dept. of Neurol., [2]Ctr. for Functional Neuroimaging, Univ. of Pennsylvania, Philadelphia, PA; [3]Dept. of Psychology, Sun Yat-sen Univ., Guangzhou, China; [4]Lab. of Applied Brain and Cognitive Sci., Shanghai Intl. Studies Univ., Shanghai, China

Abstract: Introduction: Cerebral blood flow (CBF) measurements have been widely used as biomarkers of neural activity in cognitive and clinical neuroscience studies. Arterial spin labeling (ASL) perfusion MRI can noninvasively quantify CBF thus is increasingly used to access regional brain function in humans. Previous studies have consistently demonstrated high test-retest reliability of quantitative CBF over time. However, the reproducibility of task-induced CBF activation remain unclear. Here we aimed to quantify test-retest reliability of absolute CBF values and relative CBF activation levels induced by a psychomotor vigilance test (PVT) during a well-controlled protocol. **Method**: We analyzed data from 15 healthy control subjects (6 females, mean age = 35±9 years) from a 5-day and 4-night sleep study. Participants slept 8-9 hours every night in the laboratory. Their waking and diet behaviors were continuously monitored throughout the experiment. Each subject were scanned three times on the morning of days 2, 3, and 5. Both voxel-wise and region-of-interest (ROI) analyses were conducted. Intra-class correlation coefficients (ICC) were calculated to quantify test-retest reliability across three scans. **Results**: PVT performance demonstrated very high test-retest reliability (ICC values ranged from 0.870 to 0.936) across three scans. Voxel-wise analysis of the absolute CBF values also showed very high test-retest reliability for both resting and PVT scans, with the ICC values

slightly higher during the PVT (median ICC = 0.932) than at rest (median ICC = 0.908 and 0.907). However, the test-retest reliability of relative CBF changes with task was much lower from both voxel-wise and ROI analyses, with ICC values ranging from 0 to 0.648 for the PVT-induced activation and deactivation clusters. **Conclusion:** Regardless of resting or task scans, absolute CBF showed excellent reproducibility across three scans with ICC values comparable to those of PVT performance. which are consistent with previous studies. However, task induced changes in regional CBF during the PVT showed much lower reproducibility, suggesting that PVT performance may not be maintained by a consistent neural substrate. These findings suggest a preference of using absolute CBF over relative CBF activation as a biomarker for regional brain function in future studies.

Abstract: The advent of two-photon fluorescence microscopy has opened unprecedented opportunities in revealing neuronal firing, hemodynamic changes, and metabolic activity on microscopic level *in vivo*. However, data interpretation of two-photon fluorescence microscopy on dyes with small signal change such as *β-nicotinamide adenine dinucleotide* (NADH), a key metabolic marker, faces enormous challenge because the measured signal change is often highly distorted by hemodynamic changes. Prior work [Baraghis et al, Journal of Biomedical Optics 16, 106003 (2011) and Sauer et al, SFN 2014] modeled two-photon NADH fluorescence with precise maps of cortical microvasculature and corrected for the measured NADH signal change by using the fluorescence change of Sulforhodamine 101 (SR101), a functionally inert dye topically applied to the cortex. However, we only simulated for one animal model (a rat) and one dye, NADH. Here, we extend the prior work to systematically calculate the point to point correction factor using real 3D microvasculatures in two animal models (rats and mice) and two different dyes (NADH and Oregon Green 488 BAPTA-1, OGB). We have found that for both animal models and dyes: 1) the correction factors vary significantly with the appearance of large vessels near the pial surface while they tend to be more homogeneous at deeper depths (Figure: 1st three columns show the correction factor at 40, 60, 80, 100, 120, 140, 200, 300 and 400 microns. 4th column shows the corresponding vasculatures). 2) a single-value correction factor may be used to effectively correct the hemodynamic distortion in layer II or deeper depths. The residual error after the correction is comparable to the experimental error. Our study may help quantify cellular NADH signal change and is also applicable to two-photon fluorescent measurements where changes of tissue optical properties affect measured signals, thus allowing more accurate interpretation of functional imaging studies.

Title: Assessment of brain activities using short-term gray matter changes

Authors: *Y. KABURAKI[1], T. ONO[2], E. YAMADA[2], H. EBATA[2], D. NISHIDA[2], S. KASUGA[1], J. USHIBA[3];
[1]Grad. Sch. of Sci. and Technol., Keio Univ., Kanagawa, Japan; [2]Saiseikai Kanagawa hospital, Kanagawa, Japan; [3]Dept. of Biosci. and Informatics, Fac. of Sci. and Technol., Keio Univ., Kanagawa, Japan

Abstract: Voxel-based morphometry (VBM) analysis of magnetic resonance images (MRI) has revealed structural changes in the brain gray matter following visuomotor task (Draganski et al., 2004). Recently, we found such gray matter changes occur even with relatively short-term (i.e., hours) visuomotor task (Kodama et al. in prep). Possible neurobiological factors behind such short-term structural changes may be changes in astrocytes or vessels (Berg et al., 2012), which is due to metabolic processes accompanying with neural activities in the corresponding area. It is therefore suggested a possible use of VBM as a functional measurement of a whole brain activity. In order to test its feasibility, the present study evaluated correlations between gray matter volume increase and blood oxygenation level dependent signals during saccadic eye movement task, and tested the similarity of these images. Twelve healthy volunteers participated in the study. Participants performed a total of 288 trials (six blocks) of saccade task in the MR machine. At the start of each block, the participant fixated a dot displayed at the center of a computer monitor in front of their face. After the fixation dot disappeared, a saccade target appeared rightward or leftward of the center. Dependent on the color of the fixation dot, participants were instructed to look at the opposite direction or the same direction of the target. We acquired fMRI BOLD signals during the task, and T1-weighted structural MR images for VBM immediately before and after the task. In VBM analysis, significant gray matter increases after an hour of saccade training were detected in the visual cortex, the supplementary eye field ($p<.001$, unc), the intraparietal sulcus and the basal ganglia, which is previously known to be involved in saccade tasks (Deseilligny et al., 2004). In fMRI analysis, task-related brain activities were detected in the similar brain regions to VBM analysis, suggesting that gray matter changes reflect neuronal activities in these regions. In contrast, gray matter increase was detected in the right thalamus, whereas fMRI analysis did not show significant BOLD changes. This difference may result from characteristic of the temporal pattern of neuronal activity in this region, which may be hardly detected by fMRI. Our findings open up new possibilities for functional brain imaging during motor activities, because VBM does not require movement constraint during the motor tasks like fMRI, nor invasive procedures like positron emission tomography. Future investigations are expected to evaluate quantitative relationship between motor learning or the motor activity level and gray matter volume increases.

Title: Hedonic and utilitarian values in the human brain

Authors: *K. MOTOKI, R. KAWASHIMA, M. SUGIURA;
IDAC, Tohoku Univ., Sendai-Shi, Japan

Abstract: Consumer choices are driven by hedonic or utilitarian values. People buy hedonic goods for obtaining emotional experiences such as joy, or excitement, while they pursue utilitarian goods by pursuing functional or instrumental needs. Consumer researchers suggest that these different values map onto independent components of value dimensions. However, there is a hypothesis that common specific brain regions encode different types of value of goods. Especially, it has been suggested that ventromedial prefrontal cortex (vmPFC), and bilateral ventral striatum (VS) encode a wide range of economic values, when people explicitly engage in purchasing decisions (paying money for the goods). Although previous studies examined different category of goods, they have not differentiated hedonic and utilitarian value dimensions. Therefore, it remains uninvestigated which brain regions encode explicit value representations dependent or independent of hedonic/utilitarian value dimensions. In addition to that, the same brain regions (vmPFC and VS) are considered to capture automatic economic values when explicit economic evaluations are not required. However, it remains elusive which brain regions encode automatic value representations dependent or independent of hedonic/utilitarian value dimensions. We addressed these questions by scanning participants with functional magnetic resonance imaging. We investigated the brain activations during the processing of economic valuations in both hedonic and utilitarian goods (comic books for hedonic goods and how-to-book for utilitarian goods) at explicit and automatic stages. Participants performed two decision-making task across hedonic and utilitarian goods in which they made purchasing decisions (for which values are directly explicit) or perceptual decisions (for which values are unrelated to the purchasing decisions and therefore value representations are automatic). We found vmPFC and VS to encode explicit value representations independent of hedonic/utilitarian goods, but no unique brain regions to contain explicit value representations for either hedonic or utilitarian goods. We did not find brain regions to contain automatic value representations independent hedonic/utilitarian goods. While we did not find brain regions to contain automatic value representations uniquely for utilitarian goods, vmPFC encoded automatic value representations selectively for hedonic goods. Such a commensurable nature of explicit values and an automatic value representation selectively for hedonic dimension might provide insight into consumer decision theory based on neural evidences.

Title: Biased performance monitoring of physical effort in chronic fatigue

Authors: ***M. E. VAN DER SCHAAF**[1,2], I. TONI[3], F. P. DE LANGE[3], K. ROELOFS[3], J. W. M. VAN DER MEER[4], H. KNOOP[5];
[1]Radboud Univ. Nijmegen Med. Centre, Donders Inst., Nijmegen, Netherlands; [2]Expert Ctr. for Chronic Fatigue, Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [3]Donders Inst. for Brain, Cognition, and Behaviour, Ctr. for Neuroimaging, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [4]Dept. of Intrnl. Med., RadboudUniversity Med. Ctr., Nijmegen, Netherlands; [5]Dept. of Med. Psychology, Academic Med. Ctr. (AMC), Amsterdam, Netherlands

Abstract: Chronic fatigue syndrome (CFS) is characterized by profound and disabling fatigue leading to reductions in physical performances that are not explained by lack of fitness or muscular fatigue. Clinical work has suggested that these behavioural changes arise from dysfunctional beliefs about the ability to perform physically demanding tasks.
Here, we explore how such beliefs bias feedback-driven behavioural adjustments during an effortful physical exertion task. 85 CFS patients and 29 controls exerted grip force at 30, 50 and 70% of their maximal voluntary contraction (MVC) and received directional feedback on their performance (too much, too little, or correct). Beliefs were indexed with a clinical questionnaire assessing expected levels of fatigue evoked by various daily physical tasks (PARS). Neural correlates of biases in feedback-driven effort adjustment were assessed with fMRI.
CFS patients showed a stronger force-related bias in feedback-driven effort adjustments than controls (force*group: $F_{2,111} = 7.04$, $p<.01$), while MVC (change) was matched across groups ($p>.1$). This bias was present only during trials requiring 70% of MVC. CFS patients showed smaller increases in force production after feedback indicating that too little force was produced, and larger reductions after feedback indicating that too much force was produced ($T_{111} = -2.65$, $p<.01$). Neurally, CFS-related bias was associated with weaker feedback-related signals in the dorsolateral prefrontal cortex (DLPFC, bilaterally, $p<.015$ family-wise error-corrected). Within the CFS group, larger force-related biases in feedback-driven effort adjustments were associated with lower DLPFC activity ($r = .25$, $p<.02$). CFS patients also report higher levels of fatigue expectations than HC ($T_{111}= 14.8$, $p<.001$), and higher fatigue expectations were associated with

larger behavioural biases in CFS patients ($r = -.31$, $p<.01$).
These findings show that chronic fatigue is associated with biases in feedback-driven effort-related behaviour. The DLPFC may play a critical role in biasing error-related adjustments to fit with prior beliefs about the ability to perform the task. These findings open the possibility of using objective behavioural and neural markers to index changes in CFS during therapeutic interventions that aim to change dysfunctional beliefs like cognitive behavioural therapy.

Title: Effort but not reward sensitivity is altered by sickness behaviour in humans

Authors: *A. DRAPER[1], R. M. KOCH[2], J. W. M. VAN DER MEER[3], P. PICKKERS[2], M. HUSAIN[1], M. E. VAN DER SCHAAF[4];
[1]Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [2]Intensive Care, Radboud UMC, Nijmegen, Netherlands; [3]Dept. of Intrnl. Medicine, Radboud UMC, Nijmegen, Netherlands; [4]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: Sickness in humans, associated for example with the systematic inflammatory responses to infection, is characterized by low mood and fatigue. At the behavioural level, there may be changes in motivation involving the reorganization of priorities but it is unclear which specific processes underlying motivation are altered. In rodents, recent work suggests that experimentally induced inflammation reduces high-effort choices, crucially without affecting reward preference[1].
Here, we examined the effect of systemic inflammation induced by experimental endotoxemia in humans. We tested whether bacterial endotoxin e. Coli lipopolysaccharide (LPS) affected effort or reward sensitivity using an effort-stake choice paradigm[2]. Participants first familiarised themselves with 5 different effort levels using hand-held dynamometers which they squeezed. On a trial-by-trial basis, they then made a series of decisions on whether the stake offered (5 levels) was “worth the effort” (5 levels). Of 100 offers, 26 were selected to be performed afterwards. 29 healthy young males were administered either LPS (2ng/kg; n=14) or placebo

(0.9% saline; n=15). The effort-stake task was assessed prior to LPS infusion, 2 and 5 hours post-infusion. Relationships between the acute cytokine responses (plasma levels of TNFα, IL6, IL8, IL10, IL1-ra) and changes in motivation and self-reported mood (depression and fatigue scales) were also assessed.
Experimental endotoxemia resulted in a 1.3°c increase in temperature, and marked increases in all cytokines measured. After 2 hrs, systemic inflammation increased effort ($F=3.2$, $p<0.05$) but not reward ($F=0.5$, $p>0.7$) sensitivity relative to baseline and placebo. Importantly, LPS reduced willingness to accept high effort options, irrespective of reward. These group differences were absent by 5 hrs suggesting partial recovery. The change in effort sensitivity was linked to the extent of the pro-inflammatory response. Both IL6 and IL8 levels predicted the influence of effort on decisions made at 2 hrs ($R^2=0.6$). Self-reported fatigue and depression were also increased then and associated with TNFα levels ($R^2=0.4$).
These results show that in humans inflammation affects effort but not reward sensitivity and that these changes are predicted by the acute pro-inflammatory cytokine response during experimental endotoxemia. The findings provide mechanistic insight into understanding motivational changes during sickness.

Title: Dissociating effort and reward signals in the striatum

Authors: *A. R. ARULPRAGASAM[1], D. J. COLE[2], N. IRFAN[2], M. T. TREADWAY[2];
[1]Psychology, [2]Emory Univ., Atlanta, GA

Abstract: Dopamine (DA) functioning within the striatum is believed to play a critical role in effort-based decision-making and effort-discounting. However, despite considerable research demonstrating DA's involvement in motivated behavior, the specifics of this involvement are not fully understood. While research implicates midbrain DA neurons in valuation-related aspects of decision-making and in modulating the performance of reward-seeking behaviors, growing evidence suggests that DA is also required to mobilize effort expenditure in pursuit of rewards.

To better understand how the striatum responds to effort and reward during effort-based choice, 30 healthy participants completed a sequential effort-based decision-making task while undergoing functional magnetic resonance imaging (fMRI). In this task, participants completed a series of trials in which they chose between performing no effort for a fixed small reward or 20%, 50%, 80% or 100% effort for a larger, variable reward. For each trial, information about the high-reward/high-effort option was presented sequentially; one piece of information (effort level or reward magnitude) was presented first followed by a jittered ISI and then the other piece of information. Order was counterbalanced across all levels of effort and reward. The advantage of this design is that it allows for the isolation of neural responses to effort or reward alone, and their subsequent integration. Using this task, we were interested to see how the striatum responds to the addition of high effort or low reward information following high reward or low effort presentation.

If striatal signals primarily encode discounted utility function, we might expect decreased striatal activity following the addition of high effort or low reward. Consistent with this, we observed increased nucleus accumbens activity when low effort information was presented first when compared to the addition of low reward ($p_{FWE} = 0.038$, SVC). In contrast, if the striatum also encodes the value of overcoming effortful response costs, we might expect greater striatal activity when high effort information is added. This was also observed in anterior caudate during trials in which high reward values were followed by the presentation of high effort information ($p_{FDR}<0.05$, SVC).

Taken together, these results suggest the coexistence of discounting and effort mobilization signals in the striatum. Importantly, these signals were anatomically segregated, possibly implicating differential involvement of DAergic signaling. These data have the potential to increase understanding of the neurobiological mechanisms underlying motivated decision-making.

Title: Neural mechanisms of subjective reward devaluation by cognitive and physical effort

Authors: ***M. A. APPS**[1], T. T.-J. CHONG[2], K. GIEHL[3], L. GRIMA[1], M. HUSAIN[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Macqaurie Univ., Sydney, Australia; [3]Univ. of Cologne, Cologne, Germany

Abstract: Animals and humans have to constantly make decisions about whether it is worth exerting effort to obtain rewards. Such subjective evaluations (SV) of the cost and benefit of exerting effort to obtain a reward are central to motivated behavior. Yet, effort must be exerted in different domains of behaviour. In the modern era, countless tasks we perform are highly cognitively demanding and require minimal physical exertion, but the converse is also true for many of other behaviours. However, very little is known about the computational or neural basis of how different effort costs are subjectively weighed against rewards. Is there a common, domain-general system of brain areas that evaluates all costs and benefits? We used computational modelling and functional magnetic resonance imaging (fMRI) to examine the mechanisms underlying SV processing in both the cognitive and physical domains.
Training - Participants trained on two tasks which parametrically varied in cognitive or physical effort and were rewarded if performance met a pre-specified criteria. For the cognitive task, subjects were required to make peripheral switches of attention to detect targets during a 14s trial (Apps et al., 2015, *Sci. Reports*). For the physical task subjects were required to sustain a force grip at one of six different percentages of their maximum voluntary contraction for 14s (Chong et al., 2015, *Cortex*).
Scanning - During fMRI, participants indicated their preferences between a fixed low-effort/low-reward option and a variable higher-effort/higher-reward offer separately for each effort domain. 10 choices for each task were randomly selected and executed after scanning.
Results and Conclusions - Using model comparison approaches we were able to show that individuals' motivation is significantly correlated between domains, but rewards were valued differently within each domain. The devaluation of rewards was hyperbolic for cognitive effort but parabolic for physical effort. We examined activity covarying trial by trial with SV according to the model. Strikingly, the SV of both types of effort was processed by a largely common network of areas including dorsomedial and dorsolateral prefrontal cortex, intraparietal sulcus and anterior insula. However, we also identified a unique, domain-specific role of the amygdala for processing the SV of rewards only when associated with cognitive effort. These results are the first to reveal the neurocomputational mechanisms underlying subjective cost-benefit valuation across different domains of effort, and provide insight into the multidimensional nature of motivation.

Title: Forgetting in reinforcement learning reconciles the two roles of dopamine:reward prediction error and motivational drive

Authors: *A. KATO[1], K. MORITA[2];
[1]Dept. of Biol. Sci., [2]Physical and Hlth. Education, Grad. Sch. of Educ., The Univ. of Tokyo, Tokyo, Japan

Abstract: It has been considered that dopamine (DA) has two distinct roles, (1) representing reward-prediction-error (RPE) and (2) providing motivational drive. Normative theories have been proposed for both the role as RPE and the role as motivational drive in the framework of reinforcement learning (RL). On the other hand, from a bottom-up, mechanistic point of view, underlying cellular/circuit mechanisms for the motivational role remain more elusive than those for the role as RPE. Here, we explored a unified mechanistic account for the DA's two roles in the framework of RL, with an assumption that DA, not only phasic DA but also recently observed sustained DA that has been suggested to represent motivational drive, consistently represents RPE. Specifically, in the framework of RL, we examined the effects of the decay/forgetting of leaned values that was shown in our previous study to cause sustained RPE, which could explain the observed sustained DA. To examine behavior that can reflect the level of motivation, we modeled self-paced approach towards a goal as a series of 'Go' or 'No-Go' (or 'Stay') selections, and defined 'motivation' as the time (number of time steps) required for goal-reaching. Through simulations, we found that the value-decay can enhance 'motivation', i.e., can facilitate fast goal-reaching. Mathematical analyses revealed that there are two underlying potential mechanisms: (1) a gradient of 'Go' values towards a goal generated by decay-induced sustained RPE, and (2) value-contrast between 'Go' and 'No-Go' generated because chosen values are continually updated whereas unchosen values simply decay. Our model can potentially explain several key experimental findings that suggest the DA's role as motivational drive, specifically, (i) slowdown of behavior by post-training blockade of DA signaling, (ii) severe impairment of costly seeking distant rewards but not of seeking/liking immediate rewards by DA blockade, and (iii) relationships between reward amounts, motivation levels, and DA

levels. Since DA was assumed to consistently represent RPE in our model, these results suggest that the DA's two roles, RPE and motivational drive, can be coherently understood in the framework of RL, provided there exists decay/forgetting of learned values that can be implemented as synaptic decay.

Title: A single nucleotide polymorphism in NKCC1 is associated with motivation-related activity in the human midbrain

Authors: ***R. W. LEFCO**, K. L. BIGOS, Q. CHEN, D. R. WEINBERGER, C. F. ZINK; Clin. Sci., Lieber Inst. For Brain Develop., Baltimore, MD

Abstract: Motivation deficits are a prominent negative symptom of schizophrenia, and it is therefore of clinical relevance to determine the genetic influences underlying motivation-related neural activity. Functional magnetic resonance imaging (fMRI) studies have revealed that activation of the ventral striatum (vStr) and the ventral tegmental area/substantia nigra (VTA/SN) region of the midbrain are associated with motivational processes in humans. Recently, we used random forest multiple regression to determine the influence of multi-genetic variation within distinct neurotransmitter gene-sets on motivation-evoked fMRI signals in the VTA/SN midbrain and vStr. It was determined that multi-genetic effects/epistasis in the GABA gene-set account for 3.66% of variance in motivation-related midbrain signal ($p_{empirical} = 0.00$). Within these genes, a functional single nucleotide polymorphism (SNP) in the GABAa receptor was identified as most influential, thus implicating GABAa receptor signaling as important in the neural basis of motivational processes. NKCC1 is an ion channel that can mediate GABAa receptor activity indirectly by modulating intracellular Cl- concentration, and the minor allele of a functional NKCC1 SNP, rs3087889, has been associated with increased schizophrenia risk. Therefore, in the current study, we investigated the influence of the rs3087889 NKCC1 SNP on motivation-related midbrain activity using a variation of the monetary incentive delay (MID) task in fMRI. We isolated motivation-related (high motivation cues > low motivation cues) midbrain activity in healthy subjects (n = 86) and performed a multiple regression analysis in

which this activity was regressed on rs3087889 genotype. We found that the risk-associated allele (*A*) of rs3087889 significantly predicted reduced VTA/SN midbrain motivation-related activity [peak = -6, -22, -22, t(84) = 2.54; $p < 0.01$]. These results implicate genetic variation in the NKCC1 gene as a determinant of motivation-related midbrain activity, and, because the minor allele of rs3087889 is associated with schizophrenia risk, may be relevant to the genetic basis of motivation deficits in schizophrenia.

Title: Seeing what we want to see: Motivation influences visual perception via changes in neural gain

Authors: *Y. LEONG, B. L. HUGHES, J. ZAKI;
Dept. of Psychology, Stanford Univ., Stanford, CA

Abstract: People tend to think of visual perception as a veridical representation of the physical world, but what we want can influence what we see. Previous work demonstrates that the perception of ambiguous or bistable visual stimuli is biased in favor of percepts associated with positive outcomes. In this study, we explored the neural mechanisms underlying motivational influences on visual perception. We investigated if motivation enhances preparatory neural activity selective to desired perceptual features in anticipation of a stimulus, or if it increases the neural sensitivity to those features during stimulus presentation.
Human participants performed a visual categorization task with images comprising a mixture of a face and a scene in different proportions. For each image, participants were rewarded for correctly indicating whether the image predominantly displayed a face or a scene. Prior to seeing each image, a teammate or an opponent placed a bet about whether the upcoming image would predominantly display a face or a scene. For teammate trials, participants won a bonus if teammates bet correctly, but lost money if the teammates bet incorrectly. For opponent trials, participants lost money if opponents bet correctly, but won a bonus if opponents bet incorrectly. As such, participants were motivated to see the type of image consistent with the teammate's

bets, and to see the type of image inconsistent with the opponent's bets. Crucially, the reward maximizing strategy is to ignore the bets and perform the classification as accurately as possible. Nevertheless, we found that the bets shifted participants' sensitivity to the motivation-consistent category - for the same face to scene ratio, participants were more likely to classify an image as belonging to a category if they were motivated to see that category.
We then applied multi-voxel pattern analysis methods to participants' BOLD response to quantify the level of face-selective and scene-selective activity in the ventral visual stream, both when participants saw the bet (pre-stimulus period) and when participants saw the image (stimulus presentation). Category-selective activity during the pre-stimulus period was not higher when participants were motivated to see the category, indicating that motivation did not enhance preparatory category-selective activity. Instead, motivation increased the neural gain to the motivation-consistent category during stimulus presentation. These results suggest that motivation can influence perception, and might do so via gain control mechanisms that increase neural sensitivity to motivation-consistent perceptual features.

Title: Exploring midbrain circuit dynamics of conditioned motivation

Authors: *B. T. SAUNDERS[1], P. JANAK[1,2];
[1]Dept. of Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Dysfunctional conditioned motivational states contribute to a variety of affective disorders, such as addiction, overeating, depression, and compulsive gambling, which collectively inflict a great toll on public health. Despite this, we lack a comprehensive understanding of how the brain creates motivation that can promote psychopathology, a major obstacle to establishing effective treatments. Addiction in particular is characterized by

exaggerated, compulsive drug seeking, often spurred by drug-associated cues, and a persistent threat of relapse. Dopamine neurons originating from midbrain regions like the ventral tegmental area (VTA) and substantia nigra (SN) have received attention for their role in reward-related processes, including addiction, but it remains unclear how heterogeneity within these systems maps onto behavioral function to facilitate conditioned motivation in adaptive reward-seeking states, or maladaptive states like in addiction. In a series of studies, we found that optogenetic activation of VTA DA neurons in TH-cre rats, and specifically those projecting to the nucleus accumbens core, but not shell, is sufficient to instantiate previously neutral Pavlovian cues (e.g. lights and tones) with incentive motivational value, making the cues attractive and reinforcing in their own right. By comparison, cues paired with optogenetic stimulation of SN neurons, including those specifically those projecting to the most dorsal part of the striatum, invigorated movement, but the cues themselves do not become attractive or reinforce actions. In contrast to these divergent conditioned responses, optogenetic stimulation of VTA or SN DA neurons, and also their respective projections to core, shell, and dorsal striatum, similarly reinforces self-stimulation behavior. These results suggest that DA neurons promote distinct conditioned motivational processes as a function of both anatomical location and projection target, but primary reinforcement is consistently mediated by DA neurons throughout the midbrain. In ongoing experiments, we are expanding on these results to understand these systems in the context of addiction. Using in vivo deep brain calcium imaging, we are visualizing the activity of DA and GABA neurons across the VTA and SN, and their projections to striatum, prefrontal cortex, and thalamus, to determine how different midbrain circuits encode cocaine reward and cocaine-seeking behaviors.

Title: Context-dependent development of mesolimbic network connectivity throughout adolescence.

Authors: *V. P. MURTY[1], D. MONTEZ[2], W. FORAN[2], B. LUNA[2];
[1]Psychiatry, [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The mesolimbic dopamine system continues to mature throughout adolescence into early adulthood. Neuroimaging has characterized increases in ventral striatal activation across adolescence during reward-motivated behaviors; however, relatively less work has investigated interactions between the ventral striatum and the ventral tegmental area (VTA), the source of mesolimbic dopamine neurons. The current study characterized VTA connectivity with its mesolimbic targets across adolescent neurodevelopment. To determine the developmental trajectory of this system as a function of individuals' goal states, we assessed connectivity in both neutral and rewarding contexts. FMRI data was collected in 170 individuals ranging in age between 10-30 years old. Participants completed both a resting-state task (neutral context) and a reward-motivated anti-saccade task (rewarding context). To compare results across tasks, we characterized 'background connectivity of the reward-motivated anti-saccade task, which reflects intrinsic connectivity between regions after removing task-related activity. Results indicate a significant decrease in VTA-ventral striatal coupling in the rewarding context as individual's approached adulthood ($p < 0.001$). Conversely, there were no differences in VTA-ventral striatal coupling as a function of age in the neutral context (i.e., resting state scan, $p = 0.93$). These findings support a model by which connectivity of the VTA with its mesolimbic targets is relatively stable across adolescence, however, the ability to engage this circuit in motivational-relevant contexts continuous to mature into early adulthood. Future analysis will incorporate VTA network connectivity with other mesolimbic targets including ventromedial prefrontal cortex, hippocampus, and dorsal striatum.

Title: Neural dynamics of reward effects on conflict processing: insights from simultaneous EEG and fMRI

Authors: ***H. R. PARK**[1,2], C. N. BOEHLER[1,2], P. VAN MIERLO[1,3], R. M. KREBS[1,2]; [2]Dept. of Exptl. Psychology, [3]Dept. of Electronics and Information Systems, [1]Ghent Univ., Ghent, Belgium

Abstract: Previous research indicates that motivational states are modulated by reward prospects. A large number of behavioural studies have found a robust facilitation effect of reward, which has been observed across many aspects of cognitive control, including conflict processing. Recent research has focused on this relationship between control and motivation, and how these constructs contribute to the selection of specific actions. Neuroimaging findings indicate several cortical regions that are associated with performance in both reward and conflict tasks, further adding to the evidence of a motivation-control link. Despite this, only a few studies have examined this relationship using multimodal methods, which may provide a bridge between the temporal dynamics and the neural correlates of reward and control interactions. Here, we utilised simultaneous EEG-fMRI recording to investigate the influence of reward availability in a picture-word interference (conflict) task in healthy individuals. Event-related potential (ERP) analyses revealed P3 and N450-like components (related to reward- and conflict-processing, respectively). Interestingly, incongruent trials elicited a more positive N450 amplitude compared to the control (congruent and neutral) trials, which was mainly driven by the rewarded incongruent trials, indicating a modulation of conflict by reward. fMRI analyses also identified a similar interaction in the insula and the anterior cingulate cortex (ACC), which showed smaller activation differences between the rewarded incongruent and control trials, compared to non-rewarded trials. Additionally, an interaction was also observed in the midbrain; however, here the difference was larger for the rewarded trials, potentially reflecting increased effort to resolve the conflict. Finally, intermodal correlations were performed between the N450 and ACC, which is suggested to be one of the key mediating regions involved in reward-based decision making. As hypothesised, there was a positive correlation between the ERP and BOLD signal differences for the non-rewarded incongruent minus control condition, where the incongruent trials elicited stronger neural responses in both EEG and fMRI compared to control. However, in the rewarded trials, only the N450 showed a large difference, indicating that ACC activity is strongly driven by reward that may override any conflict-related activations when averaged over time. This suggests that conflict processing within the context of reward is a transient process that may only be detected using temporally sensitive methods, highlighting the importance of multimodal recordings.

Ctr., Nijmegen, Netherlands; [4]Nijmegen Inst. for Scientist Practitioners in Addiction, Radboud Univ., Nijmegen, Netherlands; [5]Max Planck Inst. for Human Develop., Berlin, Germany; [6]Dept. of Psychiatry and Psychotherapy, Univ. Clin. Hamburg-Eppendorf, Hamburg, Germany; [7]Early psychosis department, Academic Med. Center, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: **Importance:** Disrupted brain reward processing, mainly driven by ventral striatal (VS) dysfunction, is considered a key process in addictive behaviours. However, conflicting results have been reported on the exact nature and direction of reward processing disruptions in addiction using functional Magnetic Resonance Imaging (fMRI). In the context of addiction, both hypo and hyper activation have been reported during both anticipation and outcome notification of rewards.
Objective: To identify brain reward processing disruptions during anticipation and outcome notification of monetary rewards in addicted individuals by image-based meta-analysis of fMRI studies. **Data Sources:** Pubmed until January 2015.
Study Selection: Inclusion criteria: 1) reward task involving monetary reward anticipation and/or outcome; 2) addictive behavior including substance addiction or gambling disorder; 3) healthy control group. Exclusion criteria: 1) Age < 18; 2) recreational substance use or gambling; 3) at risk group; 4) patient overlap between studies using the same task.
Data Extraction and Synthesis: Study procedures were conducted in line with the MOOSE guidelines. Using Seed-based *d* Mapping software, meta-analyses were performed with group *T*-maps from individual studies as input (83% response rate from authors for sending group *T*-maps).
Main Outcome and Measures: Estimation of cross-study consistency of between-group differences in reward-related brain activation patterns for reward anticipation and outcome.
Results: 25 studies were included in the meta-analyses representing 643 individuals showing addictive behaviors and 609 healthy controls. Data was analysed using *Seed-based d Mapping* software using non-parametric statistics and with a statistical threshold that offers a protection against false positives that is similar to a corrected $p<0.05$. The main findings include *decreased* VS activation across individuals with different types of addictive behaviour (including substance addiction and gambling) compared with healthy controls during *reward anticipation.* During *reward outcome,* substance addicted individuals showed *increased* activation in the VS compared with healthy controls, whereas individuals with gambling disorder showed *decreased*

activation in the dorsal striatum (DS) compared with healthy controls.
Conclusions and Relevance: These findings cannot be directly reconciled with any of the currently dominant addiction theories, including the Reward Deficiency Syndrome, Incentive Salience Theory or Impulsivity Theory. As such, we believe they are helpful in refining current hypotheses about reward dysfunction in addition.

Title: Structural and functional neural characterization of the Monetary Incentive Delay Inhibition (MIDI) task

Authors: *J. K. LEONG[1], K. HENNIGAN[1], G. R. SAMANEZ-LARKIN[2], B. KNUTSON[1]; [1]Stanford Univ., Stanford, CA; [2]Yale Univ., New Haven, CT

Abstract: Over a decade of human and monkey studies have shown that the structural integrity of the right ventrolateral prefrontal cortex (vlPFC) is critical for motor inhibition. Most of these studies, however, have not examined inhibition under incentivized conditions. In this study, we imaged structural connections from vlPFC, and functional brain activity associated with motor inhibition to earn monetary incentives (n=23, mean age=37, right-handed). We found that while high incentives enhanced faster motor responses to obtain incentives (paired $t(22)=4.22$, $p<0.001$), they also increased the difficulty of inhibiting motor responses (paired $t(22)=-2.88$, $p<0.01$). We then identified a white-matter tract connecting the vlPFC to the anterior insula (AIns), and also replicated characterization of a tract connecting the AIns to the nucleus accumbens (NAcc). Individual differences in the coherence of both of these tracts, in addition to functional brain activity, were independently associated with individual differences in successful inhibition for high incentives, even after controlling for age ($F(5,17)=35.06$, $p<0.0001$; AIns-NAcc: $B=0.60$, $t=7.73$, $p<0.0001$; vlPFC-AIns: $B=-0.61$, $t=-7.43$, $p<0.0001$; AIns activity:

B=0.23, t=2.52, p<0.05; vlPFC activity: B=0.29, t=3.20, p<0.01; age: B=-0.07, t=-0.9, p=0.40; all coefficients are standardized). However, it was unclear whether functional brain activity during anticipation of high incentives was blunted due to uncertainty in mixed task demands to both motorically respond as well as inhibit responses. To test this possibility, we compared brain activity in the incentivized inhibition (MIDI) task to a monetary incentive delay (MID) task that required only motor responses without inhibition. Contrasts revealed that subjects showed higher NAcc activity during anticipation of equivalently high gains in the MIDI vs the MID task (VOI analysis: paired t(22)=1.96, p=0.06). Together, these findings validate a new incentivized inhibition task, indicate that knowledge about brain structure can guide functional and behavioral models, and clarify multiple brain systems that subserve incentivized inhibition.

Title: Human mesostriatal response tracks motivational tendencies under naturalistic goal-conflict

Authors: *T. GONEN[1], E. SOREQ[2], E. ELDAR[3], E. BEN SIMON[2], G. RAZ[2], T. HENDLER[2]; [1]Dept. of Neurosurg. & FBC, TLVMC, Tel Aviv-Yafo, Israel; [2]Functional Brain Ctr., Tel Aviv Med. Ctr., Tel Aviv, Israel; [3]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom

Abstract: Goal-conflict situations, involving the simultaneous presence of reward and punishment, occur commonly in real life, and are known to unfold rapidly within our ever-changing environment. Such conflicts increase the complexity of motivational decision making and reflect well-known individual differences in the behavioral tendency to approach or avoid. However, despite accumulating neural depiction of motivational processing, the investigation of real life approach behavior and its interplay with individual tendencies is remarkably lacking. To that end, we developed a novel ecological interactive scenario which triggers motivational

behavior under high- or low- goal-conflict conditions. 55 healthy subjects played the game during an fMRI scan. Machine learning approach was applied to classify approach/avoidance behaviors during the game. To achieve an independent measure of individual tendencies, integrative profile was composed from three established theoretical models. Results demonstrated an extensive network underpinning dynamic approach behavior, including regions involved in incentive processing (e.g. Ventral Striatum [VS], Ventral Tegmental Area [VTA]), saliency tagging (e.g. Pulvinar and anterior Insula) and motor planning (e.g. supplementary motor area, premotor cortex). More specifically, approach under high-conflict involved activity confined to VTA, PAG, VS and precuneus. Notably, only VS and VTA activations during high-conflict discriminated between approach/avoidance personality profiles, suggesting that the relationship between integrative personality profile and naturalistic motivational tendencies is uniquely associated with the mesostriatal pathway. These findings are the first to unravel the multilevel relations between personality profile, real-time behavioral differences in approach tendencies and their underlying neural manifestation; thus enable new avenues for investigating approach-related psychopathologies.

Title: Differential involvement of the prefrontal cortex and the amygdala in motivation

Authors: ***I. M. WHITE**[1,2], H. HOWARD[2], Z. ABBOTT[2], W. WHITE[1,2];
[1]Psychology, [2]Neurosci. Program, Psychology, Morehead State Univ., Morehead, KY

Abstract: Previously, we reported that the combination of stress and scopolamine severely impaired simple memory and that stress augmented scopolamine-induced memory deficits, producing a condition resembling that seen in the aged and in Alzheimer's patients. This study examined the involvement of the medial prefrontal cortex (mPFc) and the basolateral amygdala (BLA) in motivation and further examined the effects of scopolamine on motivation, using two appetitive tasks with differential workloads. Male Wistar rats were shaped to press a lever for a food reward, then received NMDA (10μg/μl, 0.5μl/site) or sham lesions in the mPFc or the BLA.

After recovery, rats were given alternating sessions of fixed ratio 5 (FR5) and fixed ratio 20 (FR20). The FR20 entailed a higher workload, and food procurement on the schedule required a higher level of motivation and more sustained attention. Prefrontal lesions markedly impaired performance on FR5 and FR20, with greater deficits during FR20, reflecting an impairment in motivation due to a greater workload requiring sustained attention. BLA lesions had little to no effect on FR5 but produced a slight impairment during FR20. Scopolamine-induced deficits were greater during FR20. Neither lesions nor scopolamine affected consummatory behavior. Our results suggest that the mPFc, but not the BLA, plays a role in motivation to procure food, and that the mPFc is necessary when a greater response requirement and sustained attention are in demand. Our results also suggest that the muscarinic receptor modulates prefrontal involvement in motivation, and they predict impaired motivation in Alzheimer's patients under conditions with a greater workload.

Title: Effects of behavioral activation on the neural basis of other perspective self referential processing in subthreshold depression: An fMRI study.

Authors: S. SHIOTA[1], Y. OKAMOTO[1], *G. OKADA[1], K. TAKAGAKI[1], M. TAKAMURA[1], A. MORI[1], S. YOKOYAMA[1], Y. NISHIYAMA[1], R. JINNIN[1], R. HASHIMOTO[2], S. YAMAWAKI[1];
[1]Deparetement of Psychiatry, Hiroshima Univ., Hiroshima/Hiroshima, Japan; [2]Dept. of Language Sciences, Grad. Sch. of Humanities, Tokyo Metropolitan Univ., Tokyo/Tokyo, Japan

Abstract: It is known that subthreshold depression has a considerable impact on the quality of life, carries an elevated risk of developing a major depression, and can lead to serious functional impairment, including a negative impact on academic performance and social activity. Given

these concerns, it is very important to elucidate the pathogenic mechanisms underlying subthreshold depression and to develop effective interventions. It has been demonstrated that individuals with depression show negatively distorted evaluation of one's own self using his or her friend's viewpoint, and such altered self referential processing led to maintenance of depressive symptoms. Behavioral activation (BA) is one key component of cognitive behavior therapy for depression, and is an effective intervention for the treatment of major depression. However, brain mechanisms underlying the BA are not fully understood. We examined the effect of BA on neural activation during other perspective self referential processing in subthreshold depression. Freshmen attending Hiroshima University were recruited for the randomized controlled trial. Fifty-nine subjects underwent fMRI scans during a referential task with two viewpoints (self / other) and two emotional valences (positive / negative). For the intervention group, the scan occurred both before and after BA intervention, and the control group was also scanned twice, with an interval of 5 weeks without any intervention. We found an increased activation in the dorsal medial prefrontal cortex (dmPFC) in other perspective self reference for positive words after BA, and there was a positive correlation between the increased activation in the dmPFC and improvement of depressive symptoms. Additionally, reaction times for other perspective self referential judgement for positive words was increased in the intervention group after BA, and there was a positive correlation between improvement of depressive symptoms and the increased reaction times. BA increased dmPFC activation during other perspective self referential processing of positive words processing with improvement of depressive symptoms and increased reaction times which were associated with improvement of self monitoring function. These results suggest that BA led to increased activation in the dmPFC during other perspective self referential processing of positive words in people with subthreshold depression, which might contribute to improvement in depressive symptoms and objective monitoring function.

Title: Reward processing and expectancy violation in dyadic-interaction: an EEG analysis

Authors: *K. JENSON[1], A. LI[2], S. MAKEIG[3], G. DEAK[2];
[1]UC San Diego, LA Jolla, CA; [2]Cognitive Sci., UC San Diego, La Jolla, CA; [3]Inst. for Neural Computation, La Jolla, CA

Abstract: To investigate real-time, naturalistic social decision-making, we collected EEG within a real-time, relatively unrestricted social game. Two subjects took part in each session (N = 26; 11 complete dyads). Subjects took turns touching one of two bubble animations shown on a screen between them with the goal of eliciting a "big pop" (high reward) instead of a "dull bloop" (low reward). Subjects were naïve to the feedback selection contingencies -- touching the same bubble that the other player had touched on the previous turn produces a pop -- and thus had to learn it by trial and error. Each session consisted of a 64-trial *rule-learning* block followed by two *unpredictable* blocks (totaling 400 trials) in which the outcome contingencies were reversed in 20% of the trials (randomly selected), and lastly a block of 48 trials with the original contingencies. Late Positive Complex ('P3') features of scalp ERPs were modulated by reward and uncertainty. We used independent component analysis (AMICA) to unmix the EEG signals, then clustered the resulting independent components (ICs) using k-means based on the equivalent dipole location. We further analyzed two IC clusters that accounted for the most ERP variance from 200 to 700ms. The equivalent dipole locations of ICs contributing to these two clusters were localized to different regions of anterior cingulate cortex (ACC): one centro-medial, the other rostro-inferior. ERP amplitudes for the more centro-medial-ACC cluster were larger for high-reward outcomes ($F(3,33) = 3.02$, $p = 0.04$) whereas for the more rostral-ACC cluster ERP amplitudes were larger following unexpected outcomes ($F(3,30) = 4.34$, $p = 0.01$). These results suggest that reward and uncertainty processing exhibit unique dynamics in distinguishable cortical networks. Further, these results provide additional evidence that the LPC/P3 consists of multiple spatially, temporally and functionally distinct source processes. Incidentally, the dynamics reported showed qualitatively similar, but non-significant, trends in trials in which participants viewed their partner's actions.

Title: Feasibility of multiband EPI for detection of brain activation in the reward system

Authors: *M. TAGHIZADEH SARABI, R. KEERATIVITTAYAYUT, K. NAKAHARA, R. AOKI;
Kochi Univ. of Technol., Kami-city, Japan

Abstract: The recently-advanced multiband echo planar imaging (MB-EPI) technique has become increasingly used in functional magnetic resonance imaging (fMRI) studies. In this study to examine whether MB-EPI can detect brain activation as satisfactorily as standard EPI (ST-EPI) in the reward system, we scanned twenty-four healthy human participants (twelve females and twelve males; mean age = 20.0 years, range = 18-23 years) using both MB-EPI (multiband factor = 5, TR = 720 ms, voxel size = 3 mm^3, TE = 30 ms, slice number = 45, flip angel = 52°) and ST-EPI (TR = 2500 ms, voxel size = 3 mm^3, TE = 30 ms, slice number = 38, flip angel = 80°). Participants took part in two fMRI sessions, one with MB-EPI and the other with ST-EPI, separated by five-minute break. The order of the sessions was counterbalanced across participants. In each fMRI session, participants performed 100 trials (divided into two runs) of the monetary incentive delay (MID) task. The task included five reward cue conditions (0 yen, ±20 yen, and ±400 yen), and the outcomes were defined as either hits or misses based on the participant's reaction time to a visual target presented after the cue. To identify brain activation to reward anticipation, we contrasted the hemodynamic response to the high-gain (+400 yen) vs. low-gain (+20 yen) cue. To identify brain activation to reward outcome, we contrasted hit vs. miss outcomes in the gain (+20 or +400 yen) trials. In the reward anticipation phase, we observed significant activation in the ventral striatum both in ST-EPI and MB-EPI sessions (one-sample *t* test, $P < 0.05$, FWE corrected across the whole brain), with no significant difference between the sessions (paired *t* test, $P > 0.05$, FWE corrected within the anatomical mask of the striatum). Likewise in the reward outcome phase, both ST-EPI and MB-EPI showed significant activation (one-sample *t* test, $P < 0.05$, FWE corrected across the whole brain) in the ventromedial prefrontal cortex (vmPFC), with no significant difference between the sessions (paired *t* test, $P > 0.05$, FWE corrected within the anatomical mask of the vmPFC). The results of the current study demonstrate that MB-EPI is as useful as ST-EPI in detection of brain activation in the striatum and vmPFC: two predominant brain regions of interest related to reward anticipation and outcome phase, respectively. Given the broader spatial coverage of the brain and higher temporal resolution, MB-EPI is a promising option to study the functions of the reward system as well as its interactions with other brain regions. The advantages of MB-EPI

will be further enhanced by selecting optimal scan parameters (TR, voxel size, and multiband factor), which should be determined in future studies.

Title: Bidirectional modulation of aversive fear learning by 5-HT1A receptors in the BNST

Authors: ***C. A. MARCINKIEWCZ**, C. DORRIER, T. L. KASH;
Neurosci., Univ. of North Carolina, Chapel Hill, NC

Abstract: Serotonin is often hailed as a positive regulator of emotion, but it also has a dark side. Selective serotonin reuptake inhibitors (SSRIs) often induce a negative emotional state characterized by feelings of anxiety and panic. The circuits through 5-HT modulates which these aversive states have not been defined, but converging evidence has implicated the bed nucleus of the stria terminalis (BNST) as a critical neural substrate. Recent work in our lab suggests that 5-HT_{2C} receptors in the BNST increase excitability of a subset of CRF neurons that enhance cued fear recall, but that these actions are opposed by 5-HT_{1A} receptors. In order elucidate the role of 5-HT_{1A} receptors in fear-related behavior, we utilized a transgenic floxed 5-HT_{1A} receptor mouse to genetically delete 5-HT_{1A} receptors in the BNST. Specifically, viral vectors containing the gene for Cre recombinase or a control vector were infused into the BNST of genetically modified 5-HT_{1A} receptor mice. Using a classic tone/shock fear conditioning paradigm, we then assessed fear learning and recall. Our preliminary results indicate that genetic deletion of 5-HT_{1A} receptors in the BNST reduces cued fear but enhances contextual fear recall. These data suggest that associative fear learning may be bidirectionally modulated by 5-HT_{1A} and 5-HT_{2C} receptors in the BNST.

Title: JNK1 regulates adult hippocampal neurogenesis and controls anxiety and depressive behaviour

Authors: *F. MARCHISELLA[1], H. MOHAMMAD[1], S. ORTEGA-MARTINEZ[1], P. HOLLOS[1], K. EEROLA[2], E. KOMULAINEN[1], N. KULESSKAYA[3], E. SAVONTAUS[2], H. RAUVALA[3], B. PETERSON[4], H. VAN PRAAG[4], E. COFFEY[1];

Center, Univ. of Helsinki, Helsinki, Finland; [4]Neuroplasticity and Behavior Unit, Lab. of Neurosciences, Intramural Res. Program, Natl. Inst. on Aging, Natl. Inst. of Hlth., Baltimore, MD

Abstract: Anxiety and depression together represent the second largest cause of years lived with disability (YLD) (Vos et al. 2012), and the World Health Organization projects that by 2020, neuropsychiatric conditions will account for 15 % of YLD worldwide. Depression and anxiety show comorbidity of up to 60 %, suggesting that there is overlap in the underlying pathophysiological mechanism. Sad mood and lack of pleasure in daily situations (anhedonia) are common features of depression, while an excessive and overwhelming sense of worry and anticipation of fear are common features of anxiety.
It is widely reported in the literature that the stimulation of adult hippocampal neurogenesis, is required for the therapeutic effect of different classes of anti-depressant drugs: serotonin reuptake inhibitors, selective norepinephrine reuptake inhibitors and electroconvulsive shock (Duman 2004). Conversely, decreased neurogenesis is associated with anxiety and depression in mice (Snyder et al. 2011) and in humans (Drew & Hen 2007). Hence, targeting mechanisms that regulate adult hippocampal neurogenesis is expected to induce neuroplasticity changes that improve mood and alleviate anxiety and depression.
c-Jun N-terminal kinases (JNKs) are members of the mitogen-activated protein kinase (MAPK) family that regulate physiological and pathological processes in the central nervous system (Coffey 2014). In particular, JNK1 is a dominant regulator of neuronal differentiation during development. Here, we investigate the role of JNK1 in adult hippocampal neurogenesis using knockout mice and inhibitor infusion. Histological analysis of brain sections from these animals display significant changes in hippocampal neurogenesis, dentate gyrus volume and dendritic

morphology upon genetic ablation of *Jnk*1, as does infusion with a specific inhibitor of JNK. We will present data from a battery of behavioral tests that measure anxiety and depression-related behavior in mice where JNK signaling is disturbed following genetic ablation, pharmacological inhibition or retroviral targeting of neurogenic niche cells.

Title: Elucidating the neural circuitry of social familiarity-induced anxiolysis.

Authors: S. MAJUMDAR[1], E. A. LUNGWITZ[1], R. DU[2], K. D. ANDREWS[3], A. D. DIETRICH[4], *W. A. TRUITT[4];
[1]Indiana Univ. Sch. of Med., indianapolis, IN; [2]Carmel High Sch., Carmel, IN; [4]Anat. and Cell Biol., [3]Indiana Univ. Sch. Med., Indianapolis, IN

Abstract: The social interaction habituation (SI-hab) protocol has been used to demonstrate that rats acquire social familiarity-induced anxiolysis (SoFiA), which is a type of safety learning where rats display reduced anxiety-like behavior (anxiolysis) in the presence of a familiar partner. SoFiA acquisition is dependent on both anxiogenic stimulus and social familiarity during training sessions. Additionally, SoFiA acquisition and expression are dependent on the ventro-medial prefrontal cortex (vmPFC). *Thus SoFiA acquisition and expression can be simplified into four different constructs: social memory, anxiety, safety learning and anxiolysis and these constructs are hypothesized to be coordinated by the vmPFC.* However, the SoFiA neural circuitry has not been identified. As a first step towards elucidating the SoFiA neural circuitry we are identifying key neural structures with activity patterns corresponding to each of the SoFiA constructs. The SoFiA constructs can be isolated, by manipulating the SI-hab protocol. Briefly, the SI-hab protocol involves a baseline SI test followed by 5 daily social training sessions, which are comprised of a 5 min social interaction test. Two main factors during the social training sessions were manipulated, type of conspecific (familiar or novel) and anxiogenic stimulus (low vs high). The anxiogenic stimuli for these studies were control (dim

light) for low and the bright light challenge (BLC) for high anxiety stimulus. Anxiety-like behavior was determined by social interaction (SI) time, time experimental rat spent initiating social investigation, where SI time is inversely related to anxiety-like behavior. This resulted in four groups: 1. Control (low anxiety + novel partner); 2. Social memory (low anxiety + familiar partner); 3. Anxiety (high anxiety + novel partner); 4. SoFiA (high anxiety + familiar partner). As expected, for groups 1 & 2 SI time remained similar to baseline across all SI-hab sessions, indicating no change in anxiety-like behavior. Compared to baseline, group 3 displayed reduced SI time during all SI-hab sessions. Group 4 displayed a transient reduction in SI time in the initial SI-hab sessions, compared to baseline, and returned to baseline SI times by day5 indicating a SoFiA response. For experiment 1, rats were perfused 90 min following the last SI-hab session and brains were processed for cFos immunohistochemistry. Rats for experiment 2 were sacrificed and brains were processed for RNA isolation for immediate early gene expression (qPCR). From these tissues we are in the process of identifying brain regions with immediate early gene expression that correspond with the 4 treatment conditions.

Title: Increased anxiety and altered metabolic set-point in a juvenile mouse model of chemotherapy-induced alopecia

Authors: *M. D. BERRY[1], D. GARDINER[1], M. C. ENNIS[1,2], H. M. RIVKIN[1], P. E. MCCALLUM[2], M. S. PITTS[1,2], J. BLUNDELL[2];
[1]Biochem., Mem. Univ. of Newfoundland, St John's, NL, Canada; [2]Psychology, Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Growing evidence indicates that pharmacotherapy of cancer can be associated with an increased incidence of anxiety, depression, and cognitive impairments that persist long after

chemotherapy has concluded. In the current study we examine for the presence of behavioural markers of such deficits in our previously established model of chemotherapy-induced alopecia in juvenile, female C57BL/6 mice, and determine whether the known neuroprotectant, (-)deprenyl, can prevent such changes. All animals were housed on a reverse light cycle with food and water *ad libitum*. Mice were depilated at 5-6 weeks of age and cyclophosphamide (150 mg/kg i.p.) administered on days 7, 9, and 11 post-depilation. On day 7 post-depilation animals also had an osmotic minipump implanted intraperitoneally for delivery of either (-)deprenyl (0.01 - 1 mg/kg/day) or vehicle. At various time points post-cyclophosphamide animals were tested for anxiety (elevated plus maze), depression (forced swim) and cognition (fear memory) with euthanasia at post-depilation day 35. Weight change, and food and water consumption was monitored daily. A pronounced anorectic effect of cyclophosphamide administration was observed ($P < 0.001$) which lasted for the duration of the study. Daily administration of (-)deprenyl dose-dependently normalized weight gain. In contrast, daily intake of food and water was not altered by any of the treatments. Weight loss in the presence of normal food intake suggests a change in metabolic set-point in response to cyclophosphamide that is prevented by concurrent low dose (-)deprenyl. Although general locomotor activity of animals was not altered, cyclophosphamide administration was associated with a pronounced anxiogenic effect, with treated animals spending significantly less time in the open arms of the elevated plus maze ($P < 0.01$). This effect was also prevented in a dose-dependent manner by (-)deprenyl. In contrast, no evidence of cognitive decline was observed when tested one week following the last dose of cyclophosphamide. Forced swim data is currently being analyzed. In conclusion, at doses that induce alopecia, cyclophosphamide treatment also induces an anorectic and anxiety phenotype in juvenile, female, C57BL/6 mice consistent with clinical reports. This can be prevented by low dose co-administration of the neuroprotectant (-)deprenyl. As such (-)deprenyl may be a useful adjunct to prevent the side effects associated with cancer chemotherapy.

Title: The role of endogenous orphanin FQ/nociceptin in anxiety-like behaviors and rewarding actions of alcohol

Authors: *S. V. PEREZ[1], P. MARQUEZ[2], A. HAMID[2], A. HAMID[2], O. FARHAD[2], K. LUTFY[2];
[1]Col. of Sci., California State Polytechnic Univ. Pomona, Pomona, CA; [2]Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Endogenous orphanin FQ/nociceptin (OFQ/N) has been implicated in anxiety and the rewarding action of alcohol. However, the role of sex in this regard has not been studied previously. Thus, one of the goals of the current study was to determine if the level of anxiety or the magnitude of alcohol-induced conditioned place preference (CPP) would be different between mice lacking the prepro-OFQ/N (ppOFQ/N) and their wild-type controls, and if there would be a sex-related difference in this response. Considering that anxiety may be one of the leading causes of alcohol use disorder and alcoholism, we also examined if exposure to the elevated plus maze (EPM), that is widely used as a model of fear and anxiety, would alter the rewarding action of alcohol and whether there is a sex-related difference in this regard. Male and female mice lacking the ppOFQ/N gene and their wild-type controls were either tested for anxiety-like behaviors using the EPM test (exposed group) or left undisturbed (not-exposed group). The following week mice were tested for alcohol-induced CPP, in which mice were tested for baseline place preference on day 1, conditioned with saline/alcohol (2 g/kg) or alcohol/saline twice daily (15 min each session) on days 2-4 and then tested for postconditioning place preference on day 5. Our results showed that male but not female mice lacking the ppOFQ/N gene spent lesser time on the open arms of the EPM compared to their wild-type littermates, suggesting that null mice exhibited more anxiety-like behaviors compared to their wild-type controls and there was a sex-related difference in this regard. While there was no difference in the magnitude of ethanol-induced CPP between non-exposed mice lacking the ppOFQ/N gene and their wild-type controls, there seemed to be a greater CPP response in female mice compared to male wild-type mice but this difference was not observed between male and female mice lacking the ppOFQ/N gene. Interestingly, male but not female mice lacking the ppOFQ/N exposed to the EPM exhibited a significantly greater CPP response compared to their wild-type controls. Together, the results of the present study show that the rewarding action of alcohol was enhanced in animals exhibiting greater anxiety and endogenous OFQ/N system may serve a protective role in this regard, and there may be a sex-related difference in this regard.

Title: Effects of repeated testing on anxiety-like behaviors in the elevated plus maze and elevated zero maze in male and female C57BL/6J mice

Authors: *L. B. TUCKER[1,2], A. H. FU[1,2], J. T. MCCABE[1,2];
[1]Anatomy, Physiol. & Genet., Uniformed Servies Univ. of the Hlth. Sci., Bethesda, MD; [2]Ctr. for Neurosci. and Regnerative Med., Bethesda, MD

Abstract: The elevated plus maze (EPM) and elevated zero maze (EZM) are behavioral tests that are widely employed to assess anxiety-like behaviors in rats and mice following experimental manipulations, or to test the effects of pharmaceutical agents. Both of these tests are based on approach/avoidance conflict, with rodents perceived as “less anxious” being more willing to explore the brighter, open and elevated regions of the apparatus as opposed to remaining in the darkened and enclosed regions. There are experimental designs in which there may be a need to measure anxiety at multiple time points following an experimental manipulation, but there is a paucity of data regarding the effects of repeated testing in these apparatuses. In this experiment, male and female C57BL/6J mice were tested either daily or weekly in the EPM or EZM for a total of five exposures. Preliminary data suggest that mice tend to be more anxious in the EPM than in the EZM, as measured by the amount of time spent in the anxiogenic zones of the apparatus. Mice were more likely to habituate to the EPM than to the EZM with either daily or weekly testing, as both the total distance traveled and amount of time in the open arms of the EPM decreased with more exposures. These measures remained relatively stable in the EZM. There was a drastic effect of cohort on anxiety-like behaviors, which may have resulted from a change in housing rooms for one group of animals the day prior to the beginning of testing. However, this only had an effect on behavior in the EPM, suggesting that behavior in the EZM may be more resistant to the effects of environmental stressors. These preliminary data do not suggest any overt sex differences. In summary, results at this time indicate that the design of the EZM encourages greater exploration of anxiogenic regions in mice, and the lack of habituation to the apparatus makes the EZM more suitable for experimental designs in which repeated testing is necessary.

Title: Exploring the role of orexinergic mechanisms in mediating individual differences in fear extinction responses.

Authors: *A. C. SHARKO, K. F. KAIGLER, J. R. FADEL, M. A. WILSON;
Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Post-traumatic stress disorder (PTSD) is a severe anxiety disorder that can develop after experiencing a life-threatening trauma, such as combat service, assault, or natural disaster. Not everyone who experiences these types of traumas develops PTSD, suggesting that some neurobiological factors may confer resiliency, or risk, to the long-term negative effects of traumatic stress. Our laboratory has demonstrated that outbred Long-Evans rats show individual differences in conditioned anxiety-like behaviors, with significant variability in extinction of freezing behavior following fear conditioning, suggesting that this strain may serve as a useful model for characterizing the neurobiological mechanisms that underlie differential sensitivity to traumatic stress. The orexin/hypocretin system, in particular, has been implicated in the modulation of stress-induced anxiety-like behaviors and conditioned fear responses. Hypothalamic orexin neurons project to the prefrontal cortex and the amygdala, two brain regions known to mediate behavioral responses to stressful stimuli. Orexin neurons also project directly to cholinergic neurons in the basal forebrain, which modulate attentional processes through inputs to the prefrontal cortex and amygdala. Using dual label immunohistochemistry, Fos expression in orexinergic neurons was assessed to identify differential patterns of activation in these neuronal populations associated with individual differences in the extinction of fear-conditioned freezing behaviors. Two cohorts of rats were exposed to three tone-shock pairings, followed by extinction training two days later in a novel environment with twenty cue (tone) presentations. Rats were divided into high or low extinction groups based on freezing behavior during the last ten minutes of this extinction trial. Extinction learning was assessed two days later and tissue was collected for immunohistochemical analysis. Rats showing resistance to fear extinction (high freezers) had significantly more dual Fos/orexin-A positive cell counts in the medial hypothalamus than low freezers, suggesting that differential activation of orexin neurons may contribute to individual differences in extinction of fear responses. Interestingly, no individual differences were detected in the lateral hypothalamus. Additional studies examining

the behavioral and neurobiological effects of pharmacological manipulation of orexinergic signaling suggest that orexin activity may modulate consolidation of conditioned fear memories or expression of fear conditioned behaviors. Title: Neuronal deletion of Kmt2a/Mll1 histone methyltransferase in ventral striatum is associated with defective spike-timing dependent striatal synaptic plasticity, altered response to dopaminergic drugs and increased anxiety

Authors: *B. JAVIDFAR[1], E. Y. SHEN[2], Y. JIANG[2], B. KASSIM[2], Y.-H. E. LOH[3], Q. MA[4], A. C. MITCHELL[2], V. POTHULA[1], A. STEWART[5], P. ERNST[6], W.-D. YAO[4], G. E. MARTIN[7], L. SHEN[3], M. JAKOVCEVSKI[8], S. AKBARIAN[2];

Sch., Worcester, NY; [8]Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: *Lysine methyltransferase 2a (Kmt2a)* and other regulators of H3 lysine 4 methylation, a histone modification enriched at promoters and enhancers, are widely expressed throughout the brain but molecular and cellular phenotypes in subcortical areas remain poorly explored. We report that *Kmt2a* conditional deletion in postnatal forebrain is associated with excessive

nocturnal activity and paradoxical or blunted responses to stimulant and dopaminergic agonist drugs, in conjunction with near-complete loss of spike timing-dependent long term-potentiation (tLTP) in medium spiny neurons. Selective ablation of *Kmt2a,* but not the ortholog *Kmt2b*, in adult ventral striatum/nucleus accumbens neurons markedly increased anxiety scores in multiple behavioral paradigms. Striatal transcriptome sequencing in adult mutants identified 262 *Kmt2a*-sensitive genes, mostly downregulated in *Kmt2a* deficient mice. Transcriptional repression includes the *5-Htr2a* serotonin receptor, strongly associated with anxiety and depression related disorders in human and animal models. Consistent with the role of *Kmt2a* in active transcription, the transcriptional regulators *Isl1* and *Sp9* were downregulated and affected by H3K4 promoter hypomethylation. Therefore, *Kmt2a* regulates synaptic plasticity in striatal neurons and provides an epigenetic drug target for anxiety and dopamine-mediated behaviors.

Title: Effects of environment on behaviors in the elevated plus maze, marble arena, and hole board in the neoclomipramine rodent model of Obsessive Compulsive Disorder

Authors: *S. R. LOCKHART[1], D. D. MARINARO[1], D. S. KREISS[1,2];
[1]Psychology, Ithaca Col., Ithaca, NY; [2]Psychology, Neurosci. Program, Washington and Lee Univ., Lexington, VA

Abstract: Obsessive Compulsive Disorder (OCD) is characterized by persistent, anxiety producing thoughts accompanied by overwhelming urges to perform repetitive, ritualistic behaviors. Modern pharmacological treatments for OCD are only effective in 40-60% of patients and have an 8-10 week delayed onset. Establishment of an animal model of this debilitating disorder would provide an invaluable research tool for the development of new avenues of treatment. The current study evaluated environmental effects on an animal model of OCD based upon neonatal exposure to clomipramine, an uptake inhibitor of serotonin and norepinephrine. In

this model, experimental male Sprague-Dawley rats are administered 15 mg/kg clomipramine twice daily during neonatal Days 9-16 (= neoclom). Prior studies have demonstrated that the neoclomipramine model has both face and predictive validity assessed via the Hole Board, Marble Arena, and Elevated Plus Maze (SFN and FUN abstracts, 2013, 2014, 2015). To investigate the influence of diverse environmental conditions upon this OCD model, the present study quantified the behaviors of neoclom and control rats following long term housing in either an enriched or an isolated environment. **Results showed that neonatal exposure to clomipramine attenuated the effects of being housed in an ISOLATED environment.** Control animals reared in an ENRICHED environment spent significantly more time in open arms of EPM, less time in closed arms, and had more open arm entries and total arm entries as compared to control rats reared in ISOLATION. In the Hole Board, control rats reared in an ENRICHED environment trended toward poking less than control ISOLATED rats (p=0.057). However, neoclom ENRICHED rats only differed from neoclom ISOLATED rats in the number of pokes per hole. **Results also indicated that being housed in isolation noticeably attenuated the effects of neonatal exposure to CLOMIPRAMINE.** Compared to enriched CONTROL rats, enriched rats neonatally exposed to CLOMIPRAMINE spent significantly more time in the closed arms and had trends for less time spent in the open arms (p=0.072), less open arm entries (p=0.061), less total arm entries (p=0.065) and more pokes (p=0.063). In contrast, the only behavioral difference exhibited by isolated NEOCLOM rats versus isolated CONTROL animals was a trend for more time spent in closed arms of the EPM (p=0.070). Taken together, the present study emphasizes the importance of environmental conditions when evaluating the validity of behavioral animal models of OCD and other anxiety disorders.

Title: Stress related alterations in neurotransmitter levels in the prefrontal cortex and amygdala; an *In vivo* microdialysis study

Authors: M. MONBUREAU, A. ARANOV, H. KOOIJKER, Y. CHANG, L. YU, C. CIARELLO, M. VAN DER HART, N. MOORE, H. JANSSENS, *A. RASSOULPOUR; Brains On-Line, LLC, South San Francisco, CA

Abstract: It has been previously demonstrated that exposure to various stressors can modulate amino acids and monoamines in different brain regions. Social defeat stress has been shown to modulate dopamine (DA) levels in the basal ganglia and cortex (Tidely and Miczek, 1996), restraint stress was shown to modulate levels glutamate (Glu) and aspartate levels in the amygdala (Reznikov; 2007), cortex and basal ganglia (Moghaddam, 2006), and psychological stress was shown to modulate serotonin (5HT) levels in the amygdala and cortex (Kawahara et al, 1993). Based on some of these findings, we set out to do a side by side comparison of different stress models (chronic social defeat, psychological stress induced by foot shock, and restraint stress) on changes in a panel of neurotransmitters (NT) in the brain of freely moving rats. To this end, bi-lateral microdialysis probes were placed in the prefrontal cortex and amygdala of adult rats and the levels of DA, 5HT, Glu, norepinephrine (NE), gamma-aminobutyric acid (GABA), and glycine (gly) were measured before, during and after exposure to various stressors. We found regionally distinct changes within animals that were paradigm dependent. For example, increases in DA, 5HT, and NE were observed in the amygdala of rats exposed to foot shock while socially defeated animals showed an increase in cortical levels of DA, 5HT, NE, and GABA when exposed to aggressive animals. The current findings confirm and expand on previous published results on the ability of various stressors to modulate NT levels in different brain regions. We have been able to demonstrate that various brain regions and NT systems are differentially involved in the stress response.

Title: GLRB spastic mice reveal abnormal open space behavior

Authors: *N. SCHAEFER[1], C. RÜDT VON COLLENBERG[1], B. WACHTER[1], R. BLUM[1], J. DECKERT[2], C. VILLMANN[1];
[1]Inst. For Clin. Neurobio., Wuerzburg, Germany; [2]Dept. of Psychiatry, Psychosomatics and Psychotherapy, Wuerzburg, Germany

Abstract: *GLRB* encodes the β-subunit of the adult glycine receptor (GlyR). This inhibitory ion channel is important for fast inhibitory neurotransmission in the central nervous system. Glycine receptors form a pentameric receptor complex of two α and three β subunits. The β subunit is required for GlyR anchoring via gephyrin to the postsynaptic cytoskeleton. So far, mutations in the *GLRB* gene have been assigned to the neuromotor disorder startle disease. Patients with this rare neurological disorder suffer from exaggerated startle responses following unexpected noise or tactile stimuli.
A genome-wide association study provided evidence for a link between *GLRB* gene polymorphisms of agoraphobic (AG) patients with an anxiety phenotype based on an Agoraphobic Cognitions Questionnaire (ACQ) in healthy German volunteers. AG is characterized by abnormal open space behavior as well as distorted cognitive processes. Familial aggregation has been determined for AG and PD (panic disorder). Twin studies exhibited a respective heritability in PD and AG of about 38%-48%.
To further analyze the possible cause of AG/PD phenotype by mutations within the *GLRB* gene, we performed an analysis of agoraphobic behavior in mice with a partial *Glrb* knock-out (*spastic*). So far, *spastic* mice resemble the best characterized *Glrb* mouse model. Homozygous *spastic* mice show a neuromotor phenotype due to a splice defect within the *Glrb* gene. The splice defect generates aberrant splice products that lack exon 6 or a combination of exons 5 and 6. As a consequence, reduced amounts of full-length GlyR β protein have been observed. Heterozygous *Glrb* mutants lack about 50% of full-length GlyRβ in brain regions including cortex, cerebellum, thalamus, striatum, hippocampus, brain stem and spinal cord. Notably, heterozygous *spastic* mice show a quite inconspicuous behavioral phenotype, beside an avoidance of a novel open space, a behavior we recently confirmed to relate to agoraphobic fear in humans.
In summary, our findings provide evidence that *GLRB* allelic variation may contribute not only to the neurological disorder hyperekplexia, but also to the risk of the categorical anxiety disorder PD/AG by increasing startle response and agoraphobic behavior.

Title: FKBP51 depletion upregulates HTR1A and ameliorates BDNF reduction and anxiety-like behavior in mice under chronic stress

Authors: R.-H. HE[1], C.-Y. WANG[3], *Y.-H. LEE[2];
[2]Physiol., [1]Natl. Yang-Ming Univ., Taipei, Taiwan; [3]Chang Gung Univ., Taoyuan, Taiwan

Abstract: FK506 binding protein 51 (FKBP51) encoded by *Fkbp5* gene is a negative feedback co-chaperon of glucocorticoid receptor, and is upregulated in the brain under chronic stress. Overexpression of FKBP51 has been implicated in the drug resistance in patients with depression and bipolar disorders. 5-HT_{1A} receptor (HTR1A) and BDNF are the two major mental state mediators downregulated in stress-induced depression, but whether their expressions are regulated by FKBP51 were unexplored. In the present study, we examined the role of FKBP51 in the expression of HTR1A and anxiety-like behavior used 4-day dexamethasone (Dex) intake-induced stress mouse model. We found that 4-day Dex intake induced anxiety-like behavior in the elevated plus maze test but not depression-like behavior in the sucrose preference test. This behavioral phenotype was attenuated in Fkbp5-knockout (FKBP51KO) mice. The protein and mRNA levels of FKBP51 were elevated whereas BDNF were decreased under stress, and the latter was significantly upregulated in FKBP51KO mice. Interestingly, HTR1A expression was not affected under chronic stress in wild-type mice, but become much higher in FKBP51KO mice under stress. Together, the results suggest that FKBP51 plays important roles in the expresion of $5HT_{1A}$ receptor and BDNF in stress-induced anxiety, which provide important clues for the therapeutic strategy of stress-induced neuropsychiatric disorders.

Title: Behavioral profiles of C57BL/6 and C57BL/10 mouse substrains: implications for genetic engineering studies

Authors: *C. ST. PIERRE[1], N. M. GONZALES[2], A. A. PALMER[1];
[1]Psychiatry, Univ. of California San Diego, LA Jolla, CA; [2]Univ. of Chicago, Chicago, IL

Abstract: C57BL/6 (B6) mice are the most widely used inbred strains in biomedical research. Several B6 substrains exist that have been maintained as isolated breeding populations for

several decades. These B6 substrains are known to exhibit numerous behavioral and genetic differences. C57BL/10 (B10) mice have also given rise to a number of substrains, which are most commonly used for immunological rather than behavioral studies. We subjected a panel of thirteen different B6 and B10 substrains to a battery of behavioral tests relevant to addiction and psychiatric disorders. The panel included eight C57BL/6 strains (C57BL/6J, C57BL/6NJ, C57BL/6JBomTac, C57BL/6NTac, B6N^{-TyrC}/BrdCrlCrl, C57BL/6NCrl, C57BL/6ByJ, and C57BL/6NHsd) and five C57BL/10 strains (C57BL/10J, C57BL/10ScCr, C57BL/10ScSnJ, C57BL/10SnJ, and C57BL/10ScNHsd). We found significant behavioral differences among the substrains in the open field test, locomotor response to cocaine, fear conditioning, prepulse inhibition, and forced swim test. Our results suggest these substrains have characteristic behavioral profiles that can present a challenge or opportunity for studying mutated genes of interest in disease-relevant CNS pathways. The genetic background should be carefully considered when selecting a substrain in order to detect the predicted behavioral phenotypes and interpret them appropriately. This approach may greatly facilitate the elucidation of candidate genes underlying behavioral differences in psychiatric disorders. We are currently conducting gene expression analyses in several tissues for each substrain in an effort to further understand their behavioral differences.

Title: Effects of NPTX2 on anxiety related behaviours in mice

Authors: *G.-J. HUANG[1], S. CHANG[2];
[1]Chang Gung Univ., Taoyuan City, Taiwan; [2]Chang Gung Univ., Taoyuan city, Taiwan

Abstract: Anxiety disorders can have a significant impact on quality of life and exacerbate other psychiatric conditions associated with high morbidity and mortality such as depression. In our previous study, we used chronic exercise or antidepressants to alter animal anxiety and depression-like behaviours. We identified a list of candidate genes in the hippocampus for which changes in expression were associated with these interventions. Among these genes, we hypothesize that neuronal pentraxin 2 (NPTX2) plays an important role in anxiety. To confirm

this, we specifically knocked out this gene in the central nervous system to by crossing *Nptx2* floxed mice with Sox1-Cre mice. Interestingly, *Nptx2* KO mice exhibited higher levels of anxiety compared to WT mice. In addition, we revealed that *Nptx2* KO mice feature decreased neurogenesis and dendritic spine density together with higher HPA axis and neuronal activity following acute stress. Next, to rule out the possibility that the anxiety phenotype in *Nptx2* KO mice was due to impaired neurodevelopment, we crossed the *Nptx2* floxed mice with CAG-CreER mice to generate an inducible KO model. Our data indicated that inducible *Nptx2* KO mice featured similar deficits. In conclusion, we demonstrated that *Nptx2* influences anxiety behaviours, neurogenesis and neuronal activities.

Title: Forebrain Sirt1 regulates anxiety-like behavior

Authors: *S. GHOSH, S. MUKHOPADHYAY, S. OLKAR, U. SEETHARAM-KOLTHUR, V. A. VAIDYA;
Tata Inst. of Fundamental Res., Mumbai, India

Abstract: Sirt1 is a NAD+ dependent protein deacetylase which acts as a metabolic sensor within several tissues. Sirt1 is highly expressed in the mammalian brain, including limbic circuits such as the hippocampus and prefrontal cortex. Multiple studies have shown that Sirt1 can regulate neuronal survival and differentiation, expression of trophic factors, and synaptic plasticity within these circuits. Previous reports using brain specific Sirt1 knockout mouse lines have implicated neuronal Sirt1 in the regulation of anxiety and depression-like behavior. However, the specific brain regions via which Sirt1 exerts its effects on mood remain poorly characterized. In our study, we have used a forebrain-specific Sirt1 knockout (Sirt1KO) mouse line, generated by crossing Emx1-Cre expressing mice to mice expressing an allele of Sirt1 in which exon 4, containing the catalytic unit, is flanked by loxP sites, to test whether selective removal of functional Sirt1 from the forebrain influences anxiety or depression-like behavior.

Sirt1KO mice exhibit normal development, and were tested on a battery of anxiety and depression-like behavioral tasks upon reaching adulthood. Our results indicate that Sirt1KO animals display reduced anxiety in the open field test, with increased time spent and increased distance moved in the center. Sirt1KO mice also show anxiolytic behavior in the elevated plus maze test, with increased time spent and increased distance moved in the open arms. In contrast, depression-like behavior, as assessed by the tail suspension and forced swim tests, was unchanged in Sirt1KO mice when compared to their wild type littermate controls. Enhanced anxiolysis observed in forebrain-specific Sirt1KO mice recapitulates the decline in anxiety behavior observed in whole-brain Sirt1 knockout mice. In contrast, while whole-brain Sirt1 knockout mice also exhibit antidepressant-like behaviors, forebrain-specific Sirt1KO mice do not show any change in depression-like behavior on behavioral despair tasks. Our studies support a role for forebrain cortical Sirt1 in the regulation of anxiety behavior. Experiments are currently underway to understand the specific regulation of Sirt1-responsive signaling pathways and molecular targets that may mechanistically mediate the behavioral changes observed in the forebrain-specific Sirt1KO mice.

Title: Functional role of cortical layer VIb in mouse behaviour

Authors: *L. GUIDI[1], K. V. KORRELL[1], A. HOERDER-SUABEDISSEN[1], P. L. OLIVER[1], M. C. WILSON[2], P. O. KANOLD[3], D. BANNERMAN[1], Z. MOLNAR[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Univ. of New Mexico, Albuquerque, NM; [3]Univ. of Maryland, College Park, MD

Abstract: Subplate neurons are amongst the earliest generated in the mammalian cerebral cortex and play a critical role during the development of cortical and thalamo-cortical circuits (Hoerder-Suabedissen A, Molnár Z, 2015 Nat Rev Neurosci 16:133-46). The majority of this diverse cell group undergoes cell death over the course of postnatal development - the remainder forms cortical layer VIb. Although impaired subplate is linked to neurodevelopmental disorders (Hoerder-Suabedissen A et al, 2013 PNAS, 110:3555), little is known about the functional roles of the adult layer VIb.

Here, we investigate putative functions of these cells by inhibiting evoked synaptic transmission in a subset of VIb neurons using a Drd1a-Cre line crossed with floxed Snap25 mice. We have found that the Drd1a+ layer VIb neurons project to higher order thalamic nuclei and hypothesise they are responsible for gating transthalamic communication of cortical areas. This raises the possibility that a small population of cortical neurons regulates a range of behaviours dependent on cortical function.
Layer VIb is the only cortical cell population that responds to orexin, a key neurotransmitter for sleep and arousal (Bayer et al, 2002 J Neurosci. 22:7835-9), which is also important in regulating emotional behaviour, particularly fear and anxiety (Flores A et al, 2015 Trends Neurosci 38:550-9). Based on this, we are investigating whether layer VIb plays a role in modulating behavioural performance in tasks associated to circadian activity, anxiety and fear. Our preliminary results reveal that silencing Drd1a+ layer VIb neurons does not affect circadian rhythms in normal and abnormal light/dark cycles but it had an anxiolytic effect on a range of behavioural tasks in a cohort of VIb mutants and wildtype controls (n = 20). We found that VIb "silenced" mice spent more time in open arms in the elevated plus maze ($p<0.001$), more time in the light area of the light-dark box ($p<0.05$) and also approached novel foods more quickly ($p<0.05$). We are currently investigating this system further by manipulating function of this largely uncharacterised cortical layer.
Determining the function of layer VIb neuronal populations could reveal a novel element in cortico-thalamic circuits and how cortical areas communicate. This circuit is known to be severely disrupted in neuropsychiatric disorders and may have a major influence on the mode of information processing.

Title: Subchronic treatment with the immunosuppressant rapamycin alters behavior in rats

Authors: ***M. HADAMITZKY**, L. LÜCKEMANN, I. BENDIX, H. ENGLER, M. SCHEDLOWSKI;
Univ. of Essen, Sch. of Med., Essen, Germany

Abstract: The immunosuppressant rapamycin inhibits the activity of the mammalian target of rapamycin (mTOR), a protein kinase that is known to play an important role in cell growth, cell proliferation, and antibody production. Due to its antiproliferative and immunosuppressive properties this drug is widely used in clinical situations such as prevention of acute graft rejection after organ transplantation, as anti-tumor medication, or for the treatment of autoimmune diseases. In the brain mTOR-signaling appears to be important as well since it is involved in different physiological and pathophysiological processes. However, clinical observations show that patients undergoing small-molecule drug immunosuppression frequently suffer from mood and anxiety disorders. Whether and to what extent these neuropsychiatric disturbances occur as direct result of the patient's medical history or are attributed to treatment with the immunosuppressive drugs remains elusive in most cases. Based on our previous work, analyzing the effects of acute rapamycin on brain activity and behavior the present study investigated in rats whether and to what extent subchronic treatment with this mTOR inhibitor, better reflecting the clinical conditions in patients, affects behavior in rats, as well. We here show that subchronic rapamycin in therapeutically relevant doses increased anxiety-like behavior while depressive-like behavior and locomotor activity were not affected. Our results indicate that treatment with rapamycin may play a role in the development of unfavorable effects on neurobehavioral outcomes in patients undergoing immunosuppressive therapy with mTOR inhibitors.

Title: Models of chronic opioid exposure on avoidance behavior

Authors: *K. D. BECK[1], S. SUBBIE[2], J. SHEYNIN[3], J. FRAGALE[2], I. SMITH[4], C. E. MYERS[5];
[1]Neurosci., East Orange VAMC/NJ Med. Sch., East Orange, NJ; [2]Rutgers - Grad. Sch. of

Biomed. Sci., Newark, NJ; [3]Ann Arbor VAHCS / Univ. Michigan Med. Sch., Ann Arbor, MI; [4]Veterans Biomed. Res. Fndn., East Orange, NJ; [5]East Orange VAMC/NJMS, East Orange, NJ

Abstract: Previous research (Sheynin et al. 2016) reported that male patients in an opioid-maintenance program (e.g. methadone maintenance) acquire active avoidance behavior quicker than females in the same program or male/females control subjects. Moreover, those male patients were slow to extinguish the avoidance behavior. This study was conducted to test whether chronic exposure to methadone facilitates acquisition of an active avoidance operant behavior (lever-press) in both male Sprague Dawley rats and in an established computational model of avoidance learning. Blood measures of plasma methadone levels were assessed as the daily dosing increased to a maximum dose of 5 mg/kg. Based on those data, rats in a subsequent experiment were randomly assigned to receive 5 mg/kg methadone (i.p.), or saline vehicle, daily throughout an avoidance learning experiment. Lever-press behavior was to be acquired in order to avoid intermittent footshock, preceded by a 60 s auditory signal. Twelve acquisition sessions occurred after the first 7 days of methadone exposure. This was followed by 6 extinction sessions where the shock was no longer present. No differences were observed in the avoidance behavior; however, lower body weight was measured in those rats treated with methadone during the avoidance training period (not prior to the avoidance training). In order to try to bridge these observations to the prior human data, a computational model of avoidance learning was employed. Parameters previously associated with specific aspects of the learning process were adjusted in the computational model in order to show how the rat model may need to be altered in order to have greater face validity to the previously published human data.

Abstract: Interactions between genetic and environmental factors might be responsible for the onset of stress-related psychiatric disorders, including anxiety. The release of prefrontal amygdala neurotransmitters is increased by stressful experiences, a response that is relevant to cognitive, emotional, and behavioral coping. In addition, stress exposure elicits anxiety-like behavior and dendritic remodeling in the amygdala. Members of the miR-34 family have been suggested to regulate synaptic plasticity and neurotransmission processes, which mediate stress-related disorders. In the present study, we evaluated acute stress-induced basolateral amygdala (BLA)-GABAergic and medial prefrontal cortex (mpFC) aminergic outflow by intracerebral in vivo microdialysis in mice harboring targeted deletions of all 3 members of the miR-34-family (miR-34-TKO). Further, we also examined fear conditioning/extinction, stress-induced anxiety, and dendritic remodeling in the BLA of stress-exposed TKO mice. Our data show that miR-34-TKO mice are characterized by resilience to stress-induced anxiety and facilitation in fear extinction. Consequently, in TKO mice no significant increase was observed in aminergic prefrontal or amygdala GABA release and no significant acute stress-induced amygdalar dendritic remodeling was evident. Differential GRM7, 5-HT2C, and CRFR1 mRNA expression was noted in the mpFC and BLA between TKO and WT mice. Our results clearly indicate that the miR-34 plays a crucial role in regulating the behavioral and neurochemical response to acute stress and in inducing stress-related amygdala neuroplasticity.

Title: Broadening our understanding of intra-BLA NPY-induced stress resilience assessed with cued fear conditioning

Authors: *M. BOMPOLAKI[1], J. A. ROSENKRANZ[2], W. F. COLMERS[4], J. H. URBAN[3]; [2]Dept. of Cell. and Mol. Pharmacology, Chicago Med. Sch., [3]Physiol. and Biophysics, Chicago Med. Sch., [1]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [4]Dept. of Pharmacol., Univ. of Alberta, Edmonton, AB, Canada

Abstract: The anxiolytic and stress-buffering properties of neuropeptide Y (NPY) in the basolateral amygdala (BLA) have long been established in animal models as well as humans. Acute NPY administration in the BLA is anxiolytic as assessed with the social interaction paradigm and also plays an important role in fear extinction (Sadjyk et al., 1999; 2006; Gutman et al., 2008). Repeated injections of NPY in the BLA induce a long-lasting behavioral resilience to restraint stress (Sadjyk et al., 2008). These studies were designed to examine whether a BLA-mediated behavior would be affected in the model of NPY-induced stress resilience and tested whether the expression and/or extinction of cued conditioned fear would be altered in the model of NPY-induced stress resilience. Male rats received cannulae directed to the BLA (A/P -2.7mm; M/L +/-5.0mm; D/V -7.00mm) and repeated bilateral infusions of 10pmol NPY or vehicle (100 nl; 0.1M PBS) daily for 5 days. Social interaction was assessed at d1 and d8 to verify the efficacy of the treatment. Animals receiving NPY treatment have social interaction times that were significantly elevated from vehicle control. Two weeks after the injections, the animals underwent a traditional cued fear conditioning protocol: On day 1, animals were placed in chamber 1 and received 4 pairings of tone (1500Hz, 85dB) with foot shock (0.4mAmps; fear acquisition). The following day the rats were placed in a novel chamber and received 15 trials of the tone without foot shock at 60s intertrial intervals (fear extinction). On day 3, they were placed back in chamber 2 where they underwent the same protocol of tone presentation without foot shock to test for consolidation of extinction. On all three days, freezing behavior was monitored using the Anymaze software. Both vehicle- and NPY-treated rats displayed similar rate and amplitude of fear acquisition on day 1. On day 2, NPY-treated rats expressed significantly lower freezing in the first four sessions of the extinction phase and returned faster to their baseline freezing levels. On day 3, all rats expressed very little freezing behavior suggesting that extinction was equally consolidated. These results further validate the importance of NPY playing a role in buffering the expression of stress and reinforce the argument that repeated administration of intra-BLA NPY establishes an anxiolytic-like background that is also conducive to resilience. Importantly, NPY treatment does not impair the animals' ability to react effectively to a threat, but it does improve their ability to extinguish the associated learned fear. These findings can be of great importance for the way anxiety disorders like PTSD are viewed and treated.

Title: Goal conflict rhythmicity in a bimanual anticipatory response inhibition task shows asymmetric laterality

Authors: *S. M. SHADLI, O. HIGH, N. MCNAUGHTON;
Dept. of Psychology, Univ. of Otago, Dunedin, New Zealand

Abstract: Right frontal goal-conflict-specific-rhythmicity (GCSR) in a simple stop signal task (SST) is a potential human EEG anxiety biomarker. Anticipatory response inhibition tasks (ARITs) produce a similar stopping challenge but without the pressure of a speeded go response. With left-, right-, and both-handed stopping alternatives, the ARIT is reported by participants to generate substantial subjective anticipatory conflict. We predicted that it would show particularly large GCSR. We modified a standard ARIT to match our previous SST in having three sets of stop signal delay (SSD) values: short, intermediate, and long. The intermediate SSD values tracked 50% correct stopping to maximize goal conflict, short and long SSD values were set towards the end and start of a trial, respectively. Right frontal (F8) GCSR (the EEG power contrast of stop-go x quadratic of SSD type) was compared across stop left, stop both, and stop right trials and tested for correlations with trait anxiety and neuroticism. Stop left produced 5-12 Hz GCSR that significantly correlated with trait anxiety and neuroticism. Stop right and stop both produced only 9-10Hz GCSR, which did not correlate with trait anxiety or neuroticism. SSRT for the stop both condition was 224 ms; for stop left, 370 ms; and stop right, 570 ms. sLORETA located the overall stop-related 4-12 Hz frequency power source in the right inferior frontal gyrus (rIFG) for stop left and stop right conditions. rIFG is known to control to SST stopping. For the stop both condition, the source was the uncus. sLORETA localized the GCSR power source to rIFG for stop left and to the middle frontal gyrus for stop both, consistent with previous localization of stopping. However, power *suppression* was localized in rIFG for stop right - linked to the negative GCSR power observed in the lower frequency band (5-8 Hz). The source localization data suggests that goal conflict, like stopping, can involve more than one circuit depending on whether slower or faster go responses are being emitted, consistent with previous findings. These results show that elicitation of right frontal GCSR generalizes from the SST to the ARIT and is stronger with left hand than right hand stopping; but is not stronger in the ARIT than SST.

Title: Social modulation of conditioned and innate fear responses

Authors: V. A. GUTZEIT, 10032[1,2], M. SADSAD[3], T. L. SANTOS[3,1], S. ONG[3], R. HEN[1,4], C. A. DENNY[4,1], *Z. R. DONALDSON[4,5,6,1];

Abstract: Amongst social animals, the presence of a conspecific companion can have powerful effects on mood and behavior. In particular, the social modulation of fear and anxiety represents

a highly conserved trait, as both humans and rodents display decreases in anxiety and stress responses when an affiliative conspecific is present. However, the neural processes underlying this social buffering phenomenon remain largely unknown. Our group has found that in mice, conspecific presence decreases freezing in both conditioned and innate fearful contexts. In order to identify neural populations that may contribute to social buffering of fear responses, we used a mouse line in which *Arc*-expressing neurons are indelibly labeled following interaction with a novel conspecific. We identified a subset of cells within the infralimbic prefrontal cortex (ILPFC) of male and female ArcCreER^{T2} mice that are labeled in response to interacting with a novel, ovariectomized female conspecific but not in response to a toy mouse, novel object, or food reward. Optogenetic activation of conspecific-labeled ChR2-eYFP^{+} neurons decreases freezing in contextual and innate fearful contexts, without impacting locomotion or eliciting reward, recapitulating the effects of conspecific presence. Together, these studies suggest that activation of neurons associated with an affiliative conspecific in the ILPFC may be sufficient to mediate the effects of conspecific presence on fear responses. Thus, targeting this cell population may provide novel therapeutic opportunities that harness circuits naturally engaged by social interaction in order to treat fear and anxiety-related disorders.

Title: Individual differences in behavioral and plasma hormone responses to predator stress: Analysis of corticosterone, catecholamines, cytokines, and NPY

Authors: G. H. HARTSHORN[1], K. F. KAIGLER[1], A. C. SHARKO[1], S. K. WOOD[1], C. WOOD[1], J. NYLAND[2], J. R. FADEL[1], *M. A. WILSON[1,3];

Abstract: The aim of this project is to further the common understanding of why some individuals are more susceptible to stress-related disorders, like Post-Traumatic Stress Disorder (PTSD), than others. Individual differences in behavioral resiliency during different types of stress have been correlated with plasma cortisol, cytokines, and markers of autonomic function including neuropeptide Y (NPY) and catecholamines. In this study we used predator (ferret) odor exposure in rodents as a model of traumatic stress to examine the plasma biomarkers associated with individual differences in behavioral responses to threat. Jugular catheters were surgically implanted in male Long Evans rats and a baseline blood sample was collected prior to behavioral analysis. The rodent was exposed to a predator (ferret) odor or control (no odor) for either 15 or 60 min in a closed cylindrical testing chamber and behavioral responses (freezing, jumping, towel exploration, grooming, and rearing) were recorded. Blood samples (100 µl) were taken via the jugular catheter at 15, 30, and 60 min after predator stress along with another baseline sample taken 24-48 hours following the testing. Plasma samples were analyzed for stress hormone levels using ELISAs (NPY and corticosterone), HPLC (epinephrine, norepinephrine, and serotonin), and BioPlex analysis for cytokine levels. The recorded behavioral responses were analyzed using FreezeScan (Clever Systems Inc.) automated software as well as hand scoring, and stress hormone levels were correlated with individual differences in behavior during predator stress. Results indicate that exposure to predator odor decreased latency to freeze and towel interaction, and increased rearing behaviors, compared to the no-odor control group. Exposure to predator odor induced a sustained increase in plasma corticosterone for at least 60 min, but no significant correlations were seen between corticosterone responses and behavioral endpoints. Although exposure to predator odor failed to significantly alter plasma NPY levels, a significant correlation was seen between NPY levels at 60 min and freezing behavior. Additional analyses are comparing plasma catecholamines (norepinephrine, epinephrine) as additional biomarkers of sympathetic nervous system activation and cytokine responses following predator-induced stress. Such studies help inform our understanding of the systems underlying resiliency and susceptibility in long-term responses to traumatic stress, as well as the potential of plasma biomarkers to predict behavioral responses to stress.

Title: Inhibition of the nitrergic neurotransmission in the dorsal periaqueductal gray promotes panicolitic-like effect in rats exposed to hypoxia condition.

Authors: *A. SPIACCI, JR[1], G. GRIPP-FERNANDES[1], D. E. RIBEIRO[1], C. BIOJONE[2], P. C. CASAROTTO[2], H. ZANGROSSI, Jr[1];
[1]Sch. of Med. of Ribeirao Preto- USP, Ribeirao Preto, Brazil; [2]Univ. of Helsinki, Helsinki, Finland

Abstract: Objectives: It has been proposed that spontaneous panic attacks are the outcome of the misfiring of an evolved suffocation alarm system. Moreover, evidences suggests that hypoxia challenge is an effective stimulus to evoke panic attack in both humans and rats. Since nitric oxide (NO) plays an important hypoxia-signaling role, we evaluated the effects promotes by systemic injection of the nitric oxide synthase inhibitor aminoguanidine on panic-like escape response elicited in rats exposed to hypoxia condition. In addition, since the dorsal periaqueductal gray (dPAG), a mesencephalic structure associated to panic, harbors a hypoxia sensitive suffocation alarm system, we also investigated if similar responses would be achieved by intra-dorsal periaqueductal gray (dPAG) injection of drugs that impair the nitrergic neurotransmission. **Methods:** Male Wistar rats were injected (7days) with aminoguanidine (0, 15, 30 or 60 mg/Kg, i.p) and submitted to hypoxia chamber 30 min after the last injection. Into the chamber, after 5 min of nomoxic condition, nitrogen was flushed into the chamber up to the production of hypoxia (7% O2). The number jumps were computed during the hypoxia challenge. In another experiment, the animals were submitted to hypoxia 10 minutes after intra-dPAG injection of the NO scavenger Carboxy-PTIO (0, 0.3, 1 or 3 nmol) or the neuronal nitric oxide synthase inhibitor N-propyl-L-arginina (0, 0.04, 0.4 or 4 nmol). **Results:** Systemic injection of aminoguanidine (15 and 30 mg/Kg) reduce the number of jumps (mean ± SEM): [sal = 28 ± 8; AG 15 = 9 ± 1; AG 30 = 12 ± 2] suggesting a panicolytic-like effect. Similar results were observed with both intra-dPAG injection of Carboxy-PTIO [sal = 23 ± 2; C-PTIO 3 = 3 ± 1] and N-propyl-L-arginina. **Conclusion:** NO seems crucial for the expression of escape behavior evoked by hypoxia condition that has been associated with panic attack. Moreover, inhibition of dPAG nitrergic neurotransmission effectively reduces the escape behavior.

Title: Characterizing neuropeptide expression in the primate central extended amygdala to provide a basis for understanding mechanisms underlying anxiety

Authors: *R. KOVNER[1], A. S. FOX[1], T. SOUAIAIA[2], P. H. ROSEBOOM[1], D. A. FRENCH[1], J. A. OLER[1], J. L. FUDGE[3], J. A. KNOWLES[2], N. H. KALIN[1];
[1]Psychiatry, Univ. of Wisconsin-Madison, Madison, WI; [2]Ctr. for Genomic Psychiatry, USC, Los Angeles, CA; [3]Neurosci., Univ. of Rochester, Rochester, NY

Abstract: The central extended amygdala (EAc) is an integral part of the neural circuit mediating fear and anxiety. Our laboratory has demonstrated that two major nodes of the EAc, the central nucleus of the amygdala (Ce) and the bed nucleus of the stria terminalis (BST) are key regions in the neural circuitry mediating non-human primate (NHP) anxious temperament (AT). It is important to characterize EAc cell types in NHPs to better understand the cellular and molecular alterations that mediate AT. The Ce and BST are primarily composed of striatal-like medium spiny GABAergic neurons that can be subdivided into multiple types based on their neuropeptide profile. Although the comparison between striatal neurons and EAc neurons has been made based on shape and GABA expression, the molecular differences between the neurons of these regions have not been investigated. Using human microarray data from the Allen Brain Atlas, we identified genes that are differentially expressed between Ce and striatum. We further validated this finding in the NHP using RNA sequencing and found that many neuropeptides have significantly higher expression in the lateral Ce (CeL) compared to regions of striatum (Putamen and Caudate). Using this human and NHP gene data as a guide, we chose to study somatostatin (SST) and cholecystokinin (CCK) in more depth in the NHP EAc. To this

end, we used *in situ* hybridization to characterize the anterior-posterior (A-P) distribution of SST and CCK mRNA expression. A-P distribution is interesting because rodent work has demonstrated differences in peptide expression between anterior and posterior regions of the CeL. However, little work has been done in the NHP. To start, we focused on the expression of the SST and CCK mRNA in CeL and the corresponding laterodorsal BST (BSTL) from 4 rhesus monkeys. Using a repeated-measures multiple regression analysis we examined the effect of A-P position on expression levels. Results demonstrated a significant A-P effect on CeL-SST expression, such that SST expression increases towards the posterior CeL ($F_{4, 30}$=19.29,p=0.02). There was no significant effect of A-P position on BSTL-SST expression. We did not observe any significant effects of A-P position on CCK expression in CeL or BSTL. These experiments utilize gene data to identify differentially expressed mRNAs between striatum and Ce as a stepping-stone to identify differences in the A-P expression of neuropeptides within the primate CeL and BSTL. Understanding the A-P expression of different neuropeptide populations in the EAc will help to guide co-expression studies, to identify different neural populations and determine population-specific roles in mediating AT.

Title: Effects of caudal orbitofrontal cortex 'strip lesions' on threat-related behavior and brain metabolism in young female rhesus monkeys

Authors: *J. A. OLER[1], A. S. FOX[2], D. P. M. TROMP[1], M. K. RIEDEL[1], E. M. FEKETE[1], P. H. ROSEBOOM[1], E. A. MURRAY[3], N. H. KALIN[1];
[1]Psychiatry, Univ. of Wisconsin, Madison, WI; [2]Psychology, UC-Davis, Davis, CA; [3]Lab. of Neuropsychology, NIMH, Bethesda, MD

Abstract: Persistent and high levels of sustained anxiety, or an anxious temperament (AT), during childhood is one of the strongest risk factors for the later development of stress-related psychopathology. The nonhuman primate model of AT is ideal because of similarities between

rhesus monkeys and humans in the development of socio-emotional behavior and its underlying neural circuits, which are characterized by a high degree of integration between subcortical structures and the primates' well-developed prefrontal cortex. The orbital prefrontal cortex (OFC) is thought to play a critical role in the regulation of emotions, which is consistent with our demonstration of increased AT-related metabolism, and a significant genetic correlation between AT and metabolism within caudal OFC regions (Fox et al., 2015). Moreover, lesions of the primate OFC reduce threat-related behavioral responses (Kalin et al., 2007; Murray & Izquierdo, 2007; Bachevalier et al., 2011) and attenuate glucose metabolism within the extended amygdala (Fox et al., 2010). As part of an ongoing study examining the role of the OFC in regulating the extended amygdala at functional and molecular levels, we performed aspiration lesions of a narrow strip of the caudal OFC in six female rhesus monkeys (mean age = 2.18 +/- 0.19 years, including cage-mate controls). These OFC "strip lesions" have been shown to attenuate responses to threatening stimuli (e.g., snakes; Rudebeck et al., 2013). Structural brain imaging using diffusion weighted tractography methods demonstrate the disconnecting effects of the strip lesion on the white matter coursing through the caudal OFC. In behavioral assessments using the Human Intruder Paradigm, monkeys with caudal OFC strip lesions exhibited significant decreases in threat-related responding during the No-Eye-Contact condition (Post - Pre Δ in AT, $p < 0.05$). Preliminary FDG-PET imaging results suggest a replication of previously published findings in monkeys with large OFC lesions. Specifically, threat-induced glucose metabolism in the bed nucleus of the stria terminalis (a major component of the extended amygdala) is diminished following OFC strip lesions ($p < 0.005$, uncorrected). These results demonstrate that the gray matter and/or the white matter tracts running along/through the caudal OFC (e.g., uncinate fasciculus) are critical for the processing of threat-related information and the expression of adaptive behavioral responses to threat. All procedures were performed according to federal and institutional guidelines at the Harlow Center for Biological Psychology and the Wisconsin National Primate Research Center.

Abstract: Extreme anxiety in children is a prominent predictor of the later development of psychopathologies including anxiety disorders and depression. Using our well-established non-human primate (NHP) model of anxious temperament (AT), we identified the central nucleus of the amygdala (Ce) as a key component of the neural circuit that underlies the expression of AT. Using positron emission tomography, we found that Ce metabolic activity strongly predicts individual differences in AT, and that selective Ce excitotoxic lesions decrease AT. To further define the role of the Ce, we have begun to employ Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to selectively modulate neuronal activity within the amygdala in response to the administration of the DREADDs receptor ligands clozapine-N-oxide (CNO) or the related analog compound 21 (C21). Because CNO and C21 are known to have some off target effects in NHPs, we first assessed their effects on anxiety-related behavior in the no eye contact (NEC) condition of the human intruder paradigm. Systemic administration to rhesus monkeys (*Macaca mulatta*) of either CNO (0, 5 or 10 mg/kg; N=5/group) or C21 (0, 3 or 9 mg/kg; N=5/group) had no significant effects on NEC-induced freezing (CNO, $F_{2,12}$=2.18; p=0.16; C21, $F_{2,12}$=1.37; p=0.29) or plasma cortisol (CNO, $F_{2,12}$=2.79; p=0.10; C21, $F_{2,12}$=0.78; p=0.48). We then moved on to localized delivery of an adeno-associated viral vector type 5 that directs expression of the DREADDs version of the inhibitory human M4 muscarinic receptor as well as mCherry protein under the control of the synapsin 1 promoter (AAV5/hSyn-hM4Di-mCherry). Using real time magnetic resonance imaging (MRI)-guided surgical techniques in a cynomolgus monkey (*Macaca fascicularis*), the AAV5 viral construct was infused bilaterally targeting the Ce. Seven weeks later the monkey was sacrificed and the brain was processed for immunohistochemistry. Consistent with the extent of the gadolinium cloud visible during the MRI-guided infusion, mCherry protein was expressed in both hemispheres in regions extending beyond but encompassing the Ce. In the next study, 5 rhesus monkeys received smaller infusions

of the same viral vector into the Ce. Several months after the viral infusion, administration of either CNO (5 mg/kg) or C21 (9 mg/kg) consistently decreased NEC-induced freezing compared to vehicle in three of the five animals tested. Ongoing metabolic and functional connectivity imaging studies are identifying CNO-induced alterations. The current study shows the feasibility of using DREADDs technology in NHPs to study neural circuits underlying the expression of anxiety-related behavior.

Title: MDMA-assisted psychotherapy for treatment of chronic post traumatic stress disorder: findings from MAPS-sponsored phase 2 clinical research trials

Authors: *A. A. FEDUCCIA[1], B. YAZAR-KLOSINSKI[2], L. JEROME[1], M. MITHOEFER[1], A. EMERSON[1], R. DOBLIN[2];
[1]Clin., MAPS Publ. Benefit Corp., Santa Cruz, CA; [2]Multidisciplinary Assn. for Psychedelic Studies, Santa Cruz, CA

Abstract: The Multidisciplinary Association for Psychedelic Studies (MAPS) has completed six sponsored Phase 2 clinical pilot studies that investigated MDMA-assisted psychotherapy for treating chronic, treatment-refractory posttraumatic stress disorder (PTSD). At five study sites world-wide, 108 subjects underwent a series of non-drug preparatory and integration sessions, interspersed with two or three double-blind, MDMA-assisted psychotherapy sessions with a comparator/placebo control. Intent-to-treat findings from these studies showed medium to large between-subjects effect size in reducing PTSD symptoms after two sessions, as measured by the Clinician Administered PTSD Scale (CAPS-4), with a good safety profile. These positive results provide a basis for the continuation of the MAPS-sponsored research program into expanded Phase 3 clinical trials to provide safety and efficacy data for use of MDMA as a pharmacological adjunct to therapy for treatment of PTSD. Given the limited effectiveness of current available medications and therapeutic strategies in some people, MDMA-assisted psychotherapy holds promise as a novel treatment option and warrants further study.

Title: Safety of mdma therapy for social anxiety in autistic adults

Authors: *B. B. YAZAR-KLOSINSKI[1], C. S. GROB[2], A. DANFORTH[2];
[1]Clin. Res., MAPS, Santa Cruz, CA; [2]Los Angeles Biomed. Res. Inst., Torrance, CA

Abstract: Autistic adults who are verbal and whose autism might not be immediately recognizable to others often initially present in a clinical setting with a co-morbid diagnosis of anxiety or depression, and are at greater risk of experiencing social anxiety due to core features of autism. There are currently no FDA-approved pharmacologic treatments for autistic adults, although off-label prescription use of selective serotonin reuptake inhibitors (SSRIs) are on the rise in this population. The Multidisciplinary Association for Psychedelic Studies (MAPS) is sponsoring an exploratory Phase 2 dose-finding safety and feasibility pilot study investigating MDMA-assisted therapy for treating social anxiety in autistic adults. After three non-drug preparatory therapy sessions, 12 subjects received two double-blind MDMA-assisted therapy sessions with a placebo control, each followed by three integrative therapy visits. Participants were followed monthly during a blinded 6-month follow-up. A blinded clinician administered the Leibowitz Social Anxiety Scale (LSAS) and found promising rapid-onset reduction in social anxiety symptoms in the MDMA group with a good safety profile in preliminary analysis. Changes in social perception, emotion labeling and regulation, perceived stress, self-esteem, state and trait anxiety, depression, and quality of life were also assessed as secondary outcomes. The promising results from this small sample will be used to estimate statistical power for future studies of this novel treatment option.

Title: Identification of the first variant selective and biased NPS Receptor agonist that retains anxiolytic and memory promoting effects with reduced levels of locomotor stimulation

Authors: *S. CLARK[1], C. HASSLER[2], S. GERTZ[1], E. GAY[2], S. RUNYON[2];
[1]Univ. at Buffalo - The State Univ. of New York, Buffalo, NY; [2]Ctr. for Drug Discovery, Res. Triangle Inst., Research Triangle Park, NC

Abstract: Neuropeptide S is a 20-amino acid peptide that functions as an agonist through activation of its cognate GPCR receptor system. High expression of the Neuropeptide S (NPS) receptor has been found in the retrosplenial cortex, basolateral amygdala, parasubiculum, and various regions of the hypothalamus. Modulation of the NPS receptor has been associated with a variety of disease states including anxiety, panic disorder, PTSD, and substance abuse. Through comprehensive chemical modification and analog synthesis we have now defined a comprehensive NPS agonist pharmacophore using traditional medicinal chemistry and computational/scaffold hopping approaches. The compounds developed in our laboratory selectively activate calcium mobilization in vitro. In mice, these compounds selectively modulate a subset of behaviors for which full NPS receptor agonists are known to elicit. Further modification and testing of these analogs will be of significant value in determining the comprehensive role of NPS in modulating anxiety and responses to stress.

Title: κ Opioid receptor activation in different brain regions differentially modulates anxiety-related behaviors in mice

Authors: *Y. WANG, A. HANG, J.-G. LIU;
Neuropharm., Shanghai Inst. of Materia Medica, Shanghai City, China

Abstract: κ Opioid receptor system is widely implicated in the regulation of emotion. However, the findings about the role on anxiety in rodents are highly controversial, since both anxiogenic- and anxiolytic-like effects have been reported with κ opioid receptor activation. The mechanism and the underlying neuroanatomical substrates are unexplored. In the present study, we first investigated the effects of κ agonist U50,488H on anxiety-related behaviors over a wide range of doses, and we found that U50,488H produced dual effects in anxiety, with low dose being anxiogenic and high dose being anxiolytic. To assess the potential neuroanatomical substrates, we used phosphorylation of extracellular signal-related kinase1/2 (pERK1/2) to map the underlying neural circuits. We found that the anxiogenic effect of U50,488H was paralleled by an increase of pERK1/2 in the nucleus accumbens, whereas the anxiolytic effect was paralleled by an increase of pERK1/2 in the lateral septal nucleus. We then examined the behavioral consequences with locally microinjection of U50,488H, and we found that microinjection of U50,488H into the nucleus accumbens exerted anxiogenic-like effects, whereas microinjection of U50,488H into the lateral septal nucleus. Both effects can be abolished by κ antagonist nor-BNI pretreatment. To the best of our knowledge, the present work firstly provides the neuroanatomical sites that mediating the dual anxiogenic- and anxiolytic-like effects of U50,488H in mice. This study may help to explain current controversial role of κ receptor activation in anxiety-related behaviors in rodents, and may open new perspectives in the areas of anxiety disorders and κ receptor function.

Title: The effects of post-exposure gluccocorticoid administration in specific phobia

Authors: *A. ZLOMUZICA[1], F. PREUSSER[1], C. MERZ[2], O. T. WOLF[2], M. TEGENTHOFF[3], J. MARGRAF[1];
[2]Dept. of Cognitive Psychology, [1]Ruhr-Universität Bochum, Bochum, Germany; [3]BG-Kliniken Bergmannsheil, Bochum, Germany

Abstract: Glucocorticoids are important modulators of emotional learning and memory. Glucocorticoid administration prior to therapy has been shown to enhance the efficacy of exposure-based treatments. However, the exact mechanisms of action remain poorly understood: Glucocorticoids may exert their beneficial effects through a) inhibiting fear memory retrieval, or b) promoting the formation and consolidation of corrective experiences. Here, by administering glucocorticoids after exposure therapy, we tested whether the enhancing effects of glucocorticoids on therapeutic outcome can be attributed to extinction memory consolidation and whether glucocorticoids do also attenuate fear renewal. Compared to placebo, post-exposure glucocorticoid administration did neither lead to more anxiety reduction nor to less fear renewal at both the behavioral and subjective level. Rather than enhancing the consolidation of extinction memories, our preliminary findings support the view that glucocorticoids might exert their beneficial effects on exposure therapy by promoting the formation of new corrective experiences or inhibiting aversive memory retrieval during exposure.

Title: Medial prefrontal cortex stimulation accelerates therapy response of exposure therapy in acrophobia

Authors: *M. HERRMANN[1,2], A. KATZORKE[2], Y. BUSCH[2], D. GROMER[3], T. POLAK[2], P. PAULI[3], J. DECKERT[2];
[1]Universitaetsklinikum Wuerzburg, Wuerzburg, Germany; [2]Dept. of Psychiatry, Psychosomatics and Psychotherapy, Würzburg, Germany; [3]Dept. of Psychology, Würzburg, Germany

Abstract: Animal studies have shown that stimulation of the medial prefrontal cortex (mPFC) improves extinction of conditioned fear. This is thought to depend on an enhanced efficiency in the interplay between the mPFC and the amygdala. A recent study confirmed this in humans by showing that repetitive transcranial magnet stimulation (rTMS) of the mPFC facilitates extinction learning as evidenced in reduced responses to a conditioned threat stimulus assessed with fear potentiated startle (FPS), skin conductance response (SCR) and arousal ratings. As a crucial next translational step this study investigates whether mPFC stimulation using rTMS is an effective add-on for exposure therapy in anxiety disorder patients. Patients with acrophobia (N=43) were randomly allocated to active or sham rTMS covering the mPFC before two exposure sessions in virtual-reality (VR). Corroborating experimental animal and human studies we provide first clinical evidence that high-frequency rTMS improves exposure therapy response of acrophobia symptoms one week after the second exposure session. A follow-up three months later showed a further improvement of the acrophobia symptoms in both groups to an equal level. This study provides first evidence that stimulation of the mPFC accelerates the therapeutic effect of exposure based therapy.

Title: Environmental enrichment may produce central effects in modulating the impact of high-fat diet induced anxiety in a rat model of obesity

Authors: *E. P. WIERTELAK, S. FERGUS, J. E. MEYERS-MANOR;
Neurosci. Studies, Macalester Col., Saint Paul, MN

Abstract: The increasing prevalence of obesity in Western cultures constitutes a serious public health issue. In addition to its negative physiological health outcomes, consumption of a high-fat diet (HFD) is also linked to a variety of affective disorders, including anxiety. HFD has been shown to impact a number of neurobiological functions, including alterations in hypothalamic-pituitary-adrenal (HPA) axis activity, and decreased hippocampal neurogenesis, both of which have also been implicated in the regulation of affective states. The importance of rearing environment in the regulation of brain, behavior, and physiology has also long been recognized in biological, and social sciences. Although the effects on emotionality are less documented, environmental enrichment (EE) has beneficial effects in reducing anxiety-like behavior in animals. Exposure to complex environments alters brain structure and function, through positively regulating HPA axis activity, and inducing forms of brain plasticity, such as increased hippocampal neurogenesis and BDNF levels. However, few studies have examined the interaction between the two variables. The present study established an anxiety model in Sprague-Dawley rats through a high-fat diet (HFD) to examine the effect of environmental enrichment on HFD-induced anxiety. Subjects were grouped into either a control diet or HFD group, each of which were separated into either a non-enriched or EE housing condition for 4 weeks. The balanced design of two dietary conditions by two housing conditions allowed for investigation of main effects of diet, environment, and any interactions. Anxiety was assessed using the elevated zero maze. Results indicate that HFD induced greater anxiety, as revealed by a lower percentage of time spent in the open quadrants of the maze. However, results also showed an amelioration of anxiety-like behavior if subjects were exposed to an enriched environment, despite continuation of HFD. Considering that the beneficial effect of EE was obtained even with continuation of HFD, this study provides solid evidence that EE is an effective and practical intervention to ameliorate anxiety-like behavioral changes induced from HFD. As this effect could result through targeting a number of underlying neurobiological mechanisms, future work in this laboratory is focused on these examinations.

Title: Investigating the effects of ghrp6 in combination with citalopram to counter the metabolic and behavioral effects of chronic social defeat

Authors: *L. M. HYLAND[1], S. PARK[2], S. OOSTLANDER[1], E. VINNINS[1], A. ABIZAID, K1S5B6[1];
[2]Neurosci., [1]Carleton Univ., Ottawa, ON, Canada

Abstract: Ghrelin, a gut-derived peptide hormone, is associated with feeding, energy balance, and the stress response. Our primary goal was to test whether chronic systemic ghrelin agonist (GHRP6) administration alone, or in combination with a commonly prescribed selective serotonin reuptake inhibitor (SSRI, i.e. citalopram) would enhance antidepressant effects in mice under normal conditions or following chronic social defeat paradigm (CSDP). Interestingly, while GHRP6 treatment alone tended to increase weight in non-stressed mice, the same treatment prevented citalopram induced weight gain in stressed mice. Depression is associated with anhedonia, social deficits, and anxiety, and can be modelled in animals using tests such as the sucrose preference test, social interaction test, and the open field test. Our results indicated that after a recovery period of no stress following CSDP, there were no major effects of either GHRP6 or citalopram in improving depressive-like behaviors in these behavioral measures. These data indicates that GHRP6 may lessen the degree of metabolic side-effects seen in patients treated with SSRIs, but does not improve the behavioral effects of stress after a long recovery period.

Title: Effects of wilderness therapy on neuroendocrine measures of anxiety

Authors: A. K. EAGLE[1], S. K. YEATTS[2], E. J. TEDDER[2], K. D. MCCLUSTER[2], L. MANSER[2], *C. L. FRANSSEN[2];
[1]Biol., [2]Psychology, Longwood Univ., Farmville, VA

Abstract: Conventional treatments for anxiety include pharmacotherapy and psychotherapy techniques, however no consistently effective treatment has been found. A variety of alternative therapies- many utilizing exercise and nature exposure- have emerged; however, evidence for efficacy and efficiency relies heavily on self-reported measures of affect. Wilderness therapy is uniquely positioned to incorporate elements of both nature and exercise as well as interactions with a licensed clinical practitioner; and this combinatorial approach has proven beneficial to substance abuse, behavior disorders, and mood disorders. Anxiety disorders are comorbid for many patients seeking treatment through wilderness therapy. To better understand changes in anxiety profiles through treatment, we studied patients' neuroendocrine profiles during a wilderness therapy experience. In this project, we partnered with Blackwater Outdoor Experiences, a wilderness therapy group based in Midlothian, VA. We collected saliva samples and survey data before, during, and after a 22-day wilderness therapy trip. Samples were assayed for stress-related hormones, namely cortisol and DHEA. We present our integrative data analysis here.

Title: Anxiolytic and antidepressant-like properties of ONO-9270578, a novel TRPC4/5 inhibitor, in mice

Authors: *T. NIWA[1], A. KISHI[1], T. KITAJIMA[1], Y. KAMIMURA[2], T. SASAMURA[2], Y. HIROKA[3], T. SAITO[3], S. KATSUMATA[1];
[1]Discovery Res. Labs., [2]Exploratory Res. Labs., [3]Medicinal Chem. Res. Labs., ONO Pharmaceut. CO.,LTD., Osaka, Japan

Abstract: *Purpose:* Transient receptor potential canonical (TRPC) channel subfamily is highly expressed in the central nervous system. Ca^{2+} signaling through these channels that are activated following stimulation of Gq-coupled receptors and Ca^{2+} store depletion relates to various neuronal functions such as neuronal development, proliferation, differentiation and synaptogenesis. The mice lacking TRPC4 exhibited decreased anxiety-like behaviors in elevated plus maze (EPM) and open field test (OF) but not in acoustic startle response (ASR) and fear conditioning test (FCT). Also, the mice lacking TRPC5 exhibited decreased anxiety-like behaviors in EPM, OF and social interaction (SI) but not in ASR, FCT and novelty suppressed feeding test. These findings suggest that TRPC4 and TRPC5 may both relate to the mechanisms underlying regulation of anxiety and fear responses. Recently, we identified ONO-9270578 as a TRPC4/5 inhibitor and evaluated the effects of this compound in various behavioral tests. *Methods:* ONO-9270578 was examined on EPM, SI and marble burying test (MBT) in normal mice to evaluate the anxiolytic-like properties of TRPC4/5 inhibitor. The effects of ONO-9270578 were compared with diazepam (3 mg/kg), tandospirone (20 mg/kg) and zimelidine (10 mg/kg) in EPM, SI and MBT, respectively. ONO-9270578 was also examined on EPM in cholecystokinin (CCK) 2 receptor agonist CCK4-treated mice and SI in 5-HT_{2C} receptor agonist MK212-treated mice to confirm the involvement of Gq-coupled receptors in the effects of TRPC4/5 inhibitor. Additionally, ONO-9270578 was examined on OF and passive-avoidance test (PA) in olfactory bulbectomized (OB) mice to evaluate the effects of TRPC4/5 inhibitor on OB-induced hyperactivity and cognitive impairment. *Results:* ONO-9270578 significantly increased the time spent on open arms in EPM and the social interaction time in SI in normal mice. In these tests, the anxiolytic-like effects of ONO-9270578 were equivalent to comparative drugs. On the other hands, ONO-9270578 did not influence the number of buried marbles in MB. ONO-9270578 also significantly suppressed the decrease of time spent on open arms by CCK4 and that of social interaction time by MK212. Furthermore, ONO-9270578 significantly suppressed the increase of total movement distance on open-field and that of the number of trials

to learn passive avoidance in OB mice without affecting in sham-operated mice. *Conclusion:* ONO-9270578 showed anxiolytic and antidepressant-like effects on various behavioral tests in normal or pathological conditions, indicating TRPC4/5 inhibitor may have a potential as a treatment for anxiety and depression.

Title: The effects of sceletium tortuosum extract fraction in chick anxiety-depression model.

Authors: *M. K. JOURDAN[1], J. M. CARPENTER[2], E. M. FOUNTAIN[1], Z. ALI[2], N. ABE[2], I. A. KHAN[2], K. J. SUFKA[1];
[1]Psychology, Univ. of Mississippi, University, MS; [2]Res. Inst. of Pharmaceut. Sci., Oxford, MS

Abstract: *Sceletium tortuosum* has been reported to elevate depressed mood, relieve pain, and reduce anxiety, stress, and tension. *S. tortuosum's* major constituents are mesembrine, mesembrone and mesembranol, among others. This study sought to examine the effects of an *S. tortuosum* alkaloid enriched fraction in the chick anxiety-depression model. This model shows high predictive validity as a pharmacological screening assay. Two experiments were conducted using socially-raised male Silver Laced Wyandotte chicks (Ideal Poultry, Cameron, TX, USA). In two experiments, separate groups of 4-6 day old chicks were given IP vehicle, Imipramine (10 mg/kg), or *S. tortuosum* fraction (10, 20, 30 mg/kg in Exp. 1 or 50, 75, 100 mg/kg in Exp. 2) 15 min prior to a 60 m isolation test period. Vehicle chicks displayed high distress vocalization (DVoc) rates in the anxiety phase (first 5 m). DVoc rates declined about 50% (i.e., behavioral despair) in the depression phase (30-60 m). Imipramine attenuated behavioral despair. None of the *S. tortuosum* fraction doses attenuated behavioral despair. However, 75 and 100 mg/kg *S. tortuosum* fraction decreased DVoc rates during the anxiety phase. The findings that an alkaloid enriched *S. tortuosum* fraction shows anxiolytic effects fits well with the observation that its major constituent mesembrine binds to GABA and mu-opioid receptors. While mesembrine also inhibits serotonin reuptake, our data show that this enriched fraction does not have antidepressant properties at the doses tested.

Title: Activation of lateral hypothalamic galanin neurons reduces anxiety-like behavior

Authors: ***E. QUALLS-CREEKMORE**[1,2], A. BRUCE-KELLER[2], M. FRANCOIS[2], S. YU[2], C. MORRISON[2], H. MÜNZBERG[2];
[1]Central Leptin Signaling, [2]Pennington Biomed. Res. Ctr., Baton Rouge, LA

Abstract: Pharmacological anxiolytics are one of the most widely prescribed treatments in psychiatric disease; however, the currently available pharmacological options are often associated with negative side effects including drowsiness and physical dependence. Despite the increasing prevalence of anxiety disorders, the neural circuits underlying anxiety are not clear. There are many gaps in defining the neural circuits, and in particular, the molecular identity of proposed nuclei in the anxiety circuit. Recently, the lateral hypothalamus (LHA) has been implicated in the neural circuits regulating anxiety. The LHA contains many galanin expressing neurons and galanin signaling has been strongly associated with reduced anxiety. We hypothesize that LHA galanin neurons mediate anxiety-related behavior. To test this we activated LHA galanin neurons chemogenetically. We injected a cre-dependent adenoassociated virus to drive expression of hM3-Gq receptor in the LHA of galanin-cre mice. Clozapine-N-oxide (CNO) induced activation of LHA galanin neurons was tested for anxiety related behavior in the open field test, elevated plus maze, and marble burying test. CNO significantly decreases anxiety-like behavior in all tested paradigms. Importantly, anxiolytic effects were not accompanied by reduced arousal indicated by a modest increase in locomotor activity in the open field test. This data supports further investigation of galanin as a potential pharmacological target for the treatment of anxiety without dampening arousal, which is often associated with common

anxiolytic drugs. *Supported by R01DK092587, P20GM103629 (HM) P30DK072476 (SY, HM), T32-DK064584 (EQC)*

Title: The effects of neurotensin receptor agonists on fear-potentiated startle in male and female mice

Authors: M. VANDEN AVOND, E. RIDGE, A. FULSCHER, *A. PRUS;
Psychology, Northern Michigan Univ., Marquette, MI

Abstract: Neurotensin is a neuropeptide neurotransmitter with receptors located in areas of relevance to anxiety, including hippocampus and amygdala and interacts with a variety of neurotransmitter systems, including monoamines, acetylcholine, glutamate, and GABA. Central administration of neurotensin and systemic administration of brain penetrant neurotensin NTS_1 and NTS_2 receptor agonists produce anxiolytic effects, and $NTS_2^{-/-}$ mice exhibit deficits in fear conditioning. The present study sought to further evaluate the potential anxiolytic effects of a systemically-administered NTS_1 receptor agonist, PD149163, and a NTS_2 receptor agonist, beta-lactotensin, using the fear-potentiated startle (FPS) paradigm in male and female C57BL/6 mice. Startle chambers were equipped with a shock-grid floor, fluorescent light, and an acoustic startle speaker. Conditioning took place between the light and floor shock, and test sessions measured startle to a 90 dB noise burst while the light was on or off. Startle magnitude did not differ between the male and female mice. Mice were subsequently separated into two groups (termed "high responders" and "low responders") based upon their degree of FPS response produced following saline administration. PD149163 significantly reduced FPS and startle magnitude in both male and female high responders, but not in low responders. Beta-lactotensin reduced FPS in female high responders at a single dose, but did not reduce FPS in either group of male mice. The anxiolytic and partial 5-HT_{1A} agonist buspirone did not significantly reduce FPS in either male or female mice. PD149163 and buspirone, but not beta-lactotensin, significantly reduced

locomotor activity in an open field. Based on these findings, neurotensin receptors may be a novel target for anxiolytic compounds.

Title: Endocannabinoid modulation of reciprocal prelimbic prefrontal cortex circuits

Authors: ***D. MARCUS**, S. PATEL;
Vanderbilt Univ., Nashville, TN

Abstract: The prelimbic prefrontal cortex (plPFC) is a subregion of the medial prefrontal cortex (mPFC) that is importantly involved in anxiety and stress responses. Research has indicated that the activity of the mPFC and its ability to modulate stress response is heavily influenced by local endocannabinoid signaling. Local pharmacological activation of cannabinoid signaling in the mPFC induces an anxiolytic effect, while local inhibition of cannabinoid signaling prolongs corticosterone (CORT) secretion in response to acute stress and promotes an anxiogenic phenotype. Due to the primarily presynaptic localization of the cannabinoid receptor type 1 (CB1), the endocannabinoid system (ECS) may play a crucial role in gating excitatory glutamatergic inputs into the mPFC. In this study, we combine optogenetic projection targeting and retrograde labeling (retrobead) approaches to isolate reciprocal projections between the plPFC and two glutamatergic projection regions, the Basolateral Amygdala (BLA) and Mediodorsal Thalamus (MDT). Both of these regions have been implicated in playing a causal role in anxiety and stress response. Neither retrobead positive nor retrobead negative cells in plPFC layer 6 receiving projections from the DMT express depolarization induced suppression of excitation (DSE), an endocannabinoid mediated form of transient synaptic depression. However, both retrobead positive and negative cells in layer 2 receiving inputs from the BLA exhibited DSE. Finally, only layer 5 retrobead positive cells receiving input from the BLA exhibited DSE. These distinct modes of endocannabinoid signaling may underlie the behavioral effects of both local mPFC and global cannabinoid agonist administration.

Title: Electrochemical measurements of real-time opioid peptide fluctuations reveal a neuromodulatory role for putative methionine enkephalin dynamics in the rat striatum

Authors: *C. A. LEE, S. E. CALHOUN, S. K. SMITH, C. MEUNIER, M. DAUSH, G. S. MCCARTY, L. A. SOMBERS;
Chem., North Carolina State Univ., Raleigh, NC

Abstract: Neuropeptides regulate a broad spectrum of biological functions, from pain and analgesia to hedonic and motivational behaviors associated with reward and addiction. Opioid signaling within dopaminergic circuits has been critically implicated in both natural and drug reward-seeking behavior. However, the precise mechanisms that underlie opioid modulation of DA systems remain ambiguous. Although several methods exist for monitoring DA fluctuations, few tools are available for selectively monitoring dynamic fluctuations of endogenous opioid neuropeptides in the brain. This work employs a completely novel electrochemical approach to monitor sub-second fluctuations of tyrosine-containing opioid peptides, such as methionine-enkephalin (M-ENK), in rat brain tissue. By combining multiple scan rate voltammetry with constant-potential amperometry in every voltammetric sweep, we have measured putative M-ENK fluctuations in intact and 6-OHDA lesioned rat striatum (male) in response to treatments that elicit robust DA fluctuations in striatal tissue (cocaine, L-DOPA, and unexpected food reward). Importantly, our electrochemical approach enables selective detection of chemical species within each scan, including striatal DA release. These measurements of opioid peptide dynamics will shed new light on the modulatory role of opioid peptides in a broad spectrum of pathological disorders related to dysfunction of the DA system.

Title: Monitoring subsecond glucose dynamics in response to intravenous glucose and cocaine reveals spatially heterogeneous micro environments in the rat dorsal striatum

Authors: *S. SMITH, C. LEE, C. DOSTER, J. BAIRD, D. RAO, G. MCCARTY, L. SOMBERS;
North Carolina State Univ., Raleigh, NC

Abstract: Brain cells utilize glucose to fuel metabolic processes, and glucose consumption is increased upon neuronal activation. Real-time detection of glucose dynamics is imperative to understanding brain energy utilization and its involvement in neuropathological disorders, as well as the adaptations occurring upon exposure to substances of abuse. Extracellular glucose dynamics are dependent on two opposing forces: glucose availability (cerebral blood flow) and utilization. The location of intraparenchymal microvessels is heterogeneous and these are differentially activated in response to stimuli. Therefore, glucose dynamics are likely to be variable at the microscale. In the caudate putamen (CPu), dopamine-related neurochemical adaptations occur with many behavioral paradigms. However, far less is known regarding glucose signaling in this brain region. Attempts to assess glucose heterogeneity have been hindered by a lack of technology available for these measurements with sufficient spatiotemporal resolution. This work employs fast-scan cyclic voltammetry in conjunction with glucose-oxidase modified carbon fiber microelectrodes to monitor glucose dynamics with sub-second temporal resolution. We assessed heterogeneity in glucose signaling that occurred in response to intravenous administration of saline, glucose, and a cocktail of cocaine and raclopride. These investigations will advance our understanding of basic brain neuroenergetics, as well adaptations associated with substance abuse.

Title: Characterizing ΔFosB's transcriptional map in neuropsychiatric disorders using an HA-tagged transgenic mouse

Authors: *C. K. LARDNER, H. M. CATES, E. S. CALIPARI, E. A. RIBEIRO, J. FENG, E. J. NESTLER;
Fishberg Dept. of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Neuronal gene expression mediates persistent changes in the function of neural circuits observed in many neuropsychiatric disorders. The progression of addiction, for example, begins with short-term molecular perturbations associated with brief exposure to a drug of abuse. If drug usage persists, these molecular changes initiate long-term alterations in gene expression that activate states of cellular and circuit activity unique to the addicted brain. One well-characterized regulator of this progression is ΔFosB, a Fos family transcription factor. ΔFosB is a splice variant of FosB, arising from a truncation which lends it unusual stability due to the loss of 3' degron domains. This allows for accumulation of the protein with continued exposure to a drug of abuse. ΔFosB plays a similar role in mediating adaptations to prolonged exposure to stress. Yet the scope and extent of ΔFosB's transcriptional activity has thus far been elusive due to the lack of antibodies suitable for chromatin immunoprecipitation (ChIP)-seq. Here, we characterize a transgenic mouse line in which *Fosb* is preceded by a hemagglutinin (HA) tag. As a result, ΔFosB is expressed with an HA tag fused at its N-terminus, allowing for anti-HA targeting of ΔFosB in a number of applications, including ChIP-seq. Specific targeting of ΔFosB *in vivo* will allow for elucidating its precise genetic targets and their corresponding molecular mechanisms in mediating the onset and persistence of addiction in addition to many other neuropsychiatric states.

Title: Sorting nexin 27 in midbrain dopamine neurons regulates addictive behavior to cocaine

Authors: *R. RIFKIN, M. S. FERNANDO, P. A. SLESINGER;
Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Natural rewards and addictive drugs increase the concentration of dopamine (DA) in the brain's reward circuit by altering the activity of dopaminergic neurons in the ventral tegmental area (VTA). Activation of G protein-gated inwardly rectifying potassium (GIRK or Kir3) channels provides an important inhibitory signal for regulating the excitability of DA neurons. Sorting Nexin 27 (SNX27), which is a component of the retromer forward trafficking complex, controls plasma membrane expression of GIRK channels in VTA DA neurons. We showed previously that loss of SNX27 in VTA DA neurons results in reduced $GABA_B$-GIRK currents. Here, we hypothesize that reduced $GABA_B$-GIRK currents in mesolimbic projecting DA neurons will increase the sensitivity of mice to cocaine-dependent locomotor sensitization. We crossed $SNX27^{fl/fl}$ mice with mice expressing Cre in DA neurons, TH_{BAC}-Cre mice, to construct a conditional knockout of SNX27 in DA neurons ($SNX27_{TH}KO$). To study locomotor sensitization, mice (male and female, ages 4-8 months) were acclimated in a locomotor activity chamber and injected (i.p.) daily with saline for three days. Mice were then injected (i.p.) daily with 3.75 mg/kg cocaine for 5 days. Locomotor activity was recorded during the 45 minutes after each injection. $SNX27_{TH}KO$ mice exhibited statistically significant greater locomotor sensitization. By contrast, control mice showed no sensitization with 3.75 mg/kg cocaine. In a separate cohort of mice, we quantified the amplitude of the $GABA_B$-GIRK currents in mesolimbic projecting DA neurons. To label these DA neurons in the VTA, we injected AAV5.EF1a.DIO.eYFP into nucleus accumbens (NAc) of $SNX27_{TH}KO$ and control mice. $GABA_BR$-GIRK currents were significantly reduced in NAc-projecting VTA DA neurons of $SNX27_{TH}KO$. To study the effect of rescuing the reduced $GABA_B$-GIRK currents in $SNX27_{TH}KO$ mice, we injected AAV5.EF1a.DIO.Girk2a-eYFP into the NAc of $SNX27_{TH}KO$ mice; Girk2a does not require SNX27 for plasma membrane expression. As expected, $GABA_B$-GIRK currents were restored in VTA DA neurons of $SNX27_{TH}KO$ mice injected with AAV5.EF1a.DIO.Girk2a-eYFP. We are currently examining the role of $GABA_B$-GIRK currents in the mesocortical and mesolimbic projecting DA neurons in the locomotor response to cocaine.

Taken together, these results reveal a novel pathway for reward processing involving SNX27 and GIRK channels in VTA DA neurons and highlight SNX27 as a new therapeutic target for treating addiction. Funding: NIH R01-DA037170 (PAS) and F30-DA039637 (RAR)

Title: Psychostimulant cocaine causes microvesicle release by activating sigma-1 receptor and ARF6

Authors: *Y. NAKAMURA, S.-Y. TSAI, T.-P. SU;
Cell. Pathobiology Section, Integrative Neurosci. Res. Br., NIDA IRP, Baltimore, MD

Abstract: The sigma-1 receptor (Sig-1R) is an endoplasmic reticulum (ER) chaperone which has been implicated in many central nerve system disorders including depression, neuropathic pain, and psychostimulant addiction. The Sig-1R is a pluripotent modulator that can modulate the functions of many proteins at the ER, plasma membrane, nucleus, and cytosol. Cocaine is a Sig-1R agonist that is known to affect the cellular localization of Sig-1R that plays an important role in cocaine addiction. Here we found that cocaine can dose-dependently (0.1, 1 and 10 μM) increase the Sig-1R in the extracellular space together with a concomitant increase of extracellular microvesicles in NG-108 cells. Pretreatment of cells with BD1063, a Sig-1R antagonist, completely blocks cocaine-induced release of microvesicles and Sig-1R. However, knockdown of Sig-1R causes an enhanced release of microvesicles. Interestingly, previous studies have also reported such a dilemma in which the Sig-1R antagonist decreased ethanol consumption (Sabino et al., Psychopharmacology (Berl). 2009) while deletion of the Sig-1R increased ethanol consumption (Valenza et al., Behav Brain Res. 2016). We examined next the effect of cocaine on the activity of ADP-ribosylation factor 6 (ARF6) which is a small GTP-binding protein known to be an important signaling molecule to regulate microvesicle release and membrane trafficking. Indeed, cocaine stimulation increases the activation of ARF6 in the form of ARF6-GTP. The exact mechanism on the cocaine-induced microvesicle and Sig-1R release and its relation to cocaine addiction is currently under investigation. (Supported by the IRP/NIDA/NIH/DHHS)

Title: eIF2α-mediated translational control regulates the persistence of cocaine-induced LTP in midbrain dopamine neurons

Authors: *A. PLACZEK[1,2], G. VIANA DI PRISCO[2], S. KHATIWADA[2], W. HUANG[2], K. KRNJEVIć[3], R. KAUFMAN[4], J. DANI[5], P. WALTER[6], M. COSTA-MATTIOLI[2]; [1]Mercer Univ. Abstract: Recreational drug use leads to compulsive substance abuse in some individuals. Studies on animal models of drug addiction indicate that persistent long-term potentiation (LTP) of excitatory synaptic transmission onto ventral tegmental area (VTA) dopamine (DA) neurons is a critical component of sustained drug seeking. However, little is known about the mechanisms regulating such persistent changes in synaptic strength in the VTA. We recently found that translational control by eIF2α phosphorylation (p-eIF2α) regulates the induction of cocaine-induced LTP in the VTA. We report that in mice with reduced p-eIF2α levels, cocaine induces persistent LTP in the VTA. Moreover, selectively inhibiting eIF2α-mediated translational control with the small molecule drug ISRIB, or by knocking down oligophrenin-1 (Ophn1)—an mRNA whose translation is controlled by p-eIF2α—in the VTA also prolongs cocaine-induced LTP. This persistent LTP is mediated by the insertion of GluR2 subunit-lacking AMPARs. Collectively, our findings suggest that eIF2α-mediated translational control regulates compulsive

drug seeking by acting as a defense mechanism that prevents the conversion from transient to persistent cocaine-induced LTP.

Title: Mechanisms regulating protein synthesis in cultured nucleus accumbens neurons

Authors: ***M. E. WOLF**, M. T. STEFANIK;
Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: The synthesis of new proteins is critical for the generation and maintenance of long-lasting synaptic modifications that lead to changes in behavior. Recent electrophysiological and biochemical work from our lab suggests that, during withdrawal from extended-access cocaine self-administration, adaptations in medium spiny neurons (MSNs) of the nucleus accumbens (NAc) leading to enhanced drug seeking are maintained by dysregulated local translation in the nucleus accumbens (NAc). As a first step towards understanding these mechanisms, we used fluorescent non-canonical amino acid tagging (FUNCAT) to visualize newly synthesized proteins in NAc MSNs.

Utilizing a co-culture system, PFC neurons obtained from P1 offspring of homozygous enhanced cyan fluorescent protein (ECFP)-expressing mice were co-cultured with NAc MSNs obtained from P1 Sprague-Dawley rats. MSNs in this co-culture system express high levels of high-conductance, calcium-permeable AMPA receptors, recapitulating the state of the NAc after incubation of cocaine craving. Direct detection of de novo protein synthesis was achieved with a strategy that utilizes FUNCAT and subsequent click-chemistry fluorescence tagging for visualization of newly translated proteins. Fluorescence immunocytochemistry was used to simultaneously quantify expression of specific proteins of interest in these cells.

Initial results have confirmed that the FUNCAT signal is nearly eliminated by an inhibitor of

protein translation (cycloheximide) and have shown, using immunohistochemistry, that dendritic sites of active protein translation co-localize with ribosomal subunits. Ongoing studies are utilizing a number of pharmacological tools in order to examine the regulation of protein synthesis by AMPARs, NMDARs, and group I mGluRs.
These results will further the understanding of mechanisms controlling the regulation of local protein synthesis in the NAc under normal conditions, how such regulatory mechanisms may differ between the NAc and other brain regions, and how they may be altered in pathological scenarios like addiction.

Title: Repeated restraint stress exposure during early withdrawal accelerates incubation of cue-induced cocaine craving

Authors: *J. A. LOWETH[1], S. CHAKROBORTY[1], A. R. WEST[1], J. A. ROSENKRANZ[2], M. E. WOLF[1];
[1]Neurosci., [2]Cell. & Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: A major challenge for treating cocaine addiction is the propensity for abstinent users to relapse. Two important triggers for relapse are cues associated with prior drug use and stressful life events. To study their interaction in promoting relapse during abstinence, we used the incubation model of craving and relapse in which cue-induced drug seeking progressively intensifies ("incubates") during withdrawal from extended-access cocaine self-administration. Our recent behavioral results show that exposure to repeated but not acute restraint stress during the first two weeks of withdrawal accelerates the initial rate of incubation of cue-induced cocaine craving. These data indicate that chronic stress exposure during early withdrawal facilitates incubation of cocaine craving, which is thought to contribute to enhanced relapse vulnerability. Previous studies have shown that chronic stress exposure enhances excitatory drive to the basolateral amygdala (BLA), a region critical for behavioral responses to stress. Given that glutamate projections from the BLA to the NAc are critical for incubation of cocaine craving, we

hypothesized that cocaine withdrawal and chronic stress exposure produce a synergistic increase in BLA neuronal activity which facilitates incubation of craving. To assess this, we are investigating how repeated restraint stress during early withdrawal from extended-access cocaine self-administration impacts BLA projection neuron activity. Using *in vivo* extracellular recordings from anesthetized rats, we will compare neuronal activity between the following four groups: cocaine self-administration + control conditions, cocaine self-administration + stress, saline self-administration + control conditions, saline self-administration + stress. Changes in the firing rate of BLA neurons and in the number of spontaneously active neurons in the BLA will be assessed. In this way, we can assess the effects of cocaine exposure alone on BLA physiology, as well as the interaction between both cocaine and chronic stress exposure. These findings may identify potential mechanisms by which stress enhances cue-induced relapse vulnerability in abstinent cocaine addicts.

Title: Extended-access cocaine self-administration leads to increased GluN3-containing NMDA receptor function in the rat nucleus accumbens

Authors: *D. T. CHRISTIAN, K. Y. TSENG, M. E. WOLF;
Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Cue-induced cocaine craving intensifies or incubates during withdrawal from extended-access cocaine self-administration. After prolonged withdrawal, the expression of incubated cocaine craving is mediated by GluA2-lacking, Ca2+-permeable AMPARs (CP-AMPARs) that accumulate in the nucleus accumbens (NAc). NMDARs play a major role in Ca2+ signaling, but little is known about how NMDAR transmission may be altered during incubation of cocaine craving. However, recent studies have shown that incorporation of GluN3-

and GluN2B-containing NMDARs accompanies cocaine-induced increases in CP-AMPAR levels in the ventral tegmental area (Yuan et al, 2013). To determine if NMDAR transmission in the NAc is altered following extended-access cocaine self-administration, we utilized whole-cell patch clamp electrophysiology in NAc medium spiny neurons (MSN). Specifically, we measured evoked NMDAR-mediated synaptic responses across a range of membrane holding potentials (-80 through +40 mV; 20 mV steps). We found that cells from cocaine exposed rats during "late" withdrawal (WD>35) exhibited a significant increase in NMDAR currents at both negative (-80,-60, -40 mV) and positive (+ 40mV) membrane holding potentials when compared to saline control cells. Such shifts in the current-voltage relationship are consistent with the incorporation of GluN3 subunits into functional NMDARs. We also examined cocaine exposed animals during an earlier withdrawal period (WD13-20) which precedes the synaptic incorporation of CP-AMPARs into excitatory synapses onto NAc MSNs. Again, significant increases in NMDAR currents at both negative (-80,-60,-40 mV) and positive (+40 mV) membrane holding potentials when compared to saline control cells were found, indicating the presence of GluN3-containing NMDARs. We are currently evaluating potential GluN3-selective antagonists to examine the specific role of GluN3-containing NMDARs in the incubation model. Overall, these data indicate that alterations in NMDAR function in the NAc, likely mediated by incorporation of GluN3-containing receptors, precede the incorporation of CP-AMPARs during withdrawal from extended-access cocaine self-administration, and are then maintained throughout the period when incubated drug seeking is maximal. Title: Nucleus accumbens core miRNA expression after the incubation of cocaine craving

Authors: M. E. WOLF, *C. MURRAY;
Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: In a rat model of cocaine addiction, cue-induced cocaine craving intensifies or "incubates" during withdrawal from extended-access cocaine self-administration. Cocaine

craving is mediated in part by AMPAR transmission onto medium spiny neurons (MSN), the principal cell type in the nucleus accumbens (NAc). During incubation, incorporation of Ca^{2+}-permeable AMPARs (CP-AMPARs) strengthens NAc synapses, while group I mGluR-mediated synaptic depression shifts from an mGluR5-dependent mechanism that is expressed presynaptically to an mGluR1-dependent mechanism that is expressed postsynaptically by the removal of CP-AMPARs. Previous work from our lab has shown that these synaptic adaptations depend upon ongoing protein translation for their maintenance, and therefore may involve regulation by microRNAs (miRNAs), a class of small non-coding RNAs that repress mRNA translation. The goal of this study is to identify miRNAs that are differentially expressed in the NAc core after incubation of cocaine craving, and manipulate miRNA expression in vitro and in vivo to functionally characterize the role that specific miRNAs play in cocaine-dependent synaptic adaptations during withdrawal. We are particularly interested in miRNAs that regulate AMPAR subunit expression. To this end, rats self-administered saline or cocaine (6 h/d for 10 d) and were killed after 50 days of withdrawal. RNA isolated from the NAc core was assessed using the miRCURY LNA 7th generation microRNA microarray platform (Exiqon), which contains capture probes for all known rat miRNA. Based on these findings, we plan to manipulate the affected miRNAs within cell culture to assay potential effects on AMPAR expression on NAc neuronal processes and examine the functional correlates of the miRNAs in the incubation model in vivo. Abstract: Drug addiction is a chronic brain disease that develops gradually in response to compulsive use of psychoactive substances. These drugs, including cocaine, cause progressive, drug-dependent alterations in brain regions associated with reward and motivation, including the nucleus accumbens (NAc). These neuroadaptations, which include changes in spine morphology, gene expression and protein expression, facilitate craving evoked by drug-associated cues that underlie persistent relapse susceptibility. The ubiquitin-proteasome system (UPS), which is responsible for proteasomal-dependent protein degradation, has been shown to be involved in cocaine conditioned place preference (CPP) and cue-induced seeking following extended-access self-administration. However, how ubiquitin protein (E3) ligases, which polyubiquitinated proteins for proteasomal degradation, regulate cocaine plasticity has not been studied. Here, we examined E3 ligases Trim3, which polyubiquitinates gamma actin to regulate spine architecture, as well as Smurf1, which polyubiquitinates some members of transforming growth factor (TGF)-β superfamily involved in transcription. Following extended-access self-administration, we found dynamic changes in Trim3 and Smurf1 in the NAc that differed in subcellular fractions and were dependent on withdrawal. We will use viral and pharmacological approaches to characterize the function of Trim3 and Smurf1 in the NAc in cocaine-dependent neuroadaptations and relapse-like behaviors.

Title: Activin A is increased in the hippocampus following prolonged, but not acute, withdrawal from extended-access cocaine self-administration and mediates cue-induced reinstatement

Authors: *L. MUELLER[1], C. T. WERNER[1], Z.-J. WANG[2], J. A. MARTIN[1], A. CACCAMISE[1], A. F. STEWART[1], D. M. DIETZ[1];

Abstract: Risk of relapse in cocaine addiction is often attributed to craving evoked by cues previously associated with drug. Relapse vulnerability persists even after prolonged periods of drug abstinence due to progressive, drug-dependent plasticity that occurs in brain structures involved in reward, learning and memory, including the nucleus accumbens (NAc) and hippocampus (HPC). Drug-induced plasticity includes, among others, changes in spine morphology, protein expression and gene expression. The transforming growth factor (TGF)-β superfamily is a family of multifunctional proteins that regulate a wide variety of cellular responses, including gene expression. Recent studies have shown transcription factor SMAD3 and homodimer protein Activin A, both members of the TGF-β superfamily, and BRG1, a chromatin remodeler that forms a complex with SMAD3, are important for relapse-like behaviors following cocaine exposure in animal models of addiction. However, the role of TGF-β signaling in the HPC in drug addiction has yet to be examined. Here, we show that following extended-access cocaine self-administration, Activin A is increased in the HPC, but not the NAc, after a cue-induced reinstatement test on withdrawal day (WD) 30 but not WD1. Intra-HPC infusions of antibody directed at Activin A prior to testing on WD30, but not WD1, attenuated cue-induced reinstatement compared to vehicle controls. Importantly, cue-induced reinstatement was still reduced in antibody-treated animals when tested the following day. Together, these results suggest Activin A signaling in the HPC is increased following prolonged, but not acute, withdrawal from extended-access cocaine self-administration and is required for expression of cue-induced reinstatement.

Title: Hypermethylation of the glutamate transporter-1 gene in the nucleus accumbens after long access cocaine self-administration and withdrawal

Authors: *R. KIM, K. J. REISSNER;
Dept. of Psychology and Neurosci., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Relapse to drug abuse is associated with alterations in glutamatergic signaling within the nucleus accumbens (NAc). One particularly salient feature of these alternations is decreased glutamate uptake. The astroglial glutamate transporter, GLT-1, accounts for the majority of glutamate clearance from the synapse and thus, plays an important role in glutamatergic signaling. Drugs of abuse, including cocaine, significantly decrease GLT-1 protein expression in the NAc. Interestingly, this decrease is correlated with both degree of cocaine exposure and length of withdrawal. We have found that GLT-1 protein and mRNA levels in the NAc are differentially regulated based on exposure and withdrawal time, indicating multiple mechanisms of regulation. While short-access self-administration is sufficient to suppress protein levels, a significant decrease in GLT-1 mRNA is observed in the NAc only after long access cocaine self-administration and withdrawal. The goal of the current study is to examine the epigenetic mechanism(s) responsible for the decrease in GLT-1 mRNA following withdrawal from long access cocaine self-administration. Male Sprague-Dawley rats were trained to self-administer i.v. cocaine or saline for 6 hours per day for 10 days. Immediately following the last day of cocaine self-administration, rats remained abstinent in the home cage for 45 days. Twenty-four hours following the last day of withdrawal, rats were sacrificed and tissue was harvested from the NAc. Using an antibody against 5-methylcytosine, methylated DNA was immunoprecipitated. The amount of GLT-1 methylation was then quantified using quantitative PCR and primers specific to GLT-1. Results indicate that long access cocaine self-administration and withdrawal results in an approximately three fold increase in GLT-1 gene methylation over rats that self-administered saline. This hypermethylation of the GLT-1 gene in rats exposed to long access cocaine followed by withdrawal suggests transcription suppression is responsible for the observed decrease in GLT-1 mRNA. Future studies will examine chromatin modification and transcription factors that may also contribute to the observed decreases in GLT-1 mRNA after long access cocaine self-administration and withdrawal.

Title: Cocaine self administration alters dna methylation, hydroxymethylation, and mrna expression in rats

Authors: *K. PLOENSE[1], P. VIEIRA[2], L. BUBALO[2], G. OLIVARRIA[2], A. E. CARR[1], T. E. KIPPIN[2];

Abstract: Cocaine addiction is a chronic disorder that involves excessive, uncontrolled drug consumption. Both humans and rodents will escalate the amount of cocaine taken when it is readily available indicating that excessive intake is dependent on prior consumption. In rodents, however, escalation is not observed when access is restricted to "limited" (i.e. 1 hr) daily sessions. Here, we investigated whether control over drug intake or drug exposure are the critical factors in escalation by employing a mixed limited-contingent exposure and prolonged noncontingent exposure model. . Rats were implanted with a permanent jugular catheter and then allowed to lever press to self-administer (FI20 with a 20 s light cue paired with each infusion) saline vehicle (0.1 ml/infusion) or cocaine (0.25 mg/infusion) under 3 conditions: limited-access (1 h/ day), extended-access (6 h/day), and 1 h limited-access + 5 h non-contingent exposure (via yoking to extended access rats) to cocaine. Based on the first 10 min and first hour of daily access, we observed rapid escalation of cocaine intake in both the extended-access and limited-access + non-contingent conditions (ps < 0.05). We also observed a delayed escalation of cocaine intake in the limited-access condition within the first 10 min of self-administration ($p < 0.05$), but not across the 1 h of cocaine availability. Interestingly, escalation of cocaine intake was accelerated in the limited + non-contingent-access condition relative to the extended-access condition. However, relative to the other cocaine conditions, the limited-access + non-contingent group exhibited markedly more non-reinforced responses indicating that distinct behavioral mechanisms drive escalation by contingent versus noncontingent drug exposure (ps<0.05). Additionally, post-mortem quantification of *homer2* (a gene implicated in cocaine intake and associated) mRNA expression within the dmPFC indicated elevation only in the extended-access conditions ($p<0.05$). Rises in *homer2* mRNA were associated with distinct levels of DNA methylation, hydroxymethylation, and transcription factor binding to the *Homer2* gene. Together, these findings indicate that either contingent or non-contingent "excessive" cocaine exposure supports escalation but have differential effects on the temporal patterning of operant responsiveness as well as molecular correlates of escalation.

Title: Cell signaling pathways involved in the cocaine-induced increase in mu opioid receptor expression in PC12 cells

Authors: K. THERIAULT, F. LERI, *B. E. KALISCH;
Univ. Guelph, Guelph, ON, Canada

Abstract: Cocaine abuse has been linked to elevated mu opioid receptors (MOR) at the protein and mRNA level in key regions of the brain involved in craving and drug seeking. *In vitro* and *in vivo* studies have determined that nitric oxide (NO) and multiple signaling pathways, including phosphatidyl inositol-3 kinase (PI3K)-Akt, protein kinase C (PKC), and mitogen activated protein kinase (MAPK) pathways are involved in cocaine-induced increases in MOR expression. Furthermore, our laboratory established that in PC12 cells, NO modulates the activation of the Akt, MAPK, and PKC pathways. Whether there is an interaction between NO and these signaling pathways in cocaine-induced MOR expression in this cell line is not known. The objective of the current *in vitro* study was to investigate the role of NO in the modulation of these signaling pathways in cocaine-induced increases in MOR expression. To assess the activation of the PKC, Akt, and MAPK pathways by cocaine, PC12 cells were administered repeated intermittent treatments of cocaine (100 μM) and protein was isolated 15 minutes, 30 minutes, 1 hour, 2 hours, or 4 hours after treatment. Phosphorylated PKC, Akt, and MAPK protein levels were evaluated using western blotting. It was found that cocaine significantly activated the PKC and MAPK pathways following 30 minutes and 2 hours of treatment, respectively. To determine the modulation of these pathways by NO, cells were pre-treated with the NO synthase (NOS) inhibitor, N^{ω}-nitro-L-arginine methylester (L-NAME; 20 mM). Protein was isolated at 30 minutes and 2 hours to assess the impact of NO on the PKC and MAPK pathways, respectively. Additional data on the effects of L-NAME on these pathways will be available at the meeting. These studies will clarify the cellular effects that cocaine has on opioid systems, and may identify NO-regulated pathways as a potential target for pharmacotherapies for cocaine addiction.

Title: Sigma-1 receptor regulates cocaine-induced serotonergic action via monoamine oxidase B expression

Authors: ***Y. KIMURA**[1], A. F. HOFFMAN[2], C. R. LUPICA[2], T.-P. SU[1];
[1]Cell. and pathology section, Integrative Neurosci. Res. Br., [2]Electrophysiology Res. Section, Integrative Neurosci. Res. Br., IRP NIDA/NIH, Baltimore, MD

Abstract: The action of cocaine on dopaminergic neurons in the ventral tegmental area (VTA), and its contribution to the addictive properties of this drug have been well characterized. By inhibiting the dopamine transporter (DAT) present on axon terminals of VTA dopamine (DA) neurons, cocaine elevates extracellular dopamine DA levels. However, since the rewarding actions of cocaine are not eliminated by DAT knock down, this suggests that there are still other crucial mechanisms underlying the rewarding effects of cocaine. In this study, we explored the possibility that cocaine, through the ER chaperon sigma-1 receptor (Sig-1R) may activate VTA DA neurons by altering the expression of monoamine oxidase B (MAOB) in the upstream serotonergic neuron that terminates on GABAergic neuron near the VTA. We previously demonstrated that cocaine can suppress the gene transcription of MAOB by translocating Sig-1R to the nuclear envelope to recruit chromatin-remodeling factors that suppress the MAOB promoter. MAOB is known to be expressed selectively in the serotonergic neuron and not in any other monoaminergic neurons. In this study we confirmed a strong MAOB expression in serotonergic neurons in mouse brain. We further show that Sig-1R and MAOB are co-localized in serotonergic neurons within the dorsal raphe (DR). We examined if the expression of MAOB in DR serotonergic neurons differs between wild type vs Sig-1R knockout mice. We also examined whether the Sig-1R and MAO-B positive serotonergic neurons in DR projects to GABAergic neurons which in turn projects to DA neurons within the VTA. This Sig-1R-mediated neuronal pathway implies the crucial involvement of serotonergic neurons in the action of cocaine. These results reveal a new molecular mechanism underlying the actions of cocaine which may contribute to a better understanding of the addictive properties of this widely abused drug. Title: Nrf exacerbates cocaine addiction after social defeat stress

Authors: *Y. N. OHNISHI[1], Y. KAWAHARA[2], Y. H. OHNISHI[2], R. NEVE[3], E. J. NESTLER[4], A. NISHI[2];

Abstract: Generally, mental stress enhances irresistible impulse to addictive craving. However, the molecular mechanism is not fully understood. We reproduced this behavior in a mouse model, in which pre-exposure of mice to social defeat stress (SDS) increased cocaine preference. Motivation for preference is well known to be controlled by dopamine neurotransmission in reward system network from the ventral tegmental area to nucleus accumbens (NAc). We therefore performed microdialysis to detect dopamine levels in the NAc. Dopamine levels in the NAc increased when mice were placed in cocaine-conditioned box, and the increase in dopamine levels was significantly enhanced after SDS. As dopamine is known to be an inducer of oxidative stress, we tried whether antioxidant-rich-foods or anti-oxidative reagent decreases cocaine preference after SDS, the former had no effect, but the latter had a trend to decrease the preference and locomotor sensitization by cocaine. Next, we measured the expression level of oxidative stress response proteins, and found that nuclear respiratory factor (Nrf) was significantly increased only when mice were treated with cocaine after SDS. Furthermore, overexpression of dominant negative form of Nrf in NAc suppressed cocaine preference after SDS. Now we examine whether the anti-oxidant reagent inhibits the enhanced expression of Nrf after cocaine administration following by SDS.

Title: N-acetylcysteine decreases the motivation to self-administer cocaine in rats

Authors: *R. HODEBOURG, A.-N. SAMAHA;
Dept. of Pharmacol., Univ. of Montréal, Montréal, QC, Canada

Abstract: Chronic cocaine intake decreases basal levels of glutamate in brain regions that regulate reward, such as the nucleus accumbens. This effect correlates with the vulnerability to relapse in rats and is thought to involve downregulation of the cysteine/glutamate antiporter located on glial cells. In cocaine-experienced rats, systemic administration of the cysteine prodrug N-acetylcysteine (NAC), restores the function of the cysteine/glutamate exchanger and reduces the vulnerability to relapse. Drug addiction involves several behavioural symptoms that involve relapse to drug use during abstinence, but also an increased motivation to take drug. Indeed, spending much time and effort obtaining, consuming and recovering from drugs is one of the diagnostic criteria for addiction. Our objective here was to determine whether systemic administration of NAC influences the motivation to take cocaine in cocaine-experienced rats. To this end, rats were trained to press a lever to self-administer cocaine (0.25 mg/kg), during daily 6-h sessions. Cocaine was available intermittently during each session. Intermittent drug intake, in contrast to continuous drug intake, is more effective in producing brain and behavior changes that are relevant to addiction (Zimmer et al., 2011) and is also thought to best model the way experienced cocaine users take the drug (Beveridge et al., 2012). Thus, in a protocol adapted from Zimmer et al. (2011), cocaine was available in 6-min bins, separated by 26-min time-out periods, for 6h/day. First, we determined whether acute administration of NAC (0, 30, 60, 90 mg/kg, ip) influences the motivation to self-administer cocaine, or food, as assessed using a progressive ratio schedule of reinforcement. Acute administration of 30, 60 and 90 mg/kg NAC decreased the motivation to take cocaine without affecting the motivation for food. Next, we determined whether chronic NAC administration (0, 60 mg/kg, i.p) during withdrawal from self-administered cocaine influences the later motivation to take the drug. NAC injected daily during either 7 or 14 days of withdrawal from cocaine had no effect on the motivation to take the drug. Finally, we examined the effect of NAC treatment prior to each cocaine self-administration session on the later motivation to take cocaine. NAC treatment reduced both cocaine intake during the intermittent-access sessions and the later motivation to take cocaine. Thus, acute

treatment and chronic pretreatment with NAC are both effective in decreasing the motivation for cocaine. These findings contribute to a growing literature suggesting that NAC deserves clinical attention as a treatment for cocaine addiction.

Abstract: Repeated cocaine exposure causes compensatory neuroadaptations in neurons of the nucleus accumbens (NAc), a region known to mediate the reinforcing effects of drugs. Recent studies have suggested that the cellular energy sensor AMPK regulates neuronal morphology and membrane excitability. However, the potential involvement of AMPK in cocaine addiction is still unknown. Here we found that intravenous cocaine self-administration induced a significant decrease in AMPK activity persisting for at least 7 d of withdrawal in the NAc shell. Through direct genetic and pharmacological manipulations of AMPK signaling, we found that

augmenting AMPK activity in NAc shell markedly attenuated cocaine reinforcement of self-administration behavior, while inhibition of AMPK activity significantly enhanced cocaine reinforcement, as indicated by downward or upward shifts in fixed ratio dose-response curves. Inhibiting AMPK activity in NAc shell also increased motivation for cocaine injections on more demanding progressive ratio schedules. These behavioral findings were associated with changes in the phosphorylation of AMPK and CRTC1, and expression of CREB-dependent genes and membrane GluR1 and GluR2 in the NAc shell. Moreover, the effects of AMPK on cocaine reinforcement and motivation were prevented by expressing constitutive active CRTC1 or knockdown of CRTC1 in the NAc shell. We also found that AMPK mediated cocaine-induced dendritic spine morphology of NAc neurons. Altogether, our results indicate that AMPK regulates cocaine reinforcement and motivation through long-term remodeling of neuronal morphology and function in the NAc via transcriptional reprogramming, and its activity during cocaine use influences the development and persistence of addictive behaviors.

Title: PKCι/λ and PKMζ protein expression in mesocorticolimbic areas during cocaine behavioral sensitization

Authors: *A. VAQUER-ALICEA[1], T. ORTIZ-ITHIER, 00936[2], T. DOMINGUEZ, 00936[3], B. SANTOS-VERA[1], C. MARÍA-RÍOS[3], A. MONTIEL-RAMOS[3], R. VÁZQUEZ-TORRES[1], K. BOSQUE-CORDERO[3], T. SACKTOR[4], C. JIMENEZ-RIVERA[1];
[1]UPR Med. Sci. Campus, San Juan, PR; [2]Sacred Heart Univ., San Juan, PR; [3]Univ. of Puerto Rico Rio Piedras Campus, San Juan, PR; [4]State Univ. of New York Downstate Med. Ctr., New York, NY

Abstract: Cocaine addiction induces long-lasting alterations in the mesocorticolimbic system, some of which may be mediated by the mechanisms of long-term potentiation (LTP). Persistent phosphorylation by protein kinase M zeta (PKMζ), a brain-specific atypical isoform of PKCζ, mediates late-LTP maintenance. This notion was recently challenged when PKC/PKMζ knock-out mice showed intact LTP and reversal of LTP by infusion of its inhibitor ZIP. This suggested that LTP can develop independently of PKMζ, and ZIP may block another atypical PKC. PKCι/λ is another atypical PKC isoform whose marked homology (88%) to PKMζ makes it a potential candidate for participation in the LTP process when PKMζ is not present; and could possibly compensate for PKMζ loss in the knockout mice. Here, we aim to investigate the role PKMζ, and PKCι/λ may play in cocaine-induced LTP, using the cocaine behavioral sensitization model. To this end, we examined the total protein expression profile of PKMζ and PKCι/λ in naïve animals and at different time points of the cocaine behavioral sensitization: 24 hours after an acute exposure, 24 hours after 5 days of cocaine sensitization, and 24 hours after a 7 day withdrawal period following 5 days of cocaine sensitization. Sprague Dawley male rats (250g) received intraperitoneal cocaine (15mg/kg) or 0.9% saline injections for 1 or 5 consecutive days, and locomotor activity was recorded for 1hr. The rats were sacrificed and tissue micro punches of the ventral tegmental area (VTA), nucleus accumbens (NAc), prefrontal cortex (PFC), and hippocampus (Hipp) were subjected to protein extraction and western blot analysis. Results show no significant difference in the expression of PKCι/λ and PKMζ between all four brain areas of naïve animals. After a single cocaine exposure, PKCι/λ protein expression was decreased in the PFC. In cocaine sensitized animals PKMζ protein expression and not PKCι/λ was significantly increased in the NAc and Hipp. After a 7 day withdrawal period, PKCι/λ protein expression was significantly decreased in the hippocampus. These results suggest that PKMζ protein increase in NAc might precede important changes for the expression of sensitization; possibly playing a role in NAc LTP. PKC ι/λ protein expression decrease in the PFC after an acute cocaine exposure and after a 7 day withdrawal period may result from a compensation to increased PKMζ activity. Future measurement of phosphorylated PKCι/λ and PKMζ (activated state) will allow us to ascertain their role in cocaine sensitization and LTP formation. This may shed light into the pathological mechanisms of cocaine-related plasticity during the addiction process.

Title: Contribution of estrogen receptor subtypes to the effect of estradiol on cocaine-induced dopamine release in the nucleus accumbens

Authors: *K. E. YOEST[1], J. A. CUMMINGS[1], B. J. ARAGONA[1,2], J. B. BECKER[1,3,2]; [1]Dept of Psychology, [2]Neurosci. Program, [3]Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: There are well established sex differences in the susceptibility to addiction, where women show faster escalation of drug use and are more prone to relapse than their male counterparts. Similar findings have been reported in rodent models, where females acquire cocaine-taking behavior more rapidly than males. Gonadal hormones modulate this sex difference, as the positive subjective effects of psychomotor stimulants are enhanced by estradiol in women, and estradiol also enhances the acquisition of cocaine self-administration in female rats. Our laboratory has previously reported that acute estradiol administration also enhances cocaine-induced dopamine release in the nucleus accumbens (NAc) shell in females but not males (Yoest et al. Estradiol rapidly enhances dopamine in nucleus accumbens shell of female but not male rats. Program No. 617.12. 2014 Neuroscience Meeting Planner. Washington, DC: Society for Neuroscience, 2014. Online.) However, which estrogen receptor is mediating this effect is still unknown. The estrogen receptors ERα and GPER-1 are both expressed in the NAc (Almey et al., Hormones & Behavior, 74:125-138, 2015) and reduction of ERα in this area blocks estradiol induced place preferences (Walf et al., Neuropsychopharmacology, 32:522-530, 2007). However, ERβ mediates the effect of estradiol on cocaine-induced reinstatement (Larson & Carroll, Neuropsychopharmacology, 32:1334-1345, 2007), suggesting a potential role for this receptor as well. With this experiment, we tested the effect of acute selective estrogen receptor activation on cocaine-induced dopamine release in the NAc shell. Gonadectomized male and female rats were anesthetized and treated with either the ERα selective agonist propyl pyrazole triol, the ERβ selective agonist diarylpropionitrile, the GPER-1 selective agonist G1, or vehicle 30 min prior to administration of cocaine (10mg/kg i.p.). Fast scan cyclic voltammetry (FSCV) was used to measure stimulated dopamine release in the NAc shell both prior to and after cocaine administration. We found that activation of specific estrogen receptor subtypes differentially modulate dopamine release in the presence of cocaine. These findings further elucidate the mechanism by which estradiol exerts sex-specific effects on dopamine release. Importantly, dopamine signaling in the NAcc has been implicated in the acquisition and escalation of drug taking behaviors, aspects of addiction that are more pronounced in female addicts. A full understanding of the mechanism by which estradiol may render women more susceptible to compulsive drug use will help to develop gender-specific treatments in clinical settings.

Title: Intranasal OT reduces cocaine conditioned locomotion and elicits changes in endocannabinoid receptors within the mesolimbic system

Authors: *G. C. MOLINA-CASTRO, A. N. FIGUEROA-GONZÁLEZ, A. J. LOYOLA-VÉLEZ, E. TORRES-HERNÁNDEZ, C. S. MALDONADO-VLAAR;
Univ. of Puerto Rico, Rio Piedras Campus, San Juan, Puerto Rico

Abstract: Oxytocin (OT) is a neuropeptide secreted by the hypothalamic paraventricular nucleus (PVN) and commonly associated with social behaviors, stress responses and drug-addiction. Previous studies have shown that OT has anxiolytic properties associated with cues in a cocaine-conditioning paradigm, but the underlying mechanism remains unknown. This study aims to characterize possible mechanistic interactions between OT and the endocannabinoid system mediating cocaine conditioning and anxiety response, in particular the cannabinoid receptor type 1 (CB1) and the transient receptor potential vanilloid type-1 (TRPV1). Rats were exposed to activity chambers after receiving systemic intraperitoneal injections of cocaine (10 mg/kg) or saline 0.9%. On the last day (D7), rats received intranasal infusions of OT (1 ug/uL) or vehicle 30 minutes prior being exposed to the cue-associated environment. Our results showed that OT pretreatment reduced cocaine-paired conditioned locomotion. Preliminary western blot analysis showed an upregulation of OT receptors within the hippocampus and amygdala and a downregulation of these receptors within the prefrontal cortex (PFC). Further immunohistochemical analysis will be conducted to determine possible interactions or colocalization between OT, CB1 and TRPV1 receptors. This preliminary data suggests intranasal OT as a novel therapeutic approach of cocaine addiction.

Title: Disrupting astrocyte-neuron lactate transfer persistently reduces conditioned responses to cocaine

Authors: B. BOURY-JAMOT[1], O. HALFON[2], P. J. MAGISTRETTI[3], *B. BOUTREL[4,2]; [1]Ctr. for Psy. Neurosci., [2]Child and Adolescent Psychiatry, Lausanne Univ. Hosp., Lausanne, Switzerland; [3]Brain Mind Inst., EPFL, Lausanne, Switzerland; [4]Ctr. for Psych. Neurosci., Prilly-Lausanne, Switzerland

Abstract: Drug memories that associate contextual cues with the effects of drugs are known to shape persistent drug seeking behaviors in rodents. In abstinent humans, drug cues are known to evoke salient, persistent and overwhelming memories of drug-taking experiences, thereby inducing higher risks of craving and relapse. Since the transfer of glycogen-derived lactate from astrocytes to neurons is required for long-term memory, we explored the possibility that disrupting glycogenolysis in the basolateral amygdala (BLA) could impair the acquisition and maintenance of positive affective memories associated with cocaine-associated cues. We have observed that rats treated with intra-BLA infusions of the inhibitor of glycogen phosphorylase (DAB 300 pmol/side), 15 minutes before conditioning sessions of a conditioned place preference (CPP), failed to exhibit a clear cut preference for side previously paired with cocaine. To assess the importance of astrocyte-derived L-actate in the maintenance of cocaine- induced CPP, another group of rats received a post-conditioning administration of DAB into the BLA prior to the test. Whereas saline treated rats exhibited a strong preference for the rewarding compartment up to seven days, DAB-treated rats only transiently displayed an abolished preference for the cocaine compartment that was restored after seven days. In contrast, a double injection of DAB (15 min before and 5 hrs after contextual re-exposure) completely abolished the cocaine attractiveness for up to two weeks. Importantly, rats injected with DAB in home cages 24h prior to the test exhibited a strong CPP, suggesting a role of DAB on experience-dependent memory reconsolidation. Finally, we demonstrated that drug memory was rescued by Lactate co-administration through a mechanism requiring the synaptic plasticity related transcription factor Zif268, and extracellular signal-regulated kinase (ERK) signalling pathway. Interestingly, co-administration of DAB and Pyruvate failed to do so, demonstrating that Lactate played a non-metabolic role in this process. We then targeted the prefrontal cortex (PFC) with a similar protocol, but rats continued to exhibit a strong preference for the cocaine compartment. Taken

together, these results highlight a signaling role of astrocytic lactate in both acquisition and maintenance of cocaine-seeking behavior and open novel therapeutic avenues to reduce the long-lasting impact of drug cues on conditioned responses to cocaine.

Title: Tracking the emergence of hierarchical concept representations

Authors: *S. THEVES, D. NEVILLE, J. BELLMUND, G. FERNÁNDEZ, C. F. DOELLER; Donders Institute, Radboud Univ., Nijmegen, Netherlands

Abstract: Concepts provide the scaffolding structures to interpret the world and assign meaning to novel information. This often requires incorporating relations between knowledge entities at multiple hierarchical levels. While previous fMRI studies revealed that hippocampal and prefrontal activity scales with the acquisition of simplistic one-dimensional concepts, it remains elusive how the brain accumulates and represents knowledge at multiple levels of abstraction. Here we combined model-based fMRI with representational similarity analysis to examine local computations during learning of a two-level hierarchical category structure and their relation to neural concept representations. During scanning, participants learned to categorize artificial complex stimuli into two basic and four sub-categories according to a hierarchical rule. In each trial incremental feedback indicated up to which level in the hierarchy the participants placed a stimulus correctly. In addition to these feedback-guided learning trials, we interleaved feedback-free probe trials to track the transfer of conceptual knowledge to novel information. The amount of level-specific conceptual knowledge per trial was estimated from behaviour during learning and transfer trials in a hierarchical state-space model and regressed against brain activity to track the accumulation of hierarchy-specific conceptual knowledge. We find that behavioral performance on both category levels increased across trials and ultimately exceeded chance-level

in all participants. Importantly, the learning trials on the basic category level preceded the learning trials on the subcategory level, confirming the hierarchical nature of the acquisition process. In addition, participants acquired explicit knowledge of the categorization rules as assessed in a final debriefing questionnaire. Preliminary analyses of fMRI data indicate level-dependent involvement of striatal, prefrontal and hippocampal structures during acquisition. Before and after learning, exemplars of each category were presented in task-independent blocks to assess learning-induced changes in multi-voxel pattern similarity across exemplars. Preliminary results point towards a representational clustering of exemplars according to their position in the acquired concept structure. Finally, we aim to investigate interactions between neural concept representations, learning-related activity, and behavior. In sum, this study could shed new light on the representational dynamics underlying concept formation at different levels of abstraction.

Title: Item-specific representation during episodic memory encoding and retrieval

Authors: *G. XUE[1], X. XIAO[2], R. A. POLDRACK[3];
[1]State Key Lab. of Cognitive Neurosci. and Learning, China, China; [2]Beijing Normal Univ., Beijing, China; [3]Stanford Univ., Stanford, CA

Abstract: Contemporary models of episodic memory posit that remembering involves the reenactment of encoding processes. Although encoding-retrieval similarity (ERS) has been consistently reported and linked to memory success, the nature of the neural pattern reinstatement is poorly understood. Using high-resolution fMRI, our results obtained clear evidence for item-specific pattern reinstatement in the frontoparietal cortex (PFC) but not in the ventral visual cortex (VVC), even when the encoding-retrieval pairs shared no perceptual similarity. Nevertheless, the brain regions and voxels carrying item-specific representation differed significantly between encoding and retrieval, and the item-specificity for ERS was smaller than that for encoding or retrieval. Cross-region representation analysis suggests that the encoded representation in the VVC was reinstated in the FPC during retrieval. These results suggest retrieval might involve the reinstatement of a more abstract representation of the

encoded information, which emphasizes the constructive nature of memory retrieval that helps to serve important adaptive functions.

Title: Investigating the components of episodic memory in humans: can they be mapped using electrophysiology?

Authors: *L. A. DE STEFANO, S. E. RHOTEN, M. J. WENGER, E. J. ZOCCOLI, M. G. APPEL, S. M. TOFTELY, S. A. WETMORE, S. D. GRONLUND;
Psychology, Univ. of Oklahoma, Norman, OK

Abstract: Episodic memory retrieval relies on integration of information about what an item was, as well as when and where it was encountered. Previous research from animal lesion studies using a novelty preference paradigm found that the hippocampus and the medial prefrontal cortex were critical for different aspects of recollection of episodic events (DeVito & Eichenbaum, 2010). The present study attempts to adapt this paradigm to assess these components behaviorally and physiologically in humans using a memory recognition task. Participants studied two virtual "rooms" containing images of women, with each image presented consecutively in a random location for 4s. Between rooms, participants engaged in a go/no-go distractor task for either 15 seconds ("short" retention interval) or 3 minutes ("long"). After both rooms were studied, participants made old/new judgments with half of the items being new. Half of the images appeared in the same location as during the study phase ("stationary") with the others appearing in a new location ("displaced"). Behavioral results showed significantly longer reaction times (RTs) for new items than old, and longer RTs for long retention intervals relative to short. Electrophysiological (EEG) results show a significant main effect of old/new status in the left parietal area in the interval from 500 to 800 ms post-stimulus onset, with old items eliciting larger amplitudes than new items, but this result was unaffected by retention interval. Additionally, the effects associated with the "when" and "where" aspects of remembered events were analyzed, both with respect to their individual contributions to performance and the integration of all three aspects. Finally, trial-by-trial regression analyses were performed with results providing additional insight into the temporal evolution of all three informational components of episodic memory.

Title: Event related potentials during memory retrieval processes for fractal images in a paired-associate paradigm

Authors: ***J. M. ANDREAU**[1,2], S. A. IDESIS[1,2], S. TORRES BATAN[1], A. A. IORIO[1]; [1]Inst. de Biología Y Medicina Exptl., Capital Federal, Argentina; [2]Univ. del Salvador, Ciudad Autonoma de Buenos Aires, Argentina

Abstract: The ability to remember relies on a complex interplay of processes that we are only beginning to understand. Event-related potential (ERP) studies have proven to be powerful tools in the delineation of these processes. Nevertheless ERP components related to memory are often hard to interpret due to the nature of the stimuli (e.g. words or faces), and the memory task (e.g. retrieval vs recognition). We wondered whether a given known ERP component might in fact reflect an effective-retrieval process which is not camouflaged by another non-specific component. This study sought to solve this issue by using artificial fractal images as stimuli and by comparing two tasks which were almost the same in every aspect except the memory process. In the Delayed Match to Sample task (DMS) subjects had to pair a cue stimulus with itself (control task) and in the Delayed Paired Association task (DPA) subjects had to pair the cue stimulus with its pair associate (previously learned). Twenty students (10 women, $\bar{x}$= 23.45 ± 3.73 years) participated in the experiment. All subjects performed above 80% during the DPA learning task. Mean percentage of correct responses were 98.94 ± 1% in DMS and 96.54 ± 3.88% in DPA. Response times of correct answers were significantly faster in the DMS (680 ± 215 ms) as compared to DPA (938 ± 406 ms). EEG Activity was recorded from 30 electrodes. ERPs mean voltage were analyzed on six regions of interest, each containing the average value of a group of four electrodes and grouped between the two hemispheres as following: left anterior (F7, F3, FC5, FP1), left central (FC1, C3, CP5, T7), left posterior (CP1, P7, P3, O1), right anterior (F4, F8, FC6, Fp2), right central (FC2, C4, CP6, T8), and right posterior (CP2, P4, P8, O2). We asked which memory-related ERP component explained the differences between the two tasks. Three ERP components, P300 (200-350ms), N400 (450-600ms) and Positive Slow Wave (700-850ms) with distinct scalp topographies, were found to differ significantly among the

two tasks. These electrophysiological differences are interpreted as reflections of processes that correlated with memory retrieval processes. This approach, utilizing stimuli with a very small verbal contamination and comparing a memory task with a control task, strengthen our understanding of the ERP component implicated in memory retrieval processes.

Title: Successful memory encoding is independently predicted by slow and fast modulations of oscillatory alpha power in humans

Authors: *S. SUN[1,2], J. S. CANT[2], S. FERBER[1,3], C. J. HONEY[1];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Psychology, Univ. of Toronto Scarborough, Toronto, ON, Canada; [3]Rotman Res. Inst. at Baycrest Hlth. Sci., Toronto, ON, Canada

Abstract: Successful memory encoding appears to be associated with changes in electrophysiological rhythms (oscillations). However, in the case of memory for visual stimuli, both increases and decreases in parieto-occipital alpha band (8-12 Hz) power, as measured in human magneto/electroencephalography (M/EEG), have been linked to successful subsequent memory retrieval. Here we seek to explain these varying results, by considering the timing of the oscillatory changes, and the broader connections of alpha power with both mnenomnic and perceptual processing. Traditionally, increases in alpha power ("alpha synchronization") are thought to reflect an attenuation of bottom-up sensory processing. Thus, we hypothesized that peri-stimulus decreases in alpha power may support initial stimulus encoding by amplifying sensory input, while post-stimulus increases in alpha power may support short-term consolidation by reducing interference. In a test of this hypothesis, participants were presented

with a continuous streams of words, followed by old/new recognition tests. We recorded EEG during the presentation phase, and then contrasted the spectral signatures associated with successful encoding (hits) versus later forgetting (misses). We found that peri-stimulus decreases in alpha power over occipito-parietal sites during the presentation phase were related to successful encoding. This is consistent with the interpretation that alpha desychronization supports the initial processing of the to-be-encoded stimulus. Furthermore, we also found that post-stimulus increases in alpha power were predictive of successful encoding. This suggests that once the information has entered the system, suppression of additional incoming sensory input promotes the consolidation of information into a durable memory trace. Subsequent analyses showed that these opposing effects in the alpha band might operate at different timescales, and are independently and additively predictive of memory outcomes. These results offer a novel framework for interpreting the role of fluctuating alpha oscillations in the ongoing formation of immediate percepts and longer-term memories.

Title: Working memory network integrity in Veterans with a history of repeated blast-related mTBI: A resting state fMRI study

Authors: ***K. F. PAGULAYAN**[1,2], D. G. COOK[1,2], M. REILLY[2], E. PESKIND[1,2], N. KLEINHANS[2];
[1]VA Puget Sound, Seattle, WA; [2]Univ. of Washington, Seattle, WA

Abstract: Repeated mild traumatic brain injury (mTBI) is common among military personnel who served in the conflicts in Iraq and Afghanistan. A significant number of Veterans who sustained repeated blast-related mTBIs report ongoing cognitive difficulties, and there is emerging evidence that blast-related mTBI can be associated with alterations in brain structure and function that are evident years post injury. Although working memory difficulties are frequently reported in this population, the neural underpinnings of this particular cognitive

inefficiency remain unclear. In order to address this question, this study evaluated intrinsic functional connectivity within the working memory network in Operation Iraqi Freedom (OIF)/Operation Enduring Freedom(OEF)/Operation New Dawn (OND) Veterans with a history of repeated blast-related mTBI (N=25) and deployed controls (N=17). Average time since injury in the mTBI group was 71 months (range 18-109 months). All participants completed a neuropsychological measure of working memory called the Auditory Consonant Trigrams Test (ACT) and two 6.5 minute resting state fMRI scans. A subset of participants in the mTBI group (N=21) also completed a self-report measure of current cognitive functioning called the Behavior Rating Inventory of Executive Function-Adult Version (BRIEF-A). fMRI analyses were conducted from frontal seed regions selected because they are well-established components of the working memory network. A high percentage (62%) of Veterans with a history of blast-related mTBI reported clinically significant difficulties with working memory on the BRIEF-A, but no group differences were present on the ACT, an objective measure of working memory. The fMRI results revealed increased connectivity from the frontal seed regions to areas in the frontal-temporal-parietal regions of the brain in the mTBI group relative to the deployed controls. Further, within the mTBI group, but not the deployed control group, performance on the ACT was correlated with increased connectivity between the frontal seed regions and key components of the working memory network including superior parietal lobe and cerebellum. These correlations were present after controlling for PTSD and age, and support the possibility that long-term alterations in the working memory network may result from repeated blast-related mTBI.

Title: Acute stress-induced cortisol elevation enhances memory consolidation of highly similar items

Authors: ***A. JIANG**[1], T. TRAN[1], F. MADISON[2], A. BAKKER[3];
[1]Dept. of Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Univ. of

Maryland, Col. Park, Baltimore, MD; [3]Dept. of Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: It is well-established that stress-induced changes in cortisol significantly affect memory function. Cortisol has been shown to enhance memory consolidation, the process of converting short-term memories into long-term memories, and impair memory retrieval, the process of accessing previously stored long-term memories. However, little is known about the effect of stress-induced changes in cortisol on the hippocampus and its subregions, which have recently been shown to contribute dissociable computational functions to the consolidation and retrieval of memories. In the present study, we examined the effect of acute stress, induced by the Trier Social Stress Test (TSST), on a memory task designed to tax the functioning of the dentate gyrus and CA3 subregions of the hippocampus. The study aimed to determine whether stress-induced cortisol differentially affects hippocampus-dependent memory consolidation and retrieval processes in healthy young adults. Sixty-nine young adults completed a two-day study in which subjects either underwent the TSST immediately following the encoding part of the memory task, or immediately prior to the recognition part of the memory task on the second day. Control subjects completed the same study procedures but underwent a control version of the TSST that did not induce a stress response. Stress-induced elevation of cortisol during memory consolidation enhanced the ability to discriminate between highly similar items 24 hours later while stress-induced elevation of cortisol during memory retrieval had no significant effect on memory performance. These findings show that acute stress-induced change in cortisol differentially affects the consolidation and retrieval stages of memory function, and particularly enhances the consolidation of highly similar items, a function thought to rely strongly on the dentate gyrus and CA3 subregions of the hippocampus.

Title: Napping vs. revising for long-term retention of declarative memories

Authors: *J. N. COUSINS[1], B. L. RAGHUNATH[2], C. S. T. LOOK[2], M. W. L. CHEE[2];
[1]Cognitive Neurosci. Lab., Duke-Nus Med. Sch., Singapore, Singapore; [2]Cognitive Neurosci. Lab., Duke-NUS Med. Sch., Singapore, Singapore

Abstract: Sleep is crucial to learning and memory consolidation. It is well established that daytime naps provide benefits to declarative memory retention, relative to an equivalent period of wakefulness. However, it is unclear whether the enhanced retention associated with napping outweighs the benefits of revising learned information instead of sleeping. Clarity on this point is essential to assess the usefulness of napping to educators and students. Participants learned detailed conceptual knowledge during several learning sessions across a day. Between these sessions they were allowed a one-hour daytime nap (nap; n=23), a rest period where they remained awake (wake; n=24), or they revised previously learned information (revise; n=25). We found that revising and napping resulted in significantly better memory than wakefulness when tested immediately after learning that day. Moreover, after one week, memory in the nap group remained significantly superior to the wake group, while the enhancement observed in the revise group was no longer significant. Thus, despite the revise group having an additional hour with the learning materials, the benefits of this extra time were not as long lasting as those offered by a nap. This provides a powerful demonstration of the benefits of napping for long term retention of declarative memories, and suggests daytime naps could benefit learning in young adults.

Title: Medial PFC supports successful recall and recognition of schema-congruent information

Authors: *E. A. WING, V. IYENGAR, R. CABEZA;
Dept. of Psychology & Neurosci., Duke Univ., Durham, NC

Abstract: A recently proposed theoretical framework postulates that there is a push-and-pull relationship between the medial PFC—thought to facilitate the encoding of material congruent

with preexisting schema—and subregions of the MTL—which may preferentially encode novel or schema-incongruent material. Past research pertaining to this framework has naturally focused primarily on the encoding phase. Less is known therefore, about the retrieval processes that operate on congruent/incongruent information encoded through potentially dissociable mechanisms, or about the interaction between encoding and retrieval processes in this context. To help clarify how schema congruence influences mnemonic processes within and across phase, we examined the brain activity both during the encoding of schema congruent and incongruent word-scene pairs and also at a subsequent cued-recall phase in which subjects received the word cue and attempted to retrieve visual details of the corresponding (semantically congruent or incongruent) picture. Behaviorally, we found a schema-congruency enhancement effect whereby visual memory was more vivid for schema-congruent images. A similar enhancement was also observed in a separate test of conceptual (vs. perceptual) memory. Neuroimaging contrasts showed that activity in both medial PFC and MTL increased along with visual memory ratings for schema-congruent pairs, but for the recall of incongruent images, this memory-activity relationship was selective to MTL. Additionally, we found an interaction in medial PFC whereby activity also tracked subsequent forced-choice scene recognition performance, but only for scenes congruent with retrieval cues. Ultimately, these findings add to a growing body of research exploring the relationship between episodic memory and prior knowledge, and suggest that various forms of episodic retrieval for information differing in schema-congruence may rely on mechanisms that are sensitive to semantic relationships when information is initially processed.

Title: Psychophysiological correlates of visual working memory enhancement in video game players.

Authors: *A. BRZEZICKA[1,2], P. DOBROWOLSKI[3], J. MICHALAK[1], M. SKORKO[3], B. SOBCZYK[1], N. JERMAKOW[1];
[1]Univ. of Social Sci. and Humanities, Warsaw, Poland; [2]Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]Polish Acad. of Sci., Warsaw, Poland

Abstract: Visual working memory (VWM), or the ability to store and maintain visual information over short periods of time, is essential for acquiring and processing information. Although this system is crucial for everyday functioning, it is also very limited in capacity. Finding a way to extend this capacity is potentially beneficial for almost all cognitive (and probably not only) processes. One common daily routine that has been shown to improve VWM capacity is video game playing (in comparison studies: Blacker & Curby, 2013; Wilms, Petersen, & Vangkilde, 2013; as well as in a training study: Blacker et al., 2014). The observed performance advantage of video game players (VGPs) over non-players (NVGPs) was also shown to be correlated with anatomical changes in the brain (Tanaka et al., 2013). In our study we compared VGPs playing in different game genres on their VWM performance using two indices of its capacity: the behavioral estimate of VWM capacity (*K* scores) based on change detection paradigm performance and contralateral delay activity (CDA) indexing VWM based on changes in EEG signal recorded during task completion. 45 participants were recruited via online questionnaire: 15 NVGPs, 15 real-time strategy players (defined as playing RTS games > 5 hours per week) and 15 first-person shooter players (defined as playing FPS games > 5 hours per week). All participants were male and the mean age was similar across groups. Each participant underwent 576 trials of the change detection task (144 per load, using load 2, 3, 4 and 5). CDA was derived from parietal electrode clusters (O1, P3, PO3, P7 vs. O2, P4, PO4, P8) by subtracting averaged ipsilateral signal from signal contralateral to presented stimuli.
On the behavioral level, RTS players had higher capacity (*K* scores) than NVGPs, especially at higher loads. They were also better than FPS players, although these differences were smaller (significant set size x group interaction: $F(4.08,85.81) = 3.10$, $p = .019$, $\eta_p^2 = .129$). Psychophysiological results mimicked the behavioral. RTS players had larger CDA compared to FPS and NVGP groups, especially at load 2, where RTS players had larger CDA than did both NVGPs ($p = .016$) and FPS players ($p = .024$) and load 3, where RTS players had larger CDA than NVGPs, $p = .027$. Interestingly, averaged CDA signal was found to correlate with average *K*, but for the NVGP group only ($r = -.599$, $p = .030$). Our results show that cognitive enhancement observed in video game players has a clear psychophysiological correlate. They also support the thesis that VGPs, but especially RTS players, are able to process a larger number of representations in their VWM, which can influence the course of other cognitive functions.

Title: Chunking as a rational strategy for lossy data compression in visual working memory tasks.

Authors: *M. R. NASSAR[1], M. J. FRANK[2];
[1]Metcalf Hall, [2]CLPS, Brown Univ., Providence, RI

Abstract: Humans are capable of representing recent visual information in a robust but flexible form of working memory. The amount of information that can be stored in working memory is inherently limited, although the nature of limitations has been a subject of intense debate [1,2]. Both sides of that debate have relied heavily on models that assume independent item encoding. While recent work has highlighted item dependencies that are elicited by data compression strategies that exploit stimulus statistics, it is unknown whether such dependencies are in play for standard working memory tasks that involve unpredictable and independent stimuli [3,4]. Here we combine computational modeling with human experiments to show that under such conditions stimulus data can be, and is, compressed through joint encoding of similar feature values. To do so, we first develop a toy model of capacity-limited memory storage and find that simulated task performance is improved when stimulus values for similar items are stored as a single chunk. The simulated performance bonus for chunking was highly contingent on the statistics of each stimulus array, which could be summarized by a statistical measure of stimulus clustering. Second, we show that human subjects performing a delayed-estimation task are more accurate and confident when reporting colors from more clustered stimulus arrays. The observed performance bonus was not driven by an increase in perfect color reproductions, but rather by an increase in reproductions slightly offset from the target color, consistent with chunking. Furthermore, the bonus was larger on trials following positive feedback, suggesting a potential role for evaluative systems in the chunking process. Taken together, these findings suggest that visual item encoding is subject to a rational chunking process that sacrifices encoding precision and item independence to maximize performance in situations where capacity limits are small relative to the amount of visual information available. We consider mechanisms whereby such optimization could be achieved through efficient gating of feature representations into prefrontal memory stores.

Title: Priming facilitates pattern separation processes

Authors: D. SANDBERG, S. D. GALE, *B. KIRWAN;
Psychology, Brigham Young Univ., Provo, UT

Abstract: Pattern separation is a computational process whereby potentially similar memory representations are made as dissimilar as possible at the time of encoding. The complementary process, pattern completion, is the process whereby memory representations are retrieved given a noisy or degraded cue. Previous neuroimaging research in humans has demonstrated that the hippocampus is especially prone to perform pattern separation while the adjacent medial temporal lobe (MTL) cortex is biased toward pattern completion. Further research with patients with hippocampal damage has demonstrated a specific impairment in pattern separation in the context of spared recognition memory. The mnemonic similarity task used to assess pattern separation processes relies on explicit memory processes. However, it is unclear if implicit memory representations have an influence on pattern separation and pattern completion processes. This study used masking to present stimuli at intervals below conscious perception (<30ms) in order to measure the potential effects of implicit representations on pattern separation and pattern completion. We hypothesized that priming would facilitate pattern separation dependent mnemonic discrimination. We modified the mnemonic similarity task in which participants view novel, repeated (targets) and perceptually/conceptually similar stimuli (lures) and indicate whether images are new, old, or similar, respectively. Prior to each memory probe stimulus, we presented a masked prime for 8, 24, or 100ms. Primes preceding targets and lures were either the exact same as the memory probe stimulus or the related lure stimulus. Primes preceding novel stimuli were randomly selected from a large pool of unrelated foils. Exposure to the 24ms prime facilitated mnemonic discrimination performance when the prime matched the memory probe but interfered with mnemonic discrimination when there was a mismatch. These data indicate that priming facilitates pattern separation processing.

Title: Evidence for consolidation of pattern-separated memories in ventromedial prefrontal cortex but not in hippocampus

Authors: *D. K. BJORNN[1], A. L. HOWELL[2], B. B. ANDERSON[3], A. VANCE[3], C. B. KIRWAN[4];
[1]Psychology, [2]Neurocience Ctr., [3]Information Systems, [4]Psychology & Neurosci. Ctr., Brigham Young Univ., Provo, UT

Abstract: Pattern separation is a computational process in which similar memory traces are encoded as dissimilar as possible in order to reduce overlap. The hippocampus has been shown to be critical for this process. While there is considerable research on pattern separation over single study sessions, little is known about how these memory representations are consolidated over several days. The present study sought to examine the pattern separation process over a five-day period using functional magnetic resonance imaging (fMRI).
Fifteen participants studied images of everyday objects as they were presented one at a time on a computer screen and were instructed to indicate whether the item is generally found indoors or outdoors. After study, participants completed fMRI scans once a day for five days in which images were presented and participants again indicated whether the item is generally found indoors or outdoors. Images were composed of three categories, namely, exact repeats of studied items, items similar to studied items, and completely new images. We took repeat and similar images for each day from a different subset of the original studied images so no images were presented more than once during the scan. New images were used as a functional baseline.
A whole-brain analysis revealed a significant interaction between day and stimulus type in the ventromedial prefrontal cortex (vmPFC). Specifically, activity for repeat items increased linearly across days while activity for lure items remained near baseline. A comparison between repeat items for the vmPFC and hippocampus regions showed a significant day by region interaction, with vmPFC activity increasing for each subsequent day while hippocampal activity remained near baseline.
Both the hippocampus and vmPFC are important structures in long-term memory. Prior studies have shown that activity in the vmPFC increases as memories are consolidated and our results are consistent with these findings. Our results also give evidence for differing processes in the

consolidation of pattern-separated memory representations. While activity in the hippocampus is not affected over several days, an increase is observed in the vmPFC. Further research can focus on closer examination of the patterns of activity in hippocampal subregions over time.

Title: The effect of false recognition on memory encoding and discrimination

Authors: *N. MUNCY, B. KIRWAN;
Neurosci., Brigham Young Univ., Provo, UT

Abstract: Pattern separation is the process whereby distinct memory representations are encoded in such a way as to reduce potential overlap. Pattern completion is the complementary processes whereby memory representations are retrieved when given a partial or noisy retrieval cue. Behaviorally, pattern separation and pattern completion have been tested using mnemonic discrimination paradigms that employ either a study/test or continuous recognition format. Correct rejection of new but perceptually similar stimuli (i.e., Lure CRs) are thought to depend on accurate pattern separation processes whilst false alarms to lures (Lure FAs) are thought to reflect pattern completion processes. What has yet to be determined is whether or not Lure FAs result in a rewriting of the original memory trace or in the formation of a new memory trace that is distinct from the original. Participants studied 200 visual stimuli while performing an incidental encoding task. During the first test phase, participants were presented stimuli that were either the same as, or similar to stimuli previously seen, and the participants indicated whether the stimuli were the same or similar. This resulted in false alarm (Lure FA), correct rejection (Lure CR), hit, and miss responses. In a second surprise recognition memory test, participants were presented both the original and similar stimulus simultaneously in a two-alternative forced-choice format. High- resolution whole-brain functional MRI (fMRI) data were collected during both testing phases. Behavioral analyses indicated that second-test performance following first-test false alarms was essentially at chance; participants responded to previous false alarms with either a hit or false alarm equally (FA-FA vs. FA-Hit). Likewise, confidence ratings and response times for both FA-FA and FA-Hit were indistinguishable. FMRI activation in the left inferior frontal and supramarginal gyri during first-test FA responses predicted a second-test

correction from pattern completion to recognition (FA-Hit); that is, differential activity in these regions during first-test FAs were predictive of continued pattern completion (FA-FA) or correction (FA-Hit) in the second test. These data indicate that these regions are resilient to incorrect pattern completion.

Title: An fMRI analysis of visual unitization and the age-related associative memory deficit

Authors: ***M. B. MEMEL**, L. RYAN;
Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Healthy aging impairs associative memory -- the ability to remember associations between previously unrelated pieces of information (Naveh-Benjamin, 2000). Unitization, the process of creating one semantic representation that includes both items in an associative pair, attenuates age-related associative deficits (Zheng, et al., 2015; Bastin et al., 2013; Ahmad et al., 2014). Examples of unitized pairs include compound words (Giovanello et al., 2006; Quamme, et al., 2007) and words imagined in a specific color (Diana et al., 2011). Many studies have argued that unitizeable associative pairs rely less on hippocampal function than traditional associative pairs. For example, hypoxic patients, with damage relatively limited to the hippocampus, benefit from word pairs that can be unitized (Quamme et al., 2007). Thus, it is believed that with verbal stimuli, unitization of associative pairs allows for memory based on non-hippocampal medial temporal structures. Less is known about the benefit of unitization with visual stimuli, such as objects and scenes. Objects and scenes are two types of visual stimuli frequently encountered in the world and perceived in relation to one another. In the present study, we manipulated the degree of visual integration between objects and scenes, by presenting objects either next to their paired scene (Separated condition) or embedded within their paired scene (Combined condition) and measured associative memory performance in young and older adults while undergoing fMRI.
Based on previous studies of unitization, we hypothesized that older adults would receive a mnemonic benefit from the integration of visual associative pairs. Further, we predicted greater hippocampal activation during the encoding of Separated associative pairs than Combined pairs, due to a greater need for binding between items. Consistent with our hypotheses, visual

integration of objects and scenes improved associative memory performance in older adults. In addition, hippocampal activation was greater during the Separated than Combined condition across age groups. However, the degree of hippocampal activation during the Separated condition was related to performance in young, but not older adults. In older adults, the perirhinal cortex was the only medial temporal region that significantly predicted performance. These findings may suggest that hippocampal activation is less successful in older adults than young. Alternatively, object processing, which relies on the perirhinal cortex and is impaired in some older adults (Ryan et al., 2012) may be a greater predictor of successful associative memory with object-scene pairs.

Title: Effects of acute enhancement of cortical dopamine on cognitive control and associated neural function in mTBI Veterans

Authors: ***M. E. BALLARD**[1,2], T. A. VEGA[2], A. S. KAYSER[1,2];
[1]UCSF, San Francisco, CA; [2]VA Northern California Hlth. Care Syst., Martinez, CA

Abstract: Fifteen percent of mild TBI (mTBI) patients report persistent cognitive problems, including difficulty remembering and focusing attention. Still, there are few effective medications for treating cognitive problems in TBI patients. In this study, we set out to test whether the FDA-approved medication tolcapone, by selectively enhancing cortical dopamine tone, could improve working memory in combat Veterans with mTBI. To date, 10 Veterans with mTBI have been administered a single oral dose of 200mg tolcapone and placebo on separate sessions, in counter-balanced order, under double-blind conditions. Nine of the subjects then completed an emotional facial working memory task in the MRI scanner; the tenth subject completed the task outside the scanner. In each trial, subjects first encoded either one (low load) or three (high load) neutral or fearful faces. Then, during a delay period, they identified an arousing or neutral distractor as a face or scene. Finally, they indicated whether a presented probe face was shown during the encoding period. As expected, participants' recognition memory was less accurate in the high (vs. low) load condition (0.64 vs. 0.80, $t_9 = 7.28$, $p <$

0.0005) and when remembering fearful (vs. neutral) faces (0.70 vs. 0.74, $t_9 = 3.11$, $p = 0.013$), collapsed across drug conditions. Consistent with previous work, a larger distractor cost (i.e., lower memory accuracy) was found with congruent (face) versus incongruent (scene) distractors, collapsed across valence and drug conditions (0.70 vs. 0.73, $t_9 = 2.23$, $p = 0.052$). At the neural level, the task robustly activated the ventral visual stream and a frontoparietal network. In preliminary results, part of the frontoparietal attention network (including the right inferior parietal lobule) tended to be more active during encoding in the high (vs. low) load condition, collapsed across treatments ($p < 0.01$, uncorrected). Notably, ROI analyses revealed a significant effect of drug condition on activity in the bilateral fusiform face area (FFA) during cue encoding in the high versus low load conditions ($p \leq 0.015$), and this effect was in the same direction as a non-significant drug treatment effect on memory accuracy in the high load condition (0.62 vs. 0.66, $p = 0.18$). These findings provide preliminary evidence that the task is a useful tool for measuring acute drug effects on working memory maintenance and resistance to distraction in veterans with mTBI. Our ongoing work seeks to further elucidate the ways in which tolcapone can influence cognitive control and its neural correlates, with particular attention to functional connectivity between prefrontal and relevant higher order sensory areas.

Title: The strategic allocation of working memory and episodic memory in prospective remembering: A neural network model

Authors: M. TOMOV[1], I. MOMENNEJAD[2], K. NORMAN[2], *J. D. COHEN[3,2];
[1]Dept. of Psychology and Ctr. for Brain Sci., Harvard Univ., Boston, MA; [2]Princeton Neurosci. Inst., [3]Princeton Univ., Princeton, NJ

Abstract: The successful realization of future plans (prospective memory or PM) requires the agent to either maintain, or be able to retrieve, a goal for execution at a future time. This must be accomplished over periods during which the agent is involved in other, ongoing activities, while at the same time remaining responsive to the circumstances that demand goal execution. There are at least two distinct memory strategies that can be used to solve the PM problem: active

monitoring, which relies on working memory (WM) to maintain the goal and a preparatory attentional process to continuously monitor the environment for events that signal the opportunity for goal execution; or episodic encoding and retrieval, which initially commits the goal to episodic memory (EM) and relies on automatic retrieval at the opportunity for goal execution arises. The WM strategy relies on a system widely considered to be capacity limited, and thus can incur costs with regard to other ongoing tasks that compete for this capacity. In contrast, the EM strategy carries a greater risk of retrieval failure, and thus PM failure. Each of these strategies may be better suited to some circumstances than others and, in general, PM success may rely on striking the right balance between them. Here we describe a computational model that incorporates neural network mechanisms previously used to implement working memory (Leaky Competitive Accumulators, c.f. Usher and McClelland 2001) and episodic memory, and integrates these to address a variety of behavioral findings previously reported from five seminal experiments on PM by Einstein et al. (2005): the effect of target focality, PM task priority, different monitoring strategies, the cost of increasing the number of goal states or PM targets, and the aftereffects of PM intentions. The model offers novel predictions that remain to be behaviorally tested, and we discuss ways in which it can be extended to address additional PM phenomena, as well as a broader class of task switching effects.

Title: The influence of context elements on pattern separation

Authors: *A. HEDGES, B. KIRWAN;
Psychology, Brigham Young Univ., Provo, UT

Abstract: The memory of an item and its contextual information when it was encountered is defined as contextual memory. Researchers have proposed that the relationship of objects and their contexts is at the core of long-term declarative memory, converging on hippocampal processing. To further explore the effect of surrounding visual context on memory, this experiment evaluated behavioral performance in contextual memory task that especially taxes pattern separation processes. Most current studies of pattern separation use stimuli of isolated objects on a white background. The current experiment used objects placed in front of a background that was either congruent with the object (e.g., a shopping cart set against a grocery

store) or incongruent with the object (e.g., a gorilla set against a classroom). Adding a contextual component to memory specificity tasks is believed to increase the level of difficulty of the task by interfering with the ability to successfully perform pattern separation processes. In addition, some researchers propose that when the object matches its context, there will be more efficient discrimination between stimuli and thus more accurate responses. However, some hypothesize that repeat and similar objects presented with the same background will be more accurately remembered than objects presented with different backgrounds due to the increase of interference.
In this experiment, 71 participants (40 females) performed a two-part memory task. In the first part (study phase), participants were shown 260 images of everyday objects with backgrounds that were congruent or incongruent. The images were presented for 2500 ms with an inter-trial interval of 500 ms. In the second part (test phase), participants were shown 320 images that contained items either exactly the same as or similar to the previously studied items (repeats and lures, respectively). These images were also presented for 2500 ms with a 500 ms inter-trial interval. During the test phase, participants were instructed to ignore the backgrounds and indicate whether the item in the middle of the image had been previously studied or similar to an object previously studied.
After performing an ANOVA, we found that correct "similar" responses to lure images (indicative of correct pattern separation) was facilitated by a similar, incongruent background. On the other hand, recognition was facilitated by a repeated, congruent background. Also, a difference between males and females was found, with males performing better with recognition but not pattern separation.

Title: Dynamic neural correlates of overt and covert autobiographical memory retrieval

Authors: ***C. S. FERRIS**[1], C. INMAN[1], G. JAMES[2], S. HAMANN[1];
[1]Psychology, Emory Univ., Atlanta, GA; [2]Univ. of Arkansas for Med. Sci., Little Rock, AR

Abstract: Autobiographical memory (AM) retrieval is a complex process that recruits dynamically changing networks of brain regions as processing shifts between memory search, access, and content elaboration. In prior fMRI work we have used analyses to characterize whole-brain changes in dynamic connectivity during AM retrieval, highlighting time-varying engagement of the hippocampus, PFC, and other regions. Here we extended these investigations, using high temporal (1 second TR) and spatial (2 mm isotropic) resolution fMRI, an optimized experimental design, and both covert and overt (spoken) retrieval to test theoretical accounts of AM retrieval. Motion was minimal (<1 mm) for overt trials. After a low-level, arrow detection baseline, participants retrieved unrehearsed AMs to cue words across a long retrieval period, followed by ratings of vividness and emotion, with overt (spoken) retrieval during half of the trials. Importantly, overall movement during overt retrieval was not significantly different than movement covert retrieval. Relative to previous studies of AM retrieval, we found a similar network of activated brain regions during both the overt and covert AM retrieval, including the hippocampus, medial, and lateral PFC. A broadly similar core AM retrieval network was identified for covert and overt AM retrieval, with relatively greater hippocampal activation during memory access. Key brain activation differences between covert and overt AM retrieval included activation of speech comprehension and facial motor regions during overt AM retrieval. Across both overt and covert trials, dynamic changes in activation relative to the pre-cue baseline included hippocampal, anterior temporal, and posterior cingulate activation early in AM retrieval. During later periods of AM retrieval posterior involved in reconstruction of sensory details and fronto-parietal regions involved in working memory were activated greater than the pre-stimulus baseline. These findings provide evidence that accessing and reconstructing autobiographical memories involves the activation of memory networks that reflect changing retrieval processes both during covert and overt retrieval.

Title: Thalamo-cortical coupling is task dependent during visual working memory

Authors: *A. S. HUANG, T. M. LE, H.-C. LEUNG;
Psychology, Stony Brook Univ., Stony Brook, NY

Abstract: Previous studies in nonhuman primates and rodents showed that higher-order thalamic areas play a role in modulating cortical activity during selective attention and working memory, whereas disruption of these thalamic areas can significantly influence cortical activity and produce severe cognitive deficits. Here we examined the role of the thalamus in selective visual information processing in humans. To determine whether the thalamus would exhibit enhanced coupling with the fusiform face area (FFA) and the parahippocampal place area (PPA) when face or scene stimuli respectively are behaviorally relevant, we analyzed the thalamo-cortical functional connectivity during selective maintenance using fMRI data collected from 21 healthy young adults (12 female, 9 male). Selective maintenance of either a scene (Remember Scene) or a face (Remember Face) in working memory was manipulated by a retro cue indicating which remembered item remains task relevant. The region of interest (ROI) was a part of the thalamus that showed strongest structural connectivity with the prefrontal cortex based on the literature. Psychophysiological interaction analysis (implemented using gPPI toolbox) was applied to estimate functional connectivity of the thalamic ROI. Thalamus-PPA coupling was enhanced during the delay period of the Remember Scene condition while thalamus-FFA coupling was enhanced during the delay period of the Remember Face condition. Further, greater functional connectivity between the thalamic ROI and FFA/PPA during the delay period when the preferred stimulus is task irrelevant was associated with poor discrimination of the region's activity patterns for the preferred probe stimulus. These findings can not be attributed to mean activity differences as the thalamus was about equally active on both conditions; and thalamic activity amplitude was not correlated with classification accuracy of PPA or FFA activity patterns for the face or scene probes. These findings suggest that, beyond the previously implicated prefrontal role in working memory, thalamo-cortical connectivity may also play a significant role in selective maintenance of visual information in working memory. The thalamus may be involved in prioritizing visual representations in a visual association region when that region’s preferred stimulus is task relevant.

Title: Developmental differences in hippocampal-prefrontal mediated memory updating

Authors: *M. L. SCHLICHTING, K. F. GUARINO, A. R. PRESTON;
Univ. Texas Austin, Austin, TX

Abstract: It is uncontroversial that how we learn depends on what we already know; our knowledge stores are constantly being updated to incorporate our new experiences. In the young adult brain, related knowledge is brought to mind during new encoding and then updated through operations supported by the hippocampus and medial prefrontal cortex. Yet, how dynamic interactions between existing knowledge and new experiences shift over development remains virtually unstudied. Both the hippocampus and medial prefrontal cortex undergo continued structural change well beyond childhood, with prefrontal maturation in particular continuing into early adulthood. Previous research thus begs the question: if our underlying neural systems are maturing through middle childhood and beyond, are children and adolescents able to capitalize on their existing knowledge during new learning in the same way as adults? Here, human participants ages 7-30 years encoded AB and XY object-object associations across three study repetitions during high-resolution fMRI scanning. Critically, participants also learned related BC pairs, which included an object (B) that had been previously studied as part of an AB pair, as well as a C item from one of two visual categories (face or scene). We hypothesized that adults would preferentially reactivate related knowledge and engage updating regions during overlapping pair encoding (in the brain, condition AB ≠ XY), while children would fail to reactivate related content and use similar processes to encode all pairs, irrespective of overlap status (condition AB = XY). We found differences in hippocampal and medial prefrontal engagement across age groups specifically during overlapping (AB) encoding, suggesting developmental shifts in how we learn information that is related to prior knowledge. Using a pattern classification approach, we also found evidence for processing of the related but not but presently viewed visual category (C item, face or scene) during AB encoding in adults but not children, further suggesting that adults more readily bring their related (BC) knowledge to bear during new encoding. These results suggest fundamental shifts in the way we learn across developmental time, particularly when there is an opportunity to build upon prior knowledge. Our findings are consistent with the notion that neural maturation brings with it the ability to form increasingly flexible memories, a finding that has broad implications for how we understand and promote cognitive development in both theory and practice.

Title: Decoding memory features from hippocampal CA3 and CA1 spike trains during a delayed match-to-sample task in human

Authors: *D. SONG[1], R. HAMPSON[2], B. ROBINSON[1], V. MARMARELIS[1], S. DEADWYLER[2], T. BERGER[1];
[1]Biomed. Engin., Univ. of Southern California Dept. of Biomed. Engin., Los Angeles, CA;
[2]Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: To understand how memory information is encoded in the hippocampus, we build classification models to decode memory features from hippocampal spiking activities recorded from human subjects performing a memory-dependent delayed match-to-sample (DMS) task. Adult patients suffering from pharmacologically refractory epilepsy are surgically implanted with FDA-approved hippocampal electrodes capable of field potential (macro-) and single-unit (micro-) recordings for localization of seizures. Single unit neural activities (i.e., spike trains) are isolated and recorded from the hippocampal CA3 and CA1 regions using a Blackrock Cervello electrophysiological recording system. Cognitive and behavioral experiments consist of visual object and spatial position oriented DMS tasks, where the patients are required to remember the sample images or the locations of sample images and retrieve these memories after a variable delay to generate correct responses. Image categories are labelled by normal human subjects to provide output signals for the classification model. CA3 and CA1 spike trains around sample responses (-2s to 2s) are taken as input signals to be classified or decoded. The classification model consists of a set of B-spline basis functions for extracting memory features from the spike patterns, and a sparse logistic regression classifier for generating binary categorical output of memory features. Classification performance are evaluated with Matthews correlation coefficients. Results from multiple human patients show that classification models can extract significant amount of memory information with respects to types of memory tasks and categories of sample images used in the task, despite the high level of variability in prediction accuracy due to the small sample size (40 - 80 trials). These results strongly support the hypothesis that memories are encoded in hippocampal spiking activities and have important implication to the development of hippocampal memory prostheses.

Title: First you remember, then you see: Dynamic sampling from learned associations biases perceptual inference.

Authors: *A. M. BORNSTEIN[1], M. ALY[2], S. F. FENG[3], N. B. TURK-BROWNE[2], K. A. NORMAN[2], J. D. COHEN[2];
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]Princeton Univ., Princeton, NJ; [3]Applied Mathematics, Khalifa Univ., Abu Dhabi, United Arab Emirates

Abstract: How does experience guide perception? Perceptual decisions are typically modeled using accumulation process that integrate sequential samples of noisy sensory input. These models have been extended to incorporate past experience via static summaries: either as an initial bias towards the most-experienced option, or as an additional weight placed on sensory evidence congruent with expectation. Here, we test the hypothesis that previous experiences can also be dynamic elements of the inference process, sequentially sampled in the same manner as perceptual input.
Fifty-six participants performed a perceptual decision task in which the likely identity of a noisy image was indicated by a pre-stimulus cue. Four fractal cues each predicted one of 4 images (2 faces, 2 scenes) with variable reliability. Critically, cue-stimulus contingencies were not instructed, but learned via experience. After experiencing the contingencies, participants performed 80 test trials, on which they viewed a cue followed by a flickering stream of images from one perceptual category; one image, the target, was more prevalent than the other. The reliability of perceptual evidence was manipulated by varying the mixture proportions of the target image and the paired same-category image. Participants pressed a response key corresponding to the predominant image in the flickering stream.
Response times were bimodal, with peaks before and after the onset of the flickering stream. This bimodality is suggestive of two noisy accumulation processes: one relying on samples from learned expectations and beginning at cue onset, and the other relying on observed perceptual input and beginning at the onset of the flickering stream. Regression analyses and a formal model comparison, using a multi-stage drift-diffusion model, confirmed that behavior was

indeed best described by two accumulation processes with different drift rates, with the second process initializing at the ending state of the first.
Multivariate pattern analyses in an fMRI experiment (n=32) were used to measure neural evidence for the category of the upcoming images in the flickering stream, after cue onset but before the images appeared. Fluctuations in neural category evidence during this anticipatory period were a significant predictor of RTs, even after accounting for the other modeled factors. Together, these results show that learned expectations are a dynamic source of evidence during perceptual inference, and suggest that neural reactivation of anticipated percepts is the mechanism by which this occurs.

Title: Medial prefrontal cortex supports retrieval of integrated memories

Authors: ***N. W. MORTON**, A. R. PRESTON;
The Ctr. for Learning & Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: Memories are not formed in isolation, but rather are learned in the context of a vast store of existing knowledge. In particular, medial prefrontal cortex (PFC), through its interactions with hippocampus, has been implicated in a memory integration process whereby existing memories are updated with new information. Recent data indicate medial PFC engagement during encoding of content that overlaps with existing knowledge promotes inference decisions that require participants to reason about the relationships among indirectly experienced events. Here, we test the idea that medial PFC would be engaged selectively for inference judgments that rely on the retrieval of integrated representations versus those that rely on retrieval and recombination of individual memory traces. Specifically, we used multivariate pattern classification to quantify reactivation of existing memories during encoding of overlapping associations, which has previously been shown to be an index of memory integration. We hypothesized that evidence for encoding-related integration would be associated with enhanced engagement of medial PFC during inference itself. To test this hypothesis,

participants first learned face-object and scene-object (denoted AB) pairs. During fMRI scanning, participants then studied overlapping associations (BC) for which one object (the B item) was shared with a previously studied paired. This encoding phase was followed by a scanned inference task, during which participants made judgments about the indirect relationships between A and C items. Using multivariate pattern analysis, we isolated regions that support inference through integration by relating brain activation during correct inference trials separated by the degree of memory reactivation (A faces and scenes) during overlapping event (BC) encoding. We found that the degree to which participants reactivated related memories (A items) during encoding of overlapping (BC) associations predicted individual differences in reaction time for correct inference: Faster reaction times were associated with greater evidence for encoding-based integration. Furthermore, we found that medial PFC was selectively recruited during correct inference trials for which there was greater memory reactivation during encoding of the corresponding overlapping association. This finding is consistent with the prediction that medial PFC biases retrieval to access integrated memory networks and suggests that medial PFC serves an important role in organizing memories for related events.

Title: Complementary learning systems within the hippocampus: A neural network modeling approach to reconciling episodic memory with statistical learning

Authors: *A. C. SCHAPIRO[1,2], N. B. TURK-BROWNE[2], M. M. BOTVINICK[3], K. A. NORMAN[2];
[1]Psychiatry, Beth Israel Deaconess Med. Ctr. / Harvard Med., Boston, MA; [2]Dept. of Psychology and Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [3]Google DeepMind, London, United Kingdom

Abstract: The complementary learning systems (CLS) theory (McClelland, McNaughton, & O'Reilly, 1995, *Psychol Rev*) highlighted the computational tradeoff between tracking the details of individual experiences (episodic memory) and the regularities shared across these experiences (statistical learning), and posited that these two processes must be supported by different brain systems. In particular, the hippocampus uses a high learning rate and pattern separated representations to encode individual experiences, whereas the cortex benefits from a slow learning rate and overlapping representations in extracting regularities. However, this division of labor conflicts with recent empirical findings that the hippocampus is involved in statistical learning (Schapiro et al., 2012, *Curr Biol*; 2014, *JOCN*; 2016, *Hippocampus*). To reconcile the theory with these data, we ran simulations of statistical learning tasks using a hippocampal neural network model that instantiates the episodic learning component of the CLS theory (Ketz et al., 2013, *PLOS Comp Biol*). The model contains hippocampal subfields dentate gyrus (DG), CA3, and CA1, which learn to map between input in superficial layers of entorhinal cortex (EC) to output in deep layers of EC. There are two main pathways: The trisynaptic pathway (TSP), EC -> DG -> CA3 -> CA1, and the monosynaptic pathway (MSP), EC <-> CA1. The DG and CA3 subfields employ sparse connectivity and high inhibition, making the TSP the engine for pattern separation of episodic memories in the hippocampus. CA1 employs more overlapping representations and a relatively slower learning rate — it is more cortex-like — and has acted in extant models as a translator between sparse TSP representations and overlapping EC representations. When we exposed the model to input with temporal regularities, the MSP/CA1 took on a new role: it represented the temporal regularities, allowing the model to do rapid statistical learning. We will present simulations that demonstrate: (i) the complementary roles of the TSP and MSP in episodic and statistical learning, respectively; (ii) temporally predictive behavior and representations; (iii) preserved statistical learning in simulations of infants, who have underdeveloped TSPs; and, (iv) higher-order learning in temporal community structure and associative inference paradigms. Our simulations suggest that there are complementary learning systems within the hippocampus itself, the TSP and the MSP, which allow it to support both rapid episodic and statistical learning.

Title: Better in sequence: The role of task similarity in encoding and executing planned task sequences

Authors: *I. MOMENNEJAD[1], C. REVERBERI[2], S. MUSSLICK[1], J. COHEN[1], J.-D. HAYNES[3];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Univ. of Milan, Milan, Italy;
[3]Bernstein Ctr. for Computat. Neurosci., Humboldt Univ. Berlin, Berlin, Germany

Abstract: Most plans include orderly sequences of multiple tasks that vary in similarity. Successful realization of task sequences requires the brain to encode all tasks simultaneously, and retrieve and execute them in the correct order. However, it remains unclear how the similarity of the tasks in a planned sequence affects their computational encoding and behavioral performance, and how similarity effects change over time. Here we employed a behavioral study, functional magnetic resonance imaging (fMRI), and computational modeling in order to address these questions. On each trial participants were instructed to either perform (a) a single task or (b) a sequence of two tasks. The tasks could be parity, magnitude, or color judgment on that trial's stimulus: a number in red or green font. Notably, the numerical tasks (parity and magnitude) were more similar to each other than to color judgment. Thus, two of six sequences had similar tasks (similar sequences) and four of six dissimilar (dissimilar sequences). We found a "similarity benefit": reaction times to a given task in a similar sequence were faster compared to performing it alone. This similarity benefit was larger for the second task. We found a "dissimilarity cost" for the first task: the same task was slower as the first in a dissimilar sequence than as a single task, and the benefit of the second task was diminished in dissimilar sequences. Comparing the first run (48 trials) to the last, we found that (a) both similarity benefits and dissimilarity costs diminished over time and (b) overall there was a cost to going first and a benefit to going second. To study the encoding of task representations, we trained a searchlight multi-voxel pattern classifier on brain volumes collected during the preparation period of "single task" trials. Using this classifier, we were able to decode the identity of the upcoming tasks in "sequence trials", from frontoparietal regions (rostrolateral PFC and posterior parietal cortex) of volumes collected during the preparation period. With representational similarity analysis (RSA), we investigate whether the observed behavioral changes over time correspond to changes in the similarity of task representations in the brain. Furthermore, we are developing a neural network model of task representations to investigate mechanistic explanations of (a) when performing a task in a sequence has benefits, or costs, over performing it alone, and (b) how changes in task representations over time lead to changes in the behavioral costs and benefits of sequences. These findings bear novel consequences for a mechanistic understanding and optimal planning of task sequences.

Title: Time-dependent restructuring of memory representations strengthens associations between overlapping memories

Authors: *A. TOMPARY[1], L. DAVACHI[2];
[1]Dept of Pychology, [2]New York Univ., New York, NY

Abstract: Semantic memories are thought to emerge from the accumulation of commonalities across discrete episodic events. However, our understanding of the neural mechanisms underlying this transformation is limited. Specifically, it is unclear how memories with overlapping components are represented in terms of their shared and distinct features over time and how this supports behavior. We developed a two-day fMRI study to ask how memories become represented according to their shared or distinct components over time, and how these representations influence behavior. Each day, subjects incidentally learned a different set of objects presented in a continuous sequence. Unbeknownst to the subjects, the sequences were arranged such that some objects had an overlapping temporal context of two items. Specifically, these objects were always preceded by an identical sequence of two objects. Immediately after the second encoding session, participants completed a recognition memory test with objects from both encoding sessions. Trials were arranged to test for the integration of objects with overlapping temporal contexts. Recognition was faster when an object with an overlapping context primed the tested object. Importantly, this effect emerged only for objects learned 24 hours prior to the test. This suggests memories with overlapping information become associated over time. Furthermore, when focusing on the remotely learned sequences, participants with a stronger priming effect exhibited a greater increase in similarity between the objects that were studied with overlapping temporal contexts. Critically, no such relationship existed for the recently learned sequences. Planned fMRI analyses will assess the relationship between time-dependent changes in object representations and computations supporting the encoding of the sequences.

Title: Critical moments of learning are mediated by distinct hippocampal and frontoparietal encoding processes

Authors: *M. L. MACK[1], A. R. PRESTON[1], B. C. LOVE[2,3];
[1]The Univ. of Texas At Austin, Austin, TX; [2]Univ. Col. London, London, United Kingdom; [3]The Alan Turing Inst., London, United Kingdom

Abstract: Successful learning depends on encoding newly-learned information relative to existing knowledge. Neurobiological memory theories attribute such encoding to complementary functions of the hippocampus (HPC) and its interactions with prefrontal cortex (PFC). Specifically, HPC comparator processes that evaluate the overlap between new experiences and current knowledge trigger either pattern separation, wherein new memories are made representationally distinct from existing knowledge, or pattern integration processes mediated by PFC, wherein new information is incorporated into existing memories. Recent electrophysiological data suggest that the tendency of the HPC to trigger separation or integration may fluctuate on a moment-by-moment basis; yet, characterizing such moments of learning have proved challenging in humans given the lack of empirical methods to identify precisely when knowledge is created versus updated. Here, we overcome this challenge with a computational learning model that makes explicit predictions about when newly-encountered information is encoded through pattern separation or pattern integration. During fMRI scanning, participants learned to categorize complex objects composed of multiple features across four category learning tasks, with each task defined by different associations between category labels and combinations of object features. The learning model was fit to participants' behavior during the four learning tasks to derive trial-by-trial predictions of when a new separate memory was formed versus when existing knowledge stores were updated. These model predictions were then leveraged in univariate and multivariate classification analyses to distinguish the neural circuits

underlying moments of knowledge creation and integration. Whereas HPC was associated with model predictions for both knowledge creation and integration, separable frontoparietal regions were distinctly associated with the different encoding operations. We found a knowledge creation network associated with medial PFC and angular gyrus, and a knowledge integration circuit comprised of frontopolar, dorsolateral prefrontal, and superior parietal cortices. Our findings establish a neurocomputational framework grounded in cognitive theory for investigating how the interaction of new experiences and existing knowledge mediate successful learning.

Title: Retroactive and graded modulation of memory by reward

Authors: *E. K. BRAUN[1], G. WIMMER[3], B. VAIL[2], C. VAN GEEN[2], D. SHOHAMY[2]; [1]Psychology, [2]Columbia Univ., New York, NY; [3]Stanford Univ., Palo Alto, CA

Abstract: Adaptive decision-making can be supported by a model of how sequences of events lead to rewards. Thus, it is essential not only to remember an event that was rewarding, but also the series of events that led to it; however, often we do not know which events will later turn out to be important. To solve this problem, it is necessary for rewards to retroactively prioritize neutral memories based on later outcomes. Here we addressed the question of whether and how such retroactive modulation enhances memory for sequences of events leading to reward. Our predictions were based on two distinct physiological processes in the hippocampus. First, electrophysiological recordings in rats show that after running through a maze to a reward, hippocampal place cells replay recent experiences in reverse, which may provide a mechanism by which dopaminergic reward signals are propagated back to sequences of previous experiences. Second, dopamine increases cellular plasticity in the hippocampus. Together, these two processes provide a putative mechanism by which rewards could retroactively enhance memory. We predicted that reward would have a graded effect on memory for sequences of neutral events that preceded it, with the greatest enhancement for events that were most proximal to the reward. To test this, we developed a task in which participants navigated through a series of grid mazes, one space at a time, searching for a hidden gold coin worth $1. In each space, an incidental, trial-unique object was presented before participants moved to the next space. We

manipulated the maze outcomes so that half of the mazes ended in reward. Each maze was followed by a short rest break (15-25s). We administered a surprise recognition memory test either 24-hours or 15-minutes after encoding, allowing us to measure the effect of consolidation on reward-enhanced memory. We found that participants' memory for the objects was retroactively modulated by reward, such that memory was selectively enhanced for objects closest to the reward. This interaction between reward and proximity on memory was selective to the 24-hour condition and not found in the 15-minute condition. Moreover, we found that the reward-proximity interaction became pronounced as the length of the post-maze rest block increased. These findings demonstrate that reward retroactively enhances episodic memory for preceding neutral events, modulating memory as a function of it sequential proximity to reward. This effect is selective to reward, requires consolidation, and varies as a function of the rest time after encoding, consistent with neurobiological models of how the brain integrates memories across time and space.

Title: The influence of recent semantic learning on human visual cortex

Authors: *M. N. COUTANCHE[1], S. L. THOMPSON-SCHILL[2];
[1]Dept. of Psychology, Univ. of Pittsburgh, Pittsburgh, PA; [2]Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Humans are frequently exposed to information about the many objects, animals and people we that encounter in our environments. In addition to a suite of perceptual processes that can extract information from observed items, humans have the unique ability to discover the properties of objects through abstract communication. We have investigated how the introduction of visually relevant information -the real-world size of recently introduced animals- impacts the patterns of neural activity observed in a person's visual cortex. We scanned human

participants with functional Magnetic Resonance Imaging (fMRI) while we introduced them to novel and known animals and tools. At the start of the experiment, participants were exposed to images of these items through a simple 1-back task. Participants were next presented with, and tested on, new factual information about each new concept. Finally, a post-learning 1-back task was administered. We used multivariate pattern analysis (MVPA) to decode the neural patterns underlying the processing of the new and known animals and tools, in order to compare activity patterns before and after learning. We find that after introducing people to new information about items' real-world size, visual activity patterns for the newly introduced animals more closely resemble the activity patterns observed for similarly sized known animals. In contrast, learning semantic information about the intended motor manipulation of a new tool did not affect future visually generated activity patterns. Our findings suggest that learning information about a new visual concept might rapidly influence visual cortex neural activity.

Title: The effect of diet exposure on impulsive choice in rats: delay and reward sensitivity

Authors: *C. C. HILL, J. R. A. PIRKLE, K. KIRKPATRICK;
Kansas State Univ., Manhattan, KS

Abstract: Recent research suggests that there is a correlation between diet and impulsivity; specifically, those who consume a diet high in fat and sugar tend to be more impulsive. However, human research is unable to disentangle the direction of this relationship. Recent research from our laboratory suggests that high-fat and high-sugar diets can cause greater impulsive choice behavior. Given that diet can induce impulsivity and potentially explain the relationship between impulsivity and obesity in humans, it is critical to determine how the effects of diet on impulsivity can be addressed. One key aspect to improving impulsive choice is understanding the mechanisms of impulsive choice: delay and reward sensitivity. The present study assessed diet effects on delay and reward sensitivity and the implications for impulsive choice behavior. Rats were divided into three groups (high-fat, high-sugar, and control) where diet composition differed, and each group was given access to the same number of calories to each day. The high-fat group received chow with a lard supplement, the high-sugar group received chow with powdered sugar icing, and the control group received all chow. After 8-

weeks of exposure to the diet, all rats were then tested on two impulsive choice tasks in which individuals were presented with a choice between a smaller reward available sooner (SS) or a larger reward available later (LL). One impulsive choice task manipulated the delay to the SS choice and the other task manipulated the magnitude of the LL reward. After the impulsive choice tasks, rats completed a bisection task to determine timing deficits and a reward sensitivity task to determine their ability to discriminate between different reward amounts. The results from this experiment replicated the previous study from our lab showing that a diet high in fat or sugar induces impulsive choice, which may explain the relationship between impulsivity and obesity. In addition, it outlines the deficits of impulsive choice that could be targeted with a behavioral intervention to improve impulsive behavior that results from poor diet consumption.

Title: The durability and generalizability of neurocognitive intervention effects on impulsive choice in rats

Authors: *A. T. MARSHALL, J. R. PETERSON, C. TURPEN, K. KIRKPATRICK;
Dept. of Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: Impulsive choice behavior refers to the preference for a smaller-sooner (SS) reward over a larger-later (LL) reward when choosing the LL reward is optimal in terms of reward rate. Greater impulsive choice has been observed in individuals with ADHD, schizophrenia, and depression, as well as in substance abuse disorder, obesity, and pathological gambling. Accordingly, there have been recent efforts to develop neurocognitive interventions that may be implemented to alleviate maladaptive impulsive choice. Given the delays involved in waiting for reward in impulsive choice tasks, many interventions have targeted individuals' abilities to anticipate and time the delivery of upcoming reward, with the goal of reducing aversion to long reward delays. These efforts have been successful, suggesting that the interventions do improve self-control immediately after exposure to these interventions. However, the durability and generalizability of these neurocognitive interventions have yet to be thoroughly tested. The goal of these experiments was to investigate whether time-based neurocognitive interventions produce

long lasting (Experiment 1) and generalizable effects across different decision-making parameters (Experiment 2). In Experiments 1-2, three groups of rats were exposed to one of two intervention tasks (fixed or variable delays to reward) or a control task (i.e., no delay to reward); the fixed and variable delays were in the range of delays that were experienced in the impulsive choice task. In the subsequent impulsive choice task, SS choices resulted in 1 food pellet after 5, 10, and 20 s in successive phases, while LL choices always resulted in 2 food pellets after 30 s. Here, the time-based intervention groups made fewer impulsive choices than the control group. In Experiment 1, the rats were then exposed to this same paradigm approximately 6 months later; the rats remained in their home cages during the waiting period. In Experiment 2, the rats were then exposed to different choice paradigms, in which reward magnitude or reward delay was manipulated. Exposure to both time-based interventions reduced impulsive choice behavior across the subsequent testing of impulsive choice. Overall, these results lend further support to the use of non-invasive neurocognitive interventions to reduce impulsive choice in rats, thus unveiling a critical preclinical avenue that may be navigated for future implementation in reducing impulsivity in individuals in various subpopulations prone to making impulsive decisions.

Title: A novel open-field task for the analysis of episodic-like memory and its substituents

Authors: ***S. STUEBING**, K. KIRKPATRICK;
Kansas State Univ., Manhattan, KS

Abstract: Episodic memory is one of the first memory types to be compromised in both aging and dementia. One unique feature that distinguishes episodic memory from other memory types is its composition of three substituents - object recognition and discrimination (what), spatial navigation (where), and timing (when), which must be appropriately integrated for episodic encoding and recall. Research on episodic-like memory, the animal counterpart thereof, highlights the three underlying components of the memory type by challenging animals to

successfully assimilate previously learned what, where, and when information to solve a task. This provides an avenue for studying the memory type as a whole, as well as individual differences that exist within the what, where, and when components, which could affect an individual's ability to utilize episodic-like memory. However, current episodic-like tasks do not directly assess the what, where, and when components, nor do they evaluate whether individual differences within the substituents affect an individual's ability to successfully perform the integrated episodic-like task. But, better assessment of the substituents may provide novel insight into the nature of episodic memory decline, and therefore merits further research. As such, this project aimed to develop a novel task for studying both episodic-like memory and its substituents in rodents. By creating and piloting an open-field task that utilizes scent (what), location (where), and time of day (when), this task successfully elicited the use of episodic-like memory in rats, and elucidated individual differences in the what, where, and when substituents of episodic memory. These findings indicate that rats exhibit individual differences in the underlying what, where, and when components of episodic memory, a more thorough understanding of which could provide further insight into the nature and eventual prevention of the episodic memory decline that is seen in both aging and dementia.

Title: Systemic injection of clonidine, an alpha2-adrenergic auto-receptor agonist, interferes with state dependent modulation of hippocampal theta-gamma coupling during a spatial decision-making task

Authors: *S. AMEMIYA, A. D. REDISH;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The hippocampal theta oscillation (6-12 Hz) is thought to play a role in deliberative processes in decision making, interacting with gamma oscillations [low gamma (LG): 30-55 Hz, high gamma (HG): 60-90 Hz]. However, how the interaction of theta and gamma oscillations

modulates the decision process is poorly understood. Previous studies have reported that the noradrenergic drug clonidine makes animals more decisive, reflected as a decrease in deliberation-related head re-orienting behavior of rats (vicarious trial-and-error [VTE]), and a decrease in the alternation of hippocampal representations of possible options at a choice point. In order to test how theta and gamma oscillations underlie deliberative processes, we examined the influence of clonidine on hippocampal theta and gamma oscillatory activity from rats running a decision-making task.
Rats ran a modified Hebb-Williams maze, consisting of a changeable central path, a final decision point, and rewarded return rails leading to the start of the loop. On each lap, only one side or the other was rewarded. Three reward-contingencies were used: turn left, turn right, or alternate for reward. During the analyzed probe trials, the rewarded rule changed approximately halfway through the session. On a subset of trials, clonidine (30 μg/kg) or saline vehicle was delivered IP 30 min before the run. Hippocampal local field potentials (LFP) and cell spiking activity were recorded from the hippocampal CA1 and fissure regions. Theta phase was calculated based on actual waveform of theta. The peaks and troughs of theta waves were detected and assigned as phase 0, 180, respectively. Furthermore, we analyzed the asymmetry of each theta wave as the ratio of the length of the descending part (peak to trough) and the ascending part (trough to peak).
The theta wave was asymmetric, with the descending part longer than the ascending part. Consistent with previous studies, gamma oscillations appeared at particular phases of theta: LG power increased in the ascending phase and HG power increased in the descending phase. More symmetric theta waves included more LG power. Activity of place cells indicated that the ascending part of theta included more prospective information than the descending part. At the final decision point, control sessions showed an increase of power in LG and HG on VTE laps compared to non-VTE laps. In addition, the theta wave was more symmetric on VTE laps than on non-VTE laps around the choice point. These changes were suppressed by clonidine. Our findings suggest that hippocampal theta-gamma coupling reflects deliberative processes which can be modulated by noradrenaline manipulations.

Title: Using a novel neuroeconomic decision-making foraging task to test mouse models of addiction

Authors: *B. SWEIS[1], A. J. ASP[2], C. ZHENG[2], S. R. K. BRANCEL[2], M. J. THOMAS[2], A. D. REDISH[2];
[2]Neurosci., [1]Univ. of Minnesota, Minneapolis, MN

Abstract: New theories see addiction as a result of failures of decision-making processes. To test how cocaine exposure influenced economic decision-making, we adapted a novel foraging task for mice (Restaurant Row). The task consisted of 4 reward zones (restaurants) around a square, which were primed serially, forcing mice to run around the square, foraging for food. We modified the task to include a separate *decision zone* for each restaurant. Upon entry into a decision zone for a given restaurant, an offered delay was signaled by a repeating tone (pitch indicated delay). The mouse could then either enter the restaurant, at which time the delay started counting down (indicated by descending pitch of the delivered tones) or leave the decision zone (skipping the offer). Mice also had the opportunity to quit waiting mid-countdown. Each restaurant provided a uniquely flavored food reward. Delays were random at each encounter (1-30s) and mice had 1h to get their food for the day. This means they had a budget of time to spend by making stay or skip decisions to each encountered offer.
After 30d of task training, 8 C57BL/6J male mice received 5d of cocaine or saline (15mg/kg IP) while being tested on RRow daily. RRow testing took place during the day with injections in the evening.
Thresholds of willingness to wait were determined by fitting sigmoid curves to (1) skip/enter decisions and (2) quit/earn decisions as a function of offer length. Mice demonstrated stable skip/enter and quit/earn thresholds for different flavors revealing individual preferences similar to both rats and humans on these foraging tasks. Cocaine increased quit/earn thresholds but not skip/enter thresholds. Mice spent varied time in the decision zone, but took longer to skip offers than to accept them. When mice accepted offers that they later quit, they spent more time in the decision zone before accepting those offers than they did when accepting offers and waiting through the entire countdown. In other words, decisions to stay that resulted in earned pellets were made the quickest. Cocaine exposure increased time to accept offers but did not affect time to skip. Cocaine mice spent the most time deciding to accept offers that they later ended up quitting - behavior that is economically unfavorable. Mice displayed vicarious trial and error (VTE) behaviors in the decision zones, and showed more VTE when deciding to skip, suggesting

mice were deliberating more on these occasions. Cocaine mice displayed less VTE on these skip trials as well as on enter-then-quit trials, suggesting that cocaine exposure promotes decision-making behavior that is suboptimal on an economic task, possibly by reducing an overall capacity to deliberate.

Title: DREADDs disruption of prelimbic cortex alters hippocampal SWR dynamics during rest after a foraging task in rats

Authors: *B. SCHMIDT[1], A. D. REDISH[2];
[1]Neurosci., Univ. Minnesota, Minneapolis, MN; [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Hippocampal (HC) place cell assemblies “replay” spatial trajectories previously traversed in a temporally condensed manner during sharp wave/ripple complexes (SWR, 150-200 Hz) at food-reward sites on mazes and during post-run rest. Recent experiments have suggested an important coupling of HC and prelimbic (PL) cortex during decision-making. Recently, PL has been implicated in the retrieval and selection of hippocampal memory representations, biasing the retrieval of goal-related representations. However, a role for PL in HC replay consolidation remains largely unexplored.
We examined how PL affects HC SWR activity by reversibly disrupting PL in rats with virally-delivered h4MDi DREADDs, while recording neural ensembles from HC, PL, and ventral striatum (vStr) simultaneously from rats trained on the spatial neuroeconomic task Restaurant Row. This task reveals individual preferences of reward flavor and the cost the rat was willing to

exert to receive it. Rats ran around a circular maze divided into four zones with four evenly spaced spokes. One of four different food rewards (fruit, banana, chocolate, unflavored) was delivered at the end of each spoke. On entry into each zone, a tone indicated the delay the rat would have to wait for food and the rat was able to choose to stay (waiting out the delay) or skip the offer and move on to the next option.
Rats were run for 20 days each on this task, with alternating dosages of CNO (5 mg/kg, subQ) and vehicle control. Behavioral results from these manipulations has been previously reported, but in short, PL reduced the thresholds and disrupted vicarious trial and error behaviors. Neurophysiologically, systemic injections of CNO altered local and global neural dynamics in PL DREADD-transduced rats. CNO reduced cell yield in PL without affecting HC or vStr cell yields. CNO reduced the mutual information between spiking and task components in PL, but not in HC or vStr. CNO decreased theta (6-10 Hz), low gamma (25-55 Hz) and high gamma (65-115 Hz) power in PL. Further, CNO altered network dynamics in HC including decreasing theta and low gamma power. Interestingly, disrupting PL dynamics resulted in altered neural dynamics during HC replay. CNO administration reduced the number of HC SWR events seen during post-run rest and altered the distribution between forward and backward replays. Further, CNO in PL DREADD-transduced rats altered LFP dynamics between HC and PL as well as the HC and vStr, but not between PL and vStr, by significantly altering power correlations between low gamma and SWR frequencies.

Title: The neural correlates of experiential foraging in humans

Authors: *S. V. ABRAM[1], A. D. REDISH[2], A. W. MACDONALD, III[1];
[1]Psychology, [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Experiential foraging requires that animals economically allocate scare resources such as time. Animal models suggest that these allocations occur through interacting decision-making processes. To further develop the translation between rodent and human foraging models, we employed an experiential stay/go foraging task (the "Web-Surf Task," akin to the "Restaurant Row" rodent task). Human subjects (current N=9) had 40 minutes to forage for 4s videos from one of four categories (kittens, dance, landscape, bike-accidents), encountered sequentially. Videos were used because they are consumable on a trial-by-trial basis. Subjects were informed of the delay before video presentation. They then chose to stay and wait for the video, or skip to the next category. Viewed videos were rated on a 1-4 scale. To travel between categories, subjects clicked the numbers 1-4 as they randomly appeared on the screen.
Neurophysiological findings from rodents on the Restaurant Row task suggest that the orbitofrontal cortex (OFC) and ventral striatum are likely involved in expectations of reward, and the hippocampus (HC) may be implicated in episodic future thinking. To further develop the neurophysiological translation between species, human subjects completed the Web-Surf task during 3T functional imaging (45'; TR = 720ms; $2mm^3$).
Behavior: Humans showed individual preferences for each video category, revealing their preferences through thresholds (below which they would stay, above which they would skip). Delay thresholds correlated with stated preferences (video ratings, post-test category rankings), finding that 78% of correlations were above 0.75 for both ratings and rankings.
Neuroimaging analyses: Group-level models with choice (decision), delay (anticipation), and video viewing (consumption) events revealed anterior cingulate cortex (ACC) activation during decision, and ACC, anterior insula (AI)/OFC, HC, and amygdala activation during consumption ($p < 0.05$); all three events activated visual cortex. A composite map of decision > anticipation and consumption > anticipation found overlapping activation in the ACC, AI, HC, and visual cortex. Lastly, a contrast of stay > go (during decision) revealed activation in visual cortex. These data suggest that humans are imagining the reward when deciding, perhaps more so when electing to stay and wait. Consistent with human imaging findings, the salience network (i.e., ACC and AI) were engaged when evaluating primary rewards (e.g., videos). HC activation during decision-making is also in line with human and rodent research that links this area with imagination and episodic future thinking.

Title: A two-step decision-task for rats reveals behavioral correlates of model-based and model-free decisions

Authors: B. M. HASZ[1], *A. D. REDISH[2];
[1]Grad. Program in Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Dept. Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: Current theories suggest that mammalian decision-making depends on separable systems, including deliberation (simulation and evaluation of potential outcomes, a "model-based" mechanism) and procedural (recognition of a situation and release of well-learned action-chains, a "model-free" mechanism). Theories suggest that rat behaviors (vicarious trial and error (VTE) and path-stereotypy) reveal the use of these systems. VTE is a behavior occasionally displayed by rats as they come to a choice point in a maze and look back and forth between potential paths, and is thought to reflect an internal deliberative process. In contrast, path-stereotypy describes how a rat's behavior becomes more regular with experience. Stereotyped paths through a maze have been hypothesized to indicate procedural behavior.
A new two-step decision task dissociates model-based and model-free choices in humans (Daw et al., 2011, Neuron). We adapted this task for rats to evaluate how these rodent behavioral signatures correlate to model-based and model-free choice. The task consists of a spatial loop, in which rats encounter two left-right choices. The second choice occurs in the presence of three computer monitors, which enable dynamic control of context. The first choice (C1: A/B) probabilistically determines the context of the second choice (C2: C/D or C3: E/F). On selecting the second choice, the rat encounters a delayed reward. The four delay times (C, D, E, and F) randomly walked slowly throughout the experiment, so the rat was constantly trying to find its way to the context and choice with the shortest delay.
7 rats were trained until they were running reliably and then run on this task for 50d each. We fit several algorithms to each rat's choices: (1) random, (2) model-based, (3) model-free, (4) a constant-weight mixed algorithm, and algorithms in which (5) VTE at C1 indicated model-based decision-making, (6) VTE at C2/C3 indicated model-based decision-making, and (7) path-

stereotypy of the lap indicated model-free decision making. Consistent with the human data, the constant-weight mixed algorithm fit the data better than either the model-based or model-free algorithms alone, all of which fit better than random. However, we found that algorithms where the model-based influence depended on the amount of VTE and the model-free influence on the degree of path stereotypy fit rat behavior better than the constant-weight algorithm. This suggests that multiple decision systems do not contribute statically to choice, but rather that the influence of each system changes over time, with the amount of influence of each system revealed by behavioral correlates such as VTE and path stereotypy.

Title: Effects of blast-induced mild traumatic brain injury on cognitive flexibility in rats

Authors: *C. C. TENN[1], N. CADDY[2], M. GARRETT[2], A. GIVENS[3], B. POPESCU[3]; [2]Casualty Mgmt. Section, [1]DRDC Suffield Res. Ctr., Medicine Hat, AB, Canada; [3]Dept of Anat. and Cell Biol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Introduction: Traumatic brain injury (TBI) can result in a range of impairments from mild to severe and is an increasing concern for individuals in sports and the military. For military personnel, encounters with blast explosives frequently result in TBIs in particular, the mild form of this brain injury. Mild TBI can result in disturbance of cognitive, behavioural, emotional and physical functions. Several brain regions are commonly affected with this type of injury including the pre-frontal cortex that is responsible for the regulation of executive functioning. There are limited studies examining complex cognitive deficits such as decrease executive functions in experimental models of TBI. This study used an attentional set-shifting task (AST) to evaluate the effect of blast-induced mild brain injury on executive function and behavioural flexibility performance in rats. **Methods:** Rats were housed under controlled environmental conditions of light (12h light/dark cycles) and temperature. A mild brain injury was induced in anaesthetized animals by exposure to a single shockwave intensity of 140 kPa for 7.1ms duration. Control animals underwent the same treatment except for the shockwave exposure. Animals were placed on a food restricted diet for 7 days prior to blast exposure. Following the exposure, both groups of animals were trained and tested on the AST which involved a series of discriminative tasks of increasing difficulties. Four days post-exposure, brain tissues from these

animals were harvested for histopathological analyses. **Results:** There was no significant difference in body weights between the two groups before or after the blast exposure. All animals successfully completed the training phase reaching criterion for the simple discrimination trials. Blast animals required significantly more trials to reverse a learned rule. These animals also took significantly more trials to criterion to learn a new rule in another attentional dimension (extradimensional shift) as compared to controls. Brain sections stained with hematoxylin and eosin and luxol fast blue did not show any significant histopathological differences between the two groups at this early time point. **Conclusion:** These findings demonstrate early deficits in executive function and behavioural flexibility following a mild brain injury. Future studies will examine the timeline for cognitive recovery as well as the use of other histological methods (i.e. immunohistochemical staining procedures) for subtle changes in this type of mild brain injury.

Title: (R)-fluoxetine is more effective than (S)-fluoxetine in enhancing learning and cognitive flexibility in mice

Authors: *S. MARWARI[1,2], G. S. DAWE[3,2];
[2]Drug Develop. Unit, Life Sci. Inst., [3]Pharmacol., [1]Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Fluoxetine, a clinically successful selective serotonin reuptake inhibitor, is a racemic mixture of (R) and (S) stereoisomers. In preclinical studies, chronic fluoxetine treatment (10 mg/kg) has been shown to have antidepressant effects in behavioral paradigms that has been correlated with increased adult hippocampal neurogenesis. However, the clinical evidence on whether or not fluoxetine treatment directly brings about cognitive enhancements is still under investigation and the contribution of the enantiomers of fluoxetine in these paradigms remains

largely unknown. In this study, we investigated the effects of (R) and (S)- fluoxetine treatment on antidepressant and cognitive behavioural paradigms, and cell proliferation in the hippocampus of C57BL/6J female mice. (R)- fluoxetine had superior effects over (S)- fluoxetine in elevated plus maze (p <0.001), forced swim test (p <0.05) and tail suspension (p <0.05) tests. Likewise, in a behavioural sequencing task in the IntelliCage, in which discriminated spatial patterns of rewarded and never rewarded corners were serially reversed, (R)- fluoxetine treated mice showed rapid acquisition of the behavioural sequencing (compared to the S-fluoxetine) and cognitive flexibility in the subsequent reversal stages both in the intra- and inter-session analyses (p <0.0001). (R)-fluoxetine administration also increased neurogenesis in the hippocampus, in particular in the suprapyramidal blade of the dentate gyrus, which has been reported to play a crucial role in supporting spatial learning. The results suggest that (R)-fluoxetine that is reported to have a shorter half-life than (S)-fluoxetine nevertheless has superior antidepressant effects and more consistently improves spatial learning and memory. Such a profile not only offers an advantage in treating depression but may also confer an additional beneficial effect in managing neurocognitive impairments associated with depression.

Title: Effects of HIV/TAT protein expression on spatial memory, reversal learning and neurotransmitter levels in mice

Authors: *S. G. SEMENOVA[1], J. P. KESBY[2], A. MARKOU[1];
[1]UCSD, La Jolla, CA; [2]The Univ. of Queensland, St. Lucia, Australia

Abstract: Background: Neurotoxic viral protein TAT may contribute to deficits in dopaminergic and cognitive function in individuals infected with human immunodeficiency virus. Transgenic mice with brain-specific doxycycline-induced TAT expression (TAT+, TAT- control) show impaired cognition. However, previously reported TAT-induced deficits in reversal learning may be compromised by initial learning deficits. We investigated the effects of

TAT expression on memory retention/recall and reversal learning, and neurotransmitter function. We also investigated if TAT-induced effects can be reversed by improving dopamine function with selegiline, a monoamine oxidase inhibitor. **Methods:** Mice were tested in the Barnes maze. TAT expression was induced after the task acquisition. Dopamine, serotonin and glutamate tissue levels in the prefrontal/orbitofrontal cortex, hippocampus and caudate putamen were measured using high performance liquid chromatography. Selegiline treatment continued throughout behavioral testing. **Results:** Neither TAT expression nor selegiline altered memory retention. On day 2 of reversal learning testing, TAT+ mice made fewer errors and used more efficient search strategies than TAT- mice. TAT expression decreased dopamine turnover in the caudate putamen, increased serotonin turnover in the hippocampus and tended to increase the conversion of glutamate to glutamine in all regions. Selegiline decreased dopamine and serotonin metabolism in all regions and increased glutamate levels in the caudate putamen. **Conclusions:** In the absence of impaired learning, TAT expression does not impair spatial memory retention/recall, and actually facilitates reversal learning. Selegiline-induced increases in dopamine metabolism did not affect cognitive function. These findings suggest that TAT-induced alterations in glutamate signaling, but not alterations in monoamines metabolism, may underlie improvements in reversal learning.

Title: Extrapolation of serial stimulus patterns is disrupted following selective damage to the anteroventral thalamus in rats

Authors: *D. G. SILVA, G. F. XAVIER;
Dept. of Physiol., Univ. of São Paulo, São Paulo, Brazil

Abstract: Extrapolation of serial stimulus patterns, a type of anticipatory behavior, relies on memories of past regularities. It seems to depend upon the identification and application of rules relating sequences of stimuli, allowing anticipation of events never experienced before. According to Gray (1982) the septo-hippocampal system compares (1) anticipated information, predicted from memories of past regularities, motor programs in progress and prior experiences

on the relationship between execution of motor programs and environmental consequences, and (2) present information. The comparator would be the subiculum. This brain structure would receive present information from neocortical afferents, via the entorhinal cortex, and expected information from a "generator of predictions system" including the subiculum, mammillary bodies, antero-ventral thalamus, cingulate cortex and, again, the subiculum. The antero-ventral thalamus is in a privileged position to allow investigation of this postulated generator of predictions system. This study investigated the effect of selective damage to the antero-ventral thalamus, by topical application of N-Methyl-D-Aspartic acid (NMDA), on the ability of rats to extrapolate relying on serial stimulus patterns; Control subjects were injected with phosphate buffer. Wistar rats were trained to run through a straight alleyway to get rewarded. In each session (one per day) the rat run four successive trials, one immediately after the other, receiving different amounts of sunflower seeds in each trial. While rats exposed to the monotonic schedule received 14, 7, 3, 1 sunflower seeds along trials, subjects exposed to the non-monotonic schedule received 14, 3, 7, 1. Rats were trained along 31 sessions. On the 32nd testing session, a fifth trial never experienced before by all rats was included immediately after the fourth trial. Running times were recorded along trials. ANOVA including data of the testing session revealed a significant Trial x Surgery x Rewarding Schedule interaction effect ($F(4,96) = 6.83$; $P < .0001$). As expected, running times on the fifth trial of Control subjects exposed to the monotonic schedule were significantly longer as compared to the corresponding scores of Control subjects exposed to the non-monotonic schedule, indicating the occurrence of extrapolation. In contrast, lesioned rats exposed to the monotonic schedule did not exhibit this increase in running times on the fifth trial, indicating that these subjects did not extrapolate. In conclusion, results indicate that extrapolation relying on serial stimulus patterns is disrupted following selective damage to the antero-ventral thalamus.

Title: High sucrose diets impair performance of a behavioral pattern separation mediated touchscreen task

Authors: *A. C. REICHELT[1,2], M. J. MORRIS[3], R. F. WESTBROOK[2];
[1]Sch. of Hlth. and Biomed. Sci., RMIT Univ., Melbourne, Australia; [2]Sch. of Psychology, [3]Sch. of Med. Sci., UNSW Australia, Sydney, Australia

Abstract: Rodent models have shown that high sucrose diets can reduce adult hippocampal neurogenesis. Functionally, neurogenesis is required for minimizing interference between memories that share features, a process that involves "pattern separation". We provided rats in the sucrose group with two hours daily access to a 10% sucrose (w/v) solution for 28 days and then assessed their performance on the "Trial-Unique Non-matching to Location" task (TUNL), conducted in a touchscreen chamber as a measure of behavioral pattern separation. In this task, rats first respond to a sample location and are then rewarded if they respond to a novel rather than the sample location in the choice phase. We varied the spatial separation between the novel and the sample location in order to manipulate the demands on pattern separation. Rats that had consumed sucrose performed the non-match discrimination correctly when there was a large spatial separation between sample and the new locations, but performed at chance levels when the separation was smaller. Doublecortin immunoreactivity in the dentate gyrus of sucrose-consuming rats was significantly reduced relative to controls. Thus, daily sucrose consumption impaired behavioral pattern separation performance and reduced measures of hippocampal neuroproliferation, confirming that diet can impair pattern separation and suggesting that this impairment is due to a reduction in hippocampal neurogenesis.

Title: Cognitive dysfunction in mice lacking of PKR-like endoplasmic reticulum kinase (PERK) in dopaminergic neurons

Authors: *F. LONGO, E. SANTINI, E. KLANN;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Accumulation of misfolded proteins can cause a pathological load on cells in the nervous system, resulting in endoplasmic reticulum (ER) stress that leads to the unfolded protein response (UPR) that typically is neuroprotective. A critical component of the UPR is PERK, whose activation results in the phosphorylation of eukaryotic initiation factor 2α (eIF2α), a translation factor that controls the initiation step of protein synthesis that has been implicated in long-term synaptic plasticity and memory formation (Ma et al., 2013). Although the UPR serves a neuroprotective role via regulation of general and gene-specific translation, it also is responsible for promoting apoptotic cell death following sustained activation, which occurs in neurodegenerative disorders such as Parkinson's disease (PD). Markers of PERK/eIF2α activation have been found in PD post-mortem brain tissue, where nigral dopaminergic neurons displaying α-synuclein inclusions also are positive for phosphorylated PERK and eIF2α (Hoozemans JJ et al., 2007). Dopaminergic signaling contributes to neuronal plasticity underlying learning and memory (Broussard JI et al., 2016), by acting upon specific neural targets such as hippocampus, amygdala, and prefrontal cortex, and altered dopaminergic modulation affects the encoding and maintenance of memories (Rosen ZB et al., 2015). Our central hypothesis is that a prolonged UPR results in inhibition of general protein synthesis via PERK-dependent phosphorylation of eIF2α, resulting in the loss of synaptic proteins, synaptic failure, and ultimately, neuronal death in dopaminergic neurons. To investigate the involvement of PERK in neurodegeneration and to determine whether the deletion of PERK in dopaminergic neurons results in synaptic alteration and cognitive symptoms, we generated mice selectively lacking either one or both copies of the gene that encodes PERK in dopaminergic neurons (DAT-PERK$^{+/-}$ and DAT-PERK$^{-/-}$respectively). We examined the DAT-PERK mutant mice in a series of cognitive tasks, including the Morris water maze, novel object recognition, Y maze, T maze, and associative fear conditioning and we found that selective PERK deletion in dopaminergic neurons results in multiple cognitive phenotypes in mice. In particular, DAT-PERK$^{-/-}$ mice exhibit behavioral impairments in both hippocampus- and amygdala-dependent memory resulting in a cognitive profile that recapitulates different features of PD. These results support our overall hypothesis and are consistent with previous studies that proper regulation of PERK-eIF2a signaling is required for normal cognitive function (Ma et al., 2013; Moreno et al., 2013).

Title: Novel synaptic pathway in drug-resistant epileptic encephalopathy

Authors: *A. OROCK[1,2], S. LOGAN[1,2], Y. I. LEE[4], F. DEAK[2,3];
[1]Oklahoma Ctr. for Neurosci., [2]Reynolds Oklahoma Ctr. on Aging, Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK; [3]Geriatric Med., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma city, OK; [4]Dept. of Anatomy, Col. of Med., Dankook Univ., Cheonan, Korea, Republic of

Abstract: Introduction: Ohtahara syndrome, also known as Early Infantile Epileptic Encephalopathy (EIEE) with suppression bursts is a currently untreatable disorder that presents with seizures and impaired cognition. EIEE patients have most frequently mutations in the gene encoding the synaptic protein of munc18-1. The exact molecular mechanism is unknown how these munc18-1 mutations cause seizures and cognitive impairment but the leading haploinsufficiency hypothesis posits that they make the protein unstable. This study aims to understand the role of munc18-1 and how targeting transmitter release could be used to combat EIEE and other drug resistant epileptic disorders.
Methods: We use munc18-1+/- mice as a model of EIEE haploinsufficiency. We performed behavioral tests for spatial learning and memory using a radial arm water maze (RAWM) and the "Intellicage" behavioral platform. We performed long-term potentiation (LTP) tests to assess hippocampal memory acquisition and storage capacity of munc18-1+/- mice. We used a fluorescent FM dye assay to measure the rate of synaptic vesicle release in neuronal cultures from munc18-1+/- and wild-type controls. We created viral vectors with point mutations found in EIEE patients to transduce cultured neurons and tested the effect of these mutations on neurotransmission.
Results: These behavioral assays show that munc18-1+/- mice perform poorly in spatial learning tasks (RAWM) and reversal learning task when compared to controls (Intellicage). They also have impaired LTP and slower synaptic vesicle release rates than controls. None of the selected Munc18-1 point mutations have a dominant negative phenotype but are able to partially rescue synaptic function in munc18-1+/- neurons.
Conclusions: To our best knowledge this is the first study to demonstrate that munc18-1 mutants implicated in the severe epileptic encephalopathy of EIEE are functionally less active than ^{WT}munc18 and hence could be a possible therapeutic target for drug resistant epileptic disorders.

Title: Hippocampal activation of Rac1 regulates the forgetting of object-recognition memory

Authors: *Y. LIU, S. DU, B. LEI, L. LV, W. SHI, Y. TANG, L. WANG, Y. ZHONG;
Sch. of Life Sciences, Tsinghua Univ., Beijing City, China

Abstract: Passive or natural memory decay and interference-induced memory loss are two major forms of forgetting that are extensively studied in psychology. Whether and how these two forms of forgetting are regulated at the molecular level remain to be established for all types of memories in vertebrates. Recent studies in Drosophila led to the idea of active forgetting, as the behaviourally induced activation of the small G protein Rac1 causes forgetting. Here, we show that Rac1 activation in the mouse hippocampus plays a role in the regulation of time-based passive memory decay and interference-based forgetting of object recognition memory. Although it naturally decays within 72hrs, the inhibition of Rac1 activity in hippocampal neurons through targeted expression of a dominant negative Rac1 mutant extended memory for over 72hrs,whereas Rac1 activation accelerated memory decay within 24hrs. The recognition of additional objects led to interference-based forgetting of the original objects, and this interference-induced forgetting was blocked by the inhibition of Rac1 activity in hippocampal neurons. The evidence presented here suggests that Rac1 activation causes both time-based and interference-based forgetting of recognition memory, but exerts no effects on the formation of this memory. Indeed, the better-defined time window in the interference task allowed us to reveal interference-induced elevations in Rac1 activity. Electrophysiological recordings of long-term potentiation provided independent evidence that further supported a role for Rac1 activation in forgetting. Thus, Rac1-dependent forgetting is evolutionarily conserved from invertebrates to vertebrates.

Title: Re-examination of reward comparison hypothesis: Roles of ventral tegmental area and periaqueductal grey matter on morphine-induced aversively conditioned taste aversion and rewarding conditioned place preference

Authors: *C. WU[1], A. HUANG[2];
[1]Keelung Hosp., Keelung, Taiwan; [2]Fo Guang Univ., Yilan County, Taiwan

Abstract: A conditioned solution (CS) is paired with the unconditioned stimulus (US), which induces aversively illness or nausea effects, to produce the suppression of the CS consumption, in termed as conditioned taste aversion (CTA). Later, abused drugs have also been shown to produce the similar CTA effect. Some researchers suggest that the suppression of the CS is due to the reward comparison between CS and US. The reward value of the CS outweighs from that of the US, and thereby animals decrease the CS consumption, in called as the reward comparison hypothesis. The purpose of the present study addresses this interesting issue to dissociate from rewarding and aversive effects of abused drugs. The rewarding ventral tegmental area (VTA) and the aversive periaqueductal grey matter (PAG) were determined to assess this dissociation between abused rugs-induced CTA and CPP. Using “the pre- and post-association” experimental paradigm, we simultaneously form morphine-induce CTA in the pre-association and morphine-induced CPP in the post-association experiments. Before the CTA and CPP acquisition phase, the VTA (i.e., rewarding nucleus) and the PAG (i.e., aversive nucleus) were respectively lesioned. The 0.1% saccharin solution (CS) and the conditioned place preference were conditioned with morphine for 5 days paired and 5 days unpaired schedules. Finally, the CTA and CPP were tested for 15 min and 10 min, respectively. The results showed that VTA lesions decreased CPP effects but did not affect CTA. PAG lesions increased CTA effects but did not affect CPP. The present findings support the CTA was involved in the aversion and CPP was to control the reward. The VTA did not mediate aversive CTA effects and control rewarding CPP. The PAG did not mediate rewarding CPP effects and govern CTA effects. The reward comparison hypothesis is still challenged. Keywords: reward comparison hypothesis, conditioned taste aversion, rat NSC 102-2410-H-431-005-MY3

Title: Classic wide-waveform dopamine neurons signal reward number and identity error signals in a common framework

Authors: *Y. K. TAKAHASHI, G. SCHOENBAUM;
NIDA/NIH, Baltimore, MD

Abstract: Midbrain dopamine neurons have been shown to signal errors in reward prediction. This signal is thought to reflect the discrepancy between the value of expected and actual reward. We recently reported that error signaling of dopamine neurons in rat ventral tegmental area (VTA) was altered by disruption of input from orbitofrontal cortex that was proposed to signal information about task states. This suggests, contrary to current theoretical accounts, that dopamine error signals might contain information about predicted identity or state as well as value. Consistent with this hypothesis, here we show that dopamine neurons signal such value-less prediction errors. Neural activity was recorded from putative dopamine neurons in rat VTA. Recordings were made in a simple odor-guided choice task in which different odor cues indicated that a flavored milk solution was available in one of two nearby fluid wells. During recording, we manipulated either reward number (1 or 3 drops) or identity (chocolate- or vanilla-flavored milk) to induce value-based or value-less errors in reward prediction, respectively. Consistent with previous work, dopamine neurons showed phasic changes in firing in response to changes in reward number. However the same dopamine neurons also increased firing when the identity of reward was changed unexpectedly. These increases in firing disappeared with learning, were observed despite the rats showing similar preferences for the two rewards, and were observed in the same neurons that showed suppression of firing on reward omission. These results suggest that midbrain dopamine neurons can signal errors in predicting features of reward other than its general value.

Title: Reward expectation influences the activity of auditory striatal neurons during decision making

Authors: *L. GUO, W. I. WALKER, S. JARAMILLO;
Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: Animals constantly adapt their behavior based on environmental conditions to optimize reward and avoid punishment. To understand how neural circuits implement flexible sound-driven choices, it is necessary to identify the brain regions involved in these behaviors, and how neural activity is influenced by the outcome of a choice. The rodent caudal striatum receives direct inputs from the auditory cortex and the auditory thalamus, as well as outcome-related signals from midbrain dopaminergic innervation. This region is therefore ideally situated to integrate sensory information with feedback about the outcome of an action (i.e., reward or punishment), and potentially plays a key role in action-selection. In this study, we investigated the effects of the expected magnitude of reward on neuronal activity in the auditory striatum. Water-restricted mice were trained in an auditory categorization task where they learned to associate different sound frequencies with different reward ports to obtain water. We changed the amount of water delivered on each reward port every 150-200 trials. Isolated single units from extracellular recordings displayed frequency-selective sound-evoked responses as well as movement-related activity. A comparison of neuronal activity from trials with different amounts of expected reward revealed that a subset of striatal neurons were modulated based on reward expectancy at different time periods during the task. Our findings pave the way for future investigation of the neural circuits underlying sound-driven choices based on reward.

Title: Behavioral differences among C57Bl/6 substrains

Authors: *Y.-S. LEE, M. KANG, H.-H. RYU;
Chung-Ang Univ., Seoul-City, Korea, Republic of

Abstract: Different strains of mice show distinct behavior and physiological phenotypes. However, the differences among substrains of C57BL/6 are not well appreciated. Here, we compared three substrains of C57BL/6 (C57BL/6JBomTac, C57BL/6NCrljOri, and C57BL/6NTacSam) in a series of behavioral tasks examining both general behavior, and learning and memory. In addition, we have also performed electrophysiological analyses including long-term potentiation (LTP) in the hippocampus, which is considered a cellular mechanism for learning and memory. We found that there are significant differences between C57BL/6JBomTac and the other two substrains in their behavioral phenotypes, including motor coordination, anxiety, and freezing in classical fear conditioning. However, the three substrains show comparable levels of hippocampal LTP. Our findings provide guidelines for choosing the most appropriate substrain for the intended studies.

Title: Hippocampal mapk activity in nf1 mice model shows abnormal circadian oscillation

Authors: *L. CHEN, T. SERDYUK, Y. ZHOU, W. LI;
Bio-X Institutes,Shanghai Jiao Tong Univ., Shanghai City, China

Abstract: Neurofibromatosis Type 1 (NF1) is a common neurological disorder caused by mutations in *NF1* gene, which encodes Neurofibromin, a p21Ras GTPase activating protein. Importantly, dysfunction of *NF1* causes learning disabilities and attention deficits. Previous study showed that the learning and memory deficits in mouse model of *NF1* ($nf1^{+/-}$) appear to be caused by excessive p21Ras/MAPK activity leading to impairments in mechanism of learning and memory. In addition, it is reported that the circadian oscillation of hippocampal MAPK activity may affect a number of physiological processes, as the persistence of long-term memories. In our study, the MAPK phosphorylation activity of the $nf1^{+/-}$ mice shows abnormal circadian oscillation compared with wild-type mice littermates. The level of hippocampal MAPK phosphorylation was significantly elevated during the night in *NF1* mice model. Besides, the recording of local field potentials from CA1 (at daytime and night) showed a difference in theta-frequency and alpha- frequency power spectral densities (PSD) in neurons between wild-type and $nf1^{+/-}$ mice. Our findings suggest that the MAPK activity rhythms may play an important role in memory mechanism; these data may provide new thoughts for elaborating the cognitive defects in *NF1* mice model.

Title: Effects of mPFC inactivation during learning of an initial strategy on subsequent behavioral flexibility

Authors: *G. J. PETERS, K. M. LATTAL;
Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The rat medial prefrontal cortex is a critical node in the neural circuitry that mediates behavioral flexibility. Notably, damage to the mPFC does not impair the learning of relatively novel memory-guided strategies, but in contrast, impairs learning new behavioral strategies that

conflict with existing strategies. Thus, the emphasis in research on behavioral flexibility is typically on the functional role of mPFC during the switch to alternative strategies. However, evidence from fear conditioning indicates that subregions within the mPFC have dissociable roles when learning conflicting behaviors. Here, prelimbic cortex (PL) is important for learning and expressing an initial fear memory, and infralimbic cortex (IL) is needed for learning a competing extinction memory. Additionally, PL and IL appear to play unique roles in other forms of competitive memory processes, such as the implementation of goal-directed or habitual strategies, respectively. Given prevalent bidirectional connections between PL and IL, one intriguing possibility is that these regions contribute to general flexibility by somehow interacting to resolve the conflict between alternative behavioral strategies. If so, mPFC involvement during the acquisition of initial strategies, though often undetected in behavior, might include the encoding of memory features that guide behavioral options in the event that flexibility is required. Consistent with this idea, it has previously been observed that temporary inactivation of the mPFC only during the early stages of learning a set of discriminations paradoxically improved learning on a new competing set of discriminations, despite several sessions of equivalent performance between control and previously inactivated groups on the initial set. In the current study, we assessed whether a similar inactivation procedure would result in improved flexibility in other forms of strategy switching. We found that temporary inactivation of the mPFC at the beginning of acquisition of a visual-cue strategy again improved performance on the switch to a competing response-based strategy, despite no difference in performance during the final sessions of the initial strategy. The robust nature of this facilitatory effect indicates that processing in the mPFC during the initial stages of learning has an important influence on subsequent flexibility. Such results have implications for understanding the neural circuitry dynamics that coordinate flexible behavior, which may ultimately inform approaches to treating the numerous psychiatric disorders that involve impaired flexibility.

Title: Using trace eyeblink conditioning to uncover mechanisms of Presenilin-linked Alzheimer's Disease

Authors: *C. BLEVINS, J. SIEGEL, R. GRAY, B. V. ZEMELMAN;
Inst. for Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: Trace conditioning is a highly conserved form of forebrain-dependent learning in vertebrates. Much of the circuitry required for this cognitive task has been described, but roles of key circuit elements in learning are unknown. Moreover, variation in task performance can signal brain dysfunction. We have discovered a difference between 3xTg Alzheimer's disease (AD) model mice and non-transgenic controls in acquisition of trace eyeblink conditioning, a finding that extends to the mutant Presenilin-1 (mutPS1, M146V) knock-in model. PS1 encodes a multifunction protein that participates in neuronal calcium regulation and amyloid precursor protein (APP) processing. PS1 has gained prominence in AD after DNA genome analyses revealed that nearly 200 distinct mutations in this gene are causally linked to the most severe early-onset form of the disease. Surprisingly, both types of young AD mice expressing mutPS1 (2-3 months old) conditioned more rapidly than non-transgenic or wild-type littermate controls. No learning differences were detected using the hippocampus-independent, 'delay' version of the task. Interestingly, the differential learning enhancement extended to contextual fear conditioning, as young mutant mice displayed enhanced freezing to context (hippocampus-dependent), but not to tone (hippocampus-independent). This novel finding represents a rare opportunity to examine cellular and circuit mechanisms linking PS1 to memory function. Two hypotheses may explain our findings: Accelerated learning could stem from intrinsic changes in affected neurons, a plasticity advantage at the outset that is potentially maladaptive over time; alternatively mutPS1 may preferentially affect specific cell types or brain regions, leading to network level compensatory changes that temporarily enhance trace learning. Both phenomena could be features of AD, expressed as long-term cognitive decline. Upcoming experiments will examine the relationship between mutant animal age and accelerated learning. In addition, to explore mechanisms by which mutPS1 affects task performance, we will test the role of altered cellular plasticity in learning and use selective mutPS1 expression to study regional and cell type-specific contributions to the uncovered phenotype.

Title: If you say freeze, I'll freeze with you...how learning from self-experience affects the response to the display of defence behaviors of others

Authors: *A. CRUZ, M. MOITA;
Champalimaud Ctr. For the Unknown, Lisboa, Portugal

Abstract: We have previously shown that rats freeze upon the display of freezing by con-specifics. In addition, this form of observational freezing requires prior experience with foot-shock, suggesting that freezing becomes an alarm cue through learning. We hypothesized that, during exposure to shock, rats associate their own defense responses with aversive stimuli. Consistently, we found that rats exposed to shock that did not experienced freezing do not respond to the display of freezing by their cage-mate. Exposure to shock may also contribute to observational freezing through stress-induced sensitization. To address this issue we compared corticosterone levels after different shock exposures that led or not to freezing, and found no differences in the strength of the stress response. Still, stress could facilitate observational freezing. Hence, we subjected rats to a forced swim session, which induced a very strong stress response. However, these animals, did not display observational freezing. One remaining question is whether different triggers of freezing as animals experience and aversive stimulus lead to the same response during the social interaction. To address this issue we are currently testing how exposure to a predator cues affects responses to freezing displayed by conspecifics.

Title: The role of orbitofrontal cortex in model-based planning in the rat

Authors: *K. J. MILLER[1], M. BOTVINICK[2], C. BRODY[3];
[1]Princeton Univ., Princeton, NJ; [2]Google DeepMind, London, United Kingdom; [3]Princeton University; Howard Hughes Med. Inst., Princeton, NJ

Abstract: Planning can be defined as a process of action selection that leverages an internal model of the environment. Such models provide information about the likely outcomes that will follow each selected action, and their use is a key function underlying complex adaptive behavior. Orbitofrontal cortex (OFC) is thought to be a key structure underlying this type of behavior, though its precise role remains unclear. In previous work, we have developed a two-step repeated-trials planning task for rats (adapted from Daw et al., 2011), and shown that orbitofrontal cortex is causally involved in planning behavior on this task, as well as presented preliminary results from single-unit recordings indicating encoding of planning-related variables (Miller et al., SFN 2015; Miller et al., in prep). Here, we examine the role of the OFC in model-based planning in more detail with further electrophysiology data as well as temporally precise optogenetic inactivations. We find that single units encode model-based value signals associated with outcomes, but not with choices, supporting the idea that OFC may be involved specifically in model-based learning (Schoenbaum et al., 2009), rather than model-based choice. Further supporting this idea, preliminary data from optogenetic inactivations suggest that the OFC plays a causal role in the task at the time of learning, but not at the time of choice.

Title: Functionally selective D_1 agonists bias regulate spatial working memory in prefrontal cortex

Authors: *Y. YANG, X. HUANG, R. B. MAILMAN;
Penn State Univ., Hershey, PA

Abstract: Dopamine D_1 agonists have been shown to cause cognitive enhancement, but importance of different signaling (e.g., cAMP or β-arrestin) is not known. The current study examined two D_1 agonists, EFF0311 and CY208243, that differ somewhat in their D1 signaling bias. Specifically, EFF0311 was found to have much higher intrinsic activity in β-arrestin

recruitment than CY208243, whereas activation of cAMP synthesis was similar. These properties allowed estimation of whether functional selectivity for these two pathways influences D_1 effects on cognition. Neuronal activity was recorded in prefrontal cortex as rats performed a delayed alternation spatial working memory task in a T-maze. Neurons with sensitivity to outcome-related aspects of the task decreased their firing rate after administration of both EFF0311 and CY208243, but in dissimilar ways. Before achieved outcome (prospective encoding), EFF0311 was superior to CY208243 in enhancing similarity between correct and error outcome based on firing rates. Oppositely, after outcome (retrospective encoding), EFF0311 was superior to CY208243 in distinguishing error from correct based on firing rates. Also, compared to CY208243, EFF0311 increased local field potential oscillation mostly in the beta-band, implying enhancement of the neuronal network. Finally the behavioral performance was improved by both EFF0311 and CY208243, but EFF0311 quickened decision making although the enhancement of performance accuracy was similar. These data on regulation of spatial working memory in prefrontal cortex suggest that D_1 mediated β-arrestin recruitment may be important for the use of D_1 ligands in the treatment of memory-related disorders, although off-target actions requires further investigation.

Title: What are the cellular and molecular underpinnings of improved mouse hippocampal-dependent behavior after exposure to a Mars mission-relevant dose of space radiation? Another small step for mousekind...

Authors: *S. YUN, C. W. WHOOLERY, M. J. LUCERO, A. W. WALKER, D. R. RICHARDSON, R. P. REYNOLDS, G. PALCHIK, S. E. LATCHNEY, B. P. C. CHEN, S. G. BIRNBAUM, A. J. EISCH;
UT Southwestern Med. Ctr., Dallas, TX

Abstract: Space radiation consists of high atomic weight and energy (HZE) particles. Chronic low doses of HZE particles - as will be encountered on a deep space mission to Mars - may be detrimental to astronauts by diminishing hippocampal function and thus compromising mission success. Studies using ground-based space radiation with relatively young adult mice (2 months of age) show that HZE particles decrease hippocampal neurogenesis and performance on hippocampal-dependent tasks. However, it is unknown how HZE radiation influences the brain and behavior of "astronaut age" equivalent mice (6 months of age), or how it alters important hippocampal functions such as contextual discrimination and cellular and molecular signatures underlying this behavior outcome. To fill these knowledge gaps, C57BL/6J mice (6-month-old [Mature] mice) were exposed to HZE particles (56Fe, 600 MeV/n, 174.1 KeV/μm LET of a single exposure of 20 cGy [Non-fractionated], protracted dose of 20 cGy [Fractionated, 6.7 cGy x 3 days, 48h intervals], or 0 cGy [Sham]). Surprisingly, while Mature Fractionated and Non-Fractionated mice displayed normal locomotor activity and normal CFC, they also showed a dose-dependent increase in contextual discrimination ability (CDFC) compared to Sham. To elucidate the cellular or molecular signature contributing to irradiation (IRR)-induced improvement of hippocampal- dependent behavior in Mature mice, we first quantified the number of newborn neurons and DG interneurons, both of which regulate DG activity. However, neither was not correlated with improved pattern separation. Second, we performed unbiased screening using whole translationome sequencing with a BAC-TRAP (Bacterial Artificial Chromosome-Translating Ribosomal Affinity Purification) mouse line targeted to DG glutamatergic neurons. Relative to the translationome from Sham mice, DG glutamatergic neurons from IRR mice had increased activity-dependent global translation. Thus, HZE particle radiation unexpectedly improves pattern separation in astronaut-age equivalent mice and is accompanied with enhanced global translation in DG glutamatergic mice. We are currently performing functional tests with candidate genes to assess whether they are causal factors underlying the age-related improvement in contextual discrimination after HZE radiation exposure.

Title: Towards a principled decoding of hippocampal replay

Authors: *Y. TANAKA[1], A. A. CAREY[1], E. ACKERMANN[2], C. KEMERE[2], G. PEZZULO[3], M. A. VAN DER MEER[1];
[1]Psychological & Brain Sci., Dartmouth Col., Hanover, NH; [2]Electric and Computer Engin., Rice Univ., Houston, TX; [3]Inst. of Cognitive Sci. and Technologies, Rome, Italy

Abstract: Decoding analyses seek to determine how well a known variable, such as a sensory stimulus, can be estimated from neural data. This process can be optimized for minimum reconstruction error, which can be computed on the same data used to estimate the encoding model. Internally generated hippocampal sequences pose an interesting challenge for this framework: they are covert phenomena without a ground truth to measure decoding performance against, and the true encoding model is unknown. Decoding the content of these sequences is thought to provide access to the content of memory retrieval, consolidation and planning processes, but the output of such a process is sensitive to parameter choices. How can we choose these parameters in a principled manner in the absence of a ground truth? First, we optimized for generalization performance, i.e. decoding accuracy on data not included in the estimation of the encoding model. When run on place cell data from a T-maze task, leave-one-trial-out generalization performance was overall much worse than same-trial-tuning and average-tuning decoding performance. More importantly, the decoder parameters that resulted in optimal performance were different for the generalization-optimized decoder. These parameters, in turn, can result in different decoded output of putative replay sequences. Second, to the extent that we can approximate internally generated sequences using a generative model, we can provide a ground truth that can be used for systematically choosing a decoder. We develop such a model that simulates replays by sampling from sped-up experience. The input to the model is a temporally compressed behavioral trajectory, the model parameters are derived from assumptions of the commonly used bayesian decoder, and the output an ensemble spiking pattern. If we are using the correct decoder, output of such a generative model should match experimental data. However, systematic examination of model parameters including temporal compression, replayed path length and number of encoded environments, show that data generated from our model based on these assumptions do not match the statistics of experimentally observed replays. Taken together, these results provide specific guidelines for a

more principled decoding of hippocampal sequences that can be straightforwardly applied to current decoding methods. In addition, the generative model approach provides a framework for the explicit testing of hypotheses underlying the spiking statistics and content of hippocampal sequences that be incrementally improved by comparison with experimental data and incorporated into decoding methods.

Title: Species and strain differences in hippocampal region CA2 vasopressin and oxytocin receptor distributions in mice, rats and prairie voles

Authors: *S. YOUNG[1], J. SONG[1], O. J. BOSCH[2];
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Dept. of Behavioural and Mol. Neurobiology, Inst. of Zoology, Univ. of Regensburg, Regensburg, Germany

Abstract: One of our research groups (WSY) determined that the knockout of the vasopressin (Avp) 1b receptor (Avpr1b) in mice resulted in decreased social aggression and decreased social memory in both male and females (Wersinger et al., 2002, 2007, 2008). We subsequently became interested in the hippocampal CA2 region when we determined that the Avpr1b was highly expressed there (Young et al., 2006). As we only found Avpr1b there in the Sprague-Dawley rat and C57Bl/6j mice, we (WSY) assumed that this would be the case in all strains of rats and mice. However, other groups (e.g., OJB; Bayerl et al., 2016) detected expression outside of the CA2 region in different rat strains. This prompted us to explore the expression of the Avpr1b in more depth as well as Avp receptor 1a (Avpr1a) and oxytocin (Oxt) receptor (Oxtr) in some cases in the hippocampus. Here were report initial results indicating that 3 rat strains have different patterns of expression whereas, so far, mouse strains do not. Finally, now not surprisingly, prairie voles have different patterns of expression. We used Affymetrix's very

sensitive ViewRNA *in situ* hybridization histochemistry system to examine expression. Both C57Bl/6j and BALB/c male and female mice express Avpr1b exclusively in pyramidal cells of the CA2 and immediately adjacent CA3 areas (expression is also seen in the fasciola cinereum which might be developmentally related). Oxtr is expressed within Avpr1b pyramidal neurons as well as in hippocampal interneurons and more extensively outside the hippocampus. In the Sprague-Dawley male, virgin female and lactating female rats, Avpr1b is found in the CA2 pyramidal cells as well as the SCN. In Wistar lactating female rats, Avpr1b is not expressed in the CA2 area but is in the SCN. No cell groups were identified expressing Avpr1b in the amygdala of either strain. In the male prairie vole, Avpr1b is not concentrated in the CA2 region although scattered cells are observed through the hippocampus. Strikingly, Oxtr is expressed in the same restricted CA2 pattern as Avpr1b in mice as well as abundantly elsewhere in the brain. Avpr1b, interestingly, is observed in many areas outside the hippocampus, especially in the globus pallidus and substantia nigra pars reticulata. Avpr1a is expressed in scattered cells in hilus and all strata in the dorsal hippocampus and along CA2 stratum oriens - pyramidal cell layers in the ventral hippocampus. Avpr1a is also expressed abundantly throughout the vole brain. These findings reflect the complex changes that evolve in the rodent neurohypophysial hormone receptor distributions despite the relatively fixed patterns of expression of the nonapeptides themselves.

Title: Hippocampo-thalamo-cortical networks for episodic memory and spatial processing

Authors: *N. A. KAMBI, J. M. PHILLIPS, Y. B. SAALMANN;
Dept. of Psychology, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Episodic memory, the ability to remember objects, events and their contexts experienced in one's personal past, depends on a set of brain regions including the hippocampus, retrosplenial cortex (RSC) and anterior thalamus (ATN), which are highly interconnected with

each other. However, the precise nature of information transmission between the ATN, RSC and hippocampus in supporting episodic memory and spatial processing is largely unknown. Our study aims to characterize how the ATN communicates with the hippocampus and RSC during episodic memory recall and spatial transformations. We hypothesize that the ATN supports episodic memory and spatial processing by regulating information transmission between the hippocampus and RSC. A possible mechanism may involve the ATN synchronizing groups of neurons in the hippocampus and RSC according to episodic and spatial demands. In order to test our hypothesis, we perform diffusion MRI-guided multi-site electrophysiological recordings from interconnected sites of the ATN-RSC-hippocampus network. For this we measured network connectivity by acquiring high-resolution diffusion-weighted images (1 mm isotropic) from the 3T GE MR750 scanner with a 16-channel receive-only head coil in 6 anesthetized monkeys along 60 diffusion directions (b=1000 s/mm2 and NEX=14). We used FSL for EPI distortion, eddy current and motion correction prior to Bayesian estimation of diffusion parameters and probabilistic diffusion tractography (PDT). Our PDT results correspond broadly to that observed in neuroanatomical tracer studies. We observed overlapping projection zones of the hippocampus (subiculum) and RSC in the ATN, roughly corresponding to the ventral subdivision of ATN. Further, the likely medial subdivision of ATN connected with the hippocampus and medial cortical regions such as the posterior cingulate, anterior cingulate and orbitofrontal cortex. However, PDT data had the advantage of delineating projection zones specific to individual macaques, which cannot be precisely ascribed based on tracer data in the literature. Our data suggests that the ATN is well suited to regulate information transmission between the hippocampus and RSC, as well as medial cortex more generally, due to the indirect hippocampo-thalamo-cortical pathway. The connectivity map derived for each macaque allows us to target MRI-compatible laminar probes to interconnected sites in the hippocampus and RSC as well as their overlapping projection zones in the ATN, to monitor neural dynamics of the ATN-RSC-hippocampus network.

Title: Storing and retrieving pattern sequences in the hippocampal circuit

Authors: *M. BAYATI, S. CHENG;
Inst. für Neuroinformatik , Building NB, Room E3 / 70 ,, Ruhr-Universität, Bochum, Germany

Abstract: We recently proposed that episodic memories are best represented by temporal sequences of neural activation patterns and that the hippocampal circuit is optimized to store these sequences. One central feature in this theory, called CRISP, is that hippocampal area CA3 intrinsically produces temporal sequential activities through its abundant recurrent connections. Here, we first study the possible mechanisms by which a relatively fixed recurrent network structure in CA3 can generate neural activity sequences intrinsically. We find that the robustness of sequence generation depends on the network architecture. For instance, randomly connected recurrent networks (RCRNs) are very sensitive to noise, whereas locally connected recurrent networks (LCRNs) generate moderately robust neural sequences. Networks with sparse connectivity, which are trained with sequences of random patterns, exhibit the most robust dynamics. Next we implement a cortico-hippocampal circuit consisting of the EC-CA3-CA1-EC loop. During memory encoding, intrinsic CA3 sequences are hetero-associated with EC sequences, which are driven by sensory inputs. Downstream, CA3 sequences are hetero-associated with sequence in CA1 and finally, the CA1 patterns are hetero-associated with the sensory inputs in EC, thus closing the loop. During memory retrieval, intrinsic CA3 sequences have to be reactivated based on partial, noisy cues, which is provided to EC. Finally, the retrieved sequences in CA3 reactivate the stored sequences in EC via the CA1 layer.
We find that memory performance is determined by the network's ability to perform pattern completion of individual patterns as well as robust retrieval of sequential information from CA3. These two functions have competing requirements, i.e., the conditions that lead to good performance in one function might have detrimental effects on the other. For instance, modeling CA3 as a LCRN, the stored sequence is retrieved robustly, but the temporal correlations between patterns in the sequence impair pattern completion when decoding the CA3 pattern. On the other hand, a RCRN facilitates decoding, but sequence retrieval fails if any noise is present. Combining the advantages of each of these two models, networks pre-trained on sequences of random patterns achieve a good overall memory performance because they can encode sequences in CA3 robustly and be decoded in the feedforward connections to CA1 and EC. To conclude, we find that the cortico-hippocampal circuit shows high memory performance in storing and retrieving sequences of pattern, as hypothesized by CRISP, and that the network architecture of CA3 is critical for memory performance.

Title: Areal and cellular architecture of conserved cortical circuits in reptiles

Authors: *R. K. NAUMANN, G. LAURENT;
MPI Brain Res., Frankfurt, Germany

Abstract: To understand cortical function at a mechanistic level, we need sufficiently simple animal models that retain basic structural elements of more complex systems such as the mammalian neocortex. Our laboratory is engaged in making such animal models accessible for modern molecular, imaging and electrophysiological techniques. The diversity of reptiles and their ancestral relation to mammals and birds allows us to explore questions related to the function and evolution of vertebrate neural circuits [1,2]. To facilitate physiological studies of cortical activity in reptiles, here we aim to provide a comprehensive anatomical map of reptilian cortical areas and document our findings using web-accessible high-resolution histological sections. We study two distantly related reptile species (Pogona vitticeps and Trachemys scripta) to identify shared and derived features of reptilian cortical circuits. We use a panel of methods for circuit mapping: viral and small-molecule tracing, chemo-architecture, gene-expression, and total area cell counts. Using immunohistochemistry and in-situ hybridization for a number of regulatory (Prox1, Lmo3, Rorb, Nurr1, Satb2) and functional (Drd1, Ndst4, Pcp4, Wfs1, CB) principal cell markers we identify a large number of region specific expression patterns in reptiles. We relate these patterns to specific intra- and extra-cortical projection patterns. These comparisons can suggest function, e.g., by comparison with the mammalian hippocampal formation.
Some markers have been claimed to identify specific cortical or pallial regions; we often find them more widely expressed than previously reported. Many homologies between vertebrate cortical areas have been proposed, but few agree on specifics [3]. Most comparisons have been based on distantly related birds and mammals while reports on reptiles are relatively rare. Our data inform this discussion by identifying regulatory gene expression specific to cortical areas and relating it to functional protein expression and cortical connectivity. We conclude that precise one-to-one similarities between reptile, bird, and mammalian cortical regions may exist, but that they are an exception rather than the rule. However, by identifying common elements in the cortex of distantly related reptiles (or similar emergent properties [1]) we may learn about

general cortical circuit motifs that were expanded and modified in evolution.

Title: Entorhinal cortical drive distinguishes CA1 pyramidal neuron subpopulations

Authors: ***A. V. MASURKAR**[1], K. V. SRINIVAS[2], D. H. BRANN[2], R. A. WARREN[2], D. C. LOWES[2], S. A. SIEGELBAUM[2];
[1]Columbia Univ. Med. Ctr., New York, NY; [2]Neurosci., Columbia Univ., New York, NY, NY

Abstract: Although hippocampal CA1 pyramidal neurons (PNs) have long been thought to comprise a uniform population, recent evidence supports the existence of two distinct sublayers along the radial axis, with deep layer neurons more likely to form place cells, encoding spatial locale, compared to superficial neurons. Here we explore the potential circuitry that mediates the differential information processing in deep compared to superficial cells, using in vitro electrophysiology, two-photon imaging of spines, and optogenetics. Our results demonstrate that the direct inputs to CA1 from medial entorhinal cortex (MEC), which provide spatial information, elicit larger excitatory synaptic responses in deep compared to superficial CA1 neurons. Surprisingly, inputs from lateral entorhinal cortex (LEC), which provide nonspatial information, excite superficial CA1 neurons more strongly than deep neurons. Our experiments thus reveal a novel view of EC-dorsal CA1 connectivity, in that MEC and LEC engage CA1 PNs subtypes in different manners, and provide an important framework to understand in vivo network dynamics in different behavioral contexts.

Title: Fragile X model mice show deficits in an a novel episodic memory task

Authors: *B. M. COX, W. WANG, A. LE, L. AGHAZADAH, J. HOU, G. LYNCH, C. M. GALL;
Anat. and Neurobio., Univ. California Irvine, Irvine, CA

Abstract: Fragile X syndrome (FXS) is the most common inherited cause of autism and mental retardation. In FXS expansion of an FMR1 gene CGG trinucleotide repeat disrupts expression of fragile X mental retardation protein and prior work has shown that Fmr1 knockout (KO) mice, used to model this disorder, have disdurbances in learning in many paradigms. In studies of acute hippocampal slices we find that the Fmr1 KOs have severe deficits in long-term potentiation (LTP) in the lateral perforant path (LPP) projections which arise in the lateral entorhinal cortex (LEC) and innervate the outer molecular layer of the dentate gyrus (DG). The LEC is the most densely interconnected of cortical regions and provides one of the two major cortical inputs to hippocampus. Animal and humans studies indicate that the LEC is critical for the formation of episodic memory (the 'what', 'where', and 'when' of serial events). Thus, we tested the hypothesis that Fmr1 KOs have deficits in LPP-dependent episodic memory. We developed a behavioral task in which mice sampled pairs of different odors in 3 successive trials and then on a 4^{th} test trial they were presented with an odor from the 1^{st} trial (a familiar odor) paired with a novel odor: greater time spent exploring the novel than the familiar cue during the test trial was considered evidence of learning. To show that learning in this serial odor recognition task (SORT) requires the LPP we used the designer receptor specifically activated by designer drug (DREADD) technology to transiently inactivate the LEC during training. Specifically, the AAV construct (AAV-CaMKII-HA-hM4D(Gi)-IRES-mCitrine) was injected bilaterally into LEC of WT mice and testing began 3 weeks later. DREADD agonist clozapine-N-oxide CNO (5 mg/kg or vehicle) was injected (IP, 30 min prior to behavioral testing). Inactivation of the LPP comletely blocked SORT learning, indicating that encoding relied upon LEC function. Finally, Fmr1 KO mice exhibited markedly impaired SORT learning. These results indicate that *Fmr1*

KOs have clear impairments in an LPP-dependent episodic memory task. Future work will examine the integrity of 'where' and 'when' components of episodic memory in the Fmr1 KOs.

Title: Functional neuroanatomy of nucleus incertus networks: neurochemical diversity, neural targets and control of cognitive, affective and motivated behaviors

Authors: *A. L. GUNDLACH, E. K. E. ONG-PÅLSSON, C. E. SINGLETON, V. RYTOVA, A. SABETGHADAM, M. HAIDAR, C. M. SMITH, R. A. D. BATHGATE, S. MA;
The Florey Inst. of Neurosci. and Mental Hlth., Parkville, Australia

Abstract: The brainstem *nucleus incertus* (NI) contains a highly-conserved population of GABA/peptide projection neurons in rodent, primate (and human) brain, and studies in rats and mice suggest their putative roles in control of stress, arousal and emotion- and motivation-related behaviors [see Ma S, Gundlach AL. J Neuroendocrinol 27, 457-67, 2015]. Evidence for these functions includes observations that the rat NI receives strong CRF/CRF1 receptor signals [Ma S et al. J Physiol 591, 3981-4001, 2013], and an orexinergic innervation from lateral hypothalamus and strong OX2-mediated activation [Blasiak A et al. Neuropharmacology 99, 432-47, 2015; Sabetghadam A et al. this meeting]. Similarly, chemogenetic activation of rat NI networks with an excitatory DREADD produced sustained, heightened arousal, and increased locomotor activity and vigilance [Ma S et al. Brain Struct Funct, in press].Therefore, the aim of our ongoing studies is to further characterize the functional neuroanatomy of the NI and the nature of its

neural targets in key circuits such as the septohippocampal system, basal forebrain and prefrontal/cingulate cortex, and limbic hypothalamus and thalamus; in relation to the impact of alterations in NI and relaxin-3 neuron activity and signaling on specific behaviors. In viral-based anterograde neural tract-tracing studies, we identified strong projections ascending to major midbrain, tectal, hypothalamic, thalamic, septal and cortical regions, and descending outputs to vestibular, oculomotor and autonomic centers. Quantitative analysis of comparative immunohistochemical studies of the rat NI, confirmed that the majority of neurons in the NI are GABAergic, of which ~50% produce relaxin-3; and identified a separate group of cholecystokinin-positive GABAergic neurons that lack relaxin-3. In an important discovery, relaxin-3 NI neurons were demonstrated to exclusively express TrkA, the high-affinity receptor for nerve growth factor (NGF). We also assessed the relative proportions of NI neurons delineated by calcium-binding proteins, calbindin and calretinin. Further immunohistochemical studies identified close contacts between relaxin-3-positive fibres and populations of somatostatin- and NGF-positive neurons in hippocampus (CA1, CA3, dentate gyrus). These findings emphasize the functional diversity of NI neurons and identify a key relationship between relaxin-3 and NGF/TrkA signaling systems, with implications for our understanding of how these GABA/peptide neuronal networks regulate cognitive processing, in relation to optimal levels of arousal, attention and motivation, under normal and pathological conditions.

Title: Attenuated hippocampal CA1 pattern reactivation and replay in rats with medial entorhinal cortex lesions

Authors: *A. CHENANI[1], M. SABARIEGO[2], M. I. SCHLESIGER MACLAREN[2], J. K. LEUTGEB[2], S. LEUTGEB[2,3], C. LEIBOLD[1,4];

Abstract: During awake immobility and slow wave sleep, CA1 cell populations are active during brief bursts. The spiking of multiple cells within these bursts resembles sequences that correspond to place field sequences during running on a track or in a maze. Some of the events that correspond to those in behavior are already detectable before the beginning of a behavioral session (preplay), but corresponding events are generally most frequent during the period after a behavioral session (replay). The highly organized spontaneous hippocampal activity patterns during immobility and sleep are generally thought to reflect intrinsic hippocampal synaptic connectivity, and whether they are shaped by experience during behavior on the track or reflect innate intra-hippocampal wiring is currently debated. We previously reported that MEC-lesioned rats exhibit temporally disrupted place field firing, i.e. largely a loss of phase precession and pairwise correlation. Since such timing cues are assumed to be a main driving force for synaptic plasticity in vivo, we assumed that experience-dependent alterations of the synaptic matrix would be impaired in these lesioned rats. To test this hypothesis, we recorded hippocampal neuronal activity during sleep before and after running on a track or a figure-8 maze in control rats and in rats with extensive bilateral lesions of the medial entorhinal cortex (MEC). As previously reported, control rats displayed numerous events that correspond to maze trajectories, in particular during the sleep session after behavior, as measured by correlation to a template sequence of place fields. In rats with MEC lesions, we found that sequence replay was still significantly present but was strongly reduced compared to control rats. Furthermore, average activation of neuronal assemblies was measured by weighted projections to the significant principal components of the population vectors. Among rats in the control group, average assembly activation was higher in sleep following rather than sleep preceding the linear track sessions; such an increase was not observed in any of the lesioned rats. Our findings show that sequence replay and assembly reactivation strongly but not exclusively depend on intact MEC inputs.

Title: Functional characterization of recurrent networks within superficial layers of the medial entorhinal cortex

Authors: *I. ZUTSHI[1], M. FU[1], G. DE GUIA[1], V. LILASCHAROEN[1], J. K. LEUTGEB[1], B. K. LIM[1], S. LEUTGEB[1,2];
[1]Neurobio. Sec. and Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UC San Diego, La Jolla, CA; [2]Kavli Inst. for Brain and Mind, La Jolla, CA

Abstract: Spatial memory and navigation are thought to depend on the location-selective firing of various spatially modulated cell types, including grid cells. Grid cells are most abundant in the superficial layers (layer II, III) of the medial entorhinal cortex (mEC). Because of this overrepresentation in layers II and III, most theoretical models assume that local microcircuits within the superficial layers contribute to the generation of grid patterns. We therefore first characterized the extent of anatomical connections within the superficial layers of the mEC. Using anterograde and retrograde viral tracing techniques, we demonstrated that there is substantial anatomical excitatory connectivity between layer II and III and within layer II of the mEC, in particular within modules along the dorso-ventral axis. Next, we determined the effects of manipulating layer II pyramidal cells onto other cells within the superficial cell layers. To selectively target the mEC layer II pyramidal cells, we used a transgenic mouse line expressing cre recombinant protein under the wolfram syndrome 1 (*wfs1*) promoter and expressed channelrhodopsin in these cells. By manipulating *wfs1*+ cells while performing *in vivo* single-unit recordings in freely moving mice, we confirmed that there is both excitatory and inhibitory functional connectivity within the superficial layers. We also confirmed that both wfs1+ and wfs1- cells heterogeneously include non-spatial cells, spatial cells and grid cells, consistent with previous reports that there is no direct correspondence between known anatomical and functional cell classes. Based on these results, we sought to address to what extent the local connectivity of *wfs1*+ cells contributes to the emergence of grid cell firing patterns. Optogenetic manipulation of

wfs1+ cells gave rise to instant synchronous activation followed by a sustained inhibition across the majority of cells within the superficial mEC layers. Surprisingly, this broad local inhibition within the mEC had no effect on the spatial firing patterns of grid cells. These results suggest that while recurrent circuits exist within superficial layers of the mEC, such connectivity might not be necessary to support spatial representations. Instead, afferent projections to the superficial layers might already contain critical information that is sufficient to give rise to grid cell firing.

Title: Reorganization of the medial entorhinal spatial map is not a prerequisite for hippocampal global remapping

Authors: M. I. SCHLESIGER MACLAREN[1,3], B. L. BOUBLIL[1], J. B. HALES[4], J. K. LEUTGEB[1], *S. LEUTGEB[1,2];
[1]Neurobio. Section, [2]Kavli Inst. for Brain and Mind, UCSD, La Jolla, CA; [3]Dept. Biol. II, Ludwig-Maximilians-Universität München, Martinsried, Germany; [4]Dept. of Psychological Sci., Univ. of San Diego, San Diego, CA

Abstract: A large number of everyday experiences can be stored in memory without interference between these memories. The core circuitry for such a large-capacity episodic memory system includes the hippocampus and the medial entorhinal cortex (mEC). One of the key functions of this circuitry is the rapid generation of neuronal representations that are highly distinct from those for previously acquired memories, a process referred to as pattern separation. For contexts with minor differences, pattern separation depends on intra-hippocampal processing. Distinct contexts, in contrast, are distinguished by reorganized spatial maps in the mEC, which are thought to mediate the orthogonalization of spatial maps in hippocampus. This process is referred to as global remapping. Because changes in medial entorhinal firing patterns are concurrent with hippocampal global remapping, it was hypothesized that computations in the

mEC are a prerequisite for the formation of distinct hippocampal maps. In support of this theory, it was recently found that the partial, acute inactivation of the mEC induced remapping in the hippocampus (Miao et al., 2015; Rueckemann et al., 2016). However, while these data demonstrate that changing mEC input is sufficient to trigger hippocampal remapping, it remains unknown whether mEC is necessary to perform this function. To address this question, we performed bilateral, excitotoxic lesions of the mEC and recorded hippocampal neural activity as rats explored a familiar and a novel environment. We found that highly distinct spatial maps emerged rapidly after exposure to a novel environment, in both control rats (CON) and rats with extensive lesions of the superficial layers of mEC. Consistent with global remapping in both groups, the maps were randomly reorganized between rooms (median spatial correlation, CON: -0.04, mEC lesion: -0.09, chance: -0.03, all P-values ≥ 0.35), and similarity between rooms was much lower than baseline, which was established by repeated recording sessions within the same room (CON: 0.89, mEC lesion: 0.65, all P-values < 0.001). Importantly, global remapping across rooms was found to be intact in each mEC-lesioned rat, even in individuals with no detectable sparing of the superficial layers. Our findings suggest that the emergence of distinct hippocampal maps does not require inputs from specialized cell types in the mEC. Alternative pathways that may support the generation of distinct hippocampal maps include the lateral entorhinal cortex and/or the medial prefrontal cortex, both of which have been shown to distinguish between different contexts.

Title: Optogenetic stimulation of parvalbumin neurons in the medial septum paces theta frequency and disrupts spatial memory

Authors: *C. R. QUIRK, M. K. WRIGHT, D. F. PARSEY, G. L. DE GUIA, J. K. LEUTGEB, S. LEUTGEB;
Neurobio. Sec. and Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UC San Diego, La Jolla, CA

Abstract: The hippocampus and medial entorhinal cortex (MEC) exhibit prominent oscillations in the theta range with a frequency of approximately 6-10 Hz during movement. Theta oscillations have been hypothesized to coordinate the precise timing of cell assemblies in the hippocampus and MEC and have been suggested to support episodic memory. Inactivating the medial septal area (MSA) results in a substantial reduction of theta amplitude in the hippocampus and MEC and in substantial impairment of hippocampus-dependent memory. These findings indicate that MSA plays a key role in generating theta oscillations as well as the precise spike timing that supports memory processing. We therefore asked whether offsetting the timing by manipulating the oscillation frequency would result in memory deficits. To gain control over theta, we manipulated the medial septal parvalbumin-expressing GABAergic (PV) cells. During endogenous theta generation, PV cells discharge in rhythmic bursts that are phase locked to theta frequency. To gain control over the discharge frequency of these cells, we used a cre-dependent viral vector (AAV.EF1a.DIO.ChR2.eYFP) to selectively express channelrhodopsin (ChR2) in PV cells in MSA of PV-cre mice. We then performed LFP recordings in the MEC to confirm that rhythmic stimulation of PV cells in MSA directly controlled the frequency of theta oscillations in MEC. The stimulation reliably elicited oscillations within the endogenous theta frequency range (e.g., 8 and 10 Hz) as well as outside the normal range (e.g., 12 and 20 Hz). Moreover, this stimulation protocol did not only allow for temporal control of theta but was also immediately reversible. To address the functional role of theta oscillations in memory, mice were trained on a spatial alternation task in which animals alternated between left and right sides of a figure-8 maze. On a subset of trials the animals ran continuously between left and right arms whereas in additional trials a 2-s or 10-s delay was imposed on the central arm. Once animals reliably performed each task (>80 % correct), optogenetic stimulation occurred on half of trials on alternating blocks. Stimulating at 10, 12, and 20 Hz significantly impaired performance on 2-s and 10-s delay trials compared to no stimulation in the same subjects. Control green stimulation, which weakly activates ChR2 did not impair performance in the task, suggesting the impairment was not a result of perturbation of behavior by light. These results demonstrate a functional role for endogenously paced theta oscillations in memory and that minor disruptions in the timing of oscillations are sufficient to cause a memory impairment as severe as a hippocampal lesion.

Abstract: Alzheimer's disease is a neurodegenerative disorder characterized by progressive mnemonic deficits. In humans, synapse and neuron loss is pronounced in the hippocampal formation, a region known to have an essential role for spatial learning and navigation. Transgenic mice that over-express human amyloid precursor protein specifically in CA3 pyramidal cells (CA3-3xTg) were used a model to investigate how amyloid-beta induced dysfunction of synaptic plasticity at Schaffer-collateral synapses affects hippocampal circuits and how this relates to spatial memory deficits. To test for memory deficits, we performed a spatial alternation task on a figure-8 maze with either no delay or brief delays (i.e., 2s or 10s) at the beginning of the center alley. The delay period is known to make the task dependent on hippocampal function while the continuous version is not hippocampus dependent. In 15-18 months old CA3-3xTg animals, we observed a decrease in the number of correct trials in only the hippocampus-dependent versions of the task. In order to understand changes in network function that may underlie this behavioral phenotype, we recorded local field potentials before, during, and after the spatial alternation task in CA3-3xTg mice and control littermates. In LFP recordings from CA1, we assessed the frequency and structure of sharp-wave ripple events (SWRs) during rest and behavior. SWRs are high frequency oscillations that are generated by the CA3 autoassociative network and are believed to support memory consolidation. We hypothesized that changes in SWRs could serve as a potential mechanism underlying cognitive impairments observed in CA3-3xTg mice. In control mice, SWR frequency during quiet restfulness is low before and increased after behavioral testing. In contrast, CA3-3xTg mice already showed elevated SWR frequency preceding the behavioral task and there was no additional task-related increase after behavior. We have also investigated spatial and temporal

firing patterns of hippocampal CA1, CA3 and DG neurons in order to complete our understanding of the effect of amyloid-beta induced toxicity on hippocampal processing. Taken together, our data indicate that synaptic toxicity restricted to CA3 results in substantial hippocampal network dysfunction and in impaired hippocampus-dependent behavior.

Title: Bridging discontinuous events without hippocampus or medial entorhinal cortex: a behavioral and a physiological evaluation

Authors: ***M. SABARIEGO**[1], B. L. BOUBLIL[1], S. AHMADI[1], A. SCHONWALD[1], S. ACOSTA[1], J. K. LEUTGEB[1], R. E. CLARK[2,3], S. LEUTGEB[1,4];

Abstract: The medial entorhinal cortex (MEC) projects directly to the hippocampus and is thought to be the key source of spatial and temporal information to hippocampal place cells. However, it remains unclear to what extent the spatial and temporal firing patterns in MEC are necessary for memory-guided behavior. We hypothesize that a primary function of MEC is to generate the temporal organization of hippocampal firing which could bridge gaps between discontinuous events. To test this, rats with either a hippocampal lesion, an MEC lesion, a double-lesion (hippocampus and MEC) or a sham lesion were trained to perform a continuous spatial alternation task in which the animals alternated between left and right sides of a figure-8-maze to receive reward. After animals reached criterion, blocks of trials were introduced with 2-second, 10-second, and 60-second delays. All groups performed similarly during the trials without delay, but when a delay was imposed, the lesion groups made significantly more errors. After further training, the single lesion groups improved their performance with short delays (2

and 10-seconds) but showed a long-lasting impairment under the 60-second condition. Double-lesions prevented the partial recovery in the short delay conditions and promoted a different pattern of response, specifically during long delays, in which these animals exhibited a tendency to continue choosing one side of the maze even if the task required them to alternate. Recordings of hippocampal single units and local field potentials were performed during the spatial alternation task to investigate the mechanisms that could support the spared memory function in MEC-lesioned rats. Our results demonstrated that hippocampal spatial firing was detectable in MEC lesioned animals, but that the spatial firing was less consistent than in controls, similar to what we previously reported in tasks without memory demand. Taken together, these results suggest that even a highly degenerated hippocampal code can be used to partially support short-term memory and prevents maladaptive strategies such as perseveration on response options that no longer produce a desired outcome.

Title: Role of the medial entorhinal cortex in odor sequence learning in rats

Authors: ***J. B. HALES**, L. L. BENSTER, P. J. BRESLIN, A. CAMACHO, T. A. J. W. FISHER, A. E. MORSE;

Abstract: The hippocampus is critically involved in processing both spatial and temporal aspects of memory. Although spatially selective cells, known as place cells, were first discovered in the hippocampus in the 1970s (O'Keefe and Dostrovsky, 1971), recent studies have also reported the existence of temporally selective cells in the hippocampus, known as time cells (MacDonald et al., 2011). In the adjacent cortical area of the medial entorhinal cortex (MEC), spatial memory processing and spatially selective neuronal firing have been reported (Steffenach et al., 2005; Hales et al., 2014). However, the involvement of the MEC in temporal aspects of memory processing are less understood. A recent study reported that MEC lesions substantially disrupt theta phase precession in the hippocampus, suggesting the involvement of the MEC in temporal

organization of hippocampal firing patterns (Schlesiger et al., 2015). In order to directly examine the involvement of the MEC in temporal memory processing, we adapted an odor sequence learning task in rats, which has previously been shown to be dependent on the hippocampus (Fortin et al., 2002). Rats with either complete bilateral excitotoxic lesions of the MEC or sham lesions are presented with sequences of 5 odors. Following a 3 minute delay, a sequential order test probes memory for which of the two odors was presented earlier in the sequence. An odor identity test probes item memory by comparing an odor from the sequence with an odor that was not in the sequence. Memory for sequential order, but not odor identity, has previously been shown to depend on an intact hippocampus (Fortin et al., 2002). Results on both memory tasks will be discussed in terms of MEC involvement in temporal aspects of memory processing.

Title: Dopamine D2-type receptors in the dorsal hippocampus mediate social learning in female but not male mice

Authors: *R. MATTA, E. A. UNDERWOOD, Z. K. LEACH, A. C. VERTES, V. ATABAKHSH, M. B. DA SILVA, E. CHOLERIS;
Dept. of Psychology and Neurosci. Program, Univ. of Guelph, Guelph, ON, Canada

Abstract: Dopamine (DA) is involved in mediating motivationally relevant behaviors such as drug/alcohol addiction, food intake, and social behaviors. Previous work in our lab using systemic treatments has shown that D1-type (D1/D5) DA receptors are involved in social learning, whereas D2-type (D2/D3/D4) DA receptors are involved in feeding behavior in the social transmission of food preferences (STFP) in mice (Choleris *et al*, 2011). The ventral tegmental area (VTA) has DAergic projections to numerous limbic sites, including the septum, amygdala, nucleus accumbens, and hippocampus. In particular, the hippocampus has been previously established as an important structure in mediating the STFP. Work in our lab has shown that blocking D1-type DA receptors in the dorsal hippocampus impairs social learning in the STFP in both male and female mice (Matta and Choleris, 2014). In this study, we

investigated the role of D2-type DA receptors in the dorsal hippocampus in the STFP. We microinfused the D2-type DA receptor antagonist Raclopride (at 10, 14, 18 or 20 μg/μL) directly into the dorsal hippocampus of male and female CD-1 mice (young adults) 10min before a social interaction (where social learning occurs) with a same-sex conspecific. We found that Raclopride at 10, 18 and 20 μg/μL blocked social learning in female, but not male mice. Furthermore, the social learning impairment could not be explained by any secondary effects on feeding, since total food intake was unaffected by drug treatment. Moreover, an olfactory discrimination task using the two highest doses of Raclopride that also blocked social learning (at 18 and 20 μg/μL) showed that the social learning impairment could not be directly explained by any changes in olfaction. Thus, the female effects of dorsal hippocampal D2-type DA receptor blockade may have been specific to social learning. Our study is also attending to effects of drug treatment on various social and nonsocial behaviors during the social interactions, and possible effects of gonadal hormones. Thus, DA in the hippocampus promotes social learning differently in males and females: in males it acts through only D1-type DA receptors, whereas in females it acts through both D1-type and D2-type DA receptors.

Title: Interactions between the dorsal and ventral hippocampus and the nucleus accumbens during adaptive spatial reward learning

Authors: *M. SOSA[1], H. R. JOO[1], L. M. FRANK[2];
[1]Neurosci. Grad. Program, Kavli Inst. for Fundamental Neurosci., [2]HHMI, Kavli Inst. for Fundamental Neurosci. and Dept. of Physiol., Univ. of California, San Francisco, San Francisco, CA

Abstract: The brain's ability to associate experiences with subsequent rewards is fundamental to learning and memory, yet the neural substrates of this process are only partially understood.

Substantial evidence points to the hippocampus (HPC) and nucleus accumbens (NAc) as constituents of a critical neural circuit for spatial reward learning. A candidate mechanism for strengthening spatial-reward associations is the hippocampal sharp-wave ripple (SWR), a network event that reactivates sequences of hippocampal place cells in a manner that often recapitulates prior experience. Previous work has shown that in sleep following behavior, some NAc cells are reactivated coincidentally with hippocampal SWRs, but it remains unclear how the representations of these NAc cells relate to the learned experience. Furthermore, prior studies focused on the dorsal hippocampus (dHPC), while the ventral hippocampus (vHPC) exhibits the most direct anatomical projection to the NAc and may be critical for adaptive behavior. We therefore sought to understand how interactions between the dHPC, vHPC, and NAc support flexible, spatially guided reward learning. We recorded simultaneous single unit activity and local field potentials from these three regions in awake, behaving rats learning a spatial working memory task with changing reward contingencies. We found that NAc neurons represented various task elements including reward, were often spatially modulated, and could adapt their firing patterns with the changing reward contingencies. Moreover, NAc neurons with distinct firing patterns were differentially engaged by dHPC and vHPC SWRs during both awake immobility and sleep. Our findings indicate that the HPC engages a heterogenous population of NAc neurons at the precise time of SWRs, and that the SWR-related activity in the NAc may reflect distinct types of spatial and task associations reflective of dHPC and vHPC input.

Abstract: The hippocampus and the prefrontal cortex (PFC) are critical for transforming representations of experience into memories but the specific nature of the experiences that form memories remains unclear. The hippocampus maintains spatial representations of experience. During locomotion, hippocampal place cells with discrete place fields are activated sequentially as an animal moves through space. Previous work has shown that these sequential patterns reappear during hippocampal sharp wave-ripples (SWRs), which are hypothesized to support storage and recall of memory. Recently, our laboratory demonstrated that a distinct set of place cells signal spatial location during immobility. Whether these representations of experiences that occur during immobility are stored and reactivated during SWRs and how they manifest in the PFC is unknown. We simultaneously recorded from multiple single neurons in the prefrontal cortex and the hippocampus of awake, behaving rats to examine the interactions between these structures. We first found that immobility place cells do participate in SWRs, but strikingly, these SWRs tend not to engage place cells that are active during locomotion. Moreover, these two distinguishable patterns of reactivation are also seen in the PFC. Individual PFC cells show changes in firing rate during SWRs, but they are modulated differently depending on whether the hippocampal SWR reactivates representations associated with locomotion or immobility. These findings suggest experiences associated with states of locomotion and immobility are encoded as discrete and distinct types of memories in the hippocampal-cortical network.

Title: Scoring sequences of hippocampal activity using hidden Markov models

Authors: *E. ACKERMANN[1], K. MABOUDI[2], K. DIBA[2], G. PEZZULO[3], M. VAN DER MEER[4], C. KEMERE[1];
[1]Electrical and Computer Engin., Rice Univ., Houston, TX; [2]Dept. of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [3]Inst. of Cognitive Sci. and Technologies, Rome, Italy; [4]Dept. of Psychological & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Much is still unknown about the mechanisms underlying learning and memory, as well as the functional significance of associated hippocampal replay sequences. There is strong evidence supporting the roles of these replay sequences in a number of cognitive functions, including memory consolidation and behavioral planning. However, a statistical understanding of replay events is still lacking.
Here, we extend our previous work on using hidden Markov models (HMMs) for the sequential analysis of neural data in a number of ways. First, we introduce a novel two-component sequence score which decouples the sequential and contextual information, leading to an elegant and effective way to discriminate sequentially consistent patterns of neural activity from putative 'noise'. Moreover, we show how we can use this score to identify the underlying context and behavioral state of an animal more effectively than using the log probability for a sequence in the model directly.
Second, we show that the model leads to behaviorally relevant and interpretable results for a wide range of model parameters, so that the problem of model selection is mitigated significantly. This is especially important in the context of hippocampal replay, where behavioral correlates are not available; in the absence of behavioral correlates, we necessarily have to rely more heavily on the model to reveal underlying patterns of sequential information.Third, we discuss a number of possible approaches to order and interpret the virtual place fields learned by the model, including orderings and state associations suitable for both linear and nonlinear (or generalized) environments.
Finally, we present some preliminary results when using HMMs for online sequential analysis of long continuous recordings of neural activity. The analysis of such long duration recordings is particularly important for a more comprehensive understanding of replay content. Indeed, replay is expected to occur throughout the day, presumably representing recent, past, distant past, and never-before-experienced experiences (such as shortcuts to reward locations), yet existing analyses of replay have mainly considered recording sessions shortly before and after short term (approximately one hour) behavioral experiments. As a consequence, much of what has previously been labeled as 'noise' might in fact be consistent with past experience, and analyzing long term chronic recordings of the animal's past promises to help us understand the content and statistical characteristics of replay events.

Title: A cortical-hippocampal-cortical loop of information processing during memory consolidation

Authors: *G. ROTHSCHILD[1], E. EBAN[2], L. M. FRANK[1,3];
[1]Kavli Inst. for Fundamental Neurosci. and Dept. of Physiol., UCSF, San Francisco, CA;
[2]Google Inc., Mountain View, CA; [3]Howard Hughes Med. Inst., San Francisco, CA

Abstract: The hippocampus is critical for forming memories of daily life events, but over time these memories can become independent of the hippocampus[1-3]. The dominant model for this memory consolidation process posits that following rapid memory encoding in the hippocampus, repeated reactivation of hippocampal representations during sleep transfers information from the hippocampus to the cortex for long term storage[4-7]. This unidirectional information transfer is thought to be driven by sharp wave ripple (SWR) events[7-14], which mark periods of coordinated reactivation in hippocampus and cortex[15-19] and have been shown to directly support learning[20-22]. SWRs are generated in the hippocampus[23-25], drive excitatory responses in cortical target regions[25], and modulation of cortical neural activity has been reported to follow SWRs[15-18,26], consistent with unidirectional hippocampus to cortical information transfer. However, some observations are hard to reconcile with this model, including demonstrations that modulation of cortical activity can also precede SWRs[27,28], and that sensory stimulation can bias SWR content[29]. Thus, the direction of information flow between the hippocampus and cortex underlying memory consolidation remains unclear. Here we show that during sleep, the cortex leads a rapid cortical-hippocampal-cortical loop of information flow. We simultaneously recorded neural activity in the auditory cortex (AC) and the hippocampal CA1 region of rats as they learned a sound-guided task and during interleaving rest sessions. We examined the structure of cortical and hippocampal activity during sleep and found that reactivation in AC precedes and predicts the subsequent content of hippocampal activity during SWRs, while hippocampal patterns during SWRs predict subsequent cortical activity. Furthermore, delivering

sounds during sleep biased AC activity patterns, and sound-biased AC reactivation predicted subsequent CA1 activity, providing a potential mechanism for sensory-stimulation-biasing of memory during sleep[29-33]. These findings indicate that the reactivation of specific cortical representations during sleep could be a critical determinant of which memories are consolidated into long term stores.

Title: Characterization of hippocampal replay across learning

Authors: ***X. DENG**[1], D. F. LIU[2], M. P. KARLSSON[3], L. M. FRANK[4], U. T. EDEN[1]; [1]Mathematics and Statistics, Boston Univ., Boston, MA; [2]UC Berkeley - UCSF Grad. Program in Bioengineering, [3]UCSF, San Francisco, CA; [4]Dept. of Physiol., HHMI, Kavli Inst. for Fundamental Neuroscience, UCSF, San Francisco, CA

Abstract: Hippocampal replay events are thought to play an essential role in learning and memory. Individual replays can contain spiking patterns that reflect different categories of spatial trajectories, including sequences that are replayed in either a temporally forward or reverse order and sequences that can represent either the current environment or a previously experienced and spatially distinct environment. We also know that novelty, spatial learning and reward can modulate the prevalence of replay, but how these factors influence the direction and content of replay remains unclear.
We therefore developed a new statistical paradigm to categorize the content of hippocampal replays using a decision state point process filter. This filter simultaneously estimates the spatial

representation being replayed as well as the direction of movement and the spatial context. Here we apply this paradigm to classify the replay events of rats learning two novel spatial alternation tasks. We explore multiple different binary decision states, including the direction of movement and the local or remote nature of the representation. Our analyses allow us to characterize the frequency of specific types of replay events across specific phases of learning.

Title: Low latency, multichannel sharp-wave ripple detection in a low cost, open source platform

Authors: ***S. DUTTA**[1], C.-T. WU[2], D. LIU[4], M. KARLSSON[8], L. FRANK[5,6,7], M. VAN DER MEER[9], D. JI[2,3], C. KEMERE[1,2];
[1]Electrical and Computer Engin., Rice Univ., Houston, TX; [2]Neurosci., [3]Mol. and Cell. Biol., Baylor Col. of Med., Houston, TX; [4]Bioengineering, [5]Howard Hughes Med. Inst., [6]Kavli Inst. for Fundamental Neurosci., [7]Physiol., Univ. of California San Francisco, San Francisco, CA; [8]SpikeGadgets, LLC., San Francisco, CA; [9]Psychology & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Sharp-wave ripples (SWR) are brief bursts of ~200 Hz oscillations in the local field potential in area CA1 of the hippocampus that co-occur with dense bouts of ensemble spiking. SWR and the concomitant neural activity are associated with aspects of memory consolidation, recall, and memory-guided decision making. Temporally-specific silencing of hippocampal activity triggered by online detection of SWRs has been shown to have significant effects on memory consolidation and working memory. However, the real-time signal processing systems used to perform these experiments have been challenging to implement and inaccessible to many

researchers. Here, we present a ripple-detection module written for an open-source software platform (Trodes - https://bitbucket.org/mkarlsso/trodes). In conjunction with low-cost open-source hardware (OpenEphys - http://www.open-ephys.org, < $5K) or a pre-packaged commercial solution (SpikeGadgets - http://www.spikegadgets.com, < $15K). We achieve low latency SWR detection across multiple electrodes during ongoing neural recording experiments. Our analysis of SWR detection for real and synthetic data makes clear that the latency and accuracy of any SWR detection system are jointly limited at a fundamental level, with minimal latency of ~40-60 ms. Using a synthetic "gold-standard" data set, we demonstrate that our online open-source system can achieve accurate detection with limited additional latency (~10-15 ms), with even lower values achievable using the same module with our commercial hardware. Finally, we describe how our module can be extended to further include other information such as behavioral traces or multiunit activity in the SWR detection process. At < $5K for 32 channels of neural activity, this is a cost effective and simple approach for researchers seeking to add this experimental technique to their studies. In general, we anticipate that the use of modular signal processing blocks will significantly facilitate the dissemination of causal/closed-loop experimental techniques that represent the frontier of systems neuroscience experiments.

Title: Replay detection: a comparison between hidden Markov models and existing approaches

Authors: *K. MABOUDI ASHMAN KAMACHALI[1], E. ACKERMANN[2], H. MIYAWAKI[1], C. KEMERE[2], K. DIBA[1];
[1]Psychology, Univ. of Wisconsin Milwaukee, Milwaukee, WI; [2]Electrical and Computer Engin., Rice Univ., Houston, TX

Abstract: Formation of memory of a behavioral experience is facilitated through reactivation of neural ensembles representing that experience. Reactivation of place cells in the hippocampus following a behavioral experience have been widely studied. As the animal runs across a field, the associated place cells become active in a sequential manner. It has been shown that these sequences frequently re-occur in a time-compressed manner (so-called replay) during rest and sleep. Detection of these replay events and the extent to which their expression changes during sleep can reveal the dynamics of memory processing. Therefore, a reliable method of replay detection is of special importance. Different methods have been recruited so far to detect replay events, including rank-order correlation, template matching, and Bayesian decoding. Recently, a hidden Markov model (HMM) based approach has been proposed as another alternative. Using this model, it is assumed that temporal patterns of population activity reflect a number of underlying states and transitions between them. In the case of replay, these states most likely correspond to virtual places. Using HMMs for replay detection is promising because existing methods need explicit external position information along with the neural activity during behavior to detect replay events. However, HMMs allow for the detection of replay even when no explicit position information is available. In a preliminary analysis, we trained an HMM on behavioral data and evaluated its performance in replay detection. We found that the performance of the HMM for the detection of visually verified replay events is comparable to existing methods, and moreover, in some cases of noisy replay events, the new method outperformed others. Here, we will do a comprehensive analysis of the benefits and limitations of the HMM based approach in comparison with existing approaches.

Title: Cellular mechanisms of sparse coding in hippocampal granule cells

Authors: M. P. CHRISTENSON[1], *C. SCHMIDT-HIEBER[2], H. WEI[3], M. HAUSSER[1]; [1]Wolfson Inst. for Biomed. Res., [2]Univ. Col. London, London, United Kingdom; [3]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The hippocampus must form distinct neuronal representations of memory items in order to differentiate efficiently between similar events. Granule cells of the dentate gyrus, the first stage of the hippocampal circuit, have been proposed to perform this task in a process termed pattern separation. It is unclear how synaptic input patterns are decorrelated and converted into sparse action potential output during this process. To address this question, we performed whole-cell patch-clamp recordings from mature hippocampal neurons in head-restrained mice navigating in a virtual-reality environment. Granule cells depolarized by ~3 mV during running periods, with depolarization preceding running by up to 1.5 s. Membrane potential and running speed were tightly correlated, suggesting that granule cells may receive speed-modulated synaptic inputs. Voltage-clamp recordings revealed that mean excitatory current input increased during running, while the frequency of large multicomponent EPSCs decreased. To try to trigger plasticity, we used theta-burst current injections (5 100-ms current injections at 5 Hz). Following the induction protocol, we observed a persistent hyperpolarization of membrane potential by ~3 mV lasting up to 90 s. The extent of hyperpolarization was positively correlated with the number of evoked action potentials during theta-burst current injections. While most granule cells were silent throughout the recording duration, spatial modulation of firing could be induced by near-threshold sustained current injections, similar to previous findings in CA1 pyramidal cells (Lee et al., 2012). Unlike in CA1 pyramidal cells, spatial modulation was highly sensitive to depolarization, with the number and location of firing fields depending on the sustained current injection amplitude. Our results indicate that granule cells receive desynchronized, yet spatially specific inputs during navigation, and their output is sensitive to small changes in excitatory drive. Moreover, granule cells are suppressed in an activity-dependent manner, which may help sparsify the population activity and orthogonalize output patterns.

Title: Biologically realistic spiking model of hippocampal circuitry for enhanced machine learning

Authors: *D. J. HAMILTON, D. W. WHEELER, S. VENKADESH, K. MORADI, C. L. REES, G. A. ASCOLI;
Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: The hippocampus is a highly conserved architectural component of the mammalian brain that has evolved to perform associative learning tasks. It stands to reason that the field of machine learning, which historically has utilized multi-layered artificial neural networks and, more recently, "Deep Learning" to characterize large datasets, will benefit from exploiting specific organizational and functional principles garnered from hippocampal circuitry. Using knowledge available in Hippocampome.org, it is now possible to construct spiking neural network (SNN) models of the rodent hippocampus. This highly curated open-access resource defines hippocampal neuron types primarily based on axonal-dendritic patterning and is informed through dense coverage of peer-reviewed literature, which documents experimental evidence. Upon the foundation of these neuron types, we layer information about connectivity, intrinsic electrophysiology, input/output firing pattern relations, and molecular markers that allow us to derive a biologically realistic SNN model of the hippocampal formation. We then attempt to leverage known hippocampal circuit functionalities, such as pattern separation and auto-association, to improve the generalization ability of SNNs for machine learning. The specific application selected to vet this approach and to frame-out the computational infrastructure is automated literature mining. Since we have ready access to thousands of manually reviewed articles from local lab-based neuroinformatic literature mining efforts, we can harness their associated "ground truth" for training and testing. Through improved automated analytics leveraging biologically realistic circuitry, we strive to enhance machine learning for the advancement of science.

Title: Large-scale genetic profiles of hippocampal principal neurons through Allen Brain Atlas mining

Authors: D. J. HAMILTON, C. M. WHITE, C. L. REES, D. W. WHEELER, *G. A. ASCOLI; George Mason Univ., Fairfax, VA

Abstract: Neurons are typically classified based on their morphological, molecular, and electrophysiological properties, but rarely by combining all three of these dimensions. The open-access online knowledge base Hippocampome.org primarily defines neuron types from the rodent hippocampal formation based on their main neurotransmitter (glutamate or GABA) and the locations of their axons and dendrites across canonical sub-regions and layers (e.g. CA1 statum oriens or entorhinal layer 2). Any and all published information regarding biomarker expression (and several electrophysiological features) that can be linked to identified neuron types is then added along with the supporting experimental evidence. The resulting biochemical profile is relatively sparse: even for the best studied neuron types the expression or absence of fewer than 50 molecules has been firmly established to date. The massive mouse brain gene expression analysis conducted by the Allen Institute provides a wealth of data that when appropriately interpreted can be leveraged to substantially augment the biomarker knowledge in Hippocampome.org. In this study, we restrict the investigation to the principal cell layers of dentate gyrus (DG), CA3, CA2, and CA1, where the vast majority of the neurons are glutamatergic projecting neurons. Thus, Allen Brain Atlas (ABA) in situ hybridization data for those layers can justifiably be linked to the respective principal neuron types (i.e. Granule in DG and Pyramidal in CA3, CA2, and CA1). We filtered the whole-genome expression dataset to maximize consistency with current Hippocampome.org biomarker content. The resulting additional set of expressed/not-expressed genes expands the ~1,100 Hippocampome.org biomarker pieces of knowledge (PoK) by more than an order of magnitude, yielding a considerably more complete genetic characterization of principal neuron types in the mouse hippocampus.

Abstract: Simulation costs of biophysically detailed Hodgkin-Huxley-type neuronal models often impose limits on the scale of biologically realistic network models. However, computationally efficient Izhikevich models have been shown to qualitatively capture many experimentally observed firing-pattern types. *Hippocampome.org* is a knowledge base of neuron types in the rodent hippocampal formation, upon which we aim to build a full-scale model of the hippocampus. One of our immediate modeling goals is to create Izhikevich models that *quantitatively* reproduce various firing-pattern features of hippocampal neuron types. Previously, we developed a systematic approach to classify hippocampal neuron firing patterns and identified more than fifteen firing-pattern classes among 122 morphologically distinguished neuron types. This scheme established criteria for the classification of different firing-pattern types, such as delayed spiking, spiking with frequency adaptation, fast spiking, stuttering, and bursting. By leveraging the optimization capabilities of evolutionary algorithms (EA), we fit Izhikevich model responses to experimentally recorded and algorithmically classified firing patterns. This approach, based on EA, uses feature-based fitness functions, which also incorporate the firing-pattern class definitions. In addition, our Izhikevich models can have more than one compartment depending on dendritic invasion of neuron types across hippocampal layers. This allows layer-level specification of synaptic inputs for a neuron type in our network models. The simplified dendritic compartments are constrained based on their excitabilities and input resistances relative to the somatic compartment and directionally asymmetric spike and subthreshold signal propagation. Several of such multi-compartment models are simulated in parallel on Graphical Processing Units (GPU) in order to expedite the EA optimization process.

Title: Hippocampome.org v1.1: increasing open-access knowledge of neuron types and their properties for the rodent hippocampus

Authors: *D. W. WHEELER, C. M. WHITE, A. O. KOMENDANTOV, C. L. REES, D. J. HAMILTON, S. VENKADESH, K. MORADI, G. A. ASCOLI;
Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Hippocampome.org is an open-access knowledge base of rodent hippocampal neurons types, each defined by the patterns of axonal and dendritic presence across the parcels of the hippocampal formation. In addition to this morphological knowledge, Hippocampome.org also includes information on biomarker expression, electrophysiological properties, and connectivity for all types. The new v1.1 release constitutes a multi-dimensional expansion of this knowledge base. Since the official 2015 launch, continued literature mining has yielded the addition of 20 new neuron types, bringing the total number to 141. Notable new content includes splitting CA1 Pyramidal cells into Superficial and Deep types, due to converging evidence of multiple distinct molecular biomarkers and electrophysiological properties, and the inclusion of Adult-Born Immature Granule cells. We also track several new properties. Neuron types are now characterized by their firing patterns, and we have identified over 20 unique firing patterns. Moreover, we have developed spiking computational models for many of the neuron types contained in the knowledge base. In the biochemical dimension, we have increased molecular-expression pieces of knowledge by 75%, by leveraging inferential evidence, which is based upon experimental observations of systematic if-then logical relationships between the presence or absence of biomarkers. Further gene expression information is derived by mining Allen Brain Atlas in situ hybridization mouse data. Additionally, we have refined the connectivity information between neuron types by expanding the evidence for known synapses (or the lack thereof) in order to confirm or, in rare cases, refute our morphologically-derived potential connectivity calculations, which are based on histological and electrophysiological evidence. Finally, we have made numerous modifications to the web portal to enhance the experience of the user, including an interactive connectivity navigator and a neuron term portal offering definitions of neuron types and properties.

Title: Increasing biomarker information in Hippocampome.org using relational expression inferences

Authors: *C. WHITE, C. L. REES, D. W. WHEELER, D. J. HAMILTON, G. A. ASCOLI; Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: The ability to distinguish neurons based on molecular biomarker expression is a powerful research tool, and systematically linking these biochemical profiles to an established morphological characterization would aid in the investigation of neuronal circuitry. Hippocampome.org provides a web-based resource for bridging the morphological and biomarker-expression domains for neurons in the rodent hippocampal formation. Neuron types are defined in this framework based on their primary neurotransmitter and the presence or absence of axons and dendrites across the layers of subregions CA3, CA2, CA1, subiculum, entorhinal cortex, and dentate gyrus. The first release of Hippocampome.org contained 122 neuron types with specified axonal-dendritic patterns and expression information about 90 biomarkers. The ~850 available molecular pieces of knowledge (PoK) included the expression status of at least one biomarker for 81 neuron types. In the last year, we have augmented this compilation by leveraging published expression relationships between biomarkers to make inferences with calculable confidence. These take the forms of probability positive (neurons that express biomarker 1 are likely to express biomarker 2), probability negative (neurons that express biomarker 1 are likely not to express biomarker 2), and negative layer probability (neuron types with soma exclusively in a layer negative for a biomarker are likely negative). Addition of these inferential interpretations increases the PoK to ~1350 and raises the number of neuron types with information for at least one biomarker to 116 out of 122. Moreover, of the

14,884 pairwise comparisons of the biomarker expression profiles for these 122 neuron types, ~5,800 have different profiles with the inferential data, compared to ~3,600 without them.

Title: Coordinated grid and place cell replay

Authors: *F. OLAFSDOTTIR[1], F. CARPENTER[2], C. BARRY[1];
[1]Cell and Developmental Biol., [2]Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: During exploration, the activity of place and grid cells represent self-location. Together these cells have been hypothesised to support spatial memory and navigation. The re-activation of place cell sequences during immobility and sleep has been proposed as a mechanism for memory consolidation. Yet the role of grid cells in replay remains unknown. We co-recorded grid and place cells while rats ran on a z-shaped track and during subsequent rest. During replay, both on the track and during rest, we found grid cells were spatially coherent with place cells. Importantly, grid-place cell replay coherence was more robust during rest and for replay events depicting place cell sequences in the original (i.e. 'forward' replay) order. Moreover, during these events the grid cell spatial representation lagged that of the place cells by approximately 10ms. Finally, grid-place cell replay coherence evolved with experience, becoming stronger as the track became more familiar. Thus, our study shows close coordination between hippocampal place cells and MEC grid cells during replay, suggesting replay may be a general property of networks encoding self-location. Moreover, these findings support the view that replay is the mechanism by which memories are consolidated to the neocortex.

Title: Measuring marmoset visual recognition memory with eye movements

Authors: *S. U. NUMMELA[1], J. T. WIXTED[2], L. R. SQUIRE[2], C. T. MILLER[2];
[1]Psychology, UCSD, LA Jolla, CA; [2]Psychology, UCSD, San Diego, CA

Abstract: The common marmoset (Callithrix jacchus) is a small bodied New World monkey with the visual specializations common to other primates including a true fovea (Mitchell and Leopold, 2015) that has the stature of a rodent making the animal model potentially powerful for the study and comparison of memory between rodents and primates. Here we present data on marmosets performing a visual preferential looking task (VPLT) that has been used to study recognition memory, the ability to perceive a recently encountered item as familiar, in humans (Wilson and Goldman-Rakic, 1994) and macaques (Jutras and Buffalo, 2010), and is known to rely on the hippocampus (Zola et al., 2000).
Trials of the VPLT were initiated by fixation of a white and black spot (1°) at the center of the display for 0.25 s, followed by an image (10°x10°). The image disappeared when the marmoset's gaze moved off of the image or after a maximum looking time of 5 s. Images were displayed in blocks of 3, 4, or 5 novel images followed by repeating their presentations in a randomized order such that an image was never immediately repeated. No reward was delivered on VPLT trials, however the marmoset was given 12 s to visually forage marmoset faces to earn reward between VPLT blocks and to ensure that gaze position remained calibrated.
Preliminary results from 3 subjects indicate a preference for novel images over familiar ones by a larger amount of time spent looking at novel images than repeated images (average of 2.6 s for novel and 2 s for familiar, $p < .0001$), but this is less separable than comparable data from macaques (2.3 s for novel and 0.8 s for familiar--from Jutras and Buffalo, 2010). This results in marmosets examining novel images for greater lengths of time than familiar images in 67% of instances ($p < .0001$). Nevertheless, this preference is substantially lower than what has been reported in macaques (90%+) and may indicate a stronger stimulus driven component to marmoset eye movement when examining visual scenes.

Title: Dorsal hippocampus is necessary for visual categorization in rats

Authors: *J. KIM[1], E. A. WASSERMAN[1], L. CASTRO[1], V. SLOUTSKY[2], J. H. FREEMAN[1]; [1]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA; [2]Psychology, The Ohio State Univ., Columbus, OH

Abstract: Previous studies suggested that different neural systems mediate visual categorization with stimuli that have dense and sparse defining features. The current study examined the role of the dorsal hippocampus in visual categorization of stimuli with high or low density category-relevant features in rats. Using touchscreen apparatus, we trained rats to categorize multiple abstract stimuli into two different categories. The abstract stimulus was a pentagonal configuration of five visual features. Some of the visual features were relevant for defining the category but the others were irrelevant. Two groups of rats were trained with either high or low category-relevant feature densities (3 vs. 1). Once they reached to a criterion (≥ 75%, in two consecutive days), cannula-implantation surgery was conducted into the dorsal hippocampus. After recovery, rats were given either saline or muscimol infusions into the hippocampus of different testing sessions. They were tested with the previously trained stimuli (old) as well as the different category structures in which either the category-irrelevant features were replaced with novel ones (new), the locations of the category-relevant features were relocated (relocated), or a single category-relevant feature was presented at the center of the configuration (singleton). The results showed that the task is critically dependent on intact hippocampal function. The results also showed that the rate of learning was the same for the high and low density groups. In testing, the accuracy of the density groups was equally high in both old and new conditions. However, the low density group showed more impairment in the relocated and singleton conditions than the high density group. The results suggest that the dependence on both spatial and non-spatial properties of the category-relevant features is influenced by feature density. The hippocampus is necessary for visual categorization regardless of the density of the category-relevant features.

Title: Differential involvement of the perirhinal cortex and postrhinal cortex in different types of visual scene memory tasks

Authors: *E.-H. PARK, J.-R. AHN, I. LEE;
Dept. of Brain & Cognitive Sci., Seoul, Korea, Republic of

Abstract: Visual scene in an animal's background plays critical roles for remembering a contextual event in episodic memory, and we have previously shown that inactivation of the hippocampus impairs such capability in rats. In the current study, we studied whether the perirhinal cortex (PER) and the postrhinal cortex (POR), the two upstream regions of the hippocampus, were differentially involved in the visual scene memory task. Rats (n=4) were trained to choose either left or right arm in association with a scene stimulus in a T-maze. Specifically, a trial started when the animal entered the stem of the T-maze and, at the same time, a visual scene stimulus (among 4 scenes; zebra pattern, pebbles, bamboo, and mountain pictures) was presented via an array of 3 LCD monitors around the T-maze. The rat was required to enter one of the arms in association with the scene to obtain food reward. Once the rat learned the task to criterion, a custom-made cannula complex equipped with guide cannulae coupled with stylets was implanted, targeting PER and POR simultaneously. Post-surgical testing showed that the rat injected with vehicle (artificial CSF) into either PER or POR was not impaired in performance. Afterward, when muscimol (MUS), a GABA-A receptor agonist, was injected in POR, severe behavioral deficits were found ($t_{(3)}$=3.73, $p<0.05$), whereas PER inactivations did not result in any behavioral deficit. Since the task required the animal to choose between different places using the visual scene stimulus, the observed deficits following the POR inactivations could be driven either from the impairment in recognizing the visual scene or from forgetting the association between the scene and spatial choice response. To further test these possibilities, a separate group of animals (n=9) were tested in a modified version of the scene memory task in

which the rat should respond differentially to a common object (sand-filled jar) in association with visual scenes. Specifically, the rat must push the jar to obtain a reward underneath the jar for one visual scene, but had to dig in the sand in the jar when the other visual scene appeared. Note that, compared to the visual scene memory task, this modified version did not require spatial choice behavior, and MUS inactivations in both PER and POR produced significant performance deficits (PER: $t_{(8)}=3.63$, $p<0.01$; POR: $t_{(6)}=4.48$, $p<0.01$). Taken together, our preliminary findings suggest that the POR plays key roles in processing visual scene memory irrespective of response types, whereas the PER may only be involved in processing visual scene memory when ambiguity associated with an object must be disambiguated using the visual scene information.

Title: Pattern separation in the dentate gyrus and its role in temporal lobe epilepsy

Authors: *A. MADAR[1], J. A. PFAMMATTER[1], S. RAVI[1], E. P. WALLACE[1], L. A. EWELL[2], R. MAGANTI[3], M. V. JONES[1];
[1]Neurosci., Univ. of Wisconsin-Madison, Madison, WI; [2]Neurobio. Section, Univ. of California, San Diego, CA; [3]Neurol., Univ. of Wisconsin, Sch. of medicine and public health, Madison, WI

Abstract: The dentate gyrus (DG) is often seen as the gate of the hippocampus, filtering excitatory inputs from the cortex before they reach CA3. The recurrent connections of the CA3 network make it potentially prone to hyper-excitation and the breakdown of the upstream dentate gate has been shown to lead to seizures and to the development of temporal lobe epilepsy (TLE). The filtering properties of the healthy DG are thought to support pattern separation, a neural process that transforms similar input patterns of neural activity into less similar outputs, which would allow the formation of distinct memories of similar events and would prevent confusion between past and present perceptions. Accordingly, patients suffering from TLE not only experience spontaneous recurring seizures but are also often burdened by cognitive deficits such as memory impairments. Yet, no experimental study has established a relationship between TLE and the computational and cognitive roles of the DG.

We hypothesize that the development of TLE is correlated to a breakdown of the pattern separation ability of the DG network, and thus to mnemonic discrimination deficits. To test our hypothesis, we induced status epilepticus (SE) in C57Bl6 mice with intraperitoneal injections of Kainate, an established model of TLE, and compared them with control mice injected with saline. We assess their mnemonic discrimination performances with an adapted version of the "object pattern separation" task[1], based on the novelty recognition paradigm. We measure seizure frequency and severity with video/EEG recordings on each animal. Subsequently, their brains are dissected to assess the DG microcircuit and its computations. On one hemisphere, we use a novel electrophysiological assay in acute brain slices to determine the ability of the DG network to perform pattern separation on cortical activity patterns. On the other hemisphere, we employ immunohistochemistry to capture the extent of micro-circuit pathologies in DG acute slices such as mossy fiber sprouting, aberrant neurogenesis and interneuron loss.
Preliminary results indicate that non-injected wild-type (WT) mice are able to discriminate between a stationary object versus an object moved from its initial position during a first exploration. Additionally, in-slice pattern separation assay in WT mice allowed us to show that the output spike-trains of single DG output cells are less similar with each other than their driving inputs, demonstrating for the first time that the DG performs pattern separation of spike-trains measured at the level of single DG granule cells.

Title: Hippocampal electrophysiological activity during and after trace eyeblink conditioning

Authors: *M. S. NOKIA[1], T. WASELIUS[1], I. GUREVICIENE[1], A. LIPPONEN[1], J. WIKGREN[1], H. TANILA[2], M. PENTTONEN[1];

Abstract: Hippocampus plays a crucial role in associative learning, especially when the task is complex. One such task is the trace variant of classical conditioning of the eyeblink response. Research on hippocampal electrophysiological activity related to learning trace eyeblink conditioning has mainly concentrated on analyzing local-field potentials, namely the occurrence of theta oscillations and sharp-wave ripples. Only few studies have examined the activity of single neurons and these experiments have been limited to the time of conditioning. To further study hippocampal electrophysiological activity that takes place immediately after the learning experience, we implanted adult female New Zealand White rabbits with movable silicon probes (4 x 8 channels) in the hippocampus. The rabbits were subjected to trace eyeblink conditioning using a 200-ms, 5-kHz, 75-dB tone as the conditioned stimulus and a 100-ms airpuff towards the eye as an unconditioned stimulus. The trace period was initially 500 ms. When the animal had learned to perform an adaptive conditioned eyeblink with this set-up, the trace period was lengthened to 1000 ms. Eighty conditioning trials were presented with an intertrial interval between 30 to 60 seconds. After each conditioning session, the rabbits were transferred to a cage similar to the home cage for an additional 1-hour wireless recording session. No stimuli were presented during the wireless recording and the animal was free to move around in the cage. Typically, animals would groom and actively move about the cage for some 20 minutes after which they settled down to rest. Data from both the conditioning session and the wireless recording session were analyzed for the occurrence of sharp-wave ripples, theta and single-unit spiking. The results showed robust occurrence of sharp-wave ripples and concurrent spiking of pyramidal cells during both the conditioning session and the following cage recording.

Title: Exposure to familiar and novel stimuli yields hippocampal BOLD responses for opposite contrasts depending on the duration of the habituation to the stimuli: a fMRI study in awake rats

Authors: *C. CHWIESKO[1,2], B. BOULAT[1], D. WIEDERMANN[3], M. HOEHN[3], M. SAUVAGE[2,1,4,5];
[1]Mercator Res. Group, Ruhr-University Bochum, Bochum, Germany; [2]Intl. Grad. Sch. of Neuroscience, Ruhr-University Bochum, Bochum, Germany; [3]Max-Planck Inst., Cologne, Germany; [4]Functional Architecture of Memory Dpt, Leibniz Inst. for Neurobio., Magdeburg, Germany; [5]Med. Fac., Otto von Guericke Univ., Magdeburg, Germany

Abstract: The specific nature of information processing in the hippocampus (HIP) and its precise mechanisms is still poorly understood. We have been the first to report HIP BOLD signal in awake rats in relation to a fMRI cognitive paradigm testing for the memory for odors. Within this frame, we showed a greater BOLD effect for 'old' odors compared to 'novel' odors (contrast old-new) in the hippocampus of rats habituated with the 'old' stimuli for 5 weeks. This pattern is consistent with some reports in humans using a similar paradigm. However, other studies also reported HIP BOLD responses for the opposite contrast (new-old). We speculated that these opposite results might stem from the use of different cognitive strategies for discriminating 'new' from 'old' stimuli during the task: either the retrieval of 'old' items or a novelty-based strategy (the detection of 'new' stimuli). In animals, extensive habituation to the odor stimuli might favor a novelty-based strategy. To test this hypothesis, we investigated HIP BOLD responses in awake rats using the same behavioral paradigm, but this time, we extended the period of habituation to the odors to 13 weeks. We used a translational human to animal fMRI compatible cognitive task, which requires to retrieve/detect 'old' and 'novel' odors. This involved an extensive training of the rats in order to minimize stress levels and maximize attention to the stimuli, as well as a head fixation surgery. In addition, new hardware such as a 40 odor- olfactometer, a head fixation system and an animal carrier had to be developed. During the experiment, a set of familiar and novel odors were presented in a block design to awake rats and hippocampal BOLD responses were assessed with fMRI. In rats, which were familiarized with the 'old' odors for 13 weeks, exposure to familiar and novel odors yielded HIP BOLD signal for the opposite contrast (new-old) than the one observed, when animals were habituated for 5 weeks to the odors (old-new). Our results suggest that the duration of the familiarization to the stimuli might indeed affect the cognitive processes at state during the task and consequently the specific type of information processed in the HIP. These findings might help explaining the discrepancy existing in the literature in humans and showed this translational approach to be a valuable tool for contributing in solving major debates in human memory research.

Title: Internally generated retrospective activity in rat hippocampus.

Authors: *B. R. LUSTIG[1,2], Y. WANG[1], E. PASTALKOVA[1];
[1]Howard Hughes Med. Inst. Janelia Farm Res. Campus, Ashburn, VA; [2]Univ. of Chicago, Chicago, IL

Abstract: It is well known that activity in the rat hippocampus is influenced by the rats' position in space informed by external cues in the environment. However several studies have now shown that the hippocampus is able to internally generate patterned activity in the absence of changing external cues (Pastalkova 2008, MacDonald 2011 and 2013). To further our understanding of the relationship between activity in the hippocampus and memory, we have recorded internally generated activity in the hippocampus of rats while they perform a modified version of the W-Track alternation task (Frank, Brown and Wilson 2000, Kim and Frank 2009) that we are calling the three arm delayed sequence task. We found context dependent activity during the delay period was sufficient to differentiate the different arm trajectories. Furthermore in contrast to previous studies we found that analysis of correct and error trials revealed activity in the delay period was entirely retrospective. Thus internally generated hippocampal activity can reflect previous actions of animals, a signature of episodic memory.

Title: Functional organization of hippocampal assemblies dependent on embryonic birthdate *In vivo*

Authors: *S. REICHINNEK[1], C. HAIMERL[2], A. MALVACHE[3], R. COSSART[3];
[1]Susanne Reichinnek, Marseille, France; [2]INMED, Marseille, France; [3]Inst. de neurobiologie de la Méditerranée (INMED) - CNRS/Inserm/Aix-Marseille Univ., Marseille, France

Abstract: Cell type diversity arises during development and represents the available repertoire of neuronal behaviors which enables variable functions in different brain regions. So far, cell diversity in the hippocampus was mainly addressed in GABAergic cells. In contrast, only few studies addressed the glutamatergic CA1 pyramidal cell diversity arising from developmental and genetic parameters leading to functional and morphological differences (Graves 2012, Cembrowski 2016). We aim at understanding the relationship between the developmental temporal origin of glutamatergic neurons and their recruitment into behaviorally-relevant network dynamics and assemblies. Using an inducible genetic fate mapping approach, we are able to label neurons depending on their embryonic birth date. We use calcium imaging (GCaMP6-M) to monitor neuronal activity in head-fixed mouse voluntarily running on a cued or an un-cued treadmill using a 2-photon microscope. Monitoring hundreds of neurons in the dorsal hippocampus, we found repetitive assembly pattern and analyzed their developmental and spatial distribution during typical behaviorally relevant network oscillations e.g. theta-nested gamma and sharp wave ripples. Further on, we compare the assembly structure between minimal or location-specific external inputs. Additionally, we have probed the co-occurrence of calcium-related neuronal activity and the electrophysiological signature of the network oscillations using a contra-laterally implanted field electrode. In this way, we investigate the functional organization of neurons born at different embryonic time-points during physiological network oscillations and provide insights into how developmental origin shapes the functional organization of hippocampal microcircuits.

Title: Hippocampal-prefrontal interaction during original task learning and relearning

Authors: *Y. MACHINO[1], S. TAKAHASHI[2], Y. SAKURAI[1];
[1]Lab. of Neural Information, [2]Lab. of Neural Circuitry, Grad. Sch. of Brain Science, Doshisha Univers, Kyoto, Japan

Abstract: We often recall remote memory by using the current information as a hint. This must deal with both the current information and the past information and require activities of some brain regions, e.g. hippocampus (HPC) and prefrontal cortex (PFC). There are a lot of studies reporting that these two regions are involved in memory consolidation and retrieval. A previous study showed that the correlation between HPC and PFC activities are enhanced when the rats retain memory and it is significant for the memory consolidation to send information from HPC to PFC. There is also a hypothesis that inputs from PFC to HPC are important in memory retrieval. Moreover, it is thought that HPC is engaged in comparing newer information with older information. However, it remains unclear how HPC and PFC are involved in retrieval of remote memory. Therefore we investigated neural activities of these two regions when rats were performing tasks in which they were recalling remote memory. We used two different tasks (task-A and task-B) which were interfered to each other. In both tasks, light was presented at the right or left hole randomly. In task-A, rats had to choose the right or left hole alternately regardless of the light. In task-B, they had to choose the hole at which light was presented. First, they performed task-A until they had learned it almost completely. Next, they learned task-B, and finally they performed task-A again. When they executed task-A for the second time, they presumably recalled the information about task-A that they had performed for the first time and could learn the second task-A faster. We recorded neuronal activities and LFPs from HPC and PFC simultaneously when the rats were performing task-A for the first and second times in order to explore neural mechanisms underlying retrieval of remote memory. We report the preliminary data which suggests the possibility that HPC-PFC interaction changes between original task learning and relearning.

Title: Contextual fear encoded by hippocampal single units

Authors: *L. RAGAZZI[1], A. MOLDES-ANAYA[1], V. H. BRUN[1,2], K. B. KJELSTRUP[1,2]; [1]UiT The Arctic Univ. of Norway, Tromsø, Norway; [2]Univ. Hosp. of North Norway, Tromsø, Norway

Abstract: Dorsal hippocampal neurons have spatial firing fields that contain information about the rat's location in space (O'Keefe and Dostrovsky 1971). The resolution of the spatial information gradually declines towards the ventral pole of the hippocampus (Kjelstrup et al 2008). We asked if non-spatial firing correlates are more prominent in ventral hippocampal neurons than in dorsal. To answer this question, we have used a place preference task where the emotional significance of an environment (recording arena) could be changed while leaving the visuo-spatial cues constant. Long-Evans rats were exposed to different predator odors in a custom-made environment (a 70x70cm box divided into two compartments). Odor was delivered to one of the compartments either by a closed ventilation system or by replacing the floor mat with an identical mat coated with the predator urine. Emotional significance was measured both behaviorally (e.g. avoidance and freezing) and as changes in serum corticosterone levels. Predator odor caused rats to avoid the exposure compartment when retested 3 to 48 hours later, while neutral odors did not cause any change in compartment preference. Our results show that the initial stress response during exposure and successful context conditioning was dependent on delivery method, predator species and delay interval.
We then used the same setup for recording hippocampal single units before, during and after exposure to predator odors. The odor exposure caused remapping in the dorsal hippocampus during 30 minutes of exposure to the aversive odors, but not to neutral. Preliminary results from ventral neurons showed minor changes in firing properties. These results suggest that emotional non-spatial information is encoded by hippocampal single units, consistent with the findings of Wang et al (2012 and 2015).

Title: Contributions of the lateral and medial entorhinal cortex to the expression of fear memory

Authors: *B. S. EAST, JR[1], L. R. BRADY[2], J. J. QUINN[2];
[1]Neurosci., Tulane Univ., New Orleans, LA; [2]Psychology, Miami Univ., Oxford, OH

Abstract: The entorhinal cortex, with connections to the hippocampus, amygdala, and neocortex, is emerging as a critical, yet still underexplored, contributor to fear memory. Previous research looking at this structure has not only shown it plays a role in fear memory, but also that there may be heterogeneity of function among its two subregions: lateral entorhinal cortex (LEC) and medial entorhinal cortex (MEC). However, it is not well established what potentially unique roles these subregions of the entorhinal cortex serve as the literature has shown mixed results depending on target of manipulation and type of conditioning used. Furthermore, there have been relatively few studies manipulating both the LEC and MEC within the same experiment. In this experiment, Long-Evans rats were trained using either trace or delay fear conditioning. For trace conditioning, rats received 10 tone-shock pairings separated by a 28s trace interval. For delay conditioning, rats received 3 tone-shock pairings in which the tone and shock coterminated. The following day rats underwent intracranial surgery and received an NMDA-induced lesion to the LEC or MEC or received a sham surgery. After 7 days of recovery, rats were then given an 8-minute context test in the original context. The next day rats were tested for tone freezing in a novel context with three tone presentations. Finally, rats were tested for hyperactivity in an open field. Following either LEC or MEC lesions, freezing to context was significantly reduced in both trace and delay conditioned rats. Similarly, both LEC and MEC lesions appear to have produced a deficit in freezing for trace conditioned rats, but only LEC lesions produced a deficit in delay conditioned rats. Additionally, only LEC-lesioned rats showed a deficit in freezing during the trace interval. These data support the idea that the subregions of the entorhinal cortex play different roles in the expression of fear memory.

Title: Experience-dependent changes in hippocampal CA1 intracellular activity in novel and familiar environments

Authors: *J. D. COHEN, M. A. BOLSTAD, A. K. LEE;
Janelia/HHMI, Ashburn, VA

Abstract: The hippocampus is critical for converting novel experiences of places and events into long-term memories. To investigate the mechanisms underlying spatial learning, we compared intracellular features of dorsal CA1 activity in head-fixed mice exploring novel and familiar visual-based virtual reality (VR) environments. Consistent with previous extracellular studies in freely-moving rodents, new representations in VR were characterized by location-tuned place cell activity that appeared immediately upon exposure to novel environments, and also displayed higher firing rates compared to familiar environments. Unexpectedly, the novelty-induced increase in activity could not be explained by changes in either baseline (resting) membrane potential or somatic excitability. Instead, exploration of novel environments induced rapid increases in the amplitude of spatially tuned depolarizations (i.e., inputs to place fields) that drove increased spiking, high frequency bursting, and intracellular complex spike occurrence - signals which can induce synaptic plasticity. Furthermore, we observed that the subthreshold inputs across the entire extent of the environment became more spatially tuned with increasing experience (i.e., more similar across repeated traversals), reflecting learning of the new context. Thus, these signals may engage plasticity mechanisms that stabilize spatial representations for long-term storage. These findings provide a detailed description of spatial learning at the cellular level and should lead to new models of hippocampal memory formation.

Title: Proximo-distal heterogeneity of hippocampal pyramidal neurons along the CA3-to-CA2 transverse axis

Authors: *Q. SUN, S. A. SIEGELBAUM;
Neurosci., Columbia Univ., New York, NY

Abstract: The hippocampal CA3 region is critical for learning and memory. Although CA3 is classically viewed as a homogeneous functional unit, recent results from genomic, behavioral and place cell recording studies have provided strong evidence for a functional segregation along the CA3-to-CA2 proximo-distal transverse axis. Here we used electrophysiological recordings and optogenetics to systemically examine the heterogeneity of intrinsic membrane excitability, mossy fiber (MF) innervation, recurrent connectivity, and direct entorhinal cortical excitation across the CA3-to-CA2 transverse axis in acute mouse hippocampal slices. First, we found a pronounced gradient of intrinsic membrane excitability along the CA3-to-CA2 transverse axis. CA3c (near the dentate gyrus (DG)) exhibits the greatest input resistance (4-5 times greater than CA2) and fires more spikes in response to constant somatic current injection, followed by CA3b, whereas CA2 has the lowest input resistance and is least excitable. The proximo-distal gradient of decreasing excitability is, in part, accounted for by an increasing gradient of Ih. Thus, CA2 expresses the largest Ih, followed by CA3a, whereas CA3c has the lowest Ih. Next, we crossed ROSA26-CAG-STOP-floxed-ChR2-EYFP with POMC-Cre mice to selectively express Channelrhodopsin2 (ChR2) in DG granule cells, which allowed us to assess the strength of MF innervation. There was a decreasing proximo-distal gradient of MF responses, with the light-evoked EPSC significantly greater in CA3c compared to CA3a. Although CA2 does exhibit a light-evoked EPSC, the response is 8-fold smaller than that observed in neighboring CA3a. Furthermore, we found that CA3 and CA2 subregions are differentially excited by the CA3 recurrent collaterals. As a result of a differential excitation to inhibition ratio, CA3b receives the greatest net excitation in response to recurrent collateral stimulation compared to the other subregions. Finally, we observed an increasing gradient of direct cortical excitation, with CA2 receiving the strongest direct input and CA3c the weakest. Taken together, our findings demonstrate distinct functional gradients of intrinsic and extrinsic properties along the CA3-to-CA2 transverse axis. The heterogeneity of intrinsic membrane excitability and functional

innervation by DG, recurrent collaterals, and entorhinal cortical input along the CA3-to-CA2 transverse axis implies that these subregions may be differentially involved in pattern separation and pattern completion during memory storage and recall.

Title: Situation code in the lateral entorhinal cortex

Authors: *M. PILKIW[1], N. INSEL[1], Y. CUI[2], C. FINNEY[1], P. GURGES[1], M. D. MORRISSEY[1], K. TAKEHARA-NISHIUCHI[1];

Abstract: The entorhinal cortex is one of the brain structures thought to be responsible for the highest levels of sensory processing, representing abstract environmental information and relationships. Whereas much of neurophysiological research has focused on understanding how the medial entorhinal cortex integrates spatial information, little is known about the integration of non-spatial features of an animal's situation and the specific contribution of the lateral entorhinal cortex (LEC) in this process. We examined the coding properties of neuron populations in the LEC by recording single neuron activity while rats were trained in an associative learning paradigm under a variety of conditions. Each training session contained three epochs of 70 trials. During the first 20 trials in each epoch, a neutral stimulus (CS) was presented alone; during the subsequent 50 trials, the CS was followed by an electric stimulation to the eyelid (US), separated by a 500-ms (trace) interval. The inter-trial interval (ITI) varied between 20 and 40 s. The three epochs differed in either modality of the CS (light or sound) or conditioning chamber (i.e., spatial context), thereby allowing us to examine, within a total of six separate combinations, LEC representation of CS type, CS-US association, and the space in

which it was presented. We found that neurons not only responded to the stimuli and trace interval, but were also active during the ITI, and this activity differed between the epochs. Approximately 40% of the LEC cells showed differential firing during the ITI across all conditions, indicating selectivity for at least one of the three information types. Most of these neurons were selective for a single combination of the paradigm variables. Ensemble decoding analyses showed that the selectivity for CS modality and conditioning chamber during ITIs was stronger than that for the CS-US relationship, and this selectivity was stable for the duration of the ITI. In contrast, selectivity for the CS-US relationship was strongest during the CS and trace interval and decreased during the ITI. Selectivity for epoch was higher during ITIs that preceded trials in which the rats expressed conditioned responses (CR) compared to the trials without CR expression. This suggests that these discrete representations of past stimulus exposures in the LEC may serve as an occasion setter for an adaptive response to the upcoming CS. Our findings indicate that the LEC carries representations that depend upon the animals' history of experience in a given environment, thereby building contextual representations based on non-spatial features.

Title: Cellular network underlying enkephalin release in area CA2 of the hippocampus

Authors: ***A. FAFOURI**[1], L. THERREAU[2], V. CHEVALEYRE[2], R. PISKOROWSKI[2]; [1]Lab. de Physiologie cérébrale, équipe plasticité synaptique et réseau neu, [2]UMR 8118-CNRS/ UNIVERSITE PARIS DESCARTES, Paris, France

Abstract: The long-overlooked area CA2 is emerging as an important region for hippocampal memory formation. Area CA2 has been shown to be critical for social memory formation (Hitti and Siegelbaum 2014; Stevenson and Caldwell 2014), aggressive behavior (Pagani et al., 2014)

and appears to play an important role in detecting discrepancies between memory-driven and current sensory information converging on the hippocampus (Wintzer et al., 2014). Furthermore it has been previously reported that in area CA2, a powerful inhibitory transmission prevent CA3 inputs from driving CA2 neurons. Moreover, this highly plastic inhibition undergoes a long-term depression (iLTD) at parvalbumin-expressing (PV+) interneuron synapses and is strictly dependent on delta-opioïd receptor (DOR) activation (Nasrallah et al., 2015; Piskorowski et al., 2013). However, the cellular network required to induce the release of enkephalin, the endogenous DOR ligand, during increased neural activity is unknown. Our first goal is to determine if the source of enkephalin is intra- or extrahippocampal.
Using electrophysiology, optogenetics and confocal imaging, we are examining the cells populations that release enkephalin and determining how these cells are activated. We performed patch-clamp recordings of CA2 pyramidal neurons in acute hippocampal slices and used optogenetics to selectively evoke inhibitory post-synaptic currents (IPSCs) from PV+ interneurons. We found that the selective activation of PV+ interneurons expressing Channelrhodopsin was not sufficient to induce iLTD, suggesting that a separate population of cells is releasing enkephalin. Furthermore, using a similar strategy to selectively excite only CA3 inputs to area CA2, we found that a 10 Hz photostimulation of these axons was sufficient to evoke iLTD of inhibitory transmission. Thus, enkephalin is being released by a hippocampal source that receives excitatory input from CA3. We plan to further examine this micro-circuit and its significance for memory formation.

Abstract: Remembering and forgetting are coupled phenomena both necessary to guarantee appropriate encoding and retention of experiences. We identified transcription factors (TFs) activated by stimulation that induces late LTP at Schaffer collateral (SC)-CA1 synapses in rat hippocampal slices by using a protein-DNA binding array and found among others Wilm's Tumor 1 (WT1), a transcriptional repressor also involved in mRNA translation. After reducing hippocampal WT1 activity in rats by injection of WT1 antisense, and in transgenic mice by expressing non-functional WT1, weak HFS at the SC-CA1 synapses was able to induce persistent LTP, suggesting that WT1 acts normally as a plasticity suppressor. We identified WT1-regulated genes through mRNA-seq and RT-PCR and found members of the chemokine and interleukin superfamilies, as well as IGF2, a known target of WT1. Antagonists of the CCL2 and IGF2 receptors prevented WT1 knockdown from enhancing LTP, suggesting that through the synthesis of multiple diffusible molecules WT1 controls synaptic plasticity at the circuit level. Since induction of LTP by stimulation of SC-CA1 synapses is enhanced by activity in the temporoammonic (TA) input to CA1, and hippocampal LTM requires TA input, we asked if knockdown of WT1 might facilitate LTP by freeing CA1 neurons from this dual pathway requirement. When WT1 was knocked down in CA1, activation of the TA pathway was no longer necessary for LTP induction, nor did it enhance LTP produced by SC stimulation alone, suggesting that WT1 disrupts the normal corticohippocampal circuit-level regulation of LTP. In behavioral experiments, loss of WT1 function significantly enhanced long-term memory (LTM) in two different hippocampus-dependent tasks [CFC and novel object placement (NOP)] but when trained in a two-task sequential learning protocol (NOP training, followed 48 h later by CFC training), transgenic mice showed enhanced LTM for NOP but *impaired* LTM for the subsequent CFC; however, if CFC training was delayed 10 days after NOP training, LTM for CFC was normal, supporting the hypothesis that WT1 actively suppresses plasticity for a limited period after training, thus preserving the ability of the hippocampus to encode LTM for discrete tasks. Our data indicate that the ability of the hippocampus to repeatedly encode new memories requires a period of plasticity suppression that is transcriptionally regulated, and show that WT1 plays an important role in this systems-level function. Such a complex interplay of pro- and anti-plasticity mechanisms could contribute to learning disorders, including autism and post-traumatic stress disorder.

Title: Cholinergic modulation of DG-CA3 feedforward microcircuit dynamics and function

Authors: *L. Y. PRINCE, J. R. MELLOR;
Sch. of Physiology, Pharmacology, and Neurosci., Univ. of Bristol, Bristol, United Kingdom

Abstract: Dentate gyrus granule cells provide powerful feedforward excitatory drive onto a local circuit of CA3 pyramidal cells and inhibitory interneurons, and is believed to selectively activate subsets of pyramidal cells in the CA3 recurrent network for encoding and recall of memories. Cholinergic receptors provide a key means to modulate this circuit, increasing cellular excitability and altering synaptic release, but the combined action of these changes on information processing between the dentate gyrus and CA3 remains unknown. We recorded evoked monosynaptic EPSCs and disynaptic IPSCs in CA3 pyramidal cells in response to a range of frequencies and stimulation patterns and in the presence and absence of cholinergic agonists. The short-term plasticity dynamics of these responses were used to constrain a computational model of mossy fibre driven transmission. This model was then used to analyse how a single cell model of CA3 pyramidal cells driven by constant dendritic current is perturbed by excitatory and inhibitory synaptic input. We show how the timing, frequency, and excitatory-inhibitory balance of mossy fibre input influences the activation of CA3 pyramidal by granule cell bursts, and how the presence of acetylcholine is represented in this space. We then use a spiking network model of CA3 to study encoding and recall of neuronal ensembles driven by mossy fibre input. We find that modification of mossy fibre short term plasticity by acetylcholine alters the balance between encoding and recall. This analysis provides insights into how the dynamics of mossy fibre driven activity affect the function of the CA3 network and how this is modulated by cholinergic input.

Title: Validation of an adapted barnes maze for juvenile rats

Authors: *A. M. BEHSUDI[1], D. G. MCHAIL[1], N. VALIBEIGI[1], T. C. DUMAS[2];
[2]Mol. Neurosci. Department, Krasnow Inst. for Advanced Study, [1]George Mason Univ., Fairfax, VA

Abstract: The purpose of the current project is to develop a behavior task for juvenile rats that is compatible with *in vivo* electrophysiology to assess the neural bases of goal-directed spatial navigation. Most goal-directed spatial learning and memory tasks involve extended training or are performed in water mazes. Multi-day training tasks are inappropriate for developmental studies if the aim is to identify milestone ages for specific cognitive abilities. Water mazes have proven informative but, as always, are subject to contamination by stress and are not compatible with *in vivo* electrophysiology. In order to overcome these obstacles, we adapted the Barnes maze task for juvenile rats. Relative to the adult Barnes maze, the platform diameter and the number of escape holes were reduced. Long-Evans rats were exposed to the maze beginning at postnatal day (P) 17 or P22. Testing occurred across four days. On Day 1, animals were exposed to the platform in dim light without an escape box for fifteen minutes to get the animals to explore the entire platform. This phase is necessary to map hippocampal place cells prior to the learning and memory phases. On Days 2 and 3, animals were trained in bright light conditions to find a stationary escape box. On Day 4, a single probe trial was performed in bright lighting without an escape box present. We found that on Day 1, animals at both testing ages explored the entire platform. On Days 2 and 3 of testing animals of both age groups showed similar reductions in escape latencies across training blocks, with the older group being slightly quicker. On Day 4, subjects from both age groups exhibited similar dwell times near the escape location and distance to platform measures (1 Hz sampling rate). We have shown that the Barnes Maze can be adapted for use with juvenile rats. This project will allow for better understanding of the development of the hippocampus in a mammalian model by creating a goal-dependent task (by having a specific location for the rats to learn and remember) that is compatible with *in vivo* electrophysiology. Findings from the proposed studies will have implications for understanding, and perhaps even treating, brain injuries and several neurocognitive disorders including epilepsy, Alzheimer's disease, and autism spectrum disorders.

Title: Melatonin rescues memory dysfunctions, neuroinflmmation and neurodegeneration via RAGE/NF-$_K$B/JNK signaling in D-galactose-induced aging mouse model

Authors: ***T. ALI**, H. BADSHAH, T.-H. KIM, M.-O. KIM;
Biol., Gyeongsang Natl. Univ., Jinju, Korea, Republic of

Abstract: Here in, we investigated the underlying neuroprotective mechanism of melatonin against D-galactose-induced memory and synaptic dysfunction, increased reactive oxygen species (ROS), neuroinflammation and neurodegeneration. D-galactose was administered (100 mg/kg intraperitoneally (i.p)) for 60 days. After 30 days of D-galactose administration, vehicle or melatonin (10 mg/kg, i.p) was administered for 30 days. Morris water maze and Y-maze results indicated that chronic melatonin treatment attenuated D-galactose-induced memory deficits. In addition, melatonin reversed D-galactose-induced synaptic disorder via increasing the level of pre-and post synaptic protein markers. We also determined that melatonin enhances memory function in the D-galactose-treated mice possibly via reduction of elevated ROS and receptor for advanced glycation end products (RAGE). Furthermore, Western blot and morphological results showed that melatonin remarkably ameliorated D-galactose-induced neuroinflammation through inhibition of gliosis and decreasing other inflammatory mediators like p-IKKβ, p-NF-$_K$B65, COX2, NOS2, IL-1β and TNFα. Moreover, melatonin reduced the oxidative stress kinase p-JNK which reduced various apoptotic markers, i.e. cytochrome C, caspase-9, caspase-3 and PARP-1, and prevent neurodegeneration. Hence, melatonin rescued the D-galactose-induced memory/synaptic dysfunctions, neuroinflammation and neurodegeneration possibly via RAGE/NF-$_K$B/JNK signaling. Together, our data we suggest that melatonin could be a promising, safe and endogenous compatible antioxidant candidate for age associated neurodegenerative disorders.

Title: Self-localization accuracy in rats is influenced by landmarks and boundaries

Authors: M. L. NGBOKOLI[1], J. FERBINTEANU[3], *J. L. KUBIE[2];
[1]Physiol. and Pharmacol., [2]Cell Biol., SUNY Downstate Med. Ctr., Brooklyn, NY; [3]Physiol. & Pharmacology; Neurol., SUNY Downstate Med. Ctr. Dept. of Cell Biol., Brooklyn, NY

Abstract: Central to the "cognitive map" hypothesis is that the collective output of hippocampal place cells provides the rat with "self-localization" information. That is, the composite firing of all place cells accurately points to a location in the environment. Using behavioral techniques we investigated rats' ability to self-localize in a large apparatus where floor marks were removed by floor cleaning and regular floor rotations.
In an earlier study we described a "spatial accuracy" task, where rats rewarded with a dropped food pellet for pausing in the region of an unmarked goal[1]. Here we describe an update, using new tracking-and-reward procedures and a much larger (6ft diameter) cylindrical chamber. Rats were pre-trained in 5-min trials to pause above a goal marker for food rewards. After a 2-hour break, the animals were tested with no marker to see if their pauses (choices) clustered near the goal location. Unmarked trials are run under reward and no-reward conditions. The goal location was changed daily. Initial results indicate that most rats learn this procedure and show a tight locus of pauses when the marker is present and a variably-tight scatter when the marker is not present. Two error measures were obtained: the distance the goal to the center of pauses (centroid), and the standard deviation of pauses from the pause center. In addition, for each trial we analyzed the paths a rat takes to approach a pause. The overall finding is that, by both measures, there is appreciable self-localization error. In addition, self-localization is more accurate near landmarks and boundaries (apparatus walls) than near the center of the chamber. Finally, on unmarked trials self localization appears to improve as the trial progresses, even without rewards.

Title: Contextual latent inhibition enhances Arc protein expression in the hippocampus following testing for contextually elicited fear

Authors: ***C. D. HUDGINS**[1], T. OTTO[2];
[2]Psychology, [1]Rutgers Univ., Piscataway, NJ

Abstract: Emerging evidence suggests that the hippocampus is functionally dissociable along both its septotemporal and transverse axes. Activity-related cytoskeletal protein (Arc) has previously been shown to be tightly linked to the induction of neuronal plasticity, is expressed within hippocampal subfields, and has been implicated as a biomarker of learning. We have recently shown that trace fear conditioning enhances Arc protein levels, and that both trace conditioning and the associated learning-related enhancement of Arc can be blocked by infusing

either Arc antisense oligodeoxynucleotides (ODNs) or the NMDA receptor antagonist APV into the dorsal or ventral hippocampus prior to training. Thus while NMDAr-dependent Arc expression in both dorsal and ventral hippocampus appear to be critically involved in the acquisition of trace fear conditioning, the extent to which Arc is differentially expressed within the discrete subfields of the hippocampus following learning has yet to be fully characterized. Using traditional immunohistochemical methods, we have recently found that both exposure to a novel context and trace fear conditioning enhanced Arc expression relative to untrained control subjects; we also found that 10 days of pre-exposure to the conditioning context resulted in a marked latent inhibition of context learning, which was accompanied by a prevention of context exposure-induced Arc expression. In the present study, subjects were trained in trace fear conditioning in either a familiar (pre-exposed) context or a novel context. Arc protein expression following training was significantly higher in CA3 relative to CA1 in the dorsal hippocampus, whereas expression was notably greater in CA1 relative to CA3 in ventral hippocampus, but this enhanced expression was independent of context novelty. Interestingly, Arc protein expression following context testing in the original training context was enhanced in subjects that had been pre-exposed to that context, most notably in ventral CA1, even though these subjects demonstrated significantly less of the conditioned response. The implications for the ways in which learning is best characterized in a latent inhibition task and the extent to which Arc expression serves as a biomarker for learning and synaptic plasticity within hippocampal subregions will be discussed.

Title: Fxr1p enhances glua2 mrna translation, L-LTP and memory recall.

Authors: *E. NURO;
Ctr. for Res. in Neurosci., McGill Univ., Montreal, QC, Canada

Abstract: Proper cognitive function requires specific molecular and cellular mechanisms that allow for proper gene expression and circuitry physiology. Control of protein synthesis by mRNA binding proteins represents a major mechanism for regulating protein abundance and

site-specific localization of proteins that underlie synaptic plasticity and cognitive function. We recently discovered that a member of the Fragile X family of proteins, Fragile-X related protein (FXR1P), associates with protein synthesis machinery in neuronal dendrites and plays an important role in limiting late-phase long-term potentiation (L-LTP) and long-term memory recall. Specifically, conditional deletion of FXR1P from the postnatal forebrain enhanced hippocampal L-LTP and improved spatial memory recall (Cook, Nuro et al., Cell Reports 2014). Furthermore, loss of FXR1P increased translation of the mRNA encoding the AMPA receptor subunit GluA2. Interestingly, our findings revealed a divergence in the function of the Fragile X family of proteins whereby FXR1P represses the translation of GluA2 via its 5'UTR, FXR2P promotes the translation of GluA2 mRNA via its 5' and 3'UTR, while FMRP has no effect. We are currently following up on these results to further dissect the molecular mechanisms involved. Furthermore, using *in vivo* tools such as *in utero* electroporation in mice, we are studying the *vivo* localization of FXR1P in CA1 pyramidal cells of the hippocampus and its relationship to GluA2 protein at excitatory synapses. Future studies will also determine if and how FXR1P may be related to CNS disorders associated with cognitive and intellectual disability.

Abstract: Memories of related events and facts are stored in form of neocortical associative networks (mental Schema) and they help in rapid consolidation of new memories that are similar

in character. Although neocortex is shown to be involved, it is not clear if this is true for learning larger sets of information with content richness similar to the initial schema. In order to address this we trained animals to learn same sets of flavour place associations(paired associates) in three different ways viz., i) Solitary Learning: Two sets of association are presented independently one after the other ii) Relational Learning: Second set is presented in relation to first set and iii) Incremental Learning: The paired associates are presented in small steps. We find that only the animals that underwent relational learning were able to acquire both set of associations. Both the solitary group as well as the incremental group were unable to learn all the associations in its entirety. Comparing the three groups we show that older memories help in acquisition of new memories only if presented in a relational manner. We hypothesise and show that these interactions amongst memories can bias the animal's ability to solve problems derived from prior knowledge.

Title: Direct mutual connectivity between hippocampal CA1 and the superficial layers of the entorhinal cortex

Authors: ***J. SUH**[1,3], M. MARIOUTINA[1,3], I. WICKERSHAM[2], S. TONEGAWA[1,3,4,5]; [1]Picower Inst. Learning & Memory, [2]MIT, Cambridge, MA; [3]RIKEN-MIT Ctr. for Neural Circuit Genet., Cambridge, MA; [4]RIKEN Brain Sci. Inst., Wako, Japan; [5]Howard Hughes Med. Inst., Cambridge, MA

Abstract: The entorhinal cortex (EC) is a major input and output structure of the hippocampal formation, entertaining the role of the nodal point of cortico-hippocampal circuits. The findings of the grid cells in all layers of the EC and recent studies on the functions of EC inputs to the hippocampal CA1 indicate that each layer of the EC play a unique role in spatial representation and episodic memory processing. However, it is still unknown that how the grid formation is generated and the position of an animal is computed within the EC circuits. Furthermore, due to technical limitations, we have a limited understanding of whether or how the different sources of

inputs to EC layers are distributed with different strengths on cells in each layer, which may be essential for a mechanistic understanding of functional circuit operations in the EC. To map an intrinsic organization between EC layers and identify specific sets of inputs to these layers, we employed genetically modified and monosynaptically restricted rabies tracing methods in combination with multiple transgenic mouse lines in which Cre recombinase expression is confined to a specific layer of the EC. We found that superficial layers (II-island and III) in dorsal EC receive a similar pattern of inputs from the anterior dorsal thalamus and subcortical neuromodulatory systems including cholinergic projections from the medial septum and serotoninergic inputs from the median raphe nucleus. Furthermore, within the entorhinal-hippocampal circuits, we found that EC layer III receives extensive inputs from entire CA1, whereas layer II receives inputs from proximal CA1 and CA2. These findings are contradicting the notion that CA1 pyramidal cells mainly connect to deeper layer (V) of the EC, which subsequently connects to upper layers (II and III) of the EC. These differences probably reflect different functions of these cortical layers in mediating spatial and temporal information processes. Our results will provide a foundation of further functional dissection of the entorhinal-hippocampal circuits.

Title: Formalizing function within the hippocampal trisynaptic circuit

Authors: *W. SEVERA, O. PAREKH, C. JAMES, J. B. AIMONE;
Sandia Natl. Labs., Albuquerque, NM

Abstract: Claims regarding the functions of regions within the hippocampal formation are touted without clear definitions or experimental justification. For example, it is often taken for granted that the Dentate Gyrus (DG) performs pattern separation; the CA3 is auto-associative memory; and the CA1 forms a comparator. However, there are few mathematically rigorous models supporting the methods by which these functions are accomplished, and these theoretical frameworks often fail to fully explain experimental observations of the hippocampus, such as the

presence of adult-born granule cells in the DG or the dynamics of place cell ensembles in the CA3 and CA1. One of the affirmative examples is the formal modular code used by Fiete and colleagues to describe grid cell activity in mEC, one of the principle input regions to the hippocampus. The development of the equivalent for hippocampal regions like the DG and CA3 may provide a stronger theoretical footing upon which we can frame experimental results, and here, we introduce mathematically rigorous frameworks for these two areas. Our DG model provides provable pattern separation via a closed form, static sparse coding. We begin with an abstract formulation and generalize to a more advanced model. This allows us to incorporate constrained input patterns and mixed coding reflecting adult neurogenesis. We also discuss a method to formally embed more conventional DG models within our framework. For CA3, a region often approximated as a straightforward Hopfield-like attractor network, we instead consider a dynamical approach leveraging non-stationary limit cycles. Specifically, we formalize CA3 as a family of dynamical systems where information is coded in stable, non-fixed-point orbits. One key advantage of this approach is that it provides a mechanism by which contextual inputs can gracefully change the way in which memories are formed and retrieved. Only one system is expressed in any given context, but the concept of neuromodulation provides a method for global transitions between these systems via topological conjugacy. While these mathematical frameworks for considering the hippocampus do not challenge the conventional wisdom regarding high level hippocampal function, they seek to formalize the processes through heretofore never considered mechanisms.

Title: Neuronal plasticity of dorsal hippocampus in rats subjected to cognitive training: female and male rats

Authors: L. VILLANUEVA ESPINO[1], *A. B. SILVA[2];
[1]Lab. de Neurofisiología Exptl., Escuela de Biología, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico; [2]Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: Several lines of research have established that the hippocampus is involved in learning and memory processes, and these processes are developed through structural and physiological changes of the neural systems. Morphological changes in the brain in response to cognitive

training and environmental stimulation have been mainly obtained from male rats. According to this, the aim of this study was to determine if there are sexual dimorphism in neuronal plasticity of dorsal hippocampus after cognitive activity. Long Evans female and male rats (n=8 per sex) were used to perform four cognitive tests, which were locomotor activity in open field, Morris water maze, Barnes circular maze and object recognition task. In order to observe the effects of the cognitive tests, we compared the morphology of the apical and basolateral dendritic arborization, as well as density of dendritic spines of CA1 and CA3 regions of the dorsal hippocampus of rats that performed the tests vs. control rats. The dendritic morphology was measured using the Golgi-Cox procedure followed by a Sholl analysis. Both, female rats and male rats performed similarly in all tests, but female rats were hiperactive in locomotor activity. The morphology analysis, showed increases in the apical arborization of CA1 neurons, and increases in the density of dendritic spines of the apical and basolateral arborization of CA1 neurons and CA3 by cognitive activity effect. These results can be related with the patterns of connection that receives each neuronal type and the role played by each structure in the processing of the information. The performance of cognitive tests favors the increment in the dendritic arborization of CA1 region as well as the increase in the density of dendritic spines of CA1 and CA3 hippocampal regions without showing signs of sexual dimorphism.

Title: Alterations in touchscreen pattern separation following moderate prenatal alcohol exposure in the mouse

Authors: *J. A. KENTON, JR[1], M. JOSEY[1], B. J. CLARK[1], J. L. BRIGMAN[1,2];
[1]Univ. of New Mexico, Albuquerque, NM; [2]UNM Hlth. Sci. Ctr., New Mexico Alcohol Res. Ctr., Albuquerque, NM

Abstract: It is well established that exposure to alcohol during development leads to alterations in neurogenesis and deficits in hippocampal-dependent learning and memory. Recent evidence suggests that even more moderate alcohol consumption during pregnancy can have negative impacts on the cognitive function of offspring in the absence of hallmark morphological defects.

However, methods for assessing impairments differ greatly across species, making it difficult to translate preclinical findings into potential therapeutic avenues. We have recently demonstrated the utility of a touch-screen operant measure for assessing hippocampal function in mice. Here, we integrated a well-established 'drinking in the dark' exposure model that produces reliable, but more moderate, levels of maternal intoxication (daily dam BAC ~85 mg/dL) with a touch-screen based trial unique, delayed nonmatching-to-location (TUNL) task to examine the effects of PAE on hippocampal-sensitive behavior directly analogous to those used in clinical assessment. Briefly, PAE and SAC offspring mice were trained to touch a single visual stimulus ("sample phase") in one of 10 possible spatial locations (2x5 grid) in a touch-screen operant system. After a delay, animals were simultaneously presented with the original stimulus and a rewarded stimulus in a novel location ("choice phase"). Separate cohorts of PAE and saccharin (SAC) control mice were trained on different distinct progressions of difficulty. We found that PAE mice were able to attain performance similar to SAC control mice at progressively more difficult separations. In addition, training initially on decreased separations and then progressing to farther separations revealed differences in performance by PAE mice. Current studies are investigating alterations in neurogenesis in PAE that may drive deficits seen on the TUNL task and examining online neuronal correlates of behavior during distinct phases of pattern separation learning.

Title: Intrahippocampal growth hormone modulates spatial memory

Authors: ***K. G. HAUGLAND**[1], A. MOLDES-ANAYA[1], K. B. KJELSTRUP[1,2], V. H. BRUN[1,2];
[1]UiT The Arctic Univ. of Norway, Tromsø, Norway; [2]Univ. Hosp. of North Norway, Tromsø, Norway

Abstract: Growth hormone (GH) is a neuromodulator involved in cognitive deficits of ageing and endocrine disturbances (Nyberg and Hallberg 2013). Several studies have shown that systemic elevation of ghrelin or GH is beneficial for learning and memory (e.g. Diano et al.,

2006), however the main target areas of the brain and mechanisms of action are yet to be determined. We have altered GH levels selectively in the hippocampus of male Long Evans rats and investigated the effects on memory performance. The dorsal hippocampus was transfected with recombinant adeno-associated virus (AAV) expressing either GH, GH-antagonist (GHA) or green fluorescent protein (GFP) only. These animals with chronic intrahippocampal GH overload or deficit were subsequently tested in hippocampus-dependent memory tasks, such as the water maze and object displacement tasks. Our findings show that the GH levels affected memory in a dose-dependent manner. Preliminary results indicate that a proportion of the animals expressing high GH levels exhibited impaired spatial memory in the water maze task. Histological analysis revealed cell death in the transfected areas of some animals, probably caused by hyperexcitation in the affected neurons. In contrast, animals with no tissue damage, but still increased GH levels, displayed significantly better memory in an object displacement task. Furthermore, the memory performance of rats with high levels of GHA did not differ significantly from the control rats. To conclude, these preliminary results indicate that GH levels in the hippocampus are important for plasticity and modulate spatial memory performance in rats. Very high levels of GH may lead to hyperexcitation and eventually cell death, consistent with the view that GH facilitates long-term potentiation by increasing synaptic density. A slightly elevated GH level in dorsal hippocampus may improve cognitive performance and memory.

Title: The contribution of hippocampal oxytocin receptors to social memory processing

Authors: *T. RAAM[1,3,2], A. BESNARD[1,3,2], K. MCAVOY[1,3,2], A. VEENEMA[4], A. SAHAY[1,3,2];
[2]Dept. of Psychiatry, [1]Massachusetts Gen. Hosp., Boston, MA; [3]Harvard Stem Cell Inst., Cambridge, MA; [4]Dept. of Psychology, Boston Col., Boston, MA

Abstract: The trisynaptic hippocampal pathway dentate gyrus (DG) DG-CA3-CA1 plays a critical role in processing contextual information and object recognition. Recent studies suggest a role for the CA2/3 subregions in processing social memories, raising the question of whether and how the same hippocampal sub-regions process social and object information. Here, we used optogenetic terminal specific silencing and identified roles for distinct CA2/3 outputs in discrimination of objects and social stimuli. This double dissociation suggests that CA2/3 segregates social and object information to appropriate downstream targets through distinct neural pathways. Based on the enrichment of receptors for the social hormone oxytocin (Oxytocin receptors, Oxtr) in the CA2/3 subregions and dorsolateral septum but not in CA1, we hypothesized that oxytocin signaling in CA2/3 plays a critical role in processing social memories. In order to determine the necessity of oxytocin receptor signaling in CA2/3 in social memory, we injected AAV Cre recombinase into the CA2/3 subregion of Oxtr conditional knockout mice. Knocking out oxytocin receptors in CA2/3 produced a strong deficit in social memory processing, with no effect on object recognition. We are currently investigating the neural mechanisms by which Oxtr signaling in CA3 impacts social memory processing. Together, these studies begin to illuminate how an ancient neuromodulatory hormone, oxytocin, utilizes a basic memory processing circuit scaffold in the hippocampus to guide social behavior.

Title: Synapse formation and memory cell recruitment for associative memory

Authors: *J. H. WANG, J. FENG, W. LU, Z. LEI, Z. GAO, D. WANG;
The Inst. of Biophysics, CAS, Beijing City, China

Abstract: Associative learning and memory are essential for the cognitions. The structural and functional plasticity of the synapses and neurons are presumably associated to learning. It remains unclear about the natures and recruitment of associative memory cells that accept, storage and retrieve multiple signals. We studied this issue in mouse model of associative memory by multidisciplinary approaches *in vivo*. Pairing stimulations to whiskers and olfaction led to reciprocal cross-modal reflexes, i.e., odorant-induced whisker motion and whisker-induced olfaction response. The cross-modal reflexes were also induced by the co-activation of barrel, piriform and S1-tail cortices. In the mice that express the cross-modal reflexes, their barrel, piriform and S1-tail cortices mutually innervated by the new synapses formed from their projected axons to target cells. A substantial portion of the neurons and astrocytes in each of these cortical areas became to encode the newly acquired signals alongside the innate signal. Some of these associative memory cells expressed the different activity patterns in response to the acquired signals and innate signal, and others encoded similar pattern in response to these signals. These associative memory cells in each of these cortical regions received the synaptic inputs from the newly established afferents alongside from the innate afferents. The antagomirs of miRNA-324p/miRNA-133a attenuated the formation of associative memory, the formation of new synaptic innervation and the recruitment of associative memory cells. Thus, the co-activation of the sensory cortices initiates their mutual synaptic innervations, which drive their target neurons to be recruited as associative memory cells that encode the new learnt signals (cross-modal memory) alongside the innate signal (native-modal memory). In terms of the storage and retrieval of the associated signals, the natures of associative memory cells include the followings. They are recruited to encode multiple signals being associated. They receive multiple synaptic inputs from the cortices of signals' origins. Their axons project toward the brain areas being associatively activated, as well as other brain areas for memory presentation. Their recruitments are downregulated by altering the gene and protein expressions. The upregulation or downregulation of these neurons, their synaptic inputs and axon projections alters memory capacity. Their axons project to the contralateral cortices and make the synapse innervations that send the acquired signals for unilateral learning toward bilateral memory.

Sci., HongKong Polytechnic Univ., Hongkong, China; [5]Life Sci. and Technol., Harbin Inst. of Technol., Harbin, China; [6]Life Sci., Nanjing Univ., Nanjing, China

Abstract: Recent studies have shown that the entorhinal cortex switched neocortical plasticity and encoding of associative memory in the auditory cortex likely through cholecystokinin (CCK) projection neurons. In the present study we hypothesize that associative memory could be implanted in the anesthetized animal's brain. A bilaterally electrode-implanted rat was trained to retrieve water-reward from either the left or the right hole depending on which hemisphere of the auditory cortex stimulation was triggered after it initiated the trial. After the stimulation site of one hemisphere was infused with CCK, a previously irrelevant light stimulus was then paired with the electrical stimulation of the infused hemisphere for multiple sessions in the anesthetized rat. The auditory cortex neurons responded to the light stimulus in both anesthetized and behavioral conditions. All 6 rats approached to the "designed" hole after they triggered light stimulus instead of electrical stimulation of the auditory cortex one week after the first conditioning. We further hypothesized that the high-frequency (HF) stimulation is required to induce release of CCK that enables the encoding of visuo-auditory associative memory. With implanted stimulation electrode and optical fiber in the auditory cortex and injected AAV-DIO-eYFP-ChR2 in the entorhinal cortex in the CCK-CRE mouse, we conditioned the electrical stimulation of the auditory cortex with footshock. The mouse showed no freezing response when the light stimulus was presented. We then anesthetized the mouse, used HF laser stimulation in the auditory cortex of the cortical projection fiber of the entorhinal CCK neurons and then paired the light stimulus and the electrical stimulation of the auditory cortex with low frequency. The mouse changed to freeze when the light was presented after the above pairing, indicating that the mouse associated the light stimulus with the ES, and recalled the aversive memory. The

behavioral experiments revealed that the artificially memory was transferred to the behavioral action, providing a scientific foundation for “memory implantation”.

Title: Encoding of fear memory about complex stimulus in the mouse parietal association cortex: c-fos two-photon imaging

Authors: ***M. ROSHCHINA**[1], O. IVASHKINA[1], K. TOROPOVA[1], A. KALASHNIKOV[2], A. GRUZDEVA[1], K. ANOKHIN[1];

Abstract: In natural environment associative memory often integrate several stimuli from different sensory modalities. Previously we have developed behavioral paradigm for fear conditioning using multisensory compound stimulus that mimics complexity of natural learning. In the present study, we examined encoding of fear memory about compound stimulus by neurons of the mouse parietal cortex. We trained transgenic c-Fos-EGFP mice in a fear-conditioning task to a compound stimulus (tone + light). A week later, we performed three retrieval sessions using separate sound or light as well as the compound stimulus. To monitor neuronal activation, we performed two-photon in vivo imaging of EGFP expression in the parietal associative cortex. Based on the intensity of fluorescence, all neurons were divided into the two groups: highly- and weakly-active. Number of highly-active neurons were increased in trained mice compared to the control mice in all retrieval sessions, while the number of weakly-active neurons decreased in all the sessions. Next, we analyzed neurons that showed high fos-EGFP expression only in one of the retrieval session. We found three activation specificities of

such neurons: light-related, sound-related and compound CS-related neurons. The number of light-dependent highly-active neurons increased in the trained mice compared to the control mice. The number of sound-dependent and compound CS-dependent neurons was equal in the trained and control mice. Also with the calcium imaging we shown that neurons active during learning later respond to tone and light during retrieval sessions. Then we used c-fos immunohistochemistry to analyze activation pattern in different brain areas after optogenetic stimulation of parietal cortex. Taken together our data suggests that coding of complex associative memory in the parietal cortex involves at least three neuronal assemblies with different response specificity to the components of the compound CS.

Abstract: Associative learning is a fundamental mechanism for experience-dependent cortical modification. Though synaptic aspects of this process has been thoroughly studied, less is known about how it is implemented at the level of cortical circuits. Predictive coding theories suggest that classical conditioning leads to formation of cortical representations that differentially affect supragranular (L2/3) and infragranular (L5/6) cortical layers. While deep layers of the sensory cortex mediate top-down predictions from anticipatory model generated by frontal areas, superficial layers convey bottom-up prediction error signals that update prior representation according to sensory input. To study these processes we used auditory fear conditioning and c-Fos neuroimaging of layer-specific activation of different associative (infralimbic, prelimbic, cingular, retrosplenial, frontal associative and parietal associative) and sensory (primary auditory, ventral and dorsal areas of the secondary auditory) cortices after memory acquisition

and retrieval in mice. We found that presentation of auditory CS and footshock during training leads to activation of cingulate cortex and the ventral part of secondary auditory cortex. Retrieval of associative memory about CS a day later produces preferential activation of cingulate, prelimbic, infralimbic and parietal associative cortices. This activation was specific in L2/3, L5 and L6 of cingulate cortex and L5 and L6 of prelimbic cortex. Layer-specific analysis of the primary auditory cortex showed that memory acquisition involved proportionally more L2/3 neurons, while CS presentation during retrieval involved proportionally more L5 neurons. Thus, our data suggest that cued conditioning can lead to shift from activation of supragranular layers during acquisition phase to infragranular layers during retrieval phase in the primary auditory cortex and overall preferential activation of associative areas during memory retrieval versus sensory cortex activation during memory acquisition.

Title: Pavlovian engram conditioning: properties and imaging of neural circuitry

Authors: *K. ANOKHIN, N. VOROBYEVA, K. TOROPOVA, O. IVASHKINA;
NRC Kurchatov Inst., Moskva, Russian Federation

Abstract: Pavlov's original work on classical conditioning used reinforcement of immediately present environmental event. An important fundamental question is whether an engram of a distant past event can be also conditioned. Though there are evidence that this can happen if an engram is ecphorised in the presence of reinforcing stimulus, surprisingly little work has been done on the specific properties of such association and its neural mechanisms. Here we used a model of such engram conditioning, the context preexposure facilitation effect paradigm (Fanselow, 1990; Rudy and O'Reilly 2001) to explore associability of activated engram with a footshock reinforcement in mice, specificity of such associative memory, its durability and neural activity at its retrieval. Mice were first allowed to explore a new context A for 5 min and then at different delays received a 2 sec footshock immediately after being replaced in this context. We showed that the contextual engram in mice can be fear conditioned in the interval

from 30 min to at least 30 days between its acquisition and retrieval. Resulting association persisted for at least 30 days after such engram conditioning. The fear for the context A was specific, it did not develop if immediate shock was delivered in a context B and there was no freezing in a novel context C. We next studied how engram conditioning changes patterns of brain activity during its subsequent retrieval. For this we compared c-Fos expression induced by exploration of context A in mice from conditioned and unconditioned groups. Both groups explored the context 6 days before being tested, but the conditioned group also received immediate footshock in this context 3 days before testing. Expression of c-Fos was significantly elevated in the conditioned engram group in the areas of associative neocortex (frontal associative cortex, prelimbic and infralimbic cortex, cingular, retrosplenial and parietal cortex), in central and lateral amydgala and in CA1 region of hippocampus. Interestingly, dentate gyrus and CA3 region had similar c-Fos activation in the conditioned and unconditioned engram groups. We also performed c-Fos TRAP combined with c-Fos imaging to reveal cellular overlap in the episodes of context engram acquisition and its conditioning in the same animals. Our data suggest that engram acquisition and its conditioning though often occurring together, are distinct processes that can be isolated and studied separately.

Title: Associative fear memory to a compound cue in mice: behavioral and neuronal features

Authors: *O. I. IVASHKINA, K. TOROPOVA, M. ROSHCHINA, K. ANOKHIN;
NRC Kurchatov Institute, NBICS-Center, Moscow, Russian Federation

Abstract: Though cellular mechanisms of associative memory are commonly studied in Pavlovian fear conditioning (FC) to a single discrete stimulus, natural learning often involves complex stimuli composed of several sensory modalities. To study neural mechanisms of such learning we used FC to a compound cue (CC) consisted of auditory (tone, T) and visual (blinking light, L) stimuli. First, we showed that memory about CC and its separate components mature over different time after training: memories for CC and tone were manifested in freezing

behavior at all times tested starting from the first day after the training, whereas light component produced significant freezing response only starting from 3 days after the training. Next, we showed the same dissociation of memories in extinction experiments. Extinction of the one component of CC memory 1 day after the training did not affect memory about another component or CC. Extinction of the one component of CC memory 7 days after training resulted in extinction of memory about another component or CC. Finally, we performed c-Fos imaging of cellular activity in number of brain regions after formation and retrieval of memory for CC and its separate components. We showed that learning the CC resulted in significant activation of prelimbic cortex, lateral and central amygdala. Retrieval of memory of the CC and its separate components 7 days after the training resulted in significant activation of prelimbic and parietal association cortices, whereas basolateral amygdala was activated only after CC memory retrieval. Moreover we compared patterns of c-Fos expression after 1 and 7 days retrieval. Finally, we performed in vivo two-photon imaging of retrieval-induced c-Fos expression in the parietal cortex of fos-EGFP transgenic mice and found that there are at least three neuronal populations with different response specificity to the compound signal and its components. Taken together, our data suggests that complex stimuli can establish three different neuronal representations that can be used separately in the behavior.

Title: Comparison of neuronal activity in the mouse parietal associative cortex during fear memory formation and retrieval: *In vivo* imaging by immediate early gene expression

Authors: *A. GRUZDEVA, O. IVASHKINA, M. ROSHCHINA, K. ANOKHIN;
Natl. Res. Ctr. Kurchatov Inst., Moscow, Russian Federation

Abstract: Memories are hypothesized to be encoded by distributed cell assemblies, however little is known about consistency of activation of such neuronal populations. An essential question is how similar are these activations during memory encoding and subsequent episodes of retrieval. To study this question we investigated neuronal activity of the mouse associative

cortex in auditory fear conditioning and memory recall in response to conditioned sound. We used optic fiber recording and two-photon visualization of activated neurons in the cortex of awake transgenic mice in which the expression of enhanced green fluorescent protein (EGFP) was under the control of *c-fos* immediate early gene promoter. With optic fiber technique we characterized time course of induced fos-EGFP expression. Then we compared populations of active neurons in the same area of parietal associative cortex before learning, following learning and following memory retrieval. The largest proportion of identified neurons was active during all three conditions (79%). Most neurons, which were not active before learning, but were activated during learning, were also activated during memory retrieval (10% of all identified neurons). The small parts of identified neurons were activated only during learning or memory recall (3% or 2% respectively). Thus, our results indicate that the main part of neuronal population in the mouse parietal associative cortex that was transcriptionally activated during fear memory encoding, was then reactivated during cue-induced memory retrieval.

Title: Long-term episodic-like memory in object recognition model in three wild rodent species

Authors: *D. IVASHKIN, O. IVASHKINA, K. TOROPOVA, K. ANOKHIN;
NBICS, NRC Kurchatov Inst., Moscow, Russian Federation

Abstract: One of the key features of human memory is the ability to recall the entire complex episode in terms of what, where and when it happened. For a long time, it was assumed that episodic form of memory exists only in humans. Animals cannot give a verbal report about a personal past experience, yet episodic-like memory can be demonstrated as an integrated behavioral response for “what”, “where” and “when” questions. Dere et al. in 2005 proposed model of episodic-like memory for rodents based on the recognition of new neutral objects. This model has been used only to test the short-term memory. However, episodic memory in humans can be stored for years. Therefore, an important question is whether rodents are able to form long-term episodic-like memories in such a model. To address this problem, we used the modified version of task proposed by Dere et al. in wild rodent species: wood mice (Sylvaemus uralensis), bank voles (Clethrionomys glareolus) and field mice (Apodemus agrarius). Each

rodent received 5 experimental sessions (10 min each). During two pretraining sessions (PTS) animals explored new empty arena (PTS 1) or the same arena with 2 new objects (PTS 2, 6 h later). On training session (TS) 1 (16-18 h after the PTS 2), 4 novel objects were presented arranged in a triangle spatial configuration. On TS 2 (8 h later), another 4 novel objects were presented in a different spatial arrangement (in 4 arena corners). During the long-term memory test session (16 h after the TS 2) 4 objects were presented: old stationary (object from the TS 1 on the same position), old displaced (object from the TS 1 on the new position) and two recent objects from the TS 2 on the same positions. The duration of the active interaction with objects by animals was measured during all sessions. The “what”, “where” and “when” ratios were calculated as proportion of interaction with different types of objects. We demonstrated that duration of active interaction with objects in all rodent species increased from the first to the last experimental session, while the total exploratory behavior in the arena decreased. The presence of long-term episodic-like memory as a behavioral response to each of “what”, "where" and "when" questions was revealed only in field mice. Wood mice and bank voles were able to recall the memory only about the “where” component. We also showed that the individual variability of the exploratory behavior in bank voles and wood mice was significantly higher compared to the field mice. Thus, in this study we demonstrated the long-term episodic-like memory about the neutral event in wild rodents. The ability to form such memories may be important for the adaptive behavior of animals under the natural conditions.

Title: Roles for state-specific corticothalamic and thalamocortical communication in visual system plasticity

Authors: *J. DURKIN[1], A. SURESH[5], Q. SKILLING[2], J. COLBATH[3], M. ZOCHOWSKI[4], S. J. ATON[3];
[1]Neurosci. Grad. Program, [2]Biophysics Grad. Program, [3]Dept. of Molecular, Cellular, and Developmental Biol., [4]Dept. of Physics, Univ. of Michigan, Ann Arbor, MI; [5]Univ. of Chicago, Chicago, IL

Abstract: Orientation Specific Response Potentiation (OSRP) is a form of plasticity in primary visual cortex (V1), which is initiated by waking visual experience and dependent on subsequent sleep. OSRP consolidation is accompanied by an increase in V1 neuron firing following visual stimulus presentation, and is correlated with changes in spike-field coherence during Non-Rapid Eye Movement (NREM) sleep. Thus, we hypothesized that state-specific features of thalamocortical communication, such as NREM-specific oscillatory activity, are crucial for OSRP consolidation. To address this hypothesis, we performed two experiments using a combination of stereotrode recordings and state-specific optogenetic manipulations in mice. These experiments target distinct parts of the visual circuit, and address the necessity of both synchronization of thalamocortical activity, and thalamic (LGN) input to V1 for OSRP consolidation. For both sets of experiments, we measured OSRP across a 12-h interval following experience, the amplitude and coherence of thalamocortical oscillatory activity, and functional interactions between neurons in thalamus and cortex. We find that optogenetic inhibition of corticothalamic feedback during NREM sleep, but not Rapid Eye Movement (REM) sleep or waking, blocks OSRP. Our data suggests that synchronous activity between cortex and thalamus during NREM is necessary for OSRP consolidation. Preliminary data from LGN thalamocortical inhibition experiments indicate thalamocortical activity during REM may also play a role in OSRP. These studies will enhance understanding of both structure- and state-specific properties underlying a novel form of cortical plasticity.

Title: Impact of visual experience on oscillatory state and visual recognition memory in primary visual cortex

Authors: *R. KOMOROWSKI, S. F. COOKE, E. KAPLAN, M. F. BEAR;
Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Visual experience in the mouse can induce long-term changes in the responsiveness of primary visual cortex (V1) to a specific visual stimulus through a process called stimulus-selective response potentiation (SRP). This plasticity is thought to reflect the neural substrate of a simple visual memory stored within V1 that plays a fundamental role in the mouse's ability to behaviorally habituate to a familiar visual stimulus. Recent work in mouse V1 has revealed that interactions between the oscillatory state of cortex and an animal's behavior can have a profound impact on the processing of visual information. Here we examine the relationship between oscillatory state and neural activity in visual cortex in the context of SRP through spiking and local field potential (LFP) activity within mouse V1. We find that LFP recorded from thalamo-recipient layer IV of V1 alternates between two major states, one dominated by high-amplitude, low-frequency rhythms between 6 and 10Hz known as High-Voltage Slow oscillations (HVS) and one dominated by high-frequency (60-100Hz) gamma rhythms (HG), which reflect very different underlying spiking activity: HVS are associated largely with bursting activity in V1 and HG states are associated with tonic firing. These two states reflect very different processing modes within V1. The oscillatory state of V1 dramatically shifts towards an HVS-dominated state as a stimulus becomes progressively familiar. However, the presentation of novelty, even simply through a shift in stimulus orientation, can very swiftly shift the cortex back into a gamma-dominated state. Importantly, we show that SRP is only observable in the HG state and not the HVS state. These shifts in oscillatory state also correlate strongly with mouse behavior elicited by the onset of the visual stimulus. Our results indicate that oscillations in V1 reflect dynamics in stimulus coding within V1 that are highly modifiable by experience. Furthermore, these changes may be adaptive, allowing the animal to identify and encode information about novel and salient stimuli while conversely shifting into an offline state when information is highly familiar.

Title: Modeling perceptual learning in V4 based on changes in causal relationships between neurons

Authors: *J. D. YOUNG[1], V. DRAGOI[2], B. AAZHANG[1];
[1]ECE, Rice Univ., Houston, TX; [2]Neurobio. and Anat., Univ. of Texas-Houston Med. Sch., Houston, TX

Abstract: Perceptual learning is a well observed phenomenon but is poorly understood in terms of neurophysiology. We seek to create a model of perceptual learning in V4 based on neuronal influence. Previous research seeking to discover a neuronal explanation for visual task learning, a subset of perceptual learning, involved rhesus macaques repeatedly attempting a visual task. Monkeys were shown an image on-screen, then soon after shown a potentially rotated version of the same image and given the opportunity to identify the presence of a rotation. Analysis of local field potentials and spike timings revealed heightened local synchronization between V4 neurons during learning. We use directed information (DI), an information theoretic tool, on the same data set to quantify how the influence structure between V4 neurons changes over the time course of perceptual learning. DI is ideal for this application due its ability to compute the causal effect of one time series on another with minimal assumptions and its capacity to condition on other time series. Estimation of DI is based on a previously published technique that utilizes context-tree weighting in order to estimate probabilities for entropy estimation and therefore DI estimation.
By estimating the DI rate between neuron spike trains, we reveal different periods of DI rate change for select neuron pairs. Early and late trials of a given experiment show DI rate variation while middle trials exhibit stable DI rates. Overall, these neuron pairs exhibit significant feedback relationships. Results are compared with the accuracy of the monkey's decisions in order to determine correlation between DI rate trends and perceptual learning. We then develop a temporal network model of the time course of perceptual learning in V4. We use directed edges with weights proportional to the aforementioned changes in neuronal influence quantified by DI rate. We will test our model in rhesus macaques by stimulating V4 neurons to create the newly observed influence structure while they perform a visual task. Our stimulation technique will result in a faster perceptual learning rate. Furthermore, stimulation will restore learning capability in cases where individuals suffer from learning disabilities.

Title: An immunohistochemical approach for quantifying excitatory and inhibitory neurotransmission in areas MT and MST of the macaque monkey

Authors: *N. MALEK[1], J. NOVEK[2], R. MCKINNEY[3], M. PETRIDES[2], J. MARTINEZ-TRUJILLO[4];
[2]Cognitive Neurosci. Unit, Montreal Neurolog. Inst., [3]Dept. of Pharmacol. and Therapeut., [1]McGill Univ., Montreal, QC, Canada; [4]Robarts Res. Institute, Brain and Mind Institute, Dept. of Physiol. and Pharmacol., Western Univ., London, ON, Canada

Abstract: Functional characterizations of lower-order visual area MT (middle temporal) and higher-order multimodal association area MST (medial superior temporal) have been based on electrophysiological recordings, including mapping of receptive field size and motion-direction tuning. However, less is known about the comparative anatomy of both these areas. A recent study suggests differences in the functional roles of areas MT and MST in the macaque monkey for the coding of working memory (Mendoza-Halliday et al., Nat. Neuro., 2014), possibly due to differences in the proportion of excitatory and inhibitory neurotransmission. Previous quantitative histological examinations of excitation and inhibition have used few sampling locations at very high magnification to extrapolate characteristics of entire areas. Furthermore, it is often not known in which cortical layers such images are sampled. In order to gain a better understanding of excitation and inhibition differences in areas MT and MST in rhesus macaque monkeys, we pursued a more global approach that combined immunohistochemical staining and widefield imaging. To visualize local inhibitory expression, we targeted the main inhibitory neurotransmitter GABA with the immunohistochemical stain VGAT. To visualize excitation expression, for which glutamate is the primary neurotransmitter, we used VGlut1 and VGlut2 to stain for intracortical and thalamic inputs, respectively. Widefield fluorescence images of the entire areas of interest were acquired, cortical layers were manually drawn in, and evenly spaced sampling lines were used to acquire pixel intensity values across the cortical depth for all three fluorescence channels. Normalized profiles were obtained for each area and then statistically analyzed. We found differences in relative excitation and inhibition between MT and MST with the VGAT and VGlut1 stains, with the most apparent differences being found in layers II and III. These results provide anatomical evidence supporting the functional differences observed between these two areas.

Title: Working memory related neuronal activity is widely distributed throughout cortex during an object-based delayed match-to-sample task in the macaque monkey

Authors: *C. M. GRAY, N. DOTSON, S. HOFFMAN;
Cell Biol. and Neurosci., Montana State Univ. Bozeman, Bozeman, MT

Abstract: Task and stimulus dependent neuronal activity that continues during the memory period of a delayed match-to-sample task is considered to be the quintessential neural correlate of working memory. This persistent, mnemonic activity has been most extensively studied in prefrontal and posterior parietal cortical areas, but less so in other regions of the cortex. Consequently, much remains to be learned regarding the distribution of persistent activity. Recently, we developed a large-scale semi-chronic recording system that enables the long-term measurement of neuronal activity from up to 256 independently movable microelectrodes spanning an entire cerebral hemisphere in non-human primates. We implanted this instrument in two macaque monkeys and recorded neuronal activity for 6 and 10 months, respectively, while the animals performed an object-based, delayed match-to-sample (dMTS) task and a set of control tasks.

At the end of the experiments, the electrode tracks were identified histologically and the cortical area of each recording site was reconstructed using the Caret software package. Based on these analyses, we obtained recordings of neuronal activity from 63 separate cortical areas and 4 subcortical structures include the Caudate nucleus, Putamen, Claustrum and Thalamus. The cortical areas varied in location from V1 to area 11 along the AP axis, TEOm to area 23 along the ML axis, and F1 to TEpd along the VM axis.

We extracted single- and multi-unit activity from each recording site and determined the incidence of task-dependent and stimulus-specific activity during all phases of the task using a sliding window analysis of firing rate (Kruskal-Wallis test ($P<.05$) with correction for the false discovery rate).

These analyses revealed a widespread, but sparse distribution of task dependent and stimulus specific changes in neuronal activity throughout the cortex. Sample specific activity was most

widespread, including areas throughout primary and extrastriate visual cortex, posterior parietal areas, motor and premotor areas, prefrontal cortices and Basal Ganglia. Task and sample specific delay period activity occurred less often, but with a similar distribution, and was composed of both increases and decreases in firing rate. Sample specific delay period activity occurred throughout multiple areas of visual cortex, including striate cortex, and a number of premotor and prefrontal areas not previously described for this task.
These findings demonstrate that visual working memory-related activity is widespread throughout many regions of the cortex suggesting that short-term mnemonic representations are distributed in nature.

Title: Role of insular cortex in emotional learning

Authors: *Y. CHEN[1,2], C. S. PÉREZ[4], F. MALTESE[2], N. NADIF KASRI[2,3], B. ROOZENDAAL[2];
[1]Cognitive Neurosci., Donders Inst., Nijmegen, Netherlands; [2]Dept. of Cognitive Neurosci., [3]Dept. of Human Genet., Radboudumc, Nijmegen, Netherlands; [4]de Neurobiología, Querétaro, Mexico

Abstract: Extensive evidence from neuroimaging studies in humans consistently point toward a key role for the insular cortex (IC) in the detection of novel and salient information. Yet, little is known whether the IC is also involved in emotionally influenced learning and memory. The present study investigated whether noradrenergic activation, which is normally induced during an emotionally arousing situation, in the IC is required for the consolidation of object recognition memory. Male Sprague-Dawley rats were trained on an object recognition task for either 3 or 10 min during which they could explore two identical objects. Immediately after the training they received bilateral intra-IC infusions of norepinephrine (1.0 μg) or the β-adrenoceptor antagonist propranolol (0.3 μg). Saline-infused control rats exhibited poor 24-h retention when given 3 min of training and good retention when given 10 min of training. Norepinephrine administered after 3 min of object training enhanced retention, whereas propranolol administered after 10 min of

training produced memory impairment. Moreover, we found that in untreated groups of trained rats 10 min of object recognition training increased neuronal activity in the IC 1 h later, assessed by the number of cells expressing immunoreactivity for phosphorylated cyclic-AMP response element-binding protein (pCREB).These findings indicate that the IC is involved in regulating emotional arousal effects on the consolidation of object recognition memory.

Abstract: Mice use their whiskers to explore their surroundings and to identify the objects around them. As mice move through the environment, they must be able to attend toward and selectively respond to the small fraction of objects that are relevant to their goals. To investigate how the somatosensory system associates objects with their behavioral relevance (i.e. whether objects predict reward outcomes), we developed a head-fixed, whisker-based behavioral paradigm in which mice respond to a relevant target object and ignore a distractor.
Head-fixed behavioral tasks are useful for studying whisker-mediated behaviors because they allow for precise presentation of stimuli and permit a diverse array of techniques for recording and manipulating neural activity. Most common head-fixed behavioral paradigms require mice to discriminate between two objects by responding to one and suppressing a response to another. In such tasks, both objects are equally informative about the correct response. In contrast, we have developed a spatial localization task in which only one object (the “target”) is informative about the correct response, while a simultaneously presented “distractor” object is irrelevant. These

two objects are identical in physical characteristics (shape, size, texture, etc.) and differ only in their relevance to the animal. Mice distinguish between the two identical stimuli based on their location in the whisker field and are able to learn the association between the presence of the target and the possibility of reward. Furthermore, mice do not base their behavior on the presence of the distractor, but rather react only to the presence of the target. This task will facilitate investigation of how somatosensory thalamus, cortex, and other brain structures encode relevant tactile objects and behavioral choice. Such experiments will shed light on how the brain associates objects with their behavioral relevance, allowing animals to respond selectively to important stimuli in their environment.

Abstract: Purpose: Phototherapy has been shown to be effective for a variety of mental diseases. For example, blue light treatment can effectively improve learning and memory functions in Alzheimer's patients. However, the known retinal damage effect of blue light

stimulation limits its application. In this study, we thus investigated the effect of green light (527nm) illumination on learning and memory functions in mice. **Method:**Thy-1 H line mice were randomly divided into three groups, which received room light, blue light and green light illumination using LED sources (2.2 μmol/ m^2·s in photon density) for two consecutive weeks (12 h light / 12 h dark normal cycle). The ability of learning and memory was assessed using whisker-dependent novel texture discrimination task. Moreover, the dendritic spine plasticity of layer V pyramidal neurons in barrel cortex was examined *in vivo* using two-photon microscopy to analyze formation, elimination and turnover rate of spines. **Result:** Whisker-dependent novel texture discrimination task showed that green-light treatment significantly shortened the time for learning novel texture compared to that in room-light treatment animals. Moreover, green-light illumination also extended the retention time of novel texture memory compared to room-light treatment group. Two-photon microscopy revealed similar spine formation rates among all groups ($p>0.05$). There was significantly higher elimination rate in green light or blue light treatment mice compared to room light animals ($p<0.05$). Spine turnover rate was similar between green and blue light groups, both of which were higher than room light group ($p<0.05$). No significant difference of spine dynamic parameters has been found between green and blue light group ($p>0.05$). **Conclusion:** Green light illumination could improve memory and learning abilities of novel texture in mice, possibly via increasing spine turnover rate.

Title: Conditional knock-out of the ACAN gene removes aggrecan and WFA-positive perineuronal nets in adult mice

Authors: ***M. H. FYHN**[1], K. LENSJØ[1], D. ROWLANDS[2], V. DINH[3], M. R. ANDREWS[4], T. HAFTING FYHN[3], J. W. FAWCETT[2], G. DICK[1];
[1]Dept. of Biosci., Oslo, Norway; [2]Ctr. for Brain Repair, Univ. of Cambridge, Cambridge, United Kingdom; [3]Inst. of Basic Med. Sci., Univ. of Oslo, Oslo, Norway; [4]St Andrews Sch. of Med., St. Andrews, United Kingdom

Abstract: Perineuronal nets (PNNs) are a specialized form of extracellular matrix in the CNS that mainly enwraps parvalbumin (PV) expressing inhibitory interneurons. They assemble in parallel with the maturation of the inhibitory network and with the closure of critical period plasticity. Several lines of evidence support a role for PNNs in stabilizing synapses, limiting adult brain plasticity and in some neurological disorders. While the mature PNN is a complex structure of several components, recent work suggests that the proteoglycan aggrecan, a product of the ACAN gene, is vital for the PNNs. However, because aggrecan is essential to cartilage throughout the body, global ACAN knock-out is lethal. Thus, to investigate the role of aggrecan for PNN assembly and stability, and its contribution to brain plasticity, we have established a CRE-inducible conditional ACAN knock-out mouse. The transgenic construct is a design of the European Conditional Mouse Mutagenesis Program and has had two loxP sites inserted into the genome, flanking exon 4 of the ACAN gene. Two approaches were used to remove aggrecan from the conditional ACAN knock-out mouse, either by (1) injecting a viral vector expressing CRE recombinase under control of the synapsin promoter to obtain area specific knock-outs in adult mice, or by (2) crossing with the PV-Cre line, which expresses CRE recombinase downstream of the PV transcript. Aggrecan and PNNs was determined by immunohistochemical staining against aggrecan, PV and the PNN specific lectin *Wisteria floribunda* agglutinin. Conditional knock-out of ACAN efficiently eliminated both aggrecan and PNNs with both approaches, while the PV staining intensity remained unaltered. Adult knock-out ACAN/PV-Cre mice were lacking PNNs. This shows for the first time that aggrecan is produced by the PV neurons themselves, in line with a role of PV neurons in regulating brain plasticity. To investigate the role of aggrecan for plasticity we restricted the knock-out of the ACAN gene to the visual cortex of adult mice by using local injections of viral vectors with Cre-recombinase. Activity-dependent plasticity was induced by monocular deprivation and assessed by intrinsic optical signal imaging. Preliminary results indicate that knocking out ACAN in adult visual cortex reinstate a high level of plasticity similar to that of juveniles. Taken together, the conditional ACAN knock-out mouse can be used to target the ACAN gene, leading to loss of aggrecan and abolished PNNs as well as increased plasticity. Our results indicate that aggrecan is vital for the assembly and stability of PNNs, making the ACAN mouse a robust tool to reveal the role of PNNs in plasticity and disease.

Title: The perineuronal nets in the lateral secondary visual cortex are essential for remote visual fear memory

Authors: *K. K. LENSJØ, M. WIGESTRAND, E. THOMPSON, A. MALTHE-SØRENSEN, T. HAFTING, M. FYHN;
Univ. of Oslo, OSLO, Norway

Abstract: Compared to our knowledge of the molecular mechanisms underlying learning and memory encoding and consolidation, far less is known about remote memory storage. Recently, it was proposed that the specialized extracellular matrix structures called perineuronal nets (PNNs) may be a physical framework for long term memory storage (Tsien, 2013). Their mesh like structure, tightly enwrapping and stabilizing synaptic connections and their composition of molecules with very slow turnover rates, point in this direction but the idea remains to be tested. Here, we test this hypothesis by investigating remote visual fear memories. Recent evidence indicate that over time, visual fear memories become dependent on the lateral part of the secondary visual cortex (V2L), suggesting that secondary sensory cortices may be pivotal in long term memory storage. In order to investigate the contribution of PNNs for memory stability, we induced a remote visual fear memory in adult Sprague Dawley rats using Pavlovian fear conditioning and experimentally degraded the PNNs by local injections of the enzyme Chondroitinase ABC (chABC) into V2L. Injections of chABC were performed at different time-points in the fear conditioning learning paradigm; either prior to training or prior to retrieval of the remote memory. We found that degrading the PNNs in V2L prior to the remote memory retrieval test selectively disrupted the visual fear memory while degrading the PNNs prior to training had no effect on memory retrieval. Moreover, degrading the PNNs in the primary visual cortex had no effect on the remote memory. In order to elucidate the neural network responses underlying the impaired recall we use chronically implanted electrodes and perform simultaneous local field potential recordings from V2L and the basolateral amygdala. Together, these findings indicate that the PNNs in V2L are critical for visual fear memory processing at remote time-points, but not for memory acquisition or early consolidation.

Title: Epigenetic mechanisms gate auditory cue-reward extinction and sensory cortical plasticity

Authors: *H. D. QUINONES, C. YEN, K. BIESZCZAD;
Psychology, Rutgers, The State Univ. of New Jersey, Piscataway, NJ

Abstract: Cortical plasticity is dynamic, changing the representation of memory based on a lifetime history of experiences. Behaviorally-relevant sensory cues are transient, but can be transformed into long-term memory (LTM). Formation of LTM requires neuroplasticity that changes neural function, structure and connectivity. At a molecular level, long-term changes require gene expression. Previous research has shown that epigenetic mechanisms can selectively regulate gene expression. For example, a class I histone deacetylase (HDAC) called HDAC3 seems to be a "molecular brake" on plasticity required for LTM (McQuown et al. 2011). Blocking HDAC3 with the drug RGFP966 releases the brakes on gene expression enabling highly cue-specific LTM and cortical reorganization in the primary auditory cortex (A1) for the sound frequency of a salient cue. More cells in A1 tonotopy can become "re-tuned" to the frequency of a cue signaling a reward (Bieszczad & Weinberger 2010). Yet, tonotopy can also reorganize in the opposite direction to reduce the number of cells "tuned" to the frequency of a cue after it is extinguished. There is a significant positive relationship between the magnitude of frequency representational area in A1 and that frequency's strength in associative memory, whether in cue-reward acquisition or in cue extinction. Previous work has shown that HDAC3 inhibition via RGFP966 can enable cue-specific cortical plasticity with cue-reward acquisition learning (Bieszczad et al. 2015). The purpose of this study is to test whether HDAC3 has similar control over the cue-specific cortical plasticity for extinction, which is predicted to strengthen extinction memory. To test this hypothesis, male Sprague Dawley rats are trained to bar-press for a water reward in response to a 5.0 kHz (70 dB) pure tone in a first phase of training, and are later trained in a second phase to extinguish the bar-press response learned by the cue-reward association. During extinction training, one group of animals is injected with RGFP966 (10mg/kg; i.p.) and the other group with vehicle. A spontaneous recovery test is used to determine the strength of cue-specific extinction. A1 electrophysiology after extinction training and memory testing determine frequency-specific tonotopic re-organization. Data presented will show whether HDAC3 regulates both extinction and acquisition memory. These results are relevant in work towards a comprehensive model of the function and epigenetic regulation of

sensory cortices and their role in cued memory. It also has applications in development of treatments for cue-related addictive behaviors, and cued emotional stressors in PTSD.

Title: HDAC3 dynamically regulates discrimination learning and information storage in primary auditory cortex

Authors: *A. SHANG, K. M. BIESZCZAD;
Behavioral and Systems Neuroscience, Dept. of Psychology, Rutgers Univ., Piscataway, NJ

Abstract: Epigenetic mechanisms that modulate gene expression – such as histone modification – are key for regulating the neuroplasticity underlying long-term memory (LTM) formation. Blocking histone deacetylases (HDACs) has been shown to facilitate various forms of LTM by *releasing the brakes* on neuroplasticity (e.g. McQuown et al., 2011; Stefanko et al., 2009). Recent work in the auditory system using a simple single-tone associative learning paradigm suggests that pharmacological inhibition of HDAC3 via RGFP966 can enhance the specificity of memory for relevant sound features, and also reorganize primary auditory cortex (A1) to enhance the representation of those features (Bieszczad et al., 2015).
We designed a two-tone frequency-discrimination (2TD) task to determine if HDAC3 regulates auditory discrimination learning. This instrumental learning task can also determine the temporal dynamics of HDAC3 action on 2TD acquisition, performance and underlying plasticity in A1. Rats (male; Sprague-Dawley) learn to discriminate between two spectrally-distant frequencies: bar-press (BP) responses to only the CS+ (5 kHz) are rewarded; BPs to the second sound, CS- (11.5 kHz), result in a time-out (extended time until next trial). Sessions are followed by injections of RGFP966 (10mg/kg; *i.p.*) or vehicle (Veh). Frequency-specificity of the auditory memory formed is assessed after two weeks of daily training sessions using a stimulus generalization (SG) test, where a range of test frequencies (including the CS+ and CS-) are presented under extinction conditions. Electrophysiological recordings show the tonotopic

effects in A1 that could underlie differences in behavior.
Differences in behavioral (2TD acquisition & performance; SG) and neural (A1 tonotopic reorganization) frequency-specificity between groups will support the hypothesis that HDAC3 is a molecular epigenetic regulator of sensory information consolidation during incremental learning experiences. Data presented will show whether RGFP966-treated rats have rapid 2TD acquisition and reach asymptotic levels of performance sooner than Veh-treated rats. SG may likewise reveal sharper (more frequency-specific) memory, with more selective BPs to the CS+. Unusually rapid and frequency-specific reorganizations in A1 for the salient sounds are expected to underlie frequency-specific behavioral effects of HDAC3. Such results further specify a role for epigenetic mechanisms in learning, memory, and information storage. Furthermore, they initiate a novel investigation into the temporal dynamics of epigenetic regulators that convert the sensory details of transient experiences into LTM.

Title: Histone modification enables song-specific auditory memories in an avian model.

Authors: ***M. L. PHAN**, J. JIMÉNEZ CASTILLO, S. MAHIDADIA, S. SAAD, D. S. VICARIO, K. M. BIESZCZAD;
Psychology, Rutgers Univ. Dept. of Psychology, Piscataway, NJ

Abstract: Vocal communication relies on the brain's ability to process, learn and remember important sounds. Long-term memories (LTM) of salient sounds require the expression of genes that subserve stable changes in neural function, structure, and connectivity in the auditory areas of the brain. Molecular epigenetic mechanisms regulate gene expression required for this memory formation. For example, the enzyme histone deacetylase 3 (HDAC3) gates the transformation of an auditory experience into memory. Bieszczad et al. (2015) demonstrated that rats treated with a selective HDAC3-inhibitor (RGFP966) acquired a specific and unusually

detailed auditory associative memory for pure tones, which occurred with highly specific neuroplasticity in primary auditory cortex (A1).
We test the hypothesis that HDAC3-inhibition enables long-term neuronal memories for ethologically-relevant communication signals with complex acoustic features (Phan & Bieszczad 2016), using an avian model. The songbird caudomedial nidopallium (NCM) is analogous to superficial layers of mammalian A1 or to a secondary auditory cortex and contributes to auditory discrimination and song memory. Neurons in NCM undergo neuroplasticity in the form of stimulus-specific adaptation (SSA). SSA occurs when presented with repeated song stimuli, evoked responses to familiar (F) stimuli adapt more slowly than to novel (N) stimuli. Comparison of adaptation rate (the slope of the decrease in response amplitude as a function of repetition number) between F and N songs provides a measure of the strength of song memories. Normally, 200 repetitions of a conspecific song will lead to LTM measured ~20h later. We exposed adult male zebra finches (n=7) to ≤ 40 repetitions of 8 novel zebra finch songs, below the usual threshold for memory formation. Systemic injection of RGFP966 (n=3) or vehicle control (n=4) followed exposure. Neural responses in NCM were recorded 20h later to the 8 previously exposed F songs and to 8 never-before-heard N songs. In vehicle treated birds, SSA rates were not significantly different between the N and F songs, indicating no memory of the F stimuli (K-S test; p=0.575, D=0.084, Z=0.740). In birds injected with RGFP966, adaptation rates were shallower (less negative) for F stimuli than for N stimuli (K-S test; p=0.016, D=0.206, Z=1.50). This difference indicates that RGFP966 treatment enabled memories for specific song stimuli. Therefore, HDAC3-inhibition can effectively transform a sub-threshold auditory experience (minimal repetitions of song exposure) into a LTM of that experience, apparently by lowering the threshold number of exposure events required for memory to form.

Title: Functional footprints of impaired consciousness in mice with reduced molecular diversity of clustered protocadherin-α

Authors: *K. SHIBUKI[1,2], T. YAMAGISHI[3], D. KAMATANI[1,2], K. YOSHITAKE[1,2], H. TSUKANO[1], K. WATANABE[1], R. HISHIDA[1], K. TAKAHASHI[3], S. TAKAHASHI[3], A. HORII[3], T. YAGI[4,2];
[1]Brain Res. Inst., Niigata, Japan; [2]CREST/AMED, Tokyo, Japan; [3]Niigata Univ., Niigata, Japan; [4]Osaka Univ., Osaka, Japan

Abstract: The integrated information theory of consciousness suggests that various types of dynamic short-term memory highly integrated together in the brain produce consciousness. However, the presence or absence of specific neural mechanisms of consciousness is unknown. If complex neural circuits conceive consciousness in principle, consciousness is tightly bound to other neural functions, as observed during anesthesia or sleep. If consciousness requires specific neural mechanisms, it may be separated from other neural functions, i.e. some genetically manipulated mice with apparently normal neural functions may have impaired consciousness. We report evidences supporting the latter possibility. Clustered protocadherins (cPcdhs, α-γ) are neuro-specific cell adhesion molecules characterized by clustered gene structures. In each neuron, some of the gene clusters are randomly selected and determine the specificity of cell adhesion properties. These molecules have been supposed to play a role in formation of sophisticated neural circuits. In cPcdhα1,12 mice, only cPcdhα1 and cPcdhα12 (but not cPcdhα2- cPcdhα11) are expressed, while the total amount of cPcdhα is constant. These mice exhibit no apparent abnormality at glance. However, we found that visual short-term memory was clearly impaired in behavioral experiments using spatial cues or shape cues. Visual short-term memory of spatial information was evaluated using a T-maze test. Although cPcdhα1,12 mice exhibited a comparable performance with that of control mice in a visually-guided task, their performance was significantly impaired in a memory-guided task. Visual short-term memory of shape information was evaluated using a delayed match-to-sample test, and cPcdhα1,12 mice exhibited a nice performance in a control task with no delay while the performance was significantly impaired in a task with a delay for 20 s. Furthermore, cortical plasticity and behaviors depending on multimodal sensory integration between visual and whisker information or between visual and auditory information were clearly impaired. Since cPcdhα is distributed all over the brain, various types of short-term memory and sensory integration are likely impaired in cPcdhα1,12 mice. These results strongly suggest that specific neural mechanisms depending on molecular diversity of cPcdhα are required for producing consciousness. The present study discloses functional footprints of impaired consciousness in mice, and we hope that these footprints could be a useful key for elucidating the neural mechanisms of consciousness at cellular and molecular levels.

Title: High-throughput phenotypic profiling of genes implicated in Autism Spectrum Disorders identifies genes important for habituation

Authors: *T. MCDIARMID[1], C. H. RANKIN[2];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Psychology, The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: A major challenge to finding the causes of Autism Spectrum Disorders (ASD) is that thousands of gene mutations have been linked to the disease. To find causal links between mutations and symptoms we need a system in which we can rapidly manipulate genetic variation and measure the resulting phenotype. One endophenotype found in ASD is decreased habituation. Habituation is a form of learning observed as a decrease in responding to repeated stimulation. Habituation has been conserved through evolution, making it amenable to study using genetic model organisms such as *Caenorhabditis elegans*. Here, we use a machine vision system, the multi-worm tracker, to assay mechanosensory habituation in 52 strains of *C. elegans* each carrying a mutation in an ortholog of an ASD-linked gene to determine which genes disrupt habituation when mutated. Our screen identified several habituation mutants from the ASD-linked genes; these genes fall into three main functional groups: cell-adhesion molecules, ion channels, and transcription factors. Of note, CTNNB1(*bar-1*), FAT3(*cdh-4*), and CREBBP(*cbp-1*) mutants all showed decreased habituation across multiple behavioural measures. Rescuing *C. elegans* disrupted habituation phenotypes with orthologous human genes will confirm functional homology between *C. elegans* and human genes. If the human gene rescues the worm phenotype we can then rescue with human variants found in ASD and categorize them in to variants that rescue and those that do not. This will allow us to group variants into functional categories that may shed light on their role in ASD.

Title: Alcohol's effect on habituation involve Ga/cAMP/PLA and the Gao/DGA/DAG pathway in *Caenorhabditis elegans*

Authors: C. LIN[1], S. MIRHADI[2], S. SOO[2], *C. H. RANKIN[1];
[1]Univ. British Columbia, Vancouver, BC, Canada; [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Alcohol intoxication impairs learning, but the underlying mechanism is not well understood. Habituation is a type of learning measured as a gradual decrease in response to repeated stimuli that is not due to fatigue or adaptation. Using the genetic model organism *Caenorhabditis elegans*, we investigated the roles of several candidate genes in the effect of alcohol on habituation. Animals were exposed to 400mM ethanol for 30mins (~0.08% BAC) and then their behavior and responses to 30 mechanical stimuli (taps) delivered at 10s Inter-stimulus interval were tracked using the Multi-Worm Tracker. Wildtype animals respond to the tap stimuli by moving backwards (reversals), and the probability and magnitude of this reversal response gradually decrease as the number of tap increases. On alcohol, wildtype worms habituate to the taps faster and more deeply than unexposed animals. Interestingly, wildtype worms on alcohol also shifted their responses to taps from reversals to faster forward movement over the course of habituation. Our initial genetic analysis showed that some genes implicated in other behavioral effects of alcohol in C. elegans were also involved in alcohol-dependent habituation phenotypes (BK channel, Neuropeptide Y receptor), however some other implicated genes were not (D1 receptor. We tested the role of the Gαs/cAMP/PKA pathway and Gαo/DGK/DAG pathway in alcohols effects on habituation. In the Gαs/cAMP/PKA pathway, Gαs (*gsa-1),* adenylyl cyclase (*acy-1)* and the negative regulator cAMP phosphodiesterase (*pde-4),* were both found to be involved in the deeper habituation induced by alcohol, however the regulatory subunit of PKA (*kin-2)* may not to be. In the Gαo/DGK/DAG pathway, Gαo *(goa-1)* was found to be involved in the deeper habituation induced by alcohol, but another member of the pathway, *unc-13,* was not. This study identified novel mechanisms underlying learning impairment under alcohol intoxication.

Title: A neuropeptide mediated integration of habituation and sensitization to repeated optogenetic stimulation promotes escape in *C. elegans*

Authors: *A. YU, E. ARDIEL, C. RANKIN;
The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Habituation is a highly conserved, but poorly understood phenomenon. To identify molecular components mediating habituation, we took advantage of a high-throughput *C. elegans* learning assay using optogenetics for controlled neuronal activation and real-time computer vision software for automated behavioral tracking. We implicated neuropeptides in habituation of ASH-mediated reversals and performed a targeted RNAi screen to identify candidate receptors. Through subsequent mutant analysis and cell-type specific rescue, we show that pigment dispersing factor (PDF) ligands function redundantly to promote habituation via PDFR-1-mediated cAMP signaling in both neurons and muscles. Behavioral analyses of a number of components of the locomotion during learning acquisition indicated that different components of the behavior showed different patterns of plasticity. Mutant analyses and rescues revealed that aspects of response habituation occur primarily in neurons and locomotion sensitization primarily in muscle as part of a shifting behavioral strategy orchestrated by PDF signaling to promote dispersal. This suggests that habituation reflects a coordinated change in several behaviors to produce a coordinated response. This is in contrast to the traditional definition of habituation as learning to ignore stimuli. In addition, it leads to questioning single response-centric analyses of learning.

Abstract: Cephalopods (*Octopus*, Squid, Cuttlefish, and *Nautilus*) have evolved a degree of behavioral flexibility that rivals that of many mammals. The Vertical Lobe (VL), a structure unique to cephalopods containing intricate memory circuitry, parallels mammalian analogues like the hippocampus in cell number and function, but has evolved independently within the distant molluscan lineage. We used integrative Next-gen sequencing technology and bioinformatic analyses, followed by anatomical validation using in-situ hybridization, to identify the first molecular maps of signaling molecules implemented in cephalopod memory circuitry. We constructed, sequenced and analyzed *Octopus* neural transcriptomes of various tissues (including VL, CNS, SFL-Superior Frontal lobe, and Arm Cords), and individual cells from sub-populations within the VL and other neuronal tissues, including the Amacrine (Am) Interneurons and Large Efferent (LE) Neurons that make up the VL. We compared these transcriptomes to the publically available *Octopus* genome and our gastropod mollusc neural transcriptomes including *Aplysia californica*. We identified 16,194 transcripts in the VL (RPKM >/=1) and found 4,139 (25.5%) appear to be cephalopod-specific. Remarkably, indicators for many memory related signal molecules and transmitters like NO (NOS), GABA (GAD), and acetylcholine (ChAT) were not identified in VL transcriptomes, suggesting a distinct cephalopod-specific complement of molecules independently recruited in the organization of learning and memory-forming circuits. We used the well characterized neuropeptide (NP) precursor complement of *Aplysia* to find 22 homologs in *Octopus* VL and 23 in the SFL. We have systematically cloned and mapped expression of NPs, and have localized 9 NP to the components of the VL circuit. NPX3 is abundantly expressed in the cell bodies of the MSF, where the afferent tract the VL originates

and NPX1 localizes to the cell bodies of each VL gyrus. Next we used unbiased computational predictions and manual annotation to identify putative signaling molecules form the VL transcriptomes. From this we have identified 4 cephalopod-specific abundant transcripts, one of which, NPX2 localizes to all cell bodies in the VL and Subfrontal lobes. Among the 6 NPs that localize to the VL LE neuron, 2 unique cephalopod NPs, NPX4 and 5, are abundant in *Octopus*, but absent in the ancestrally branching Nautilus CNS (which lacks a VL). This expansion of novel signaling molecules in the VL circuit is likely a key feature of the unique memory systems of cephalopods, further implying extensive parallel evolution of cephalopod brains and memory circuits in particular.

Title: Pavlovian fear conditioning in the terrestrial caribbean hermit crab coenobita clypeatus

Authors: *A. P. BLAISDELL, M. T. DO, L. J. TEOPENGCO, J. E. SCHROEDER; Psychology, UCLA, Los Angeles, CA

Abstract: *Coenobita clypeatus* is a species of terrestrial Caribbean hermit crab previously shown in our lab to emit defensive behavior to a threatening visual stimulus. We investigated fear conditioning in *C. clypeatus* using an audiovisual cue as the conditioned stimulus (CS) and being agitated in a small cup as the unconditioned stimulus (US). In the experimental Group Paired, the CS was paired with the US. In the control Group Unpaired, the CS and US were presented on separate trials in an explicitly unpaired manner. Conditioning consisted of one session of 10 trials. For Group Paired, each trial consisted of placing the subject in a clear plastic cup attached to a rod. After the crab emerged from its shell, the CS was presented for 5 s. 2-s after the onset of the CS, the cup was agitated by gently manually rotating the rod for 3 s. At the end of the trial, the CS and US co-terminated. In Group Unpaired, each trial consisted either of a 5-s presentation of the CS or a 3-s presentation of the US, with five of each type of trial, their order pseudorandomized in the session. For both groups, a 60-s intertrial interval (ITI) separated each trial. Presentation of the agitation US caused crabs to hide in their shell (the unconditioned response). For all subjects in Group Paired, but none in Group Unpaired, hiding or freezing responses to the CS prior to the onset of the US developed over the course of 10 trials. We report

on the features of the CS that control the conditioned response, and the duration of learning. This procedure produces strong and reliable fear conditioning in *C. clypeatus*, and will allow for investigations into the psychological and neural basis of Pavlovian conditioning in the terrestrial hermit crab.

Title: MK-801 and methiothepin immediately before reconsolidation produce different types of amnesia in snail Helix lucorum

Authors: *S. SOLNTSEVA[1,2], A. V. SHEVELKIN[1,3], O. I. EFIMOVA[4], P. V. NIKITIN[1], S. A. KOZYREV[1], V. P. NIKITIN[1];

Abstract: Considerable progress has been made in understanding the neurophysiological and molecular mechanisms of long-term memory formation and stabilization. Amnestic processes such as memory loss, forgetting, and amnesia, are far less extensively studied, despite their theoretical, social, and medical importance.
We studied time course of amnesia produced by impairment of memory reconsolidation by NMDA glutamate receptor antagonist (MK-801) or 5-HT/dopamine receptor antagonist (methiothepin) immediately before reminder in snails *Helix lucorum*. Amnesia was induced by MK-801 or methiothepin with following reminder procedure two days after food aversion conditioning. We attempted to train these snails again three or ten days after amnesia induction and found faster learning than at the initial training at 3rd day after amnesia induction. However, 10 days after the methiothepin/reminder, we observed that time course of food aversion conditioning was similar to that at initial training. While, the repeated training 10 days after MK-801/reminder did not produce long-term memory in snail at all.
Thus, we demonstrated that impairment of memory reconsolidation by 5-HT/dopamine receptor

antagonist/reminder or NMDA glutamate receptors antagonist/reminder induces different types of amnesia. Both types of amnesia have similar time course of repeated learning at early period of time (it's successful and proceed faster), but they are different at late period of time (learning is successful only after methiothepin/reminder but not after MK-801/reminder). Our results suggest that the treatment of amnesia should take into account its stage of development.

Title: Origins of behavioral complexity in animals without brains: multiple specialized nerve nets.

Authors: *W. N. FROST[1], J. BERG[2], C. BRANDON[1], T. NOREKIAN[3];
[1]Dept Cell Biol. and Anat., The Chicago Med. Sch., North Chicago, IL; [2]Biol., Lake Forest Col., Lake Forest, IL; [3]Friday Harbor Labs., Friday Harbor, WA

Abstract: Sea anemones have the most primitive nervous system in the animal kingdom. Lacking a brain or CNS, they utilize a nerve net architecture consisting of diffusely distributed neurons, with no ganglia or other centralization. Despite such limited brain power, they have a surprisingly rich behavioral repertoire. For example, the anemone Stomphia displays directed attacks, rapid withdrawals, circular sweeps of the tentacles, rhythmic swimming, and post-swimming righting behaviors. Furthermore, it can distinguish between different predator species, and employs different response strategies to each. Stomphia preferentially attacks the nudibranch Aeolidia papillosa, stinging with its tentacles and then withdrawing, often several times in sequence, to drive the predator away. If unsuccessful, it switches strategies and launches a rhythmic, vigorous escape swim. Stomphia always immediately swims to the seastar Dermasterias imbricata. Strategy switching and multiple sophisticated behaviors. How are these possible with only a "primitive" nerve net organization?
In this study we used confocal imaging of alpha tubulin (neurons) and phalloidin (myoepithelial contractile bundles referred to here as muscle) to examine the nerve net organization of the animal's mesenteries - plate-like structures radiating from the central pharynx to the body wall

that contain the muscles mediating several of these behaviors. One side of each mesentery has a longitudinal retractor muscle that rapidly withdraws the tentacles and shortens the body during defensive withdrawals. The other side has a diagonal parieto-basliar muscle that produces the alternating whole-body bends of the escape swim.
Imaging revealed the presence of several distinct nerve nets associated with the mesenteries. Above each muscle was a diffuse nerve net, with axons running in all directions. Processes from this net then descended to contact a highly organized net of bipolar neurons arrayed in linear fashion along the length of each muscle bundle. A similar dual-net structure was recapitulated for the parieto-basilar muscle on the opposite side of the mesentery. The predominantly connective tissue mesoglea lying between these two nerve net / muscle systems contained a third net of diffuse multipolar neurons, many with long, axon-like processes that appears well situated to mediate communication between the muscle-specific nerve nets on each side of the mesentery. Our results support the idea that in the absence of the nervous system centralization evolved by most other organisms, sea anemones do many things we do through the use of multiple specialized but decentralized nerve nets.

Title: Role of modulatory interneurons in memory lapses after single-trial reward conditioning

Authors: *D. PRICE, M. CROSSLEY, G. KEMENES, P. R. BENJAMIN, T. NOWOTNY, I. KEMENES;
Neurosci., Univ. of Sussex, Brighton, United Kingdom

Abstract: The feeding system of the pond snail, *Lymnaea stagnalis*, is a well-established model for understanding the neural mechanisms of memory consolidation. Following a single pairing of gamma-nonalactone (GNL), the conditioned stimulus (CS) and sucrose, the unconditioned stimulus (US), a long-term appetitive memory is formed, lasting for weeks. It has previously been shown that a non-synaptic change, a persistent depolarisation of the soma of a modulatory interneuron, the cerebral giant cell (CGC), is involved in the maintenance of long-term memory in *Lymnaea*.

Much less is known about the cellular changes underlying the actual process of memory consolidation. It has been reported in vertebrates and invertebrates that there are brief periods during memory consolidation when the recall of memory is impaired. In *Lymnaea* such periods of vulnerability of the memory trace have been identified both *in vivo* and *in vitro*. To better understand the underlying cellular mechanisms of this process, we recorded the response of two tonically firing modulatory interneurons to the CS, at lapse and non-lapse points.
It is already known that the CGC responds with an increased firing rate when sucrose is applied to the lips. We have now discovered that the CGC can also respond to the CS at a non-lapse point (1 hour), but not at a lapse point (2 hours). This suggests a possible role for the CGC in the conditioned feeding response.
Because the pleuro-buccal interneuron (PlB) exerts strong inhibition on many cell types in the feeding system, including the CGC, it was hypothesised that changes in PlB activity may also be involved in forming the conditioned feeding response. However, no change in the firing activity of PlB was observed during application of the CS in trained individuals.

Title: Cued memory maintenance is different from context memory maintenance

Authors: *P. M. BALABAN, M. ROSHCHIN, A. ZIUZINA, A. VINARSKAYA, A. MALYSHEV;
Inst. Higher Nervous Activity & Neurophysiol. RAS, Moscow, Russian Federation

Abstract: Retrieval of memory followed by reconsolidation maintains the memory, while retrieval without following reconsolidation results in extinction of memory. In our study in terrestrial snail Helix we made an attempt to describe the conditions in which the retrieval of cued and context memories leads either to extinction or reconsolidation. In the network underlying the withdrawal behavior of this mollusk, sensory neurons, premotor interneurons, motor neurons, and modulatory for this network serotonergic neurons are identified, and recordings from representatives of these groups were made before and after aversive learning *in*

vitro. In the network underlying feeding behavior, the premotor modulatory serotonergic interneurons and motor neurons involved in motor program of feeding are identified, and activity of interneurons was monitored during and after aversive learning. The hypothesis tested in this study concerns the activity of the "reinforcing" serotonergic neurons that is suggested to be the gate condition for the choice between extinction/reconsolidation triggered by memory retrieval: if these serotonergic neurons do not respond during the retrieval, then we will observe the extinction; while if these neurons respond to the CS during memory retrieval, we will observe the reconsolidation phenomenon. Analysis of changes in neural activity after aversive learning *in vitro* showed that modulatory serotonergic neurons of feeding behavior do not demonstrate significant changes, while responses to food in withdrawal behavior premotor interneurons (containing FMRFa) changed qualitatively, from under threshold EPSPs to strong depolarization and spike discharges. Responses to food in identified serotonergic neurons involved in withdrawal (whose activity was shown previously to be necessary and sufficient for reinforcement of long-term synaptic plasticity) also changed from absence of responses before training session to a high-frequency spike discharges to the food stimuli, thus implying that during reactivation of aversive memory the serotonergic cells are activated and are involved in the reconsolidation process. In behavioral experiments it was shown that impairment of functioning of the serotonergic system with the neurotoxin 5,7-DiHT resulted in **complete extinction of context memory** after several reactivations, while **cued memory** to a specific type of food was significantly reduced but still was present. Thus, participation of the “reinforcing” serotonergic neurons in memory retrieval can be the gate condition for the choice between extinction/reconsolidation for context memory but not for cued memory

Title: Assessment of alternative strategies for gene knockdown in intact CNS or intact animals of *Aplysia* californica

Authors: M. Y. ZHENG, S. LU, P. SHRESTHA, K. HARRIS, *T. W. ABRAMS;
Pharmacol., Univ. of Maryland Med. Sch., Baltimore, MD

Abstract: With the availability of the nearly complete *Aplysia* transcriptome (Orvis et al, 2015), the number of genes that that are of interest to investigate to understand their contribution to any particular cellular or behavioral process has increased dramatically. The traditional approach for more than two decades of knocking down gene expression in single pre- or postsynaptic neurons by injection of antisense, siRNA or morpholinos now seems extremely limiting. For example, several lines of cellular electrophysiological evidence suggest that the small G protein Arf plays a central role in switching the *Aplysia* sensory neuron-to-motor neuron synaptic connection to a silent state during homosynaptic depression. Five *Aplysia* Arf GEFs have been identified, any of which may participate in this synaptic switch. All five are expressed in the presynaptic sensory neurons. Pharmacological and molecular studies, including dominant negative manipulations, have provided contradictory evidence as to the identity of the GEF responsible for activating Arf at presynaptic release sites. Thus, more efficient knockdown strategies are needed for efficient assessment of the contributions of each of these 5 Arf GEFs, which may act in combination. Based on the experience of Rajasethupathy et al (2009) with penetratin-coupled 2'-O-methyl antisense oligos and our experience with morpholinos (Lin et al, 2010), we are comparing externally applied penetratin-coupled 2'OMe antisense oligos, penetratin-coupled BNA antisense oligos and Vivo-Morpholinos targeted to each of the five Arf GEFs. In preliminary experiments, extracellularly applied Vivo-Morpholino targeted to ApBRAG was highly effective in knocking down BRAG protein expression after 2-3 days of whole ganglia in culture.

Title: Presynaptic and postsynaptic effects of *Aplysia* cysteine-rich neurotrophic factor during long-term synaptic facilitation

Authors: *A. ALEXANDRESCU[1], T. J. CAREW[2];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY

Abstract: The molecular mechanisms governing long-term memory (LTM) formation are highly conserved across species. One such conserved mechanism is neurotrophic factor signaling which, in addition to being critical for developmental plasticity, is known to contribute to adult synaptic plasticity underlying LTM. While it is known that neurotrophic factors are released locally at synapses in response to neuronal activity involved in LTM formation, their precise pre- and postsynaptic effects remain to be elucidated. The marine mollusk *Aplysia* has proven to be a powerful model system for studying cellular and molecular mechanisms of LTM formation. In *Aplysia*, long-term facilitation (LTF) of monosynaptic connections between identified sensory and motor neurons (SNs and MNs) contributes significantly to LTM for sensitization. Moreover, the SN-MN microcircuit can be reconstituted in culture, offering single cell spatial resolution for the examination of endogenous neurotrophic factor signaling *in vitro*. Our laboratory has identified a novel neurotrophic factor, *Aplysia* cysteine-rich neurotrophic factor (ApCRNF), which shares structural and functional characteristics with mammalian neurotrophic factors (Pu et al. 2014). We previously showed: (i) when paired with subthreshold analog training for sensitization (1 tail nerve shock), exogenous application of recombinant ApCRNF induces ERK/MAPK activation in SNs, a molecular signature required for both LTF and LTM formation, and ii) ApCRNF is released in the medium surrounding the CNS in an activity-dependent manner. Here we studied endogenous ApCRNF signaling in the SN-MN co-culture system. Using immunocytochemical and *in situ* hybridization analyses, we found that both ApCRNF protein and mRNA are localized to the cytoplasm of both SNs and MNs. Furthermore, we found that blocking endogenously released ApCRNF with an anti-ApCRNF antibody, blocks the induction of LTF induced with an activity-dependent training protocol (1 pulse of 5HT in the presence of high KCl). Our findings show that ApCRNF is synthesized in both pre- and postsynaptic neurons and is required for the induction of activity-dependent LTF. Our current studies are focused on determining the critical source of ApCRNF release within the SN-MN microcircuit during the induction of LTF.

Title: Memory enhancement by IGF2 precedes evolutionary acquisition of IGF2 affinity for the IGF2 receptor

Authors: *N. KUKUSHKIN, T. J. CAREW;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Insulin and related growth factors (IGFs) are important integrators of growth-, energy- and development-related signaling in most metazoans. IGFs generally act through receptor tyrosine kinases (RTKs). Thus, proliferative and pro-survival effects of mammalian IGF2 are mediated predominantly by the IGF1 receptor (IGF1R), an RTK to which both IGF1 and IGF2 have high affinity. IGF2 mediates memory consolidation, enhances memory and prevents forgetting in the rat (Chen et al., 2011). Surprisingly, these effects are not dependent on IGF1R but instead require IGF2R, an additional, non-RTK receptor with preferential affinity to IGF2. The affinity of mammalian IGF2R to IGF2 is widely assumed to be a result of a recent evolutionary gain of function observed exclusively in mammals. In most metazoans, the orthologs of IGF2Rs function in lysosomal sorting. To test if IGF2-mediated enhancement of memory is indeed dependent on its interaction with IGF2R, we studied the effect of human IGF2 on long-term facilitation (LTF) of sensorimotor (SN-MN) synapses in *Aplysia*, whose IGF and IGF2R orthologs lack all residues critical for their interaction in mammals. Strikingly, a 1h pretreatment of the pleural-pedal ganglia (which contain the SNs and MNs) with human IGF2 subsequently enhanced activity-dependent LTF, indicating that IGF2 can act independently of IGF2R.
To study this effect further, we monitored the state of multiple intracellular signaling pathways upon IGF2 treatment. Surprisingly, administration of IGF2 caused an acute repression of phosphorylation by multiple key Ser/Thr kinases (PKA, PKC and Akt) in SN-MN synapses, but especially in the somata of SNs, which are located in the pleural ganglion (separated from the synaptic compartment by the pleural-pedal connective). This repression was abolished (i) by IGF1R inhibitors, and (ii) when the connective was severed before treatment with IGF2, suggesting that retrograde signaling from the synapse to the soma is required to repress Ser/Thr kinases in response to IGF2. Consistent with this view, when the connective was severed prior to IGF2 delivery, IGF2 now produced activation of Ser/Thr kinases in the SN somata. Finally, when ganglia were pretreated with IGF2 for a short period (15 min), subsequent induction of LTF was decreased, consistent with the acute repression of Ser/Thr kinases. Thus, our results reveal the presence of at least two opposing, temporally and spatially specific effects of IGF2 on LTF, and further, suggest the surprising conclusion that the enhancement of LTF by IGFs precedes evolutionary acquisition of IGF2:IGF2R binding.

Title: cGMP induces a decrease of the intrinsic excitability of *Aplysia* neuron B51 similar to that caused by sensitization training

Authors: A. GOLDNER, M. WAINWRIGHT, *R. MOZZACHIODI;
Dept. of Life Sci., Texas A&M Univ. Corpus Christi, Corpus Christi, TX

Abstract: When *Aplysia* is exposed to aversive stimuli, it exhibits concurrent enhancement of defensive withdrawal reflexes (i.e., sensitization) and suppression of feeding. The duration of these behavioral modifications depends on the amount of training, with a single sensitization trial inducing changes lasting for at least 2 h, but not for 24 h, and four repeated trials inducing long-term changes persisting up to 24 h (Acheampong et al. 2012).
Our lab has recently identified decision-making neuron B51 as a site of plasticity underlying the training-induced suppression of feeding. In particular, sensitization training causes an increase of B51 burst threshold, which is indicative of a decrease of the neuron's intrinsic excitability (Shields-Johnson et al. 2013; Weisz et al. 2013). The goal of this project was to investigate which second-messenger system(s) was responsible for the decrease of B51 intrinsic excitability. Previous findings indicate that elevation of the cytosolic levels of cAMP produced an increase of B51 intrinsic excitability. Therefore, we tested the hypothesis that another cyclic nucleotide, cGMP, could contribute to the decrease of B51excitability induced by sensitization training. Either cGMP or vehicle was iontophoretically injected into B51 using pulses of hyperpolarizing current of -20 nA. To mimic the single-trial sensitization paradigm, one 30-s pulse was used. The membrane properties of B51 (i.e., burst threshold, resting potential and input resistance) were measured prior to and at different time points after injection (15 min, 30 min, 45 min, 1 h, 2 h). Following cGMP injection, B51 burst threshold was significantly increased for up to 45 min, compared to the vehicle-injected cells. B51 burst threshold did not differ statistically between the two groups at the 1 and 2 h time points. No cGMP-induced changes in resting potential or input resistance were observed at any time point.
To mimic the long-term sensitization paradigm, we used a treatment consisting of four 30-s pulses of injected cGMP/vehicle, spaced 30 min apart. B51 membrane properties were measured prior to and 24 h after treatment. Twenty-four hours after treatment, B51 burst threshold was significantly increased in the cGMP group, compared to the vehicle group. No cGMP-induced changes in resting potential or input resistance were observed 24 h after treatment.

These findings indicate that cGMP injection induced a decrease of B51 excitability analogous to that produced by both single-and multiple-trial sensitization training protocols.

Title: Using directed information to infer functional connectivity in neuronal networks

Authors: ***Z. CAI**[1], C. L. NEVEU[2], J. H. BYRNE[2], B. AAZHANG[1];
[1]Electrical and Computer Engin., Rice Univ., Houston, TX; [2]Neurobio. and Anat., The Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: The ways in which organization of individual neurons into circuits enables learning, memory and other brain functions is poorly understood. With the advancement in large-scale simultaneous neuronal recording techniques, it is becoming possible to delineate the circuits underlying these recordings, which will also enable us to examine reorganization of these circuits during learning processes. In our experiments, multichannel analog data was obtained from the buccal ganglion of *Aplysia* using voltage sensitive dye (VSD) recording and converted into binary spike trains. Directed information (DI) was used to measure unidirectional influence between neuron pairs, with context tree maximizing (CTM) algorithm serving as the estimator for their stochastic properties. CTM is a data-driven, consistent estimator that automatically finds the best model based on a cost criterion. The analyses also included other biophysical properties such as whether the connections are excitatory or inhibitory and whether their actions were fast or slow. A connectivity diagram with neurons as nodes and connections as edges was then generated and parameters such as the in-/out-degree and the net-flow of a node were calculated. The method was validated using several realistic Hodgkin-Huxley network models where it not only correctly identified the direct connections but also was robust against synapses with nonlinear dynamic properties such as depression and facilitation. The algorithm was applied to VSD recordings. It detected several putative connections, sources, and sinks. This method of augmenting large-scale recording techniques with signal processing tools to construct functional connectomes offers an automated tool to map neural circuits and the ability to capture changes in

synaptic strength as well as the saliency of neurons across different epochs, which will help identify network modifications due to learning and decision-making.

Title: Mechanism of doxorubicin-mediated persistent ERK activation and enhanced excitability in *Aplysia* sensory neurons

Authors: ***B. COUGHLIN**, H. LAKSHMINARASIMHAN, J. H. BYRNE;
Neurobio. and Anat., Univ. of Texas Hlth. Sci. Ctr., Houston, TX

Abstract: Chemotherapy-induced learning and memory deficits are gaining attention given the increasing number of cancer survivors. Elucidation of the molecular and biophysical perturbations to neurons induced by chemotherapeutic agents may provide insights into mechanisms underlying cognitive deficits. A single, brief exposure of *Aplysia* sensory neurons (SNs) to the anthracycline doxorubicin (DOX) leads to an increase in levels of phosphorylated extracellular signal-regulated kinase (pERK) and p38 mitogen-activated protein kinase (p-p38 MAPK) immediately after treatment. DOX also leads to an increase in SN excitability 24 h after treatment (Liu et al., J. Neurosci. 34:13289, 2014). The increase in pERK persists for 24 h after treatment while the increase in p-p38 MAPK reverses within 2 h of treatment cessation (Lakshminarasimhan et al., 2015). Here, we investigated the persistence of, and mechanism underlying the DOX-induced excitability change and phosphorylation of ERK. DOX treatment resulted in a persistent increase in SN excitability for as long as 48 h after treatment ($p = 0.0001$), accompanied by a decrease in firing threshold ($p = 0.0001$), and an increase in input resistance ($p = 0.001$). U0126, a MEK inhibitor and SB 203580, a p38 MAPK inhibitor, were used to examine the role of ERK and p38 MAPK activation in the persistent increase in excitability. Application of U0126 concurrently with DOX prevented the increase in excitability 24 h after treatment ($p = 0.009$). In contrast, application of SB 203580 during DOX treatment did not affect excitability ($p = 0.7$). Therefore, the long-lasting increase in excitability appears dependent on ERK but not p38

MAPK activation during DOX treatment. Application of U0126 concurrently with DOX did not prevent the persistent activation of ERK ($p = 0.6$). Application of U0126 at a later time point (23 h after the end of DOX treatment) also did not reverse the activation of ERK at 24 h ($p = 0.5$). Application of SB 203580 during DOX treatment did not affect the persistent activation of ERK at 24 h ($p = 0.7$). Collectively, these results suggest that mechanisms other than MEK activation may be required for persistent ERK activation. Further, long-lasting ERK activation and excitability may be mediated by different mechanisms. Persistent enhancement of ERK activation and excitability are similar to changes that occur during learning, suggesting the memory deficits associated with chemobrain may be due to occlusion or saturation of the underlying pathways.

Title: Combining voltage-sensitive dye (VSD) imaging with extracellular nerve recordings aid in the identification of neurons

Authors: *C. NEVEU[1], R. COSTA[2], R. HOMMA[2], S. NAGAYAMA[2], J. BYRNE[2];
[1]Neurobio. and Anat., The Univ. of Texas Med. Sch. At Houston, Houston, TX; [2]Neurobio. and Anat., UTHealth, Houston, TX

Abstract: VSD imaging can be used to simultaneously record spike activity in 10s-100s of neurons, which provides important advances in our understanding of circuit dynamics. To better understand the physiological role of the neuronal activity it is important to identify the recorded neurons which requires information of not only the size, position, and phasic activity but also the axonal projections of each neuron. Previous research has combined extracellular nerve recording and VSD to characterize neuronal projections of neurons in the feeding network of *Aplysia* (Morton et al. 1991), but did not attempt to identify the recorded neurons. Here we combined VSD recordings and extracellular nerve recordings to identify neurons in order to ascertain their role in feeding motor patterns. A first step in the process was a meta-analysis of previous extensive research characterizing the neurons of the buccal ganglia. Of the 51 neurons that have been studied to date about 14% were local interneurons, 45% send a single ipsilateral projection,

and 18% send projections through multiple nerves. The phasic activity of all neurons was also categorized. 63% were active during either protraction or retraction or both, while only 10% were active during post-retraction. We next characterized the projections and phasic activity of neurons and compared our results with our catalogue in order to identify neurons. Suction electrodes were applied to 7 nerves that connect the buccal ganglia to the periphery (ipsi and contra Bn1,2,3 and ipsi-Rn). Ganglia were stained with RH-155 and the activity of the nerves and VSD were recorded simultaneously for two (2 min) recordings separated by 15 min. A projection was considered to occur if a spike in the nerve followed a spike in the cell with a consistent delay. Using this information from the meta-analysis we identified up to 9 neurons during a single recording. With future experiments we hope to refine our methods to increase our ability to identify neurons and to identify new neurons which have yet to be characterized. We hope to use this technique in the future to track changes in each neuron before and after learning and compare the changes of each neuron between animals.

Title: Transcriptional correlates of forgetting of long-term sensitization memory in *Aplysia* californica

Authors: *R. CALIN-JAGEMAN[1], I. E. CALIN-JAGEMAN[2];
[1]Psychology, [2]Biol., Dominican Univ., River Forest, IL

Abstract: Long-term memories can be maintained indefinitely, but most encoded memories are eventually forgotten. How, then, are long-term memories maintained? And is forgetting due simply to the passive decay of maintenance mechanisms or to an active removal process? We are addressing these questions through the study of long-term sensitization (LTS) of the tail-elicited siphon-withdrawal reflex of *Aplysia californica*. Specifically, we are combining microarray, qPCR, and promoter analysis to characterize the transcriptional networks activated at 1 hour, 1 day, and 1 week after the induction of LTS, time-points which reflect encoding, maintenance, and forgetting, respectively. Our approach leverages several strategies to ensure high sensitivity

and replicability: adequate sample sizes, confirmation in independent samples, within-subjects comparisons, and a focus on a single, homogenous set of neurons specifically involved in the expression of LTS memory. Our results show that initial encoding produces strong and rapid regulation of about 80 transcripts. This initial transcriptional response to LTS training ramifies during maintenance, with over 600 transcripts strongly regulated 1 day after induction. As forgetting sets in, essentially all of these maintenance-related transcriptional changes fade away, but overlaid on this decay process there seems to be an activation of a very small set of putative forgetting-related transcripts. We are now seeking to identify promoter motifs that help coordinate the transcriptional responses related to encoding, maintenance, and forgetting.

Title: Learning effect on the response time of S-cluster of *Aplysia* to taste observed by voltage sensitive dye imaging

Authors: *T. YANAGI[1], Y. YOSHIMI[1], T. NAGAHAMA[2];
[1]Dept. Applied Chem., Shibaura Inst. of Technol., Tokyo, Japan; [2]Dept. Biophysics, Toho Univ., Tokyo, Japan

Abstract: Taste is an important sense for determining whether the intaken food to be ingested or rejected for survival. A marine gastropod *Aplysia* has large neurons and shows clear taste preferences, which is modified by the experience and learning. We attempted to analyze the neural network which generates ingestive or rejective response by using fluorescent voltage sensitive dye (VSD) imaging. Buccal mass and buccal ganglion was isolated with retaining connection between them via buccal nerves. The neurons in the ganglion were stained with VSD (Di-4-ANEPPS) in the presence of tetraethylammonium (TEA) chloride to prolong the action potential. Then the responses of the fluorescent image were monitored after administration of preferred ($_L$-asparagine, *Undaria*, *Porphyra*) or unpreferred taste (distilled water, $_L$-aspartic acids) to radula inside the buccal mass. VSD imaging revealed that theVSD imaging revealed that the S cluster neurons responded to unpreferred taste more rapidly (latency of *ca.* 2 s) than preferred one (latency of *ca.* 4 s). In the present experiments *Aplysia* learned to reject $_L$-

asparagine by an electrical shock during tasting it. Then the latency of the S-cluster response to the L-asparagine in the trained *Aplysia* was shortened to 2 s like that to the unpreferred tastes. Conversely *Aplysia* learned to inject L-asparatic acid by the subsequent rewarding with *Porphyra* extract. Then the latency of the S-cluster response to the L-asparatic acid in the trained Aplysia was prolonged to 4 s like that to the preferred tastes. These results indicate that the peripheral neural circuit probably decides the behavior responding to the taste before the S-cluster neurons receive the signals of the taste.

Title: Epitranscriptomic landscape of single neurons: Insights in the memory mechanisms

Authors: *A. B. KOHN[1], M. BASANTA SANCHEZ[2], L. L. MOROZ[3,4];
[1]Universtiy of Florida Whitney Lab., Saint Augustine, FL; [2]Univ. of Albany, The RNA Inst., Albany, NY; [3]Univ. of Florida, Neuroscience and McKnight Brain Institute, FL; [4]Whitney Lab. for Marine Biosci., St Augustine, FL

Abstract: Post-transcriptional changes in RNA have the potential to influence the epigenetic landscape. There are over a hundred RNA modifications. These chemical changes to nucleotides do not alter the sequence of RNA but can alter gene expression and has recently been described as part of a so-called epitranscriptome. Methylation of adenosine to N6-methyladenine (m6A) is the most prevalent internal modification on mRNA and long non-coding RNA with up to 20% of the human mRNA methylated. However, little is known about biological roles of RNA modifications. Here, we used *Aplysia californica*, a prominent model organisms to study learning and memory, and directly chemically characterized the scope of the epitranscriptome focusing at the level of individual functionally identified neurons. We determine that 4% of the total RNA was methylated in Aplysia. RNA-seq and computation analysis of the *Aplysia* genome shows that all the enzyme families involved in RNA methylation/demethylation are present in varying amounts from developmental states to single neurons following neuroplasticity tests. For the first

time RNA modifications were identified and quantified in single neurons using ultrasensitive mass spectrometry (MS) in combination ultra-high performance liquid chromatography. Different cholinergic neurons in *Aplysia* showed different and distinct RNA modifications. In addition to the RNA modification, we also discover cell- and tissue specific RNA editing in *Aplysia*. This adds another layer to the epigenetic regulation forming a complex epitranscriptomic landscape. RNA editing is a process of targeted alterations of nucleotides in all types of RNA molecules (e.g., rRNA, tRNA, mRNA, and miRNA). As a result, the transcriptional output differs from its genomic DNA template. RNA editing can be defined both by biochemical mechanisms and by enzymes that perform these reactions. We found full a repertoire of predicted RNA-editing enzymes in the genome of *Aplysia* including several expansions of enzyme families compared to what has been described in mammals. In summary our data indicate that both single-cell transcriptome and epitranscriptomes are unique features of identified neurons providing novel insights into genomic bases of neuronal individuality and plasticity.

Title: *Aplysia* neurotrophin acts as a presynaptic autocrine signal to regulate protein synthesis in the presynaptic neuron during the induction of intermediate-term facilitation produced by 5HT at *Aplysia* sensorimotor neuron synapses

Authors: ***I. JIN**[1], H. UDO[3], S. KASSABOV[1], R. NICOLLS[2], H. ZHU[1], L. KIM[1], E. R. KANDEL[1], R. D. HAWKINS[1];
[1]Dept. of Neurosci., [2]Pthology and Cell Biol., Columbia Univ., New York, NY; [3]Dept. of Biol., Kyushu Univ., Fukuoka, Japan

Abstract: The transition from short-term facilitation (STF) to intermediate-term facilitation (ITF) produced by 5-HT at sensorimotor neuron synapses of *Aplysia* is characterized by two major changes: the recruitment of postsynaptic as well as presynaptic mechanisms of facilitation

and the activation of protein synthesis in both the presynaptic and postsynaptic neurons (Jin et al., 2011). We found that spontaneous glutamate release from the presynaptic neuron acts as an anterograde signal to recruit postsynaptic mechanisms during the induction of ITF (Jin et al., 2012a, b). *Aplysia* neurotrophin (ApNT) released from the presynaptic neuron also contributes to the recruitment of postsynaptic mechanisms by (1) acting as an autocrine signal that forms a positive feedback loop with its receptor (ApTrk receptor) and PKA in the presynaptic neuron, thus enhancing spontaneous release of glutamate and ApNT (permissive role), and (2) acting as an anterograde signal to activate ApTrk receptors on the postsynaptic neuron during the induction of the ITF (Jin et al., Soc. Neurosci. Abstr. 2014, 2015). We have now asked, how is protein synthesis activated during the transition to ITF? We find that the positive feedback loop also regulates protein synthesis in the presynaptic neuron through activation of presynaptic ApTrk receptors. In vertebrates, activation of the TrkB receptor by its ligand BDNF induces protein synthesis via two downstream signaling pathways, PI3K/Akt and Ras/ERK (Robinet and Pellerin, 2010). We found that activation of presynaptic ApTrk receptors in *Aplysia* also increased the amount of p-AKT and p-ERK1/2 in the presynaptic neuron ($p< 0.001$ for both) and more specifically, the activation increased the amount of phospho-eukaryotic translation initiation factor 4E (p-eIF4E), the rate-limiting component of the eukaryotic translation apparatus ($p< 0.001$). Consistent with these results bath application of the protein synthesis inhibitor anisomycin reduced the increase in mini frequency produced either by mature ApNT or by activation of the presynaptic ApTrk receptor ($p< 0.05$ for both). These results suggest that the positive feedback loop in the presynaptic neuron plays two major roles during the induction of the ITF: (1) it contributes to the recruitment of postsynaptic mechanisms and (2) it regulates protein synthesis in the presynaptic neuron. The positive feedback loop may also play an important role in the transition to long-term facilitation (LTF) by increasing the levels of presynaptic PKA and MAPK sufficient for translocation of these two kinases into the nucleus, where they activate transcription during the induction of LTF (Martin et al., 1997).

Title: *Drosophila* SLC22A transporter is a memory suppressor gene that influences cholinergic neurotransmission to the mushroom bodies

Authors: *Y. GAI, Z. LIU, I. CERVANTES-SANDOVAL, R. DAVIS;
Dept. of Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: The mechanisms that constrain memory formation are of special interest because they provide insights into the brain's memory management systems and potential avenues for correcting cognitive disorders. RNAi knockdown in the *Drosophila* mushroom body neurons (MBn) of a newly discovered memory suppressor gene, Solute Carrier DmSLC22A, a member of the organic cation transporter family, enhances olfactory memory expression, while overexpression inhibits it. Immunohistochemistry coupled with super-resolution microscopy revealed that the protein localizes to the dendrites of the MBn, surrounding the presynaptic terminals of cholinergic afferent fibers from projection neurons (Pn). Transport assays using expression of DmSLC22A in HEK 293 cells and *Drosophila* primary neurons show that this plasma membrane protein transports cholinergic compounds with the highest affinity among a battery of in vitro substrates that were tested. Feeding flies choline enhanced memory; an effect blocked by overexpression of the transporter in the MBn. Functional imaging indicates that DmSLC22A knockdown enhances the calcium responses at the MBn calyx due to odor-triggered excitation of cholinergic Pn, while overexpression restrains them. Furthermore, genetic manipulation of cholinergic neurotransmission at Pn:MBn synapses revealed that overexpression of DmSLC22A in MBn suppresses the enhanced memory expression due to AChE knockdown in the Pn. The combined data show that DmSLC22A is a memory suppressor protein that limits memory formation by helping to terminate cholinergic neurotransmission at the Pn/MBn synapse.

Title: Scribble scaffolds a signalosome for active forgetting

Authors: *I. CERVANTES-SANDOVAL[1], M. CHAKRABORTY[2], C. M. MACMULLEN[2], R. L. DAVIS[2];
[1]Neurosci., The Scripps Res. Inst., Jupiter, FL; [2]Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: Forgetting, one part of the brain's memory management system, provides balance to the encoding and the consolidation of new information by removing unused or unwanted memories or by suppressing their expression. Recent studies identified the small G-protein, Rac1, as a key player in the *Drosophila* mushroom bodies neurons (MBn) for, active forgetting. Subsequently it was discovered that a few dopaminergic neurons (DAn) that innervate the MBn mediate forgetting. Here we show that Scribble, a scaffolding protein known primarily for its role as a cell polarity determinant, piece together the intracellular molecular machinery that constitutes the signal for normal forgetting. Knocking down *scribble* expression in either MBn or DAn impairs normal memory loss. Scribble interacts physically and genetically with Rac1, Pak3 and Cofilin within MBn, nucleating a forgetting signalosome that is downstream of dopaminergic inputs that regulate forgetting. These results bind unrelated molecular players in active forgetting into a single signaling pathway: Dopamine>Dopamine Receptor> Scribble> Rac> Cofilin.

Title: The role of presynaptic D2 receptor in dopamine neuronal excitability and synaptic release underlying *Drosophila* larval olfactory associative learning

Authors: C. QI[1], *D. LEE[2];
[1]Biol. Sci., [2]Ohio Univ., Athens, OH

Abstract: Dopamine (DA) plays an important role in modulating neuronal signaling and cognition. Therefore, understanding the molecular properties of DA signaling is an essential step in decoding the sub-cellular physiology underlying associative learning. The physiological

functions of DA are mediated through G-protein coupled receptors. Generally, DA receptors can be divided into two subfamilies: excitatory D1- and inhibitory D2-like receptors. In Drosophila melanogaster, it has been shown that postsynaptic D1 receptors are involved in associative olfactory learning both in adults and larvae. However, it is expected that inhibitory D2 autoreceptors modulating synaptic DA release also play a crucial role in olfactory learning. Currently, little is known about the role of presynaptic D2 receptors (DD2R) in Drosophila associative learning. In this study, we wanted to examine how presynaptic DD2R regulates functional properties of DA neurons and thus olfactory learning in Drosophila.First, we examined the role of presynaptic DD2Rs in Drosophila larval associative learning. In the olfactory conditioning, an odor pentyl acetate was used as a conditional stimulus (CS), and 1M sucrose (appetitive) or 0.1 percent quinine (aversive) was used as an unconditional stimulus (US). Late third instar larvae (92-96h) were collected and trained for 30 min, then their performance towards CS was tested and compared to the control group with no US. Using a UAS-DD2R-RNAi line crossed with a DA-specific driver (TH-Gal4), we observed that knockdown of presynaptic DD2R impaired both appetitive and aversive learning in F1 larvae. As DD2R is an inhibitory G-protein coupled receptor, we hypothesized that, DD2R autoreceptor mediates olfactory learning through down-regulation of DA neuronal excitability and presynaptic DA release. In a well-established Drosophila primary neuronal culture, action potential (AP) frequency in GFP-marked DA neurons can be measured using the whole-cell patch technique. Our results show that the DA neuronal AP frequency was inhibited by a D2 agonist quinpirole (10 microM), indicating an inhibitory role of DD2R in DA neuronal excitability. Further, we were able to measure distinct DA synaptic currents in GFP-marked DA neuronal processes using amperometry method with a carbon-fiber electrode. We are currently examining the role of DD2R autoreceptors in DA neuronal excitability and synaptic DA release using genetic and pharmacological approaches. We also plan to study the role of presynaptic D2 receptors in DA neuronal excitability and synaptic DA release in the intact larval brain.

Title: A fine-grained analysis of dopamine as a reinforcer of operant behavior in *Drosophila*

Authors: *C. C. ROHRSEN[1], B. DE BIVORT[3], B. BREMBS[2];
[2]Developmental Biol. and Neurogenetics, [1]Regensburg Univ., Regensburg, Germany;
[3]Organismic and Evolutionary Biol., Harvard Univ., Cambridge, MA

Abstract: Dopamine (DA) is known to be involved in assigning value to events, in both in vertebrates and in invertebrates. For instance, in Drosophila, DA neurons are known to play an essential role in associative conditioning. The valence of learning depends on the DA cluster involved: whereas the protocerebral anterior medial cluster (PAM) mediates appetitive conditioning, the protocerebral posterior lateral cluster 1 (PPL1) mediates aversive conditioning. Studies in the fruit fly have focused in these two clusters because the neurons in these clusters project to the mushroom body, an essential brain structure for olfactory classical conditioning. It is currently not known to which extent DA neurons are involved in modulating ongoing action selection and choice behavior. For assessing the role of different sub-populations of DA neurons in mediating valence, we took advantage of flies expressing the optogenetic channel Chrimson under different DA promoters. These transgenic flies were tested in different decision-making paradigms where reinforcement is contingent on their ongoing choices. Our results highlight the potential, but also the technical hurdles which need to be surmounted to unleash the potential of this optogenetic technique in behaving animals. In addition we construct a model with estimated valences for each of the DA clusters to explain the fly behavior under these conditions. Taken together, the results suggest that there may not be a clear relationship between which neurons mediate, say, appetitive classical conditioning and which neurons can functionally replace reward or punishment in operant situations.

Title: Hormonal convergence in regulation of *Drosophila* long-term memory

Authors: *S.-S. LEE, M. E. ADAMS;
Neurosci., Univ. of California Riverside Dept. of Cell Biol. and Neurosci., Riverside, CA

Abstract: During insect development, the endocrine peptide ecdysis triggering hormone (ETH) regulates ecdysis (cuticle shedding) by orchestrating sequential activity in downstream peptidergic ensembles. Although ETH signaling molecules persist during adulthood in *Drosophila*, their functional roles have yet to be revealed. Here we show that ETH is required for *Drosophila* long-term memory (LTM) performance through direct and indirect actions on the mushroom body. ETH promotes juvenile hormone (JH) synthesis during adulthood. Suppression of ETH and JH signaling in adult males impairs LTM. In particular, RNA knockdown of either ETH or JH receptors in mushroom body neurons compromises LTM, revealing a hormonal convergence in the same functional subdivision to regulate memory formation. Increased release of ETH not only improves LTM performance by the traditional conditioning, but also reduces the training period necessary for memory formation. ETH enhancement also leads to longer-lasting memory. Our findings suggest a model for convergence of ETH and JH signaling in *Drosophila* LTM formation that parallels previously reported instances in mammalian models.

Title: Generating a new fly model for GALT-loss

Authors: V. BAGGETT[1], J. FRIDOVICH-KEIL[3], *T. ZARS[2];
[1]Div. of Biol. Sci., [2]Univ. of Missouri, Columbia, MO; [3]Dept. of Human Genet., Emory Univ., Atlanta, GA

Abstract: Galactosemia is a rare genetic disorder that affects 1 in 50,000 newborns and can lead to infant death if dietary galactose is not removed immediately. Three types of galactosemia have been described, one for each of the three enzymes within the galactose metabolism pathway (the Leloir pathway). The most prevalent - type 1 - or loss of function of galactose-1-phosphate uridyltransferase (GALT) gene is known as classic galactosemia (CG). Even with removal of dietary galactose and alleviation of acute symptoms, chronic disease states are associated with neural dysfunction and behavioral changes. Models of GALT loss have been established in yeast, mouse, and *Drosophila.* While each of these models has their limits, experiments demonstrate oxidative stress and glycosylation defects as primary factors responsible for neuronal changes.

With this, we hypothesize that drastic cellular changes with loss of GALT will result in behavioral changes. Preliminary results with a dGALT10 mutant fly show an abnormal latency to re-explore after training in place learning. Due to the nature of the dGALT10 allele, we are generating a new GALT-null mutant in which we specifically excise the catalytic domain. We will test for cellular and behavioral changes in this new model, which will provide targets for treatments in CG patients.

Abstract: Decision-making, behaviorally, is a process of choosing between at least two options. Using a novel behavior setup, we study freely-moving flies' learning the and decision-making process and mechanisms underlying such processes in the fruit fly, Drosophila melanogaster. Can flies make decisions against their innate behaviors? To answer this question, I built a novel behavior apparatus in which single flies experienced heat stress when and only when it was moving. Flies have an innate heat avoidance behavior. When they experience uncomfortable heat, they increase their locomotion activity. In this new paradigm, flies were trained to stop walking when encountering heat. After two spaced training sessions, flies showed significant inhibition of their locomotion activity compared to controls.

Title: Cdc42-dependent forgetting regulates repetition effect in prolonging memory retention

Authors: *X. ZHANG, Q. LI, L. WANG, Y. ZHONG;
Sch. of Life Sci. Tsinghua Univ., Beijing City, China

Abstract: Repeated learning is a daily-used and powerful way to improve memory. A fundamental question is how multiple learning trials add up to improve memory. While the major studies of such a repetition effect so far all emphasize the strengthening of memory formation, the current study reveals a novel molecular mechanism through suppression of forgetting. We find that single-session training leads to formation of anesthesia-resistant memory (ARM) and then activation of the small G protein Cdc42 to cause decay or forgetting of ARM within 24 hrs. Repetition suppresses the activation of Cdc42-dependent forgetting, instead of enhancing ARM formation, leading to prolonged ARM. Consistently, inhibition of Cdc42 activity through genetic manipulation mimicked the repetition effect while repetition-induced ARM improvement is abolished by elevated Cdc42 activity. Thus, only the first session in repetitive training contributes to ARM formation, while the subsequent sessions are not devoted to acquiring information, but to inhibiting forgetting.

Title: Mushroom body-Dopaminergic recurrent network in *Drosophila*

Authors: *Y. JIANG, S. KUNES;
Harvard Univ., Cambridge, MA

Abstract: Dopamine has been established as a simple reinforcement signal in aversive and appetitive memory in fruit flies. Yet in mammalian systems, dopamine acts in accord with the difference of an experience from expectation (ie. prediction error). Specific dopamine neurons (DANs) can be activated by an aversive stimulus such as electric shock or reward stimulus such as sugar. We have found a population of DANs that not only represent Unconditioned Stimuli (US) but also respond to Conditioned Stimuli (CS) as a result of conditioning. We refer to them as *plastic DANs* (pDANs). In live imaging experiments, animals were presented with US and CS stimuli while neuronal Ca2+ activity was monitored. We found that some DANs that innervate the mushroom body (MB) lobes that respond to both US (shock) and CS (odor), including gamma3, gamma4,beta'1 and beta'2 DANs. Those DANs gradually generate differential responses to the CS+/CS-. For example, the gamma4 DAN diminishes its response to CS+ and increases/maintains its response to CS- during and after training with coincident US presentation. To further understand the functions of these special pDANs, we sought to uncover a collection of neurons that might work together with them in a network. We identified more mushroom body output neurons (MBONs) required for aversive memory and novel classes of plastic odor-responsive neurons using the assay mentioned above. We found that MBONs, as expected, as well as a novel class of interneuron (Recurrent Loop Neurons,RLNs) feedback onto pDANs. Activation or inhibition of certain MBONs or RLNs can activate or inhibit pDANs. In addition, we found that some RLNs oscillate or burst in a certain way similar to pDANs. Considering that MBONs can be activated by odor-responsive intrinsic MB cells and that pDANs release dopamine onto these neurons, we propose a recurrent neural network model involving both intrinsic and extrinsic MB neurons. Our behavioral data indicates that this neural network is required to drive memory stabilization in Drosophila. In addition, training flies by standard electric shock paradigm not only induces aversion to CS+ but also attraction to CS-. We show that CS- activates appetitive DANs during aversive training, which induces attraction to CS-. Attraction to CS- further biases fly's choices away from aversive CS+.

Title: Characterization of a Classical Conditioning protocol using discrete stimuli to uncover dynamics of connectome plasticity in *C. elegans*

Authors: L. K. ALFILER[1], A. H. BLACK[1], *J. K. ROSE[2];
[1]Behavioral Neurosci. Program, [2]Psychology, Western Washington Univ., Bellingham, WA

Abstract: The well-described nervous system and connectome of *C. elegans* allows for the study of plasticity mechanisms within identified neural networks and has led to the discovery of several mechanisms of learning and memory. The goal of the current work is to establish a Classical Conditioning protocol employing discrete stimuli to allow for precise and controlled stimulus delivery, and thus greater manipulation of training parameters to reveal both dynamics and mechanisms of connectome plasticity. Previously, our lab has paired a blue light (~480 nm; unconditioned stimulus) with a mild mechanosensory vibration (Vib; neutral stimulus) resulting in increased responsiveness to the Vib stimulus alone, considered to have resulted from the convergence of neuron activation signals likely at the command interneurons. When the number of pairings was increased to five, each pairing presented one minute apart, a more robust increase in responsiveness to the Vib stimulus alone was measured. To further probe the optimal training parameters for conditioning, the intertrial interval was increased to 5 minutes and extinction for this learning was explored. As well, the potential for spaced training to increase retention duration was also tested by delivering multiple pairings during distinct training periods. Finally, earlier studies in our lab have demonstrated the *unc-43*(gk452) mutant strain (ortholog to $CaMKII_{\gamma}$) shows a deficit in associative chemotaxis, therefore the role of this molecule in blue light/Vib network plasticity was also investigated. By introducing and characterizing a training protocol in *C. elegans*, whereby extent of associative conditioning can be prescribed, current and future studies aim to identify and examine mutants of additional signalling genes involved in network dynamics and learning.

Title: Differential changes in rate and ensemble temporal dynamics during sleep following de novo spatial experience

Authors: *G. DRAGOI, J. SIBILLE;
Psychiatry, Yale Univ., New Haven, CT

Abstract: Ensembles of hippocampal CA1 place cells fire sequentially along the trajectory of the animal. The sequence of place cells expressed during run is replayed during post-run sleep, a phenomenon thought to represent the memory of the run experience. However, the sequence of place cell firing during run is also correlated with temporal sequences occurring during the pre-run sleep periods, a phenomenon called preplay. Preplay is believed to represent the pre-configuration of the hippocampal network into cellular assemblies and to facilitate the rapid encoding of novel spatial information in naïve animals. Activation of place cells during run in novel spatial environments results in stronger Bayesian decoding of animal's trajectory during post-run (replay) compared with pre-run sleep (preplay) in previously trained rats. In contrast, in naïve mice, the incidence of temporal sequences of neuronal firing that are correlated with place cell sequences during run, calculated using template-matching procedure, is similar in the post-run (replay) and pre-run sleep (preplay). To further understand the effect of run experience on the hippocampal network dynamics during sleep and explain the conflicting difference between decoding and template matching results, we performed recording of ensembles of CA1 neurons from two independent groups of adult naïve rats (group M, n=3; group Y, n=3). For each pre-run and post-run session, using template matching method, each temporal sequence event during sleep was correlated with the place cell sequences during run (two templates/animal; data correlations) and the results were compared with correlations between the temporal sequence event and 500-times shuffled place cell sequences (1,000 shuffles/event, using 2 templates; shuffle correlations). The results for the two independent groups of rats were remarkably similar. Both pre-run and post-run events were stronger correlated with the run templates (data correlations) compared with the shuffle templates (shuffle correlations) and, for both groups, pre-run and post-run correlations were not different. The incidences of significant preplay and replay events (template matching) were also not different. In contrast, for both groups, the average firing rates of pyramidal neurons were higher in the post-run compared with the pre-run sleep, which can explain the stronger Bayesian decoding of animal's run trajectory during post-run (replay) compared with pre-run sleep (preplay). We propose that specific novel spatial

experiences induce firing rate changes in the hippocampal network during sleep, which are integrated into stable, homeostatic ensemble temporal dynamics.

Title: Dynamic resonance controls oscillation frequency in optogenetically induced sharp-wave ripples.

Authors: *D. C. KLORIG, G. ALBERTO, D. GODWIN;
Neurosci. Program, Wake Forest Hlth. Sci., Winston Salem, NC

Abstract: Neural processing occurs in parallel across circuits of varying complexity and size. Multiple streams of information are coordinated in time; yet, the brain lacks a fixed global clock. Variable myelination allows for fine tuning of transmission speeds and processing time, however myelination is relatively fixed, at least on time scales relevant to brain function. At these time scales, oscillatory dynamics in neural populations are thought to temporally coordinate activity. We describe a simple mechanism, governed by the interplay of excitatory and inhibitory processes, by which oscillatory activity varies over a range of frequencies. Using optogenetic light ramp stimuli to induce, rather than evoke, ripple frequency oscillations in area CA1 of freely moving mice, we characterized the dependence of oscillation frequency on the magnitude of the depolarizing input to pyramidal cell populations and using pharmacological manipulation, on the time constant of pacing GABAergic inhibition. A spiking network model is presented that captures the experimentally observed dynamics. As predicted by the model, CA1 exhibits locally

governed resonance in the ripple frequency range that changes with the magnitude of the depolarizing input to the excitatory population. We propose that such an arrangement could allow the frequency of the oscillation, and therefore the temporal window of integration, to vary depending on the number or magnitude of active synaptic inputs, while holding input selectivity constant. Activity involving larger populations of cells, by virtue of the dynamics of E-I networks, would have increased processing speeds and shorter integration times. Such a mechanism could instantiate a dynamic time base that varies depending on the size of the active population, thus keeping overall integration time constant and allowing for efficient parallel processing.

Title: Using DREADDs to compare the effects of inactivating CA3 versus the CA3-CA1 projection on the memory for sequences of events.

Authors: ***J. S. A. ASEM**[1], M. H. KASSIR[1], N. B. MIRZA[1], N. N. CHMIELEWSKI[1], G. A. ELIAS[1], C.-W. NG[1], T. A. ALLEN[2], N. J. FORTIN[1];
[1]Neurobio. and Behavior, Univ. of California (Irvine), Irvine, CA; [2]Psychology, Florida Intl. Univ., Miami, FL

Abstract: The ability to temporally organize information is fundamental to many perceptual, cognitive, and motor processes. Temporal organization is also a defining feature of episodic memory, as the memory for individual events includes information about when they occurred. In particular, the ability to remember sequential relationships among events or stimuli is shared by a variety of species including humans, non-human primates, and rodents. Our laboratory has recently developed and validated a cross-species paradigm to test nonspatial sequential memory; recent work using this approach has demonstrated that the hippocampus plays a critical role in this ability. Notably, whole hippocampal inactivations produce substantial deficits in the memory

for a sequence of items (Allen et al., in prep.), and electrophysiological recordings show that dorsal CA1 neurons discriminate the temporal context in which items are presented (Allen et al., 2016). In particular, such neurons fire differentially to odors depending on whether they were presented in sequence or out of sequence. Here, we aim to further investigate the specific hippocampal circuitry supporting this form of sequence memory and, specifically, the role of subregion CA3. Computational models suggest that CA3 may be particularly well-suited to code for sequential relationships among items because of its high degree of recurrent connections. To test this hypothesis, we compared the effects of whole CA3 inactivation to specific CA3-CA1 projection inactivation using designer receptors exclusively activated by designer drugs (DREADDs). Subjects consisted of ten Long-Evans rats, who underwent bilateral infusions of either AAV9 (experimental virus) or rAAV8 (control virus) into dorsal CA3, as well as bilateral implantation of guide cannulae into dorsal CA1. After reaching criterion in the olfactory sequence memory task, neuronal inactivation is induced by clozapine-N-oxide (CNO) injections, with phosphate-buffered saline (PBS) as a control. Systemic CNO injections inactivate the entire CA3 subregion, whereas local infusions specifically block CA3-CA1 communication. This approach allows for testing the general contribution of CA3 as well as the specific role of the CA3-CA1 pathway in the ability to remember a sequence of items.

Title: Nonspatial sequence coding varies along the CA1 transverse axis

Authors: ***C. NG**[1], G. A. ELIAS[1], J. S. A. ASEM[1], T. A. ALLEN[2], N. J. FORTIN[1]; [1]Neurobio. & Behavior, Univ. of California, Irvine, CA; [2]Psychology, Florida Intl. Univ., Miami, FL

Abstract: The hippocampus plays a critical role in the memory for sequences of events, a defining feature of episodic memory. To shed light on the fundamental mechanisms supporting

this capacity, we recently recorded neural activity in CA1 as rats performed a nonspatial odor sequence memory task (Allen et al., 2016, *JNeurosci*). Briefly, the task involves the presentation of repeated sequences of odors at a single port and requires rats to identify each item as "in sequence" or "out of sequence". Our main finding was that, while the animals' location and behavior remained constant, a proportion of CA1 neurons fired differentially to odors depending on whether they were presented in or out of sequence (sequence cells). Here, we further examined if such sequence coding varied along the distal-to-proximal axis of the dorsal CA1 region, as suggested by recent anatomical and electrophysiological evidence that odor information may be more strongly represented in the distal segment (compared to the proximal segment, which may predominantly represent spatial information; Igarashi et al., 2014). Recorded neurons were grouped according to their targeted section of CA1, from distal (section 1: ~1 mm ML) to proximal (section 4; ~5mm ML). Preliminary results indicate that while sequence cell coding was observed across the distal-to-proximal extent of CA1 we recorded, it was significantly higher near the transition zone between distal and proximal regions (section 2; ~2.5mm ML). More specifically, in that particular segment of CA1, we observed an increase in the proportion of sequence cells, as well as an overall increase in the magnitude of sequence cell coding and in sequential information content (measured across all cells in that segment). These results suggest nonspatial sequence memory coding is not uniformly distributed along the transverse axis of CA1, and that this distribution does not simply follow the expected gradient based on the modality of the information.

Title: Characterizing the time course of radiation-induced brain changes in memory performance and network activity in rats

Authors: *N. N. CHMIELEWSKI, C.-W. NG, J. S. A. ASEM, G. A. ELIAS, C. L. LIMOLI, N. J. FORTIN;
Univ. of California, Irvine, Irvine, CA

Abstract: Cranial radiation-induced debilitating effects on cognition have long been observed in surviving brain cancer patients. However, the fundamental neural mechanisms causing these persistent cognitive decrements are still unclear. To address this issue, we used a rat model to quantify the progression of memory deficits induced by clinically-relevant doses of X-ray and examine the corresponding changes in neural activity. In the first experiment, rats were trained on a nonspatial sequence memory task, which was previously shown to have strong behavioral parallels in rats and humans (Allen et al., 2014) and to depend on similar hippocampal and prefrontal cortical circuits in both species (Allen et al., in prep; Boucquey et al., submitted). Briefly, the task involves repeated presentations of a sequence of four odors at a single odor port and requires rats to identify each odor as "in sequence" or "out of sequence." After reaching criterion, rats underwent cranial radiation treatment and task performance was assessed over a period of 10 weeks. Performance on the task decreased 6 weeks after irradiation, consistent with past findings of radiation-induced cognitive decrements in common rodent behavioral paradigms associated with hippocampal and prefrontal function. In the second experiment, arrays of recording electrodes were implanted post-irradiation into task-critical and control brain regions. Local field potentials (LFP) were then recorded as rats ran along a two-dimensional track. Compared to controls, irradiated rats began showing changes in LFP power in radiosensitive hippocampal CA1 and CA3 subregions as early as 3 weeks post-irradiation (decreased power for frequencies < 8 Hz, increased power for 8-10 Hz). These data suggest that this approach can detect radiation-induced changes in neural activity prior to cognitive sequelae. Ongoing efforts are aimed at elucidating the cause of these changes in LFP activity and establishing a link with the subsequent emergence of behavioral impairments.

Title: Distinct contributions of hippocampal, prefrontal, perirhinal and nucleus reuniens regions to the memory for sequences of events

Authors: *N. J. FORTIN[1], J. A. ASEM[1], C.-W. NG[1], C. R. QUIRK[2], T. A. ALLEN[3], G. A. ELIAS[1];
[1]Dept. of Neurobio. and Behavior, UC Irvine, Irvine, CA; [2]Neurobio., Univ. of California San Diego, La Jolla, CA; [3]Psychology, Florida Intl. Univ., Miami, FL

Abstract: A critical feature of episodic memory is the ability to remember the order of events as they occurred during an experience. Accumulating evidence indicates that this capacity is supported by a network of structures centered on the hippocampus (HC) and prefrontal cortex (PFC). However, the distinct contributions of the HC and PFC remain unclear and very little is known about the specific role of other structures in this network. To address this issue, we trained rats to criterion on a nonspatial sequence memory task, which involves repeated presentations of a sequence of odors in a single odor port and requires animals to correctly identifying whether each odor is presented "in sequence" or "out of sequence." We then assessed task performance following localized temporary inactivations induced by infusions of fluorophore-conjugated muscimol, with saline infusions as control. Specifically, we examined the effects of inactivating HC or PFC (group 1) as well as regions with known anatomical and functional relationships with both structures, the perirhinal cortex and nucleus reuniens (PER, NRe; group 2). We found that overall performance was impaired after inactivation of each of these regions, indicating that they all make critical contributions to the ability to detect violations in the order of items presented in the sequence. Importantly, a detailed analysis of performance across odors and sequence positions revealed distinct patterns of impairment across regions. HC inactivations produced a modest impairment that was consistent across odors and positions, indicative of a general deficit in the ability to retrieve previously learned item-in-position associations. NRe inactivations produced an impairment of greater magnitude that was characterized by a flat accuracy gradient across all out of sequence items, suggesting an inability to take advantage of the representations that normally lead to higher performance on specific types of out of sequence items. In contrast, deficits following PFC inactivations appeared primarily due to an inability to keep track of the ordinal position in the sequence, and PER deficits to an inability to determine whether a repeated item is presented in its correct sequence position. Collectively these results demonstrate that each region makes distinct contributions to the memory of sequences of events.

Title: Prefrontal neurons track ordinal position within a sequence of events

Authors: *G. A. ELIAS[1], C.-W. NG[1], J. A. ASEM[1], T. A. ALLEN[2], N. J. FORTIN[1]; [1]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA; [2]Psychology, Florida Intl. Univ., Miami, FL

Abstract: A key characteristic of episodic memory is its sequential organization. The hippocampus and prefrontal cortex have been identified as central structures within a network supporting the memory for sequences of events. In a recent study, we recorded neural activity in CA1 as rats performed a nonspatial odor sequence memory task and found that individual neurons coded for specific odors as well as specific conjunctions of odor and sequence position information (Allen et al., 2016, *JNeurosci*). Moreover, a significant proportion of CA1 neurons fired differentially whether odors were presented in the correct or incorrect sequence position, suggesting that the CA1 region plays a key role in sequence memory by supporting item-in-position associations. Here, we recorded prefrontal neurons (prelimbic region) in rats performing the same task to examine the role of the prefrontal cortex in this form of sequence memory. Briefly, rats received repeated presentations of a sequence of odors and had to determine whether each odor was presented in the correct sequence position or not. Preliminary results show that a majority of prefrontal cells (~65%) exhibited increases in activity in relation to specific task events and/or behavioral responses, and that this activity was modulated by ordinal position within the sequence. The majority of these cells (~60%) modulated their firing rate linearly; either increasing or decreasing their activity across sequence position. The remaining cells (~40%) exhibited a non-linear modulation across sequence positions, characterized either by preferential firing to the first and last sequence position (u-shaped function across positions) or to the intermediate positions (inverted-u function). Importantly, positional modulation in prefrontal neurons was present in time windows that preceded odor presentation, indicating that these cells represented the sequence position of the upcoming trial. This high prevalence and diversity of ordinal position coding in prefrontal neurons starkly contrasts with the high prevalence of odor and odor-in-position coding observed in CA1, highlighting that hippocampal and prefrontal

circuits make distinct contributions to sequence memory. Specifically, these results suggest that the prefrontal cortex plays a key role by dynamically tracking the animal's ordinal position within a sequence of events.

Title: Environmental enrichment normalizes hippocampal timing coding in a malformed hippocampus

Authors: *M. MAHONEY[1], A. E. HERNAN[1], W. CURRY[1], G. RICHARD[1], M. LUCAS[2], A. MASSEY[1], R. SCOTT[1,3];
[1]Univ. of Vermont, Burlington, VT; [2]Geisel Sch. of Med. at Dartmouth, Hanover, NH; [3]Univ. Col. London, London, United Kingdom

Abstract: Malformations of cortical development (MCDs) are structural and functional disruptions in neural networks. These network abnormalities are associated with learning and memory impairments and epilepsy. It is not known whether learning and memory can be improved, and if such improvement is possible, what the neural network therapeutic targets are. Injection of methylazoxymethanol acetate (MAM) at embryonic day (E) 17 produces a rat model that recapitulates many aspects of human MCDs, including cognitive deficits. We recently showed that environmental enrichment improves spatial cognition in MAM rats, although the mechanism for this is unknown. Using in vivo single unit recording, we show here that environmental enrichment completely resolves abnormal fine spike timing characteristics of CA1 hippocampal pyramidal cells in MAM animals. This is associated with improvement in spatial coherence, a surrogate measure of spatial cognition. We characterized fine spike timing using a neuronal endophenotype called a post-spike filter (PSF) and show that environmental enrichment restores the number of neurons that exhibit temporally modulated firing. Among neurons with temporal structure, the PSFs in MAM neurons show that neuronal firing is less precisely modulated, particularly in theta (6-12 Hz), indicating poorer temporal coding in MAM animals. Remarkably, environmental enrichment completely normalizes these changes. Moreover, PSF

parameters predict the spatial coherence of pyramidal cells, suggesting that coherence is dependent on circuit-level mechanisms that determine fine spike timing and that modulation of fine spike timing may be the mechanism by which spatial coherence is restored. MAM enriched animals have more PV interneurons than unenriched counterparts providing a potential cellular mechanism for improvements in temporal firing. This is the first system-level mechanism of cognitive improvement after environmental modification that has been shown in any model of human neurological disease. The results have far-reaching implications, as they suggest that even developmentally abnormal neural networks can be improved postnatally and that interneuron modulation could be a novel therapeutic approach for improving cognitive outcomes in neurological disease.

Abstract: In animals' environments many biologically significant events occur with spatial and temporal regularity. The ability of an animal to learn the spatiotemporal variability of stimuli is known as time-place learning (TPL). The present study investigated the interaction between a Food Entrainable Oscillator (FEO) and the Light Entrainable Oscillator (LEO) in a daily TPL task. Rats were trained in an operant conditioning chamber that contained two levers that distributed a food reward such that one lever provided a food reward in morning sessions, while the other lever provided food in afternoon sessions. We expected that having access to an FEO, in addition to the LEO, would provide rats with more accurate depictions of time of day, leading to better performance. Rats received either one meal per day (1M group), which allowed them to

have access to the FEO, or many meals per day (MM group), which did not allow them to have access to the FEO. As predicted, 1M rats had a significantly higher percentage of correct presses than MM rats across nine blocks. Once rats successfully learn the task, they will be made arrhythmic by shifting the light dark cycle by 3 hours per day as in Zelinski, Hong, & McDonald, 2014 to determine the effect of disruption of the LEO on the task. Manipulation of the light dark cycle will allow for a better understanding of the interaction between the LEO and FEO, therefore providing a more complete understanding of how circadian rhythms are related to learning and memory.

Title: Properties of cerebellar neurons during suprasecond time estimation.

Authors: *K. L. PARKER, B. J. DECORTE, Y. KIM, A. J. NESSLER, N. S. NARAYANAN; Dept. of Neurol., Univ. of Iowa, Iowa City, IA

Abstract: The cerebellum is involved in the temporal control of action. Here we explored the activity single neurons in the lateral (dentate) cerebellar nuclei (LCNs) in interval timing on the scale of seconds. We hypothesized that cerebellar neurons would similarly encode suprasecond epochs of time in both animals. We found that inactivating the cerebellum with GABA agonist, muscimol, impaired interval timing, while optogenetic stimulation and infusions of GABA antagonist, gabazine, could improve interval timing. This was particularly apparent in animals

with frontal dysfunction. To study LCNs neurons, we implanted recording electrodes in LCNs in rodents trained to estimate 3 and 12 second intervals. We found that LCNs have robust temporal processing and cue-evoked burst of low-frequency activity. To further explore this phenomenon, we analyze neuronal synchrony and population dynamics of neurons in the LCN during timing. We also examined LCN activity around movements and task events, and examined the relationship of cerebellar neuronal activity to cerebellar field potentials. We compared cerebellar LFP activity in rodents to EEG activity from cerebellar regions in humans. These data could have relevance for understanding the role of the cerebellum in temporal processing.

Title: Timing impairments and cerebellar abnormalities in Prickle2 mice: implications for autism

Authors: *A. J. NESSLER[1], Y. KIM[1], S. WU[2], L. P. SOWERS[3], D. ANTIC[4], J. D. AXELROD[5], A. G. BASSUK[2], N. S. NARAYANAN[1], K. L. PARKER[1];

Abstract: Autism spectrum disorders involve abnormalities across brain systems, resulting in a myriad of symptoms including behavior inflexibility, cognitive dysfunction, learning impairment, altered social interactions, and time perception. Recently, it was reported that a common variant in the Wnt gene *PRICKLE2* was present in individuals with autism. Providing additional support for the role of Prickle2 in autism, mice with disrupted Prickle2 exhibit similar phenotypes to individuals with autism including altered social interaction, learning impairments, and behavioral inflexibility. Additionally, Prickle2 disruption results in hippocampal neuronal

abnormalities including reduced dendritic branching, synapse number, and post-synaptic density size. Autism can involve the cerebellum. As Prickle2 is strongly expressed in Purkinje cells, this animal model presents a unique opportunity to investigate cerebellar abnormalities associated with autism-like phenotypes. We studied the performance of Prickle2 knockout mice in interval timing, a task that requires subjects to estimate an interval of several seconds using a motor response that involves the cerebellum. Prickle2 knockout mice trained in a fixed 12 second interval task were impaired during the first 3 days of learning. Over successive days of training they acquired accurate timing to the level of litter mate controls. Additionally, we explore structural abnormalities in animals with Prickle2 disruption using immunohistochemistry and stereology. These data suggest a role of the cerebellum in cognition and could inspire novel cerebellar-targeted treatments for cognitive impairments in autism spectrum disorders.

Title: Initiation, continuation, adjustment, and termination: primary components of an ICAT model describing striatal-cerebellar interaction in temporal processing.

Authors: *E. PETTER, N. A. LUSK, W. H. MECK;
Duke Univ., Durham, NC

Abstract: The contributions of cortico-cerebellar and cortico-striatal circuits to timing and time perception has often been a point of contention. Dissociations between these two systems have been based on sub- vs. supra-second timing, duration-based vs. beat-based timing, and automatic vs. controlled timing. While some of these dichotomies arise out of different experimental constraints (e.g., psychophysical task or limitation in the range of time intervals studied), it is still uncertain whether these systems compete or cooperate with each other during temporal processing. We examined the cerebellum's contribution during timing tasks as fMRI suggest a role in temporal processing. This is supported as the neural architecture of the cerebellum makes it an ideal structure for temporal processing, with Purkinje cells in the cerebellar hemispheres integrating temporal aspects of salient stimuli. Furthermore electrophysiological studies show neural activity in cerebellar deep nuclei are modulated by the temporal regularity of stimulus presentations. In the current study, we attempted to identify the role of the cerebellum in both

sub- and supra-second timing using the duration bisection task with anchor durations of 200 vs. 800 ms and 2 vs. 8 s alternating within subjects and between sessions. To initially investigate the different components of the cerebellar-striatal network, we lesioned the dentate nucleus bilaterally. This caused impairments in reversal learning suggesting an inability to adjust. In order to further investigate components of temporal processing, we used in vivo recording techniques to measure temporal properties in striatal neurons during supra-second peak procedure tasks. This work in addition to previous literature suggests cortical-thalamo-striatal networks lend themselves to continuation of timing as well as initiation and adjustment during rhythmic stimuli. This data allows us to establish a parsimonious framework for the roles of the cerebellum and striatum in terms initiation, continuation, adjustment, and termination phases of temporal processing.

Title: A systematic exploration of temporal bisection models across sub- and supra-second ranges.

Authors: *N. A. LUSK, E. A. PETTER, W. H. MECK;
Psychology & Neurosci., Duke Univ., Durham, NC

Abstract: An integral component to the validity of timing models is their ability to accurately fit behavioral data from detection and discrimination tasks. Two of the most prominent timing models are the Sample Known Exactly (SKE), based on scalar timing theory, and the pseudo-logistic model (PLM). Currently, there is no standard by which behavioral data is fit, resulting in the implementation of both theoretical and atheoretical models, such as generalized logistic functions (L4P). Additionally, evidence accumulation models based on drift diffusion processes (DDM) have been utilized for modeling temporal bisection data. As many facets of timing behavior are quite nuanced, such as differences in precision across sub- and supra-sec durations, the variation in fitting models makes the interpretation of conflicting results difficult. Therefore, a comparative evaluation of these models was conducted to assess their ability to capture both quantitative and qualitative properties of timing data from the duration bisection procedure. As the DDM fits temporal bisection data in a fundamentally different way than the other three models, analysis was limited to within model comparisons using varying parameterizations.

Psychometric functions from rats, trained on a bisection task using sub-sec (200ms vs. 800ms.) and supra-sec (2s vs. 8s) conditions, were fit with each of the four models. Quantitative assessment of the fits used standard error of the regression (SE) as well as the Akaike Information Criterion (AIC) to evaluate model parsimony. The Weber fraction (WF) and point of subjective equality (PSE) were calculated for individuals and compared across both sub- and supra-sec durations within and between models. AIC analysis found the theoretical models vastly out performed the L4P, with the PLM being most parsimonious with the supra-sec data (AICc = -41.85), and the SKE and PLM both provided substantial explanatory power ($\Delta_i < 1$) for sub-sec data. Furthermore, differences existed in the PSE with the PLM and L4P being significantly different from the AM for sub-sec durations, while the PSE for the SKE was not. Three DDM models were analyzed with varying degrees of freedom. The DDM allowing for non-decision time, drift rate, and starting point to vary across signal durations was found to provide far great explanatory power ($\Delta_i > 10$) than the simpler models which only allowed for variation in drift rate or drift rate and starting point. These results demonstrate the need for a shift away from atheoretical models and towards theoretically based models such as the SKE or PLM, which provide greater parsimony as well as provide for greater qualitative analysis and interpretation of the data.

Title: Geometric bisection by rats on the temporal bisection task is an artifact of delay discounting

Authors: *C. D. KOPEC[1], C. D. BRODY[2];
[1]Princeton Univ., Princeton, NJ; [2]HHMI / Princeton Univ., Princeton University, NJ

Abstract: The Temporal Bisection Task has been widely used for many decades in both human and nonhuman subjects to study the subjective perception of time. Briefly, on each trial subjects are presented with a probe duration and asked to report which of two previously learned reference durations the probe duration is closest to. The bisection point is given as the probe duration that elicits a “long” response 50% of the time. While human subjects tend to bisect near

the arithmetic mean of the two reference durations, nonhuman subjects tend to bisect near the geometric mean. One possible explanation for this difference is that human and nonhuman subjects either perceive the passage of time or compute decisions regarding temporal information differently. Here we present an alternative explanation.
Previously we developed a behavioral model that incorporates delay discounting of reward to guide behavior on a range of temporal processing tasks. This model not only provides a good fit to the rats' overall choice behavior, bisecting at the geometric mean, but also provides a good fit to the moment-by-moment response behavior during the performance of each trial and for a number of odd behaviors, including: multiple choice reversals during a single trial, choice reporting failures, and reversals in the psychometric function for durations shorter than the short reference duration or longer than the long reference duration. The model is also able to quantitatively predict the shift in the bisection point if the rewards associated with a "short" or "long" response are unequal.
We therefore hypothesized that if the temporal discounting of rewards is an important influence guiding response behavior, eliminating it as a motivating force should reveal the rat's true bisection point. To test this we modified the Temporal Bisection Task to eliminate any differences in discounted reward value between the two choice options at all moments in time. While rats bisected near the geometric mean on the classic Temporal Bisection Task, they shifted their bisection point to the arithmetic mean on the modified version of the task, in agreement with human performance. The difference in bisection point between human and nonhuman subjects is therefore likely not a result of any differences in how we process temporal information, but rather a result of different strategies being used to solve the same task. By eliminating discounted reward value as a decision-making strategy, leaving only the temporal information of the stimuli, we reveal that rats and humans perform similarly on the Temporal Bisection Task.

Title: Representations of elapsed time in hippocampal CA1 during a temporal bisection task

Authors: *A. SHIMBO[1,2], E.-I. IZAWA[1], S. FUJISAWA[2];
[1]Keio Univ., Tokyo, Japan; [2]Riken BSI, Wako, Japan

Abstract: Quantification of intervals is one of the most important ability for guiding appropriate behavior to survive. In particular, measuring temporal information in seconds to minutes range, referred to as interval timing, was involved in various behaviors, such as foraging, decision making, associative learning, and sequential motor learning. Although the importance of interval timing is recognized, the neural mechanisms of the interval timing are largely unknown. Recent studies have shown that hippocampal 'time cells' fire at temporarily successive moments in working memory task (Pastalkova et al., 2009; MacDonald et al., 2011), though the contributions of time cells to interval timing has not been investigated yet. To clarify the role of time cells in interval timing, we have newly developed a temporal bisection task. In this task, rats were required to discriminate 5 or 10 seconds interval, running on a treadmill, for making a correct choice. We recorded neural activities in CA1 during the periods in which rats were required to measure elapsed time from a start of running, and found that a subset of CA1 neurons showed firing activities depending on time from a trial start. These neurons fired as successive moment in the interval like time cells, and showed stable phase precessions on theta oscillations in CA1. These results indicate that time-dependent sequential activities of pyramidal cells in the hippocampus underlies the mechanisms for bisecting interval timing and may inform the passing time to other brain regions to solve the interval timing task.

Title: Temporal and rate coding in hippocampus for integrations of non-spatial information

Authors: *S. TERADA;
Kyto Univ., Saitama, Japan

Abstract: Hippocampal pyramidal cells use both rate coding (i.e., place fields) and temporal coding (i.e., theta phase precession) for spatial navigation. However, much remains unclear how the hippocampus represents information and temporal relations during integrations of non-spatial events. Here we have newly developed a non-spatial associative memory task for rats under the head restriction, which is named cue-combination task. This task requires rats to associate two multimodal sensory cues (sound and odor cues) to determine a correct choice (left or right lever). Large-scale extracellular single unit recordings in the CA1 during this task revealed that some portion of the pyramidal cells were activated to specific sensory stimuli, combinations or

decisions, as the form of rate coding. On the other hand, the spiking of these neurons showed robust phase precession to theta oscillation, so that the past, current and future events were compressed and represented within a single cycle of theta oscillation. These results suggest that rate and temporal coding in hippocampal neurons independently contribute to integrations of multiple information for associative memory.

Title: A gap in time: Extending our knowledge of temporal processing deficit in the hiv-1 transgenic rat

Authors: *K. MCLAURIN, L. M. MORAN, H. LI, R. M. BOOZE, C. F. MACTUTUS; Dept. of Psychology, Univ. of South Carolina, Columbia, SC

Abstract: Approximately 50% of HIV-1 seropositive individuals develop HIV-1 associated neurocognitive disorders (HAND), which commonly include alterations in executive functions, such as inhibition, set shifting, and complex problem solving. Executive function deficits in HIV-1 are fairly well characterized, however, relatively few studies have explored the underlying dimensions of neurocognitive impairment in HIV-1. Deficits in temporal processing, caused by HIV-1, may manifest prior to early symptoms of impairment in higher level cognitive processes. Cross-modal prepulse inhibition (PPI), a translational measure of temporal processing, was studied in ovariectomized female HIV-1 transgenic (Tg) rats, which expresses 7 of the 9 HIV-1 genes constitutively throughout development. HIV-1 Tg animals exhibited an insensitivity to the manipulation of interstimulus interval (ISI) in both auditory PPI and visual PPI, replicating previously reported temporal processing deficits in HIV-1 Tg rats. To extend our knowledge of temporal processing deficits in the HIV-1 Tg rat, gap prepulse inhibition (gap-PPI) and gap threshold detection were also conducted. A relative insensitivity to the manipulation of ISI was observed in gap-PPI. HIV-1 Tg animals exhibited a profound differential sensitivity to the

manipulation of gap duration. Presence of the HIV-1 transgene was diagnosed with 88.9% accuracy using gap threshold detection. Understanding the generality of temporal processing deficits in the HIV-1 Tg rat is vital to modeling neurocognitive deficits observed in HAND and may aid in the development of a diagnostic screening tool.

Title: Neural processing for impulse control in medial prefrontal cortex and hippocampus

Authors: *A. MASUDA, C. SANO, S. FUJISAWA, S. ITOHARA;
RIKEN Brain Sci. Inst. - Wako, Wako-Shi, Saitama, Japan

Abstract: Impulsivity is a major characteristic of patients with drug abuse and psychological disorders. Dysfunctions of the medial prefrontal cortex (mPFC) and hippocampus can lead impulse control disorders, characterized by mistimed actions or decisions without due consideration of their consequences. However, it is not well known the relationships between activities of these brain regions. Here, we recorded the activities of single neurons in hippocampal CA1, dentate gyrus (DG), and mPFC, of mice performing a delay-based decision-making task in a T-maze. Large and small rewards were allocated to each side arm with or without a delay, respectively. The delay duration in the large-reward arm was progressively increased in each block (0, 5, 10, 20 and 40 s) in each session. The choice ratio to the large reward-delayed arm was negatively correlated with the delay durations. Putative excitatory and inhibitory neurons were identified by cell type classification with waveform parameters. Sizable amount of CA1 and DG excitatory neurons showed significant increases (about 40% of the population) in their firing rates during long (>20 s) delay periods. Increase of firing rates during long delay was found in mPFC neurons as well (about 40% of the population). Next, we investigated the place-dependency of the delay-activated neurons by switching the large reward-delayed arm with the small reward-non-delayed arm. Numerous (about 70 %) delay-activated neurons found in CA1 and DG were location selective (neurons specifically fired on one side) whereas few delay-activated neurons in mPFC (30 %) were location selective. Our findings

indicate that mPFC neurons encode the information for discounting reward values by a delay and that hippocampal neurons encode the information for both value and positions.

Title: Hippocampal and prefrontal cortical temporal coding in a model of cortical malformation

Authors: ***A. E. HERNAN**[1], M. MAHONEY[1], R. C. SCOTT[1,2];
[1]Neurolog. Sci., Univ. of Vermont Col. of Med., Burlington, VT; [2]Inst. of Child Hlth., Univ. Col. London, London, United Kingdom

Abstract: Malformations of cortical development (MCDs) are the result of an insult during the neuronal migration process that leads to structural and functional abnormalities in neural networks. In humans, MCDs are often associated with intractable epilepsy and cognitive deficits. In this study we used the embryonic day 17 methylazoxymethanol acetate (MAM) model to examine the impact of these MCDs, independently of seizures, on neural networks that subserve cognition. Using concurrent single unit recording in the medial prefrontal cortex (mPFC) and CA1 of the hippocampus during a working memory task that requires cross-talk between the two structures, we hypothesized that MAM animals would have significant alterations in rate and temporal coding within and between CA1 and mPFC that underlie cognitive deficits. To address this hypothesis, we used a generalized linear modeling (GLM) approach to directly model neuronal firing in both brain regions in MAM and control animals at baseline and during a delayed non-match to sample task. Preliminary data indicate that this GLM approach robustly captures *in vivo* spike train dynamics, that neuronal firing is modulated by several relevant task parameters and that significant firing correlations exist between neurons in CA1 and mPFC. We find that hippocampal temporal and rate coding are disrupted in MAM animals relative to controls; however the relationships between this and abnormalities in PFC, and the relationships between these parameters and cognition are currently being investigated. Understanding the systems-level mechanism of cognitive deficits in animals with MCDs could lead to novel therapeutic targets that maximize cognition.

Title: Optogenetic manipulation of frontostriatal circuits during interval timing

Authors: ***E. EMMONS**, B. DECORTE, K. PARKER, N. NARAYANAN;
Univ. of Iowa, Iowa City, IA

Abstract: Here we investigated the dynamics of temporal processing in the medial frontal cortex (MFC) and striatum in an interval-timing task. This elementary cognitive task involves working memory and attention and, importantly, is impaired in schizophrenia. First, we trained rats on an interval-timing task with a 12-second delay. Following training, animals were injected in the MFC with viral vectors to express ChR2 and ArchT optogenetic proteins. Animals were simultaneously implanted with microwire electrode arrays surrounding a fiberoptic cannula in the dorsomedial striatum. After waiting 4 weeks for viral expression, we inhibited and stimulated neurons in the dorsomedial striatum with 561-nm and 473-nm light, respectively. Medial frontal projections to the striatum that expressed optogenetic proteins were directly modulated by laser administration. Interval-timing behavior was altered in response to ArchT stimulation and subsequent inhibition of frontostriatal projections during the trial. Behavior was also altered in response to ChR2 stimulation at 4 and 20 Hz. Electrophysiological activity recorded at the site of stimulation in the dorsomedial striatum demonstrated a pronounced change in neural activity during both ChR2 and ArchT stimulation. Gradual changes in neural activity over time, or "ramping" activity, were found in striatal neurons during interval-timing behavior. These patterns of "ramping" activity are one possibility for the encoding of temporal information at a neural level. Ramping was diminished in the striatum when interval timing was impaired, suggesting that temporal information may be represented at the neural level by ramping activity. We also examined the population dynamics of these effects. These data demonstrate the importance of frontostriatal circuits in basic cognitive processing and suggest strategies for further elucidation of cognition.

Title: Direct and indirect pathway function in interval timing behavior

Authors: ***B. J. DECORTE**[1,2], M. MATELL[3], N. NARAYANAN[2];
[1]Neurosci., [2]Univ. of Iowa, Iowa City, IA; [3]Psychology, Villanova Univ., Villanova, PA

Abstract: Interval timing, the perception of time in the seconds-to-minutes range, is critical for adaptive behavior and is impaired in a variety of illnesses (e.g., Parkinson's disease, Huntington's disease, Autism Spectrum Disorder, etc.). Interval timing is often examined using the peak interval (PI) procedure. In a typical PI task, the onset of a discriminative stimulus (e.g., houselight) indicates that reinforcement may be earned for responding after a set "criterion duration" has elapsed (e.g., 6 seconds). During non-reinforced probe trials, in which the stimulus is presented for 3-4 times the length of the criterion duration, average response rates resemble a Gaussian distribution, peaking around this criterion time. In the current study, we examined how the direct and indirect pathways mediate responding during the PI procedure. Rats were trained on a PI task in which a houselight signaled a 6 second delay to reward. Once trained, cannulas were implanted into the dorsomedial striatum. We infused the D1 antagonist (SCH-23390) or the D2 antagonist (Sulpride) to manipulate direct and indirect pathway function, respectively. We found that the D2 antagonist shifted responding rightward, consistent with prior work on systemic injections of D2 antagonists and D2-over expressing mice. These results suggest striatal D2 receptor blockade slowed internal clock speed, and provide insight into the role of dorsomedial striatum and temporal control of action.

Title: Hallucinogen-induced alteration of timing performance is mediated by 5-HT2A: Insights from a mouse discrete-trials interval timing task

Authors: *L. M. KLEIN[1], M. A. GEYER[2], A. L. HALBERSTADT[2];
[2]Psychiatry, [1]UCSD, San Diego, CA

Abstract: Interval timing, i.e. discrimination of durations in the seconds to minutes range, is imperative for organization of behavioral sequences, anticipation of outcomes, and information processing. Altered interval timing disrupts assessment of relationships between sensory stimuli, resulting in disorganized or contextually inappropriate behavior. Schizophrenia (SZ) patients demonstrate deficits in temporal judgment that may underlie positive symptoms such as delusions and misattribution of causality. Classical hallucinogens effectively model the positive symptoms of SZ across species and reliably compromise the accuracy and precision of temporal discrimination in humans. Similar mechanisms may thus underlie timing alterations in SZ and hallucinogen intoxication. Though many perceptual effects of hallucinogens are associated with 5-HT2A receptor activation, the mechanism by which hallucinogens alter timing is unclear. We developed a discrete-trials interval timing task for mice, optimized to assess interval timing during pharmacological manipulation. C57BL/6J mice were presented with two levers following a variable interval after trial initiation (10 intervals; 2.5-10.5 s). Responding on lever A was reinforced if the interval was <6.5 s, and responding on lever B was reinforced if the interval was >6.5 s. Proportional choice for lever B at each test duration was analyzed using a 2-parameter logistic function, allowing estimation of the bisection point (T50), a measure of clock speed, and the difference limen (DL), a measure of timing precision. Challenge with the structurally distinct hallucinogens lysergic acid diethylamide (LSD), psilocin, and 2,5-dimethoxy-4-iodoamphetamine (DOI) during this task revealed consistent dose-dependent alterations in timing across the 3 structural classes: reduced % lever B responding at long intervals and increased T50 (LSD: 1 mg/kg IP; psilocin: 0.8 mg/kg SC; DOI: 3 mg/kg IP), and increased DL (psilocin: 0.8 mg/kg SC; DOI: 3 mg/kg IP). Administration of 25CN-NBOH, an agonist selective for 5-HT2A, dose-dependently recapitulated all three alterations of timing (6 mg/kg SC), suggesting that hallucinogens alter timing via their effects on 5-HT2A. The effects of DOI (3 mg/kg IP) on timing were blocked by the highly selective 5-HT2A antagonist M100907 (0.03 mg/kg SC), but

were unaffected by the 5-HT2C selective antagonist SB242084, consistent with a 5-HT2A-dependent mechanism. These findings further validate the translational utility of the mouse discrete-trials interval timing task and clarify the mechanism of a key perceptual alteration induced by hallucinogens with relevance to SZ.

Title: Sodium butyrate facilitates the acquisition of the "Stop" response threshold for peak-interval timing - Role of Histone acetylation in temporal extinction learning.

Authors: *B. A. CAHN, W. H. MECK, C. L. WILLIAMS;
Psychology and Neurosci., Duke Univ., Durham, NC

Abstract: In the peak-interval (PI) timing procedure, the subject is first presented with fixed-interval (FI) trials only, during which the onset of a light or tone reliably predicts the time at which reinforcement will be made available (target duration). In order to characterize the accuracy and precision of interval timing, un-reinforced probe trials are randomly intermixed within an experimental session after sufficient training with FI trials. For a probe trial, the signal stays on long past the target duration and no reinforcement is provided. Only by maintaining partial reinforcement (e.g., continued reinforcement on FI trials and non-reinforcement on probe

trials) across multiple sessions do subjects learn to stop responding once the target duration has passed. Despite these observations, there is still little understanding concerning how the "Start" and "Stop" response thresholds are acquired and what the underlying molecular mechanisms for the partial-extinction learning on un-reinforced probe trials might be. A pivotal role has been demonstrated for histone acetyltransferase CREB-binding protein and histone deacetylases (HDACs) in the epigenetic modification of memory and synaptic plasticity. HDAC inhibitors block the activity of histone deacetylases and thus increase histone acetylation thereby facilitating various types of learning and memory. As a consequence of these findings, the current experiment was designed to investigate whether systemic injection of the potent histone deacetylase inhibitor sodium butyrate (NaB) would facilitate the acquisition of the "Stop" response threshold in a 20-s PI procedure. Following 14 sessions of baseline FI 20-s training, rats were transferred to a 20-s PI procedure and given ip injections of either 1.2 g/kg NaB in a volume of 0.5 mL (n=12) or saline (n=12) for 5 consecutive sessions, after which the rats receive another 5 sessions of PI testing with no injections. The results indicated a significant effect on the development of temporal inhibition following the target duration as early as the first 2 hr session. This improvement in temporal sensitivity as measured by the curvature of the PI response functions continued through the "wash-out/recovery" phase until the final 2 sessions at which time both the NaB and control rats demonstrated nearly symmetrical peak functions centered around 20 s. Follow-up microinjection studies will determine the role of histone deacetylases in the dorsal and ventral striatum in setting the "Start" and "Stop" thresholds for interval timing.

Title: Prelimbic cortex activation correlates with SSRI fluoxetine's effectiveness to reduce the impact of emotional distracters on interval timing

Authors: *A. R. MATTHEWS[1], M. BUHUSI[2], C. V. BUHUSI[2];
[1]Dept. of Psychology, [2]Utah State Univ., Logan, UT

Abstract: Selective serotonin reuptake inhibitors (SSRI) are a primary medication for affective disorders like depression and anxiety. SSRI fluoxetine (FLX) has beneficial effects on attention and working memory, e.g., decreasing emotional response to negative events. We hypothesized that FLX improves maintenance of information in working memory, and decreases the disruptive effect of emotional events on cognitive processing. Among the processes impaired by emotional events, and whose dysregulation is documented in affective disorders, is timekeeping in the seconds-to-minutes range (interval timing). Presentation of task-irrelevant emotional distracters during a peak-interval (PI) procedure results in considerable delays in responding relative to neutral distracters (Matthews et al 2012 Front Int Neurosci 6: 111). Here we examined the neural correlates of chronically administered FLX in regard to the delaying effect of anxiety-inducing distracters on interval timing. Rats were trained in a PI procedure as in Mathews et al. 2012. Half the rats received 16 days of chronic systemic FLX administration, while the others received vehicle injections (VEH). Afterwards, rats were tested by presenting an anxiety-inducing distracter and evaluating the timing delay in distracter trials relative to no-distracter (PI) trials. Chronic FLX administration significantly decreased the delaying-effect of the anxiety-inducing distracter relative to VEH. The timing delay after the anxiety-inducing distracter (relative to PI trials) was inversely correlated with neuronal activation (cFos counts) in prelimbic cortex (PrL) (R^2=0.47, $p<0.01$), but not in infralimbic cortex (R^2=0.14, $p>0.05$): The higher the PrL activation the more effective was FLX in reducing the timing delay after the anxiety-inducing distracter, suggesting that one locus of action of FLX in reducing the delay after anxiety-inducing distracters is PrL. Indeed, the delay after anxiety-inducing distracters was reduced by local infusions of FLX into PrL (Matthews et al. Program No. 85.18, 2015 Neuroscience Meeting Planner). Together, these results identify PrL as a structure involved in the relative sharing of resources allocated to interval timing and emotion (Buhusi & Meck 2009 Philos Trans R Soc B 364: 1875-85).

Title: The impact of vmPFC and hippocampal lesions on episodic segmentation and relational memory

Authors: *M. R. DULAS[1], M. C. DUFF[2], N. J. COHEN[1];
[1]Beckman Inst., Univ. of Illinois - Urbana-Champaign, Urbana, IL; [2]Communication Sci. and Disorders, Neurology, & Neurosci., Univ. of Iowa, Iowa City, IA

Abstract: Previous work in temporal order memory has shown that, in healthy participants, context boundaries result in segmentation effects, wherein within-context information is remembered as closer together than across-context information, even when equidistant. Further, imaging evidence has suggested the ventromedial prefrontal cortex (vmPFC) and the hippocampus play critical roles in these relational memory and segmenting processes. The present study investigated segmentation effects for spatial information, their interaction with relational memory, as well as the impact of lesions to the vmPFC and hippocampus on these effects. On each block of the task, participants studied 8 objects, presented one at a time on different locations of a grid, divided across two contexts (scenes). At test, participants judged how far apart pairs of these objects were, and also answered two relational memory questions: in which context and in which half of the set of 8 (first or second) did each object appear. Participants included both patients with hippocampal and vmPFC lesions, as well as healthy comparison individuals. Healthy participants showed robust segmentation effects, rating within-context pairs as closer together than equidistant across-context pairs. Further, these segmentation effects were positively correlated with relational memory accuracy. Hippocampal patients were at chance for these judgments, regardless of the distance, and also showed significant impairments for both relational memory questions. Patients with vmPFC lesions performed similarly to healthy comparisons on all tasks, except they did not show segmentation effects, rating equidistant across-context and within-context pairs as the same distance. The results suggest that, in healthy adults, episodic segmentation may be useful in supporting later relational memory judgments. Further, while the hippocampus is likely necessary for all forms of spatial and relational memory judgments, even for small sets of items, the vmPFC may play a particular role in using contextual boundaries to bias memory representations via episodic segmentation.

Title: Enhanced temporal order memory for events preceding contextual boundaries during navigation

Authors: *I. BRUNEC[1,2], J. D. OZUBKO[3], M. MOSCOVITCH[1,2], M. D. BARENSE[1,2]; [1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Rotman Res. Institute, Baycrest, Toronto, ON, Canada; [3]Dept. of Psychology, SUNY Geneseo, Geneseo, NY

Abstract: Route representations learned during spatial navigation are reconstructed from memory by relying on turns as boundaries segmenting the path. The ability to detect and predict contextual boundaries has been shown to depend on the hippocampus (Zacks et al., 2007). In rodents, spatial boundaries are associated with hippocampal cell ensemble preplay, which is thought to reflect the prediction of turns and route trajectory (Erdem & Hasselmo, 2012). Here, we aimed to join the literatures on event boundaries and navigation. We used a naturalistic virtual reality navigation paradigm to test memory for spatial and temporal contextual information for events preceding event boundaries. Half of the participants actively navigated along a route and half were passively led through the route. Participants in both conditions were stopped for different durations at several intersections which were either followed by turns (event boundaries) or stretches of road in same direction (no boundary). We tested participants' ability to discriminate between the ordinal positions and wait durations for pairs of intersections along the route. We found that memory for temporal order, but not event duration, was significantly improved for events followed by boundaries. This effect was unique to the active navigation condition, suggesting that passive route following does not result in a similar improvement in memory, despite the fact that intersections followed by turns were subjectively recollected more in both conditions. We propose that the observed memory boost is advantageous in predicting and segmenting upcoming events along a route and serves as a mechanism of encoding navigationally salient events. Such enhanced memory further enables more successful separation of the sequential positions in which spatial locations were encountered. These findings are consistent with the notion that recollection supports whichever feature is most relevant to the task at hand, in line with the hippocampus supporting consciously processed information.

Title: Striatal novelty responses reverse with retrieval demands

Authors: *N. A. HERWEG[1], T. SOMMER[1], N. BUNZECK[1,2];
[1]Dept. of Systems Neurosc., Univ. Med. Ctr. Hamburg, Hamburg, Germany; [2]Dept. of Psychology, Univ. of Luebeck, Luebeck, Germany

Abstract: The striatum and pallidum have been implicated in relaying novelty signals from the hippocampus to dopaminergic midbrain neurons. The same areas, however, also respond to retrieval success in recognition tasks, suggesting that these areas do not code novelty per se but dynamically adapt to the current behavioral context. Here, we used fMRI in healthy humans to test the prediction that encoding vs. retrieval orientation, as induced by task context, modulates striatal old/new effects. To this end, participants were initially familiarized with a set of scene stimuli in a target detection task. Subsequently, they viewed these old images intermixed with new ones and either classified them (i) as indoor vs. outdoor (encoding) or (ii) as old vs. new (retrieval), while fMRI and eye tracking data were recorded simultaneously. After leaving the scanner, subjects performed a final recognition task. As hypothesized, a cluster including parts of the striatum and pallidum displayed a significant interaction of task context and old/new status, which was driven by stronger responses to novel images in the encoding context and the reversed pattern, i.e. stronger responses to old images, in the retrieval context. An interaction was also evident in pupil size. Here, the old>new effect was more pronounced during retrieval than during encoding mode. Taken together, our findings provide compelling evidence that mnemonic signals in the basal ganglia flexibly adapt to explicit recognition demands. This mechanism might be mediated by dopaminergic neuromodulation and indicates that the degree of salience of old and new information is context dependent.

Title: Spatio-temporal dynamics of short-term working memory maintenance and scanning of verbal information

Authors: *T. KAMBARA[1,2], E. BROWN[3], J.-W. JEONG[1,4], N. OFEN[1,5], Y. NAKAI[1], E. ASANO[1,4];

Ctr., Detroit, MI; [5]Inst. of Gerontology and Dept. of Psychology, Wayne State Univ., Detroit, MI

Abstract: Humans briefly maintain speech sounds such as those conveyed in verbal phrases and scan those mental representations to generate relevant responses during verbal communication. Here, we determined the spatio-temporal dynamics of such short-term maintenance and scanning of verbal information, by intracranially measuring high-gamma activity at 70-110 Hz during a working-memory task. Patients listened to 2 or 4 letters and were instructed to remember those letters over a two-second interval, following which they were asked to determine if a subsequent target letter was presented earlier in that trial. The auditory presentation of the letters sequentially elicited high-gamma augmentation in the superior-temporal and precentral gyri, bilaterally. During the two-second maintenance period, high-gamma augmentation was observed in the precentral gyri with left hemispheric dominance, and this occurred to a greater extent during the maintenance of 4 compared to 2 letters. During the scanning period following target presentation, high-gamma augmentation was observed in the inferior-frontal and supra-marginal gyri also with left hemispheric dominance. Finally, at the onset of the response, high-gamma augmentation was observed in the pre- and post-central gyri, bilaterally. These results support the notion that short-term maintenance of verbal information is supported by the precentral gyrus, whereas scanning to determine of a match for an auditory stimulus is supported particularly by the left inferior-frontal and supra-marginal gyri.

Title: Evidence for persistent activity-based attractor states from human single-neurons during short term memory maintenance

Authors: *J. KAMINSKI[1], S. SULLIVAN[1], J. CHUNG[2], I. ROSS[3], A. MAMELAK[1], U. RUTISHAUSER[1,2,4];
[1]Neurosurg., [2]Neurol., Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]Neurosurg., Huntington Mem. Hosp., Pasadena, CA; [4]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Sustained neuronal firing is thought to be a principle mechanism by which information is maintained in short term memory (STM). Such activity has been hypothesized to form attractor states, which are mathematical representations of preferred and stable network configurations. This hypothesis rests on theoretical models and experimental evidence in macaques but has not been demonstrated in humans. We performed human single-neuron recordings in neurosurgical patients to test for the presence and properties of attractors during the maintenance of information in STM. We recorded from two regions: the medial temporal lobe and the medial frontal cortex. We used a modified Sternberg task with pictures as study material. To improve neuronal responses, images were selected for each patient individually using a screening task. We observed 83 (12.3%) neurons in the screening task, mainly in hippocampus and amygdala, with selectivity for one of the images. These cells showed sustained activity that was selective for the content of STM during the delay period of the task. We analyzed the dynamics of neuronal activity using demixed PCA (dPCA) in order to extract components relevant for encoding picture identity. An analysis of neural trajectories in dPCA space during the time when subjects held an item in memory showed that the multidimensional distance between conditions with different images held in memory was significantly larger than expected by chance. At the same time, we also observed that the velocity in state space was low and not significantly different from baseline levels. Together, this indicates neural trajectories that form stable attractors. Furthermore, we found that the quality of the identified attractors was relevant for STM performance because the extent of drift away from attractors in each trial predicted later retrieval accuracy and speed of response. This observation is the first evidence in humans that

single-neurons code information in STM by means of persistent firing activity, and that this persistent activity forms stable attractors.

Title: Targeted training: Assessing the effects of online brain training on cognitive function

Authors: ***K. M. LYONS**[1,2], A. PEARCE[2,1], T. NGUYEN[2,1], A. M. OWEN[2,1], B. STOJANOSKI[2,1];
[1]Univ. of Western Ontario, London, ON, Canada; [2]Brain and Mind Inst., London, ON, Canada

Abstract: 'Brain training' is built on the idea that general cognitive functioning can be improved through the regular use of online computerized tasks that target specific cognitive domains. While the idea that brain training will improve general cognitive functioning is appealing, reliable evidence in support of this is unconvincing (Thompson et al., 2013; Owen et al., 2010). What remains contentious is not that performance cannot be improved by training, but, instead, whether training transfers to unrelated tasks. Using Cambridge Brain Sciences, a set of online cognitive assessment tests, the current study investigated whether extensive training on a working memory task produced improved performance on two tasks with similar or different neural and cognitive profiles. Participants first benchmarked on the two test tasks, spatial span and digit span, which served as their baseline measure. They then trained on a visuospatial working memory task, for thirty minutes a day, five days a week for four weeks (ten hours total). One day after training was complete, participants were tested again on the spatial span and digit span tests. As expected, performance on the training task (visuospatial working memory) significantly improved over the training period ($p=0.016$), and this provided evidence for direct transfer. However, when performance on the test tasks was compared before and after training, no change was found in mean score for either the spatial span ($p=0.26$) or the digit span tasks ($p=0.80$). Perhaps only those who benefited the most from training showed transferrable gains on the test tasks? To test this hypothesis, "high trainers" were selected based on their rate (slope) of improvement on visuospatial working memory task. Despite benefiting more from training, this

did not transfer to improved performance on the spatial or digit span task. Our results suggest that participants show direct transfer (to the same task) only after extensive training and, even then, no matter how beneficial the training, no measurable transfer to any other task is evident.

Title: Evoked potential to word presentation correlates with its inherent recall probability

Authors: *M. KATKOV[1], M. TSODYKS[1,2];
[1]Weizmann Inst. of Sci., Rehovot, Israel; [2]Columbia Univ., New York, NY

Abstract: *In this contribution we provide electrophysiological evidence for recently proposed model of memory retrieval from long-term memory, according to which the size of encoding representation of a given word is positively correlated with the probability to recall this word in a free recall experiment.*
Despite the ability of humans to memorize a huge amount of information; recalling this information without relevant cues is a challenging task. This is manifested in, for example, free recall experiments, where participants are prompted to recall as many words as possible from just presented list of randomly assembled words. Participants are making mistakes even for shortest lists of 2-5 items with progressively smaller fraction of correctly recalled words with increasingly longer lists. We have recently proposed a mechanism for memory retrieval which attributes limited recall capacity to two basic phenomena. 1) Items in long-term memory network are represented by random groups of neurons. 2) In the absence of external cues, just recalled item (JRI) plays a role of an internal cue, triggering a recall of an item having the largest overlap with JRI. This mechanism inherently leads to the existence of “easy” and “difficult” words for recall - statistically items having larger representation are easier to recall since their overlaps with other representations will be larger on average. Analysis of behavioral data revealed that

distribution of recall difficulties across different words is indeed consistent for different randomly selected groups of participants. In the current contribution we analysed scalp electrical activity in the brain (EEG) collected in the M. Kahana lab (UPenn) during list acquisition. In particular, we computed the average (across all presentations for all participants) normalized evoked response for each word separately. Next, we computed correlation coefficient of normalized responses at each time point and each electrode with the fraction of times the word was recalled when presented. Results showed two waves of highly correlated activity at 250-400ms and 450-700ms with the largest correlation coefficient in a single electrode being 0.25 for the first wave and 0.15 for the second wave. This result is consistent with our basic assumption that words characterized by a larger group of encoding neurons (and hence the ones that reactivate larger neuronal population during presentation) have intrinsically higher probability to be recalled.

Title: Brain regions associated with value-driven encoding of novel kaleidoscope images

Authors: ***M. S. COHEN**, L. Y. CHENG, K. HAQUE, K. A. PALLER, P. J. REBER; Dept. of Psychology, Northwestern Univ., Evanston, IL

Abstract: Information tends to be remembered better when it is known to have relatively high value for the future. This effect is thought to occur either due to dopamine-driven strengthening of encoding in the hippocampus (e.g., Adcock et al., 2006), or due to modulation of the use of semantic strategies to encode words (e.g., Cohen et al., 2016). In the present study, we examined whether value can also strengthen memory for abstract, novel kaleidoscope images, for which little semantic processing can be done. Each image was presented in one of four quadrants, with two images, one high-value item and one low-value item, presented in different quadrants on each encoding trial. At test, individual items were presented centrally, and participants attempted to judge whether a given item was old or new, as well as recall the original spatial location.

Multiple study-test cycles were used, with aggregate feedback provided after each test, in order to encourage participants to use metacognition to develop strategies that maximize their point score. After all cycles were complete, a second test, a forced-choice recognition test with highly similar foils, was completed. Accuracy on the yes-no quadrant test was higher for high-value items, suggesting that encoding was modulated by value in this paradigm. Results from fMRI showed that successful encoding of kaleidoscope images and spatial source information (quadrant at study) was associated with increased activity in a network of brain regions including superior and inferior lateral occipital cortex, posterior parietal, inferior lateral temporal/fusiform cortex, and putamen, relative to trials in which neither image was successfully encoded. There were also related regions in which activity was stronger when only a high-value image was successfully encoded, relative to trials in which only a low-value image was encoded successfully. Thus, we can begin to understand the neural circuitry in which modulation of activity by value leads to strengthening of subsequent memory for both the item and its spatial location. Behavioral pilot results with this paradigm also indicated that while high-value items showed enhanced recognition driven by explicit memory, the accuracy of guess responses on the forced-choice test, believed to be driven by implicit memory, tended to be greater for low-value than for high-value items. Thus, our results also provide a first step towards understanding the encoding that impacts the relative weighting of information from implicit and explicit memory systems in memory judgments.

Title: Familiarity-novelty detection is an intrinsic property of cortical microcircuits with NMDA receptor-dependent synaptic plasticity

Authors: *X. ZHANG[1], H. JU[2], T. B. PENNEY[3], A. M. J. VANDONGEN[2];
[1]NUS Grad. Sch. For Integrative Sci. and E, Singapore, Singapore; [2]Neurosci. & Behavioural Disorders Program, Duke-NUS Med. Sch., Singapore, Singapore; [3]Psychology, Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Familiarity and recollection are two processes underlying recognition memory. Evidence from functional imaging studies shows that cortical regions surrounding the

hippocampus become active when a human subject senses a familiar input, whereas recollection relies on activation of the hippocampus itself. To deepen our understanding of familiarity-novelty detection, we simulated biologically plausible neural network models of cortical microcircuits consisting of 2,000 – 15,000 spiking neurons with random recurrent connections, following the "liquid state machine" paradigm. Network activity evoked by the sensory input (spatially-differentiated images) altered synaptic efficacy through NMDA receptor-dependent synaptic plasticity, which in turn resulted in the network responding more strongly to a previously seen image via unsupervised learning. Small networks of 2,000 spiking neurons were able to encode the features of a human face image and identifiy it accurately out of a set of 30 test images. Large networks of 15,000 spiking neurons were able to identify multiple familiar faces simultaneously with high accuracy. When the simulated network model became sufficiently complicated in structure, multiple familiarity traces could be retained in the same network by forming partially-overlapping subnetworks. These subnetworks were composed of potentiated and depressed synapses that were modulated by the corresponding sensory inputs. A very large number of input-representative subnetworks that differ slightly from each other can co-exist in the network, giving the model a promisingly high capacity. Therefore, we suggest that cortical microcircuits with NMDA receptor-dependent synaptic plasticity have an intrinsic ability for detecting familiar sensory input patterns. This ability does not require a specialized wiring diagram or supervision, and can be expected to emerge naturally in developing cortical circuits. Meanwhile, electrophysiological recordings from animals indicate that single cell activity within the cortical regions can represent familiarity. Therefore in addition to network firing rate response, we also investigated neuronal activity before and after sensory exposure and found that "grandmother-cell" neurons exist in our network model. Fisher's discriminant analysis was applied to select the critical neurons whose activity can be used to predict input patterns. Intriguingly, as sensory exposure was prolonged, the selected critical neurons tended to appear more at deeper layers of the network model, which might suggest a strategy of recruiting hidden circuits in the network for incremental information storage.

Title: Time-resolved single-trial multivariate pattern decoding as a continuous measure of working memory load using EEG spectral power

Authors: *E. ASTRAND;
Innovation, Design, and Engin. (IDT), Mälardalen Univ., Västerås, Sweden

Abstract: Decoding cognitive information from brain signals by using multivariate pattern classification methods is becoming increasingly popular. Most studies have however only classified the information into pre-defined states which consequently limits the possible applications. Working Memory (WM), the capacity to remember and manipulate relevant information during a short time period, is central for human cognition. Because many psychiatric populations (i.e. ADHD, depression, substance abuse and many more) have impaired WM capacity, the potentials of extracting WM load and applying it as a feedback signal in a training protocol to enhance the underlying brain activity pattern, is supported by observations that individuals with high WM capacity evoke a more discriminative activity pattern when performing WM tasks. This study investigates the temporal dynamics of WM-induced EEG spectral power patterns and the feasibility of extracting a continuous measure of WM load by using time-resolved single-trial multivariate pattern decoding.
Brain activity was recorded, using a 64-active EEG-channel system, on 16 healthy individuals while they performed two versions of the n-back task. Specifically, the 1- and 2-back tasks were performed in two separate blocs, during which participants were asked to respond with a button press, yes or no, for each stimulus, whether it matched the stimulus presented 1 or 2 steps back (1-back and 2-back task, respectively). A complex EEG power spectrum over the scalp is observed as WM load increases, including a significant decrease in alpha power (~8 to 12Hz) over parietal electrode locations and significant increase in theta power (~3 to 7Hz) over frontal electrode locations. Moreover, temporal dynamic changes in the EEG power spectrum are observed at the presentation of a visual stimulus for theta but not for alpha power suggesting that different underlying mechanisms of WM are reflected by these oscillations. By applying multivariate pattern decoding, using linear regularized regression, the output of the binary classifier is shown to correlate with the strength of the EEG activity pattern that is induced as WM load increases, as well as with overt behavior, suggesting its applicability as a continuous measure in online monitoring and as a feedback signal in rehabilitation protocols. These results shed new light on the extraction of cognitive information from EEG spectral power by using time-resolved single-trial multivariate pattern decoding.

Title: Modulation of pupillary light responses by saccade preparation, working memory, and microstimulation of the superior colliculus

Authors: *C.-A. WANG[1], D. P. MUNOZ[2];
[1]Queens Univ., Kingston, ON, Canada; [2]Queen's Univ., Kingston, ON, Canada

Abstract: Pupil size changes constantly, mainly to regulate the amount of light entering to the retina, with pupil constriction to luminance increases and dilation to luminance decreases. This illumination-dependent pupillary modulation has thought to be independent from the top-down influence such as spatial attention. However, it was shown recently that while maintaining central fixation, pupil size is smaller when spatial attention is guided to bright, compared to, dark surfaces, demonstrating the attentional modulation on illumination-dependent pupillary responses. However, the underlying neural mechanism is poorly understood. A large body of research has suggested the close relationship among spatial attention, saccade programming, and working memory, however, the influence of these processes on pupillary light responses is yet explored. Here, we examined the modulation of illumination-dependent pupillary responses by saccade preparation, working memory, and microstimulation of the superior colliculus (SC), a midbrain structure causally involved in shifts of spatial attention and gaze. We hypothesize that enhanced pupillary light responses when the visual (patch) stimulus is presented at the location 1) corresponding to an upcoming saccade destination, 2) activated in spatial working memory, or 3) corresponding to the stimulated region in the SC saccade map. While requiring subjects to maintain central fixation, we presented bright and dark surfaces in two different locations that matched either an upcoming saccade destination (visual delay task), a remembered location (visual memory-guided task), or the stimulated SC site, and another patch was presented at a control location in the opposite visual field. Our results first showed an enhanced illumination-dependent pupillary responses when stimuli were presented at the location corresponding to an upcoming saccade destination or at a location that was activated in memory representation. Moreover, we found that SC microstimulation modulated pupillary light responses in a similar manner, with enhanced illumination-dependent pupillary responses while stimuli presented at the location corresponding to the stimulated SC site. Our results demonstrate that spatial selection for saccade programming and spatial activation in working memory had similar effects on pupillary responses, suggesting the shared neural mechanisms among saccade programming,

working memory, and spatial attention. Furthermore, the SC results provide direct evidence arguing that the SC is mediating this modulation of pupillary light responses.

Title: Hippocampal synchronization and neocortical desynchronization accompany successful memory formation

Authors: ***B. GRIFFITHS**[1], S. MICHELMANN[1], B. STARESINA[1], M. WIMBER[1], R. CHELVARAJAH[2], D. ROLLINGS[2], V. SAWLANI[2], H. HAMER[3], S. GOLLWITZER[3], G. KREISELMEYER[3], S. HANSLMAYR[1];

Abstract: An abundance of studies demonstrate a link between episodic memory formation and neural oscillatory activity. However, their findings often conflict with some reporting synchronization, and others desynchronization, in the face of successful encoding. In a step to resolve this contradiction, a recent opinion paper proposed that both are necessary for memory formation (Hanslmayr, Staresina & Bowman, Trends in Neurosciences, 2016). Specifically, synchronized theta and gamma oscillations within the hippocampus serve to bind information into a coherent episode while neocortical low frequency desynchronized activity facilitates information processing relating to the to-be-encoded stimulus. Here, we test the spatial specificity of this hypothesis. We engaged epileptic patients with hippocampal depth electrodes in a typical associative memory paradigm. Patients were presented with either a video or a sound, followed immediately after by a word which they had to vividly associate with the video/sound. Preliminary analysis has revealed hippocampal theta and gamma power increases and neocortical low frequency power decreases (3-20Hz) for later remembered items relative to later forgotten items. These findings support the theory that a synchronized hippocampus and desynchronized neocortex facilitate episodic memory formation.

Title: Human memory recall is affected by the phase of low frequency EEG oscillations during stimulus presentations.

Authors: ***A. JALALI**, M. S. TATA, A. J. GRUBER, A. LUCZAK;
Dept. of Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Previous studies using electroencephalography (EEG) have shown that low frequency oscillations play an important role in successful memory formation in humans. These studies have linked performance to theta (4-7 Hz) oscillations in awake subjects and slow-wave activity (SWA) during sleep. There is also abundant evidence that memory consolidation is facilitated by slow-wave sleep, in which EEG is dominated by low frequency oscillations. During sleep, the phase of the SWA at the onset of the stimuli affects the recall accuracy in a location memory task. We hypothesized that an analogous phenomenon may take place in the awake state such that the phase of low frequency EEG oscillations at the onset of stimuli will affect memory recall. In order to test our hypothesis, participants performed a word-nonword matching memory task while EEG signals were collected with a 128-channel Electrical Geodesic Incorporated sensor net. The task consisted of four blocks, each with an encoding phase in which novel word-nonword pairs were presented every 5 seconds for 100 seconds (20 pairs total), followed immediately by a test phase in which subjects where shown one of the words and presented with 4 target nonwords. A correct recall occurred when subjects selected the nonword previously paired with the word. We presented every one of the 20 words in series during the test phase. We found that recall performance was higher when the stimuli were presented at a particular phase in the theta and delta bands of EEG collected from the frontal cortex, but not EEG collected from posterior cortical regions. We thus suggest that visual information related to language may be

more readily encoded into short-term memory during particular phases of ongoing cortical neural activity.

Title: Resting state functional connectivity between hippocampal and prefrontal brain areas is associated with the renewal effect

Authors: ***A. GOLISCH**, L. M. SCHWEIZER, B. GLAUBITZ, M. TEGENTHOFF, S. LISSEK;
Dept. of Neurol., BG Univ. Hosp. Bergmannsheil, Bochum, Germany

Abstract: Renewal describes the recovery of an extinguished response if the context during retrieval differs from the context of extinction. This context-dependent learning phenomenon is above all mediated by hippocampal activation. In associative learning tasks, participants showing the renewal effect (REN) exhibit higher hippocampus activation during acquisition and extinction compared to participants without renewal (NoREN). Moreover, REN participants also show higher ventromedial prefrontal activation during retrieval than NoREN participants, while NoREN participants exhibit higher activation in dorsolateral prefrontal cortex. Consequently, a connection of the hippocampus with prefrontal areas might be conceivable as a mechanism underlying the renewal effect. In this study we performed both task-based and resting state fMRI at 3T in order to assess brain activation during extinction retrieval. We observed significantly higher hippocampus activation in REN participants. These task-related hippocampal clusters were used as seeds in subsequent seed-based functional connectivity analyses on resting state patterns in REN and NoREN participants. After extinction retrieval REN participants showed stronger hippocampal connectivity with dorsolateral and ventromedial prefrontal brain regions as well as with cingulate gyrus than NoREN participants. Therefore, our data suggest a hippocampal-prefrontal network that is specifically involved in extinction learning and thus mediating the renewal effect. These present findings moreover support previous observations that REN participants use distinct encoding strategies in context-related tasks, which reflect in their brain activation as well as in their connectivity patterns.

Title: Modality-independent differential effects of ongoing EEG beta and theta power on memory formation

Authors: ***S. L. SCHNEIDER**[1], S. SCHOLZ[2], M. ROSE[1];
[1]Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg Eppendorf, Hamburg, Germany; [2]Dept. of Psychology in Educ., Univ. of Muenster, Muenster, Germany

Abstract: Recently, elevated ongoing EEG power in the theta (3-7 Hz) and low beta (13-17 Hz) frequency range before being exposed to a new stimulus has been associated with successful subsequent memory formation for visual stimulus material. However, so far, it has been unclear whether this activity is merely specific to visual processing or whether it reflects a state that generally facilitates the encoding of new information, independent of stimulus modality. To shed light on this issue, the present study investigated the relationship between neuronal pre-stimulus oscillations and verbal memory formation in different sensory modalities. A within-subject design was employed to identify oscillatory states related to successful memory formation for written and spoken words in an incidental encoding task. Further, we investigated whether similar neuronal states promote encoding not only of the stimulus itself, but also of the context in which it is presented, as implemented by a background picture. Results revealed similar EEG activity to be associated with subsequent memory for the stimulus itself in both modalities. Elevated power in the low beta band 800 - 200 ms prior to stimulus onset differentiated successful from failed memory formation for both written and spoken words. In contrast to the stimulus-encoding related effects in the low beta band, increased pre-stimulus theta power was found before successful compared to failed encoding of the associated context. It is suggested that ongoing pre-stimulus beta activity reflects a memory-promoting state and is likely to be moderated by modality independent attentional processes. Ongoing theta power on the other hand is suggested as an indicator of enhanced binding of interlinked information.

Title: Distracted from distraction: interactions of prefrontal and cerebellar regions with the default mode network shield cognition from distraction under high working memory load

Authors: *A. S. WEIGARD, S. J. WILSON, C. HUANG-POLLOCK, Z. SHAPIRO, H. GALLOWAY-LONG;
The Pennsylvania State Univ., University Park, PA

Abstract: Human cognitive performance is often disrupted by distractions related to sensory stimuli and affective states, but, paradoxically, a wealth of evidence also suggests that higher working memory load buffers cognitive processing from the impact of distraction. Although the neural mechanisms that mediate this buffering effect are not currently known, it has been posited that regions involved in working memory maintenance and cognitive control inhibit the processing of basic sensory and affective information during high load. However, it is also possible that these regions reduce distraction under high load by suppressing activity in the default mode network (DMN). As the DMN redirects attention from task-relevant processing to rumination and other off-task cognitions, interactions with this network may serve to suppress these cognitions in order to prevent distraction. The current study utilized an aversive odor manipulation to identify neural structures that buffer performance from distraction under high working memory load, and employed context-specific connectivity analyses to determine whether these structures interact with other brain regions related to the DMN or basic sensory and affective processing.
As expected, a significant interaction between distraction conditions and task load demonstrated that response times were impacted by the aversive odor manipulation in a low load (1-back) but not a high load (3-back) working memory task. Areas in the left dorsolateral prefrontal cortex (DLPFC), left ventrolateral prefrontal cortex (VLPFC) and the right cerebellum displayed load by distraction interactions consistent with a role in load-related buffering effects. The VLPFC and cerebellar regions each displayed evidence of context-specific negative connectivity with DMN structures (medial prefrontal cortex and the posterior cingulate / precuneus, respectively). In contrast, there was no evidence for context-specific connectivity with regions that mediate basic sensory and affective information processing.
Results suggest that suppression of DMN-mediated processing is a plausible mechanism though which regions that support cognitive control prevent distraction under high, but not low, working

memory load. Furthermore, they are consistent with developing theories of the role of the cerebellum in cognition which highlight this region's role in coordinating cognitive processes to optimally suit task demands.

Title: Imaging the future: The core episodic simulation network dissociates as a function of timecourse and integration demands

Authors: *P. P. THAKRAL[1], R. G. BENOIT[2], D. L. SCHACTER[1];
[1]Psychology, Harvard Univ., Cambridge, MA; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Episodic simulation - the construction of a mental representation of a possible future event - is an adaptive function that has been consistently associated with enhanced neural activity in a set of neural regions referred to as the core network. This network includes the medial parietal and prefrontal cortex, medial temporal lobe, including the hippocampus, and lateral temporal and parietal cortex. Much work remains to be done to elucidate the contributions of individual regions within the core network to specific features of episodic simulation. In the current functional magnetic resonance imaging study, we investigated whether regions of the network could be dissociated as a function of the timecourse of their engagement during simulation (i.e., whether neural activity is transient or sustained), and also assessed whether regions of the network vary as a function of the integration demands of a simulated event (i.e., an event with fewer or more components). Participants imagined future events in response to place, person, and object cues. We manipulated the integration demands of the simulation task by varying the number of event components that participants were cued to include in their simulated event (3, 4, or 5). Cues were presented for 5 seconds followed by a variable delay fixation period for 8-12 seconds. Participants were instructed to continually simulate the event throughout the delay period. Transient neural activity was defined as activity specific to the cue period and sustained neural activity was defined as activity associated with the delay period. Relative to a

non-episodic control task, sustained simulation-related activity was identified in the majority of the core network. Additional analyses revealed that activity in the medial parietal and dorsolateral prefrontal cortex was further modulated as a function of integration demands (i.e., 5 > 3). Of particular interest, while the hippocampus was insensitive to integration demands, we observed a temporal dissociation within the hippocampus. Specifically, transient activity was identified in the anterior hippocampus and sustained activity was identified in more posterior hippocampal regions. Consistent with prior theories of hippocampal function, the anterior hippocampal activity may reflect the initial retrieval of gist-based information associated with a simulated event and the posterior activity may reflect further detailed processing of the simulated event. The present findings thus indicate that regions within the core episodic simulation network dissociate as a function of timecourse as well as the integration demands of a simulated event.

Title: Brief electrical stimulation to the human amygdala enhances recognition memory for neutral images

Authors: *C. S. INMAN[1], J. R. MANNS[2], K. R. BIJANKI[1], D. I. BASS[1], R. E. GROSS[1], S. HAMANN[2], J. T. WILLIE[1];

Abstract: Emotional events are often better remembered than neutral events, and this benefit depends on the amygdala. We have previously demonstrated that brief basolateral amygdala electrical stimulation enhances memory in rodents. This study examined whether human amygdala stimulation immediately following the presentation of neutral object photographs enhanced later recognition memory. We recruited 13 epilepsy patients undergoing intracranial EEG (iEEG) with depth electrode contacts placed in basolateral amygdala and subregions of the hippocampus. During continuous iEEG, each participant was presented a series of photographs of neutral objects, half of which were followed immediately by a unilateral stimulation to the amygdala (8 trains of 50-Hz pulses for 1-second at 0.5 mA after image offset). No epileptiform activity was elicited by the stimulation. Participants reported no awareness of the stimulation. Recognition memory and subjective confidence for half the photographs was tested immediately after the study session and for the other half of the photographs the following day. On the

recognition memory test administered the following day, participants recognized neutral objects initially followed by amygdala stimulation more accurately than control objects. The result was similar when only high-confidence judgments were included. On the immediate recognition memory test, participants performed similarly for both object conditions. These results are similar to the previous results from rodents. The extent of the one-day memory enhancement was inversely correlated with neurocognitive deficits as measured by IQ. Specifically, patients with lower IQ generally showed greater memory enhancement specifically on the one-day test (interaction in stimulation condition by test delay controlling for full-scale IQ). We are also currently investigating the effects of amygdala stimulation on network oscillatory activity, autonomic physiology, and emotional processing. The current results indicate that brief electrical stimulation to the human amygdala can enhance item-specific memory for neutral stimuli even in the absence of awareness of the stimulation, reflecting a key role of the amygdala in prioritizing experiences for long-term storage in declarative memory. Amygdala stimulation likely engages amygdala-hippocampus connections that normally serve to prioritize memory for emotional events and may provide a therapeutic route for patients with memory deficits.

Title: Is encoding into visual working memory a parallel process? Evidence from statistical modelling and EEG decoding.

Authors: *E. S. DALMAIJER[1], M. STOKES[1], M. HUSAIN[2];
[1]Exptl. Psychology, [2]Nuffield Dept. of Clin. Neurosci., Univ. of Oxford, Oxford, United Kingdom

Abstract: *Background*
Visual Working Memory (VWM) is a highly limited resource that we use to temporarily store information on items that we encounter. How different items are encoded into VWM remains unclear. Some think individuals can encode multiple items in parallel. An alternative idea is that encoding is serial, with only one item being processed at a time. This notion is fundamental to

the binding problem, and several contemporary models of VWM. However, despite a large body of work, there is little consensus in the existing literature.
Methods
We used a whole report task in which participants were asked to remember a single or two Gabor patches simultaneously. Stimuli were shown for various durations (ranging from 0 to 580ms), and were masked directly after. Participants sequentially indicated the colours they remembered on two continuous colour wheels. On a version of the task with a single exposure duration of 200ms, we recorded electroencephalography (EEG) data that we later subjected to a classification algorithm.
Results
If two items were presented, the first response's accuracy matches that of a single item trial, and the second response is significantly worse. We modelled the distributions of errors as a function of exposure duration, to estimate the probabilities of participants remembering none, only one, or both of the Gabor orientations. This demonstrated that the probability of remembering no item reduces with exposure duration, whereas the probability of remembering both items increased. Crucially, the probability of remembering only one item could be completely predicted by the probability of remembering both. This is in line with a parallel encoding framework.
Discussion
The resolution of an item's representation in VWM increases with encoding duration. Importantly, we demonstrate that this is a parallel process: Multiple items can be encoded at the same time, although not necessarily at the same rate.

Title: Retrieval as a fast route for consolidation: evidence from decontextualization and semanticization of memory representations

Authors: ***A. C. SANCHES FERREIRA**, M. WIMBER;
Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Retrieval can act as a powerful memory enhancer. While this observation has been well established in the cognitive literature, the neurocognitive mechanisms underlying such enhancement are still unknown. We here tested the possibility that retrieval solidifies memories through online reactivation mechanisms similar to those involved in offline memory consolidation (e.g. during sleep). If retrieval does indeed depend on neural memory reactivation, one would expect that new episodic memories, initially rich in contextual detail, will become gradually decontextualized as they undergo repeated retrieval, and will transform into gist-like semantic representations. To test these *decontextualization* and *semanticization* hypotheses, we conducted a pattern fMRI study. Participants encoded scene-object pairs, with objects belonging to a number of different semantic categories. They then either retrieved or restudied the objects over two sessions, 48 hours apart. Using representational similarity analysis (RSA), we traced the dynamic changes in item-specific and categorical activation patterns representing each memory in higher order visual areas. Results show that contextual information encoded at study (such as background colour) becomes lost across retrieval repetitions to a greater extent than across restudy ones. Moreover, retrieved (as opposed to restudied) objects become, neurally, less individualised, and more semanticized. Taken together, these findings support the hypothesis that retrieval can act as a fast route to memory consolidation.

Title: Effects of learning time on brain activation and connectivity during recent and remote associative memory retrieval

Authors: *D. GUO[1], L. ZHAN[1], G. CHEN[2], J. YANG[1];
[1]Dept. of Psychology,Peking Univ., Beijing City, China; [2]Scientific and Statistical Computing Core, Natl. Inst. of Mental Hlth. (NIMH)/National Inst. of Hlth. (NIH)/Department of Hlth. and Human Services (DHHS), Bethesda, MD

Abstract: When stimuli are learned by repetition, they are remembered better and retained for a longer time. However, it is unclear what neural mechanisms underlie the learning effect over time. To address this issue, we explored whether the hippocampus (HPC) and other brain regions

were differentially involved in associative memory after face-scene pairs were learned once or six times. The associative memory was tested at four time intervals, i.e., 20-min, 1-day, 1-week, and 1-month, when participants performed an associative recognition task to judge whether the word pairs were old. The results showed that compared to learning once, learning six times significantly increased the activation in the HPC and posterior cortical regions, and decreased the activation in the orbitofrontal cortex (OFC). In addition, the physiophysiological interaction (PPI) analysis showed that there was stronger correlation between the HPC and parahippocampal place area (PPA) after repetitive learning (vs. learning once), and stronger correlation between the HPC and OFC after learning once (vs. learning six times). In regard to the time change over time, learning once induced the HPC activation decreased and PRC activation increased over time; and learning six times induced the activation of HPC, parahippocampal cortex (PHC) and PPA increased over time. These results suggested that learning experience enhance the involvement of the HPC and posterior regions in associative memory, and there are two different mechanisms for consolidating and retrieving associative memory according to the learning experience.

Title: Mapping cortical representations of semantic similarity using Wikipedia and Google News

Authors: ***E. L. ZIPPI**, N. W. MORTON, M. L. MACK, A. R. PRESTON;
The Univ. of Texas, Austin, TX

Abstract: Cognition acts on a rich semantic structure that extends beyond visual features, such that concepts are represented in terms of both meaning and perceptual characteristics. While numerous studies have shown that regions within the visual system organize categories according to their perceptual properties, less is known about whether meaning-based representations are present within the same regions. Here, we employ models of semantic similarity derived from Wikipedia and Google News to interrogate whether multivariate patterns in visual regions could be explained by the semantic similarity among stimuli. Participants viewed images of famous people and places during fMRI scanning to estimate neural responses

to each stimulus. Semantic models generated predictions for the relative similarity of each pair of stimuli within visual subcategories (i.e., male and female for faces; manmade and natural for scenes). Two different models were constructed to quantify semantic relationships. The first model estimated semantic similarity based on word co-occurrence in a text-corpus constructed from Wikipedia articles corresponding to each stimulus. Natural language processing tools and dimensionality reduction techniques produced vector representations for each of the articles, from which the cosine between each pair was used to estimate semantic similarity. The second model used representational vectors for each stimulus built from a Google News text-corpus and a continuous bag-of-words algorithm from Google's publically available word2vec. We compared the predictions made by the two models to neural similarity matrices that quantified the pairwise correlation between activation patterns for each stimulus. To separate effects of low-level visual similarity on neural response from those related to semantic structure, we contrasted the correlation between neural response and semantic models with that of the visual models. We found a significant correlation between neural measures of representational similarity within lateral occipital and fusiform cortex and the model-based semantic similarity predictions. In contrast, early visual cortex, lateral occipital, and parahippocampal representations were correlated with predictions from a low-level visual model. In particular, inferior temporal cortex was significantly more correlated with the semantic models than the visual model, suggesting it may play a larger role in semantic representation than visual representation. These findings demonstrate that the rich semantic structure found in web-based text corpora can be leveraged to reveal the neural codes of semantic meaning.

Title: Bistable entropy networks predict human memory formation

Authors: *R. HAQUE[1], A. VAZ[2], R. YAFFE[3], K. ZAGHLOUL[1];
[1]Natl. Inst. of Hlth., Bethesda, MD; [2]Duke Univ., Durham, NC; [3]Johns Hopkins, Baltimore, MD

Abstract: Oscillatory activity in the human cortex has been widely implicated in memory and learning, particularly in the theta and gamma bands. Recent evidence has suggested that much of what is assumed to be oscillatory change may be stochastic volatility or arrhythmic activity. In this study, we recorded intracranial EEG from 33 patients undergoing a paired associates

memory task. For successfully remembered items, we found significant decreases in entropy and significant increases in the range and variance in the right hemisphere. Alternatively, we observed significant increases in sample entropy and significant decreases in range and variance in the left hemisphere. These time-domain metrics also demonstrated better discrimination of the LFP signal than frequency based metrics during successful memory. Given these results, we suggest the exploration of metrics that directly describe LFP distortions rather than those that abstract into the frequency domain.

Title: Representations of spatial priority during nonspatial working memory

Authors: M. RAHMATI[1], M. J. PAYTON[1,2], T. C. SPRAGUE[1], C. E. CURTIS[1], *K. K. SREENIVASAN[2];
[1]Dept. of Psychology, New York Univ., New York, NY; [2]New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates

Abstract: It has been established that a several cortical areas encode spatial priority - a weighted representation of space that combines information about stimulus salience and task-relevance signals. An intriguing hypothesis is that these signals, although spatial in nature, may provide the means by which non-spatial feature information can be maintained in working memory (WM). The present study sought to dissociate spatial priority from feature information held in WM to investigate how spatial priority representations may contribute to feature WM. Observers saw 4 sample Gabor gratings - one in each quadrant - and were cued to maintain the orientation of one of these gratings in WM. After a delay, a second cue indicated the quadrant in which the test grating would appear. After a second delay, the test grating appeared, and observers indicated whether the grating matched the orientation of the original sample grating. Critically, during the second delay, retrospective priority for the spatial location of the sample grating and prospective priority for the spatial location of the test grating are dissociated.
Individual observers' population receptive fields (pRFs) were estimated using fMRI in an independent scan. pRF maps were then used to reconstruct estimates of spatial priority during the

second delay period. In visual area V2, reconstructions demonstrated a persistent representation for the original (i.e., currently irrelevant) sample location. This finding suggests that feature WM involves retrospective representations of the spatial location at which the feature was initially encoded. In contrast, reconstructions from parietal region IPS0 demonstrated a representation of the upcoming probe location. Together, these results demonstrate an interrelationship between spatial priority and feature WM, and indicate that multiple representations of spatial priority may be required for the independent maintenance of features and spatial priority.

Title: Different paths to the same destination: information-integration category learning with and without feedback

Authors: *Y.-W. WANG, V. V. VALENTIN, F. G. ASHBY;
Psychological & Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Information-integration (II) categorization is believed to be a procedural skill. Evidence suggests that II learning is mediated by the basal ganglia, and is best acquired via immediate feedback. Since humans have multiple learning systems, an important question is whether II learning is also possible by other brain systems. Thus, the present study investigates whether II learning is possible in the absence of feedback. Although several previous studies reported that II observational learning (OL) was impaired relative to feedback learning (FL), these conclusions were drawn by comparing average scores in the OL and FL conditions, which obscures individual differences. We studied these issues more closely using a new OL paradigm, which was similar to a series of A/not A tasks. Previous research showed that Parkinson's disease patients seem to learn A/not A categorization normally, thus it might provide a way of learning without mediation of basal ganglia, although none of the A/not A studies had used II categories to our knowledge. Specifically, in our OL condition, participants were asked to memorize figures from one of two categories in each block, and to categorize figures without receiving any feedback at the end of each block; in our FL condition, figures from both categories were shown

in a randomly mixed order, and participants were asked to categorize the figures and would receive correct or incorrect feedback on each response. We compared the ratio of successful learners and unsuccessful learners, as well as learning curves of successful learners in both conditions, and found two major results: 1. Learning curves of successful learners in OL and FL did not show significant differences; 2. fewer participants successfully acquired optimal strategies in OL than in FL. Our findings suggest that II learning might be possible in some participants without mediation of the basal ganglia. Instead, we propose that for these successful participants, the cortical-striatal-cortical circuits that mediate feedback-based II learning are replaced by direct cortical-cortical circuits that bypass the basal ganglia.

Title: Long-term sequence training alters movement representations in primary motor cortex

Authors: *P. BEUKEMA[1,2], T. VERSTYNEN[3,2];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Efficient production of a sequence requires binding temporally independent movements into single, unified action chunks. This process should be reflected by increases in the similarity of each movement's response times (i.e, increased correlation in temporally adjacent response speeds) as well as a shift in the neural representations of each action. We trained human subjects (Sequence Group, N=9, 6 male) to perform a 32-item sequence of finger movements across 25 training sessions (5 weeks). The sequence was constructed such that some finger combinations exhibited higher frequency pairings (e.g. index followed by ring) than others. A second group (Control Group; N=9, 6 male) underwent the same 25 training sessions but instead performed pseudorandomly ordered movements on each day without exposure to the sequence. A hierarchical agglomerative clustering algorithm applied to reaction times of each

element in the 32-element sequence revealed a well ordered clustering structure of the trained movements in the Sequence group, with distances between successive elements in the dendrogram being decreased following training. As expected, the Control group exhibited no significant distance changes in their clustering structure during the same trial blocks. The binding of sequence elements observed in the behavioral data should also be reflected as concomitant changes in the movement representations in primary sensorimotor areas. To assess this, the cortical representations of each effector were mapped before and after training using fMRI (Siemens Verio 3T scanner,32 channel head coil, TR: 2000ms, TE: 30.0ms, MBAF, 3, 66 slices). During each scan, subjects performed each of the four finger movements separately to facilitate isolation of the motor representations controlling each finger using representational similarity analysis (Kriegeskorte et. al., 2008). In the Sequence group, a non-parametric permutation test searchlight revealed regions along the anterior central sulcus with significant decreases in representational distances following training that were qualitatively different in both magnitude and location compared to the Control group. These results suggest that movement representations reorganize with training to facilitate binding of independent actions into unified chunks.

Title: Neural substrates of risky spatial decisions under conditions of perceptual uncertainty

Authors: *K. JARBO, T. D. VERSTYNEN;
Psychology, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: To maximize expected gain and avoid losses on visually guided spatial decisions (Trommershäuser, Maloney, & Landy, 2008) a global network of cortical and subcortical brain regions integrates spatial uncertainty (Gottlieb & Balan, 2010) with costs and expected reward (Hsu, Bhatt, Adolphs, Tranel & Camerer, 2005) to bias selections of a target away from a penalizing distractor. Using a visually guided spatial decision-making task, we examined how

sensory uncertainty (low vs. high target variance) and cost (no penalty vs. penalty) interact when making spatial decisions. Across three consecutive sessions (two behavioral, one MRI), participants (N=20) used a mouse to maximize their point total across several hundred trials by attempting to select the center of a spatially presented target. A distractor was presented adjacent to the target and, on some trials (penalty trials) points were lost based on the proximity of the selection to the center of the distractor. Behaviorally, participants avoided the distractor both when losses were incurred and when target estimation was less certain. While selection endpoints were also more variable under high target variance, a significant interaction between variance and penalty biased selections away from the distractor more strongly than either main effect. Functionally, we identified task-related activity in a broad network of interconnected cortical and subcortical regions that correlated with variability in selection bias. Distributed clusters of significant activity (all $t(19)s > 4$, FDR-corrected $q = 0.01$) were present in orbitofrontal, dorsolateral prefrontal, and posterior parietal cortex as well as distinct dorsomedial regions within the caudate and putamen, bilaterally. These cortical regions match a previously identified structural network thought to support the integration of reward and spatial attention during decision-making (Jarbo & Verstynen, 2015). Together, these results identify a plausible neural substrate that allows for integrating estimations of risk with perceptual uncertainty during spatial decisions.

Title: A biologically-constrained hybridization of reinforcement learning and accumulator models for adaptive decision-making

Authors: *K. E. DUNOVAN[1,2], T. VERSTYNEN[3,4];
[1]Psychology, [2]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA;
[3]Psychology Dept., [4]Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Cognitive process models, such as reinforcement learning (RL) and accumulator models of decision-making, have proven to be highly insightful tools for studying adaptive

behaviors as well as their underlying neural substrates. Currently, however, two major barriers exist preventing these models from being applied in more complex settings: 1) the assumptions of most accumulator models break down for decisions involving more than two alternatives; 2) RL and accumulator models currently exist as separate frameworks, with no clear mapping between trial-to-trial learning and the dynamics of the decision process. Recently we showed how a modified accumulator model, premised off of the architecture of cortico-basal ganglia pathways, both predicts human decisions in uncertain situations and evoked activity in cortical and subcortical control circuits (Dunovan et al. 2015). Here, we present a synthesis of RL and accumulator models motivated by recent evidence that the basal ganglia acts as a site for integrating trial-wise feedback from midbrain dopaminergic neurons with accumulating evidence from sensory and associative cortices. We show how this hybrid model can explain adaptive, multi-alternative (2- & 4-choice) decisions in a computationally efficient manner. More importantly, by parameterizing the model to conform to various underlying assumptions about the architecture and physiology of basal ganglia pathways, model predictions can be rigorously tested against observed patterns in behavior as well as neural recordings. The result is a biologically-constrained and behaviorally tractable description of trial-to-trial learning effects on decision-making among multiple alternatives.

Title: Sensory uncertainty influences value-based risky decisions

Authors: *R. M. FLEMMING[1], K. JARBO[2], T. D. VERSTYNEN[2];
[1]Neuroscience, Psychology, Univ. of Pittsburgh, Pittsburgh, PA; [2]Psychology, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Many value-based decisions, such as gambling on a risky choice with a potentially high reward, are contingent on sensory signals and feedback from past choices; however, it remains unclear how sensory evidence may impact these types of risky decisions. Using a spatial decision-making task, we manipulated sensory uncertainty (i.e., spatial variance), value

magnitudes, and probability of punishments, we examined how the reliability of a stimulus biases feedback-based risky decisions. Two target stimuli were simultaneously presented (300ms duration) as two Gaussian distributions of dots with means separated by 100 to 200 pixels and spatial variances that could be increased to manipulate sensory uncertainty. In 800 trials, subjects (N = 20) used a mouse to select the center of either a Risky Target that had a specified probability of large reward or could incur a comparable penalty, and a Stable Target, which yielded consistent smaller rewards, but varied in spatial uncertainty across trials. Feedback was based on the selection endpoint distance from the center of the chosen target. Given the choice between the two targets, subjects began to choose the Risky Target more frequently ($F(3,57) = 43.8366$, $p < 0.001$) when the reward to penalty ratio was greater than 2:1. Subjects also chose the Risky Target more frequently when the spatial uncertainty of the Safe Target was high ($F(3,57) = 24.9440$, $p < 0.001$), resulting in a significant interaction ($F(9,171) = 4.6506$, $p < 0.001$) between feedback signals and spatial uncertainty on risky decisions. Our results show that risky choices become more viable as the perceptual uncertainty of the "safe" choice is increased relative to a risky alternative.

Title: Rapid learning of the value of choices from delayed feedback during navigation in humans: computational and neural mechanisms

Authors: ***G. WIMMER**[1,2], S. SCHÖNIG[2], L. AUSTERMANN[2], L. MEISSNER[2], M. HEBART[3,2], C. BÜCHEL[2];

Abstract: Rewards exert a strong influence on learning and decision making. While dopaminergic and striatal mechanisms can only support reinforcement learning when feedback occurs within several seconds of predictive events, many salient events in life are preceded by sequences of events and actions that occur over significantly longer timescales. To account for learning from these common situations where feedback is delayed, alternative computational models and neural mechanisms are necessary. In the current experiments, we tested whether candidate models, including eligibility traces, forward planning, and post-feedback replay can account for behavioral performance and neural activity during learning. In our experiments, participants navigated temporally extended sequences of three unique rooms (states), leading to a reward or loss up to 50 seconds later. Each sequence was followed by a 15 sec rest period. In order to examine early learning, the task included 8 intermixed sequences that were only repeated 4 times. Behaviorally, participants exhibited acquisition of optimal choices after only one or two experiences. Further, in a separate experiment, for a subset of sequences only experienced once, participants were reliably able to identify whether a start state led to a reward or loss. These results demonstrate rapid learning across long delays that cannot be accounted for by traditional striatal learning mechanisms. In our fMRI study, we utilized specific visual categories of stimuli in each state of navigation (faces, scenes, objects, and motion). This allowed us to use multivariate classification and representational similarity analyses (RSA) to test for predictive effects related to forward planning as well as maintenance-related effects related to eligibility and replay during rest breaks. Our behavioral and neural results provide insight into how the brain can rapidly learn from and use delayed reward feedback in later decision making.

Title: Visual salience effects on reinforcement learning

Authors: ***J. SCHOMAKER**[1], W. EINHÄUSER[2], B. C. WITTMANN[1];
[1]Biol. Psychology, Justus-Liebig Univ., Gießen, Germany; [2]Inst. of Physics, Chemnitz Univ. of Technol., Chemnitz, Germany

Abstract: Highly salient visual stimuli can draw attention as evidenced by gaze behavior. It has been suggested that reward learning is enhanced for these stimuli, but the underlying mechanisms are yet unclear. Pupil responses, which are linked to locus coeruleus activity, have been proposed to reflect surprise, thereby providing an index of learning. In the current eye-tracking study, we investigated the role of visual salience in a probabilistic reinforcement learning task. On each trial, participants chose from a circular array with three neutral everyday objects and received feedback on the reward outcome. Visual contrast (low/high) and monetary reward probability (low/high) varied between objects. Visual salience influenced attentional allocation: While high-reward stimuli were fixated earlier and with higher probability than low-reward stimuli, this effect was enhanced when salient stimuli were rewarded and attenuated when salient stimuli served as low-reward distractors. Learning, in contrast, was improved when salient stimuli were rewarding but not impaired by salient distractors. Participants were more likely to choose a salient than an equally rewarding non-salient object, both for low and high reward probabilities. The pupil response to reward feedback was decreased on trials when a salient stimulus compared to a non-salient stimulus was rewarded, suggesting that visual salience strengthened participants' expectations regarding reward outcomes. Taken together, our findings suggest that reinforcement learning is biased by attentional mechanisms.

Title: The sensitivity of Reward Positivity to prediction errors at 2 levels of hierarchy

Authors: *D. SHAHNAZIAN, C. B. HOLROYD;
Psychology, Univ. of Victoria, Victoria, BC, Canada

Abstract: Principles of hierarchical reinforcement learning (Botvinick, Niv, Barto, 2009) implicate learning at different levels of hierarchy from different sources of information. To learn at different levels of hierarchy, an agent has to calculate prediction errors associated with each level of hierarchy. With electroencephalogram, prediction errors correlate with a frontocentral event-related potential occurring 240-340 ms post-feedback, termed reward positivity. This component is posited to originate in the anterior cingulate cortex. The hierarchical reinforcement

learning theory of anterior cingulate cortex (Holroyd & Yeung, 2012) raises the possibility that this brain region is sensitive to reward prediction errors at multiple levels of hierarchy. To investigate whether the reward positivity is sensitive to prediction error at two levels of hierarchy, we recorded electroencephalogram (EEG) from human participants engaged in two-level hierarchical gambling task modified from Diuk et al. (2013). In this task, performance is improved if learning happens at both levels of the hierarchy. We found that the reward positivity is sensitive to reward information at both levels of hierarchy. This finding is consistent with an involvement of the anterior cingulate cortex in hierarchical reinforcement learning.

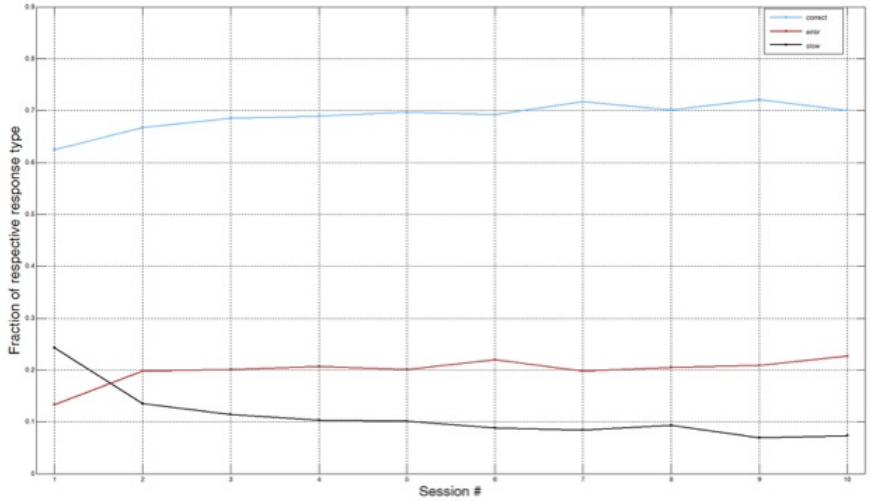
Title: The success of learning from errors: the role of high-gamma EEG and peripheral physiological responses

Authors: *S. S. BERBERICH[1], M. VOELKER[1], L. FIEDERER[1], E. ANDREEV[1], S. CONTZEN[1], A. SCHULZE-BONHAGE[2], W. BURGARD[3], T. BALL[1];
[1]iEEG and Brain Imaging Group, [2]Epilepsy Ctr., Univ. Med. Center, Freiburg, Freiburg, Germany; [3]Dept. of Computer Sci., Albert Ludwigs University, Freiburg, Freiburg, Germany

Abstract: How humans learn from errors is a matter of great interest in neuroscience, yet many aspects of the underlying brain mechanisms and the role of peripheral physiological processes in error-based learning still remain unclear.
Here, we investigated error-related learning in 30 healthy subjects during a classical Eriksen flanker task. Subjects had to use either the left or right hand to respond to the visual stimuli and were instructed to avoid errors in the form of "slow" trials exceeding a pre-defined time limit. EEG data were acquired with a 128-channel system optimized for detection of high-frequency EEG components. To ensure an optimal signal-to-noise ratio, recordings took place in an electromagnetically shielded cabin and with full optical decoupling of all devices. We acquired peripheral physiological data using a high resolution binocular eye tracker and a two-channel

ECG and computed the individual heart rate variability as a parameter previously implicated in learning processes.
Consistent with the instruction stressing the importance of speed over accuracy, the number of slow trials decreased during the experiment (Fig. 1A). Further, we could show a significant post-error heart-rate deceleration, while pupil size was significantly bigger following error trials compared to correct ones. Both parameters showed an opposite yet similar temporal profile (Fig. 1B). In the EEG data, we found high-gamma band (HGB) spectral power increases in the frequency range up to 120 Hz approx. 100 ms post-error and over the frontal midline region. Across subjects, the amplitude of the individual frontal-midline HGB response was significantly correlated with the individual learning performance, as well as the heart rate variability and error-related pupil size response.
Our findings reveal a novel response pattern consisting of central (frontal midline HGB) and peripheral (pupil size, heart-rate variability) components predictive of the individual success in learning from errors and thus open up a new window on the mechanisms contributing to learning via the error-monitoring network.

A) Average fraction of response types



B) Relative pupil size and heart rate during the averaged course of a trial

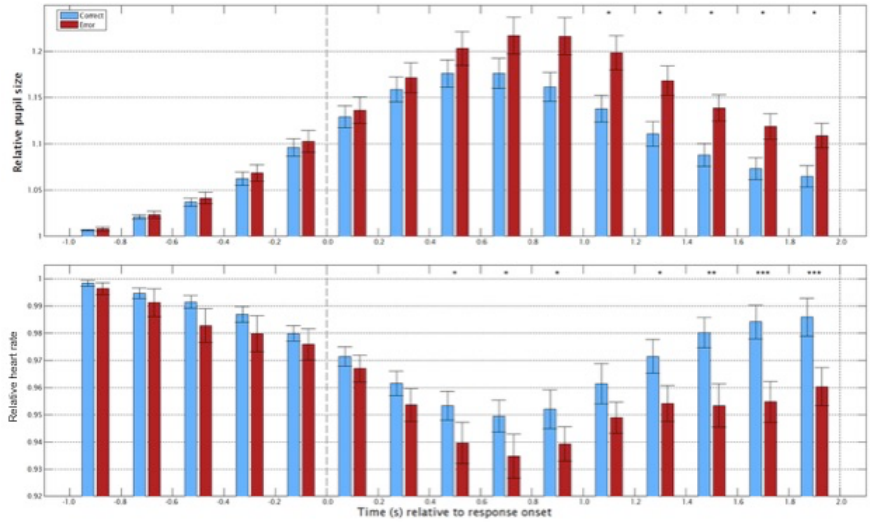


Fig. 1:

A) Average fraction of response types per session for all 30 subjects. Correct trials are indicated by the blue line. The red line shows error trials due to choice of the incorrect hand, while error trials due to exceedance of the time limit are marked by the black line.

B) Relative pupil size and heart rate during the averaged course of error (red) and correct (blue) trials for all 30 subjects. Trial cutting was locked to response onset. Significant differences are marked with an asterisk. Response onset is marked by the left dotted vertical line. The right dotted vertical line indicates feedback onset.

Med. Ctr. Freiburg, Freiburg, Germany

Abstract: The nature of human error processing and the underlying cerebral mechanisms are of great interest in neuroscience, and error-related brain responses may provide information useful to improve the accuracy of brain-machine interfaces (BMIs). So far, many studies focused on error-related responses below 30 Hz. We were interested in error-related effects in the high-gamma band (HGB, 50-150 Hz), as this frequency range is thought to reflect local cortical information processing more directly than lower frequencies.
30 healthy subjects performed a flanker task as classically used to study error processing (Gehring et. al, 1993). Under time pressure, the subjects had to use the left or right index finger to respond to the respective flanker. Recordings of 128-channel EEG were acquired within an optimized setting for non-invasive EEG high-gamma mapping in an electromagnetically shielded cabin with full optical decoupling of all devices and high-resolution binocular eye tracking. Additionally, 3 patients with pharmacoresistant epilepsy and implanted stereo-EEG (SEEG) electrodes performed the identical task.
As our main result, we show for the first time error-related HGB spectral power modulations up to 120 Hz in non-invasive EEG (Fig. 1A), which could also be used for decoding on a single-trial basis. Additional SEEG data (Fig. 1B) revealed possible sources of these effects, including the premotor cortex. Additional responses were seen in areas not reflected in the non-invasive EEG, such as hippocampus and insula. Importantly, based on the eye-tracking data, we show that the error-related effects in the gamma range cannot be explained by differences in eye movements

including micro-saccades, which had a different spatial distribution compared to the error-related effects.

Our findings open a new window for investigation of the complex neuronal processes related to error perception and ensuing behavioral adaptation. Furthermore, the decodability of error-related HGB responses indicates that these novel error-related brain signals may also be useful for BMI applications.

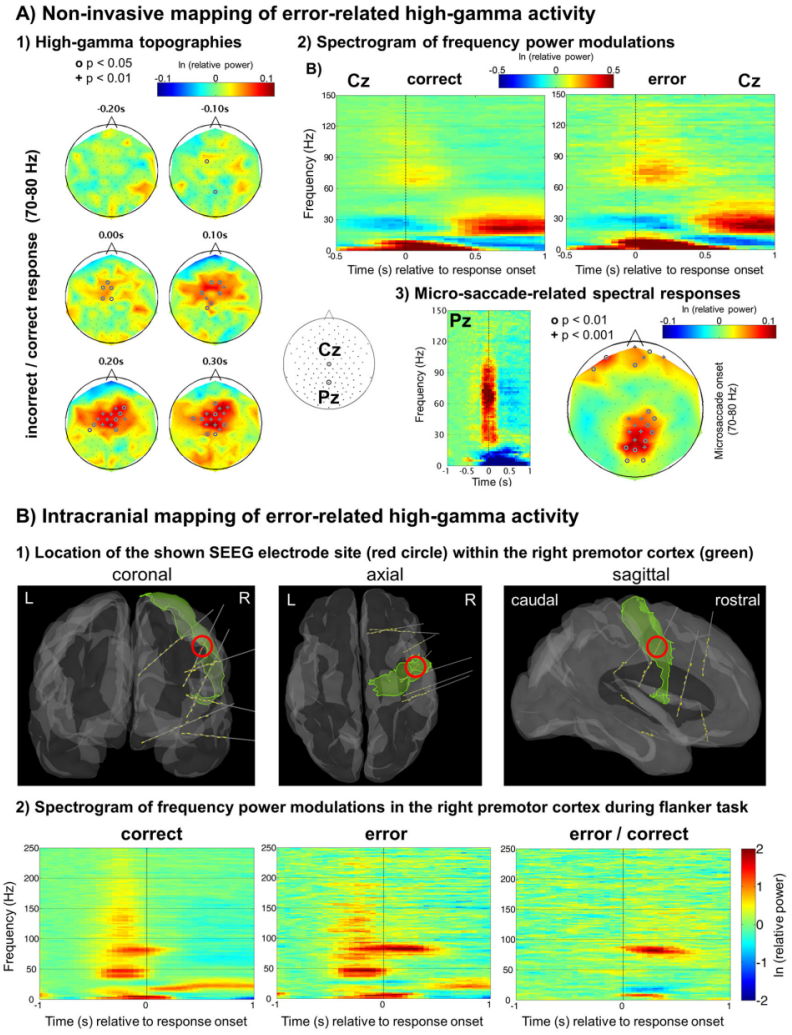

Fig. 1 : Mapping of error-related high-gamma activity in non-invasive and intracranial EEG
A) Topography (1) and spectrogram (2) of error-related high-gamma activity measured with non-invasive EEG in 30 healthy subjects. The high-gamma power increase was significantly stronger in false responses with a spatial focus on fronto-central sites. In comparison, saccade-related spectral responses (3) are distributed frontopolar and centro-parietal.
B) Error-related high-gamma responses in stereo EEG (bipolar re-referencing). The electrode location was close to cortex surface of the right premotor cortex (1). Spectrograms (2) show a broadband gamma power increase prior to movement onset in both correct and false responses, followed by a pronounced high-gamma peak between 70-90 Hz only in incorrect responses.

Title: Humans cache multi-step stimulus expectancies in reinforcement learning

Authors: *E. RUSSEK[1], I. MOMENNEJAD[2], M. M. BOTVINICK[3], N. D. DAW[2], S. J. GERSHMAN[4];
[1]CNS, NYU, New York, NY; [2]Princeton Univ., Princeton, NJ; [3]Google DeepMind, London, United Kingdom; [4]Harvard Univ., Cambridge, MA

Abstract: Contemporary theories of decision making suggest human choice evaluation reflects an influence of model-based (MB) and model-free (MF) strategies, associated with distinct neural systems. Whereas MB simulates the sequence of states that will follow a choice and sums their rewards, MF caches future reward estimates. In two studies we employed varieties of revaluation to test the hypothesis that humans also engage in a third strategy, the successor representation (SR). SR caches predictions of which states will follow a choice, aggregating over multiple steps, but can flexibly alter the rewards paired with those states. Each trial of Study 1 (N = 58) had two phases. In a training phase, subjects were exposed to two three-state sequences, rewarded at terminal states. In a revaluation phase, subjects were exposed to a switch in either the reward paired with each terminal state (reward revaluation) or the terminal state to which each middle state transitioned (transition revaluation). Before and after revaluation, subjects indicated their relative preference for visiting the initial state of either sequence. While subjects showed revaluation in all conditions, they were relatively better following reward compared to transition revaluations ($p<.005$). This asymmetry suggests an influence of SR in addition to MB and MF strategies. SR, unlike MF, can adapt rapidly to changes in reward structure by updating reward predictions. However, unlike MB, SR does not represent one-step transitions and cannot adapt rapidly when they are changed. Each block of Study 2 (N = 88) started with a training phase in which subjects made a choice to transition to a second-level state, then a second choice to transition to a rewarding terminal state. In a revaluation phase, subjects experienced reward and transition revaluations, and a novel revaluation in which learning about a terminal-state reward change caused a change in their second-level choice preference (policy revaluation). Caching prevents the SR from altering predicted future states to those implied by the new

second-level choice preference. Although subjects were able to alter stage 1 choices in all conditions, they were relatively better at reward revaluations compared to both transition ($p<.005$) and policy ($p<.02$) revaluations. These results suggest use of intermediate caching strategies, between MB and MF, that trade off flexibility with computational efficiency. Ongoing fMRI investigation of Study 1 seeks neural evidence of SR-prescribed caching. Using category-specific visual responses, we ask whether transition revaluation failures are accompanied by neural evidence of cached multi-step state predictions.

Title: Disentangling the contributions of episodic memory and incremental learning to value-based decisions

Authors: *K. D. DUNCAN[1], R. T. GERRATY[2], B. B. DOLL[2,4], N. D. DAW[5,4], D. SHOHAMY[2,3];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Dept. of Psychology, [3]Zuckerman Mind, Brain, Behavior Inst. and Kavli Ctr. for Neurosci, Columbia Univ., New York, NY; [4]Dept. of Psychology, [5]Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Learning from past choices and their outcomes guides adaptive decisions. Major advances have been made in understanding how such learning is accomplished over the course of repeated experiences with a fixed set of options, a process well described by reinforcement learning models. Many choices, however, are made between options with which we have sparse experience. Less is known about the cognitive and neural mechanisms by which single episodes are retrieved to support decisions and how this process interacts with incremental learning. We hypothesized that choices based on single past episodes are likely to depend on episodic memory mechanisms in the hippocampus, which are dissociable from striatal-dependent incremental value learning mechanisms. To test this hypothesis, we developed a task in which value-based decisions can be made using both episodically and incrementally learned values. On each trial, participants chose between two cards to win money. Participants could base choices on two

separate features: the color of the 'deck' (blue or red) or the picture of an object on the card (different for each card). The outcomes for each deck were probabilistic and varied slowly over time, allowing participants to incrementally learn which deck had a greater probability of reward. Separately, each object perfectly predicted the card's value, allowing participants to use their memory of a single previous trial to increase winnings. Critically, the value of the deck vs. the objects was not correlated (r=.07), allowing us to track the influence of each type of value on a trial-by-trial basis. This opens the door to the behavioral and neural characterization of each form of learning and their interaction. We found that participants' choices were best predicted by a model that included both incremental learning of deck-values, estimated using a Q-learning algorithm, as well as one-shot episodic memory for object values. Moreover, the strength of episodic memory learning was modulated by the uncertainty of deck values: participants were more likely to use object values from trials that occurred when the deck value was least certain. This effect was not driven by changes in reaction time during object value learning and deck uncertainty did not influence the use of object values, suggesting that uncertainty did not affect participants' attention to objects. These results demonstrate that both incrementally learned values and one-shot memory for distinct episodes guide value-based choices and that their relative contributions are modulated by uncertainty.

Title: Examination of the effectiveness of transcranial direct current stimulation (tDCS) to augment cognitive bias mitigation training

Authors: *A. MCKINLEY[1], T. L. CHELETTE[2], L. K. MCINTIRE[3], J. NELSON[3], C. GOODYEAR[3];
[1]Air Force Res. Lab., New Carlisle, OH; [2]Air Force Res. Lab., Wright-Patterson AFB, OH; [3]Infoscitex, Dayton, OH

Abstract: Cognitive bias problems are seen in many professions where analysis is an important component (e.g., intelligence, law enforcement, medicine, aviation, journalism, and scientific

research). When an intelligence problem invokes these cognitive biases, analysts may draw inferences or adopt beliefs that are logically unsound or not supported by evidence. Cognitive biases in analysis tend to increase with the level of uncertainty, lead to systematic errors, filter perceptions, shape assumptions and constrain alternatives. The Sirius Program produced computer games to train participants and measure their proficiency in recognizing and mitigating the cognitive biases that commonly affect all types of intelligence analysis. Recent research has demonstrated that transcranial direct current stimulation (tDCS) can accelerate learning and enhance declarative memory (e.g. McKinley, et al., 2013) and can affect the medial prefrontal cortex (mPFC) neural response to making a mistake (Reinhart & Woodman, 2014). A spike of negative voltage that originates from this area of the brain milliseconds after a person recognizes a mistake reinforces the brain to learn and retain information from errors. The hypothesis is that interaction with a video game with constant error feedback, along with tDCS stimulation could lead to significantly more effective training and measurably increased retention of the bias. A total of 21 male and female active duty Air Force volunteers participated in the experiment. All participants were given a test to assess their level of cognitive bias. Next, they played the cognitive bias training game while receiving real (n=10) or sham (n=11) tDCS at 2mA over mPFC. They then completed a post-training test to assess their cognitive bias. All participants returned 1 week later for a follow-up test. The results suggest that the sham tDCS group significantly reduced their level of cognitive bias after training and this effect remained 1 week later. However, the cognitive bias scores for the tDCS group did not significantly change. Because of the mPFC's involvement in learning from mistakes and retrieval of recent and remote memories, it was anticipated that stimulation of this region would enhance the cognitive bias training. However, the data suggest that tDCS interfered with the training and prevented participants from learning to mitigate their cognitive biases. Tronel and Sara (2003) showed that interfering with the mPFC following learning disrupted recall. Hence, it is possible that the tDCS paradigm applied herein augmented the natural activity of the mPFC in a way that impaired encoding or retrieval of the information presented.

Title: Hemodynamic response function for prediction errors in the ventral striatum

Authors: *G. B. HERMSDORFF[1], Y. NIV[2];
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Recent years have seen a proliferation of studies in which computational models are used to specify a set of hypotheses regarding learning and decision-making in humans, which are then tested against data from fMRI. Much of this model-based fMRI effort focuses on the nucleus accumbens or ventral striatum (VS), where the blood oxygenation level dependent (BOLD) response has been shown to reflect reward prediction-error signals putatively from dopaminergic afferents. To make sensible inferences about neural activation in this area from fMRI data, it is important to accurately model the hemodynamic response function (HRF) of the VS, i.e., the hemodynamic response evoked by a punctate neural event in the VS. A canonical HRF, mapped for sensory cortical regions, is commonly used for analyzing activity throughout the brain despite the fact that hemodynamics are known to vary across regions. Here we use data from an experiment focused on learning from prediction errors to fit a VS-specific HRF function. Our results show that the VS-specific HRF differs significantly from the canonical HRF, most importantly peaking at 6 sec after the event, rather than at 5 sec as in the canonical HRF. We demonstrate the superiority of the VS HRF in modeling prediction-error data by showing that using the new VS-HRF increases statistical power. This result is particularly relevant to fMRI studies in neuroeconomics and reinforcement learning as many of these rely on fine-grained analysis of VS BOLD activity to distinguish between important but subtle differences in computational models of learning and choice. We therefore recommend the use of this VS-specific HRF for future fMRI studies of the VS. More broadly, our study highlights the importance of the HRF model used in determining the significance of the results obtained in classical univariate fMRI analysis.

Title: Reward expectation in the human sub-thalamic nucleus

Authors: *J. R. FLYNN[1], H. Z. SHOUVAL[2], A. FENOY, Jr.[3];
[1]Neuroscience, Biology, and Anat., Univ. of Texas, Houston, Houston, TX; [2]The Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX; [3]Mem. Hermann Hosp., Houston, TX

Abstract: The ability to make predictions about the environment is critical for an organism's survival, and the reward system in mammals is critical to this ability. Various reward centers have been shown to project to the sub-thalamic nucleus (STN), and recent evidence in animal models suggests that the region is involved with reward expectation. Our experiments extend these results and specifically test for reward expectation in the human STN.
Parkinson's Disease patients (n=11) were asked to participate in our study during a deep brain stimulator (DBS) implantation procedure (see Fig 1A). During this procedure, recording microelectrodes were implanted within the ventral STN. Patients were presented with a visual stimulus of a green dot, followed one second later by either a reward (32 trials) or nothing (8 trials). The reward stimulus was sugar water administered orally via a syringe pump. For additional controls, a set of 20 trials was performed where patients were simply given sugar water at random with no visual stimulus. The reward/non-reward conditions were analyzed and compared using the recorded LFP data.
Our analysis has shown a heterogeneous response, which is unsurprising given the variability in recording location. 39% of the electrodes across 10 patients showed significant population activity that appears to encode for prediction error in the β and γ bands; i.e., the neural activity changed when the subject did not receive an expected reward at the appropriate time (See Fig 1B for example). Additionally, we see approximately 23% of electrodes across 6 patients show a significant response solely for when the reward was administered. These results are in line with the aforementioned animal studies, showing that STN activity is related to either reward stimuli and or the expectation of reward stimuli. Future studies will be done to link these results to the reward system as a whole using precise position data of the recording electrodes.

Title: General and specific modulation of reward identity representations in human OFC after satiety

Authors: *J. D. HOWARD, T. KAHNT;
Northwestern Univ., Chicago, IL

Abstract: A hallmark of goal-directed behavior is the ability to flexibly pursue specific goals in the context of general motivational changes. For instance, finding both food and shelter is important, but just because we find food does not mean we should abandon the search for shelter. The same applies to food choices, where in a sated state, cues related to non-sated food items often continue to facilitate consumptive behavior. The implication is that even when sated, the brain maintains specific representations of non-sated outcome expectancies. We have previously shown that human orbitofrontal cortex represents the identity of expected food odor rewards. However, the mechanisms by which these representations are updated after satiety to reflect changes in expected reward value are not known. Here we combined functional magnetic resonance imaging (fMRI) with appetizing food odor stimuli and a sensory-specific satiety paradigm to address this question. Human subjects (N=17) first learned to associate visual symbols with two distinct food odors. Subjects then performed a task in which they made choices among these symbols in order to receive low-intensity (i.e. low value) or high-intensity (i.e. high value) versions of the odors while undergoing fMRI. Scanning was conducted first while participants were hungry, and then immediately after they had eaten a meal corresponding to one of the odors to satiety. In the hungry state, subjects reliably chose symbols associated with the high-intensity version of both odors. After eating, although ratings of hunger and desire to eat were diminished, subjects continued to choose the high-intensity version of the non-sated odor, while choices related to the sated odor were shifted towards the low-intensity. Multivoxel pattern analysis of the fMRI data revealed that representations of both odor identities in medial orbitofrontal cortex (mOFC) were completely abolished by satiety, while in lateral orbitofrontal cortex (lOFC) representations of the non-sated odor persisted in the full state. Moreover, we observed uniform satiety-related changes in outcome value in the ventral striatum (VS) and the ventromedial prefrontal cortex. These findings were mirrored by general satiety-related changes in connectivity between mOFC and VS, while coupling between lOFC and VS remained significant after the meal only for the non-sated odor. Taken together, these results suggest that

VS integrates information related to general changes in motivational state via mOFC, and identity-specific changes in value via lOFC, providing evidence for a novel mechanism by which separable regions of the OFC exert differential control over feeding behavior.

Title: Reinforcement learning is not directly modulated by sensory prediction errors

Authors: *D. E. PARVIN[1], M. J. BOGGESS[1], S. D. MCDOUGLE[2], J. A. TAYLOR[2], R. B. IVRY[1];
[1]UC Berkeley, Berkeley, CA; [2]Princeton Univ., Princeton, NJ

Abstract: Spilling a cup of hot coffee, at best, represents a failure to obtain an anticipated reward, and in some instances painful punishment. Obviously, it is not the coffee's fault but rather a failure of movement execution. Although this credit assignment appears intuitive, current decision-making models lack a mechanistic account of this process.
Recently, we explored this problem by employing a reaching version of a two-armed bandit task in which the failure to obtain an expected reward could result from motor execution errors (McDougle et al 2016). In this version of the task, participants showed a diminished risk-averse bias compared to that observed in a standard keyboard pressing version of the task, in which failed outcomes are attributed to malfunction of the bandit and not execution errors. Furthermore, we found that individuals with cerebellar degeneration failed to modulate their behavior between the two conditions. These results were consistent with a reinforcement-learning model in which value updating was gated by cerebellar-dependent sensory prediction errors (SPEs). The SPEs served as a signal to attenuate changes in value that normally occur following (negative) reward prediction errors.
Here, we tested this hypothesis by manipulating SPEs, independent of other possible confounding variables. In the original study, participants received movement feedback in the form of a cursor presented at the endpoint position of the movement. Unbeknownst to the participant, the experimenter controlled the cursor position, introducing small perturbations to control outcomes on some trials. Thus, movement feedback was veridical on some trials whereas

fake on other trials. This type of feedback may have induced a sense of control over the outcome in participants and it also prevented us from observing aftereffects, a hallmark of adaptation. To control for this in the current study, execution errors were signalled by the appearance of a cursor at an invariant midpoint location between the two targets. While participants are aware that the cursor in these displays does not indicate their hand position, a cerebellar-dependent adaptation system has been shown to treat this signal as an SPE and continues to adapt movement. Despite clear signatures of this adaptation, there was no effect on participants' choice behavior compared to a condition in which the visual feedback was absent. In both conditions, we observed the traditional risk averse bias. These results suggest that SPE signals do not directly solve the credit assignment problem, rather they may serve as a signal for the sense of competence in one's ability to produce actions that will achieve desired outcomes.

Title: Delays and dopamine at different times during reinforcement learning in Parkinson's disease patients

Authors: *J. P. GROGAN[1], D. TSIVOS[2], B. E. KNIGHT[3,4], R. BOGACZ[5], A. WHONE[4], E. J. COULTHARD[1,4];

Sci., Univ. of Bristol, Bristol, United Kingdom; [2]Univ. of Stirling, Stirling, United Kingdom; [3]Univ. of West England, Bristol, United Kingdom; [4]North Bristol NHS Trust, Bristol, United Kingdom; [5]Nuffield Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Dopamine has been heavily implicated in reinforcement learning, however, recent work has begun looking at the role of dopamine in the expression of reinforcement learning, via consolidation, retrieval or exploration/exploitation mechanisms. We tested 18 Parkinson's disease (PD) patients and healthy age-matched participants (HPP) on a modified version of the Probabilistic Selection Task (PST), which tests to what extent participants learn from positive vs. negative feedback. In this task the participants were presented with pairs of cards and had to

learn which card to choose. One of the cards (A) was associated mainly with positive feedback, while another card (B) was associated predominantly with negative feedback. Thus the fraction of subsequent testing trials in which participants choose A and avoid B measures the tendency for learning from positive and negative feedback, respectively. Participants were tested with and without a 24 hour delay between learning and testing. Patients were ON or OFF their dopaminergic medication for learning, and in the 24 hours delay condition were also ON or OFF medication for the 24 hour test. We also tested PD patients on the canonical version of the PST. We looked at the different amounts of choose-A and avoid-B behaviour caused by the different medication states and delays. We found that after the 24 hour delay, PD patients and HPP showed a significant bias to avoid-B over choose-A, which was not affected by medication state at either time of learning, or time of testing. However, when patients were tested immediately after learning there was no such bias. This suggests that the information learned during reinforcement learning is not static, but is affected by delays between testing, and that this may affect the balance between positive and negative reinforcement learning. Computational reinforcement learning models with differential decays for the positively and negatively learned information were explored and fit to the data, and show that decay/consolidation mechanisms can account for the data.

Title: Striatum represents bayesian surprise, not reward prediction error, in rule learning.

Authors: *I. C. BALLARD[1], S. M. MCCLURE[2];
[1]Psychology, Stanford Univ., Stanford, CA; [2]Arizona State Univ., Tempe, AZ

Abstract: Objective: Humans naturally group the world into coherent categories defined by membership rules. While it is possible to learn these rules using stimulus-response associations, humans also have the ability to explicitly reason about rules. We sought to determine whether the

striatum, which reliably shows activation that scales with reward prediction error and is thought to be a part of the brain's reinforcement learning system, would also show prediction error responses in a task where people learn explicit rules.
Methods: We acquired functional magnetic resonance imaging data from subjects while they learned the category labels of stimuli with deterministic feedback. The stimuli had three dimension (shape, color, texture), and each dimension had two possible feature values. Subjects learned rules in blocks ranging from simple (e.g., blue stimuli are category 1) to complex (e.g., blue and square or checkered are category 1). We fit a series of reinforcement learning models that learns rules implicitly as well as a Bayesian rational rules model that reasons explicitly over rules.
Results: We exploit a difference in the learning signals between reinforcement learning models (reward prediction error) and Bayesian updating (surprise). Reward prediction error is a signed learning signal that is larger for positive than negative feedback. In contrast, surprise in our task was generally larger for negative feedback. In the neural data, we find greater BOLD signal responses to negative relative to positive feedback in both the striatum and ventral tegmental area. This pattern of responses is inconsistent with reward prediction error signaling. Further, we find that activation in the striatum scales parametrically with the Bayesian surprise signal. We propose that the striatum updates stimulus and action values, rather than representing learning signals per se. Although value updating and prediction error are perfectly correlated in reinforcement learning models, rule updating and surprise are not. We demonstrate that the striatum and caudal inferior frontal sulcus (cIFS) activation varies parametrically with rule updating and exhibits functional connectivity during feedback.
Conclusions: We conclude that the striatal feedback response does not represent prediction error as part of a reinforcement learning algorithm. Rather, its response scales with the relevant learning signal underlying learning because it is involved in updating a model of stimulus-response demands of the environment. We conclude that the striatum, in cooperation with the cIFS, is specifically involved in updating the values assigned to rules, rather than representation of error.

Title: Retrospective choice codes for causal learning

Authors: *E. D. BOORMAN[1], Z. KURTH-NELSON[3], L. RONDOT[3], M. GARVERT[3], R. J. DOLAN[3], T. E. BEHRENS[2];
[1]FMRIB Ctr., Univ. of Oxford, London, United Kingdom; [2]FMRIB Ctr., Univ. of Oxford, Oxford, United Kingdom; [3]Univ. Col. London, London, United Kingdom

Abstract: Introduction
Humans have a remarkable capacity to flexibly pursue their goals in changeable environments. Such adaptive behavior requires the appropriate attribution of particular outcomes to particular past choices based on knowledge of the environment's causal structure. Here, we couple computational modeling of learning with multivariate 'representational' analysis approaches to reveal how particular reward identities are associated with their antecedent causal choices.
Methods
We scanned 20 healthy subjects with functional MRI while they performed a decision task. In condition 1 subject choices were resolved after a brief delay. In condition 2, comprising separate blocks of trials, choices were not resolved until subjects had witnessed the outcome of their *previous* choice and made a *second* decision. This manipulation meant the relevant causal choice was the most recent choice in condition 1 and the previous choice in condition 2. Preprocessing and univariate FMRI analyses were carried out using SPM12 and multivariate analyses using a nonlinear support vector machine implemented in Libsvm and Matlab 2014a.
Results
Behavior: Multiple linear regression analysis revealed that in condition 1 subjects appropriately credited outcomes to the *most recent* choice, ($choice_{t-1}Xoutcome_{t-1}$: $t(19)=9.07$, $p<0.0001$) but not the previous choice ($choice_{t-2}Xoutcome_{t-1}$: $t(19)=1.13$, $p>0.1$). Conversely, in condition 2 subjects instead appropriately credited the *previous* choice ($choice_{t-2}Xoutcome_{t-1}$: $t(19)=3.177$, $p=0.0025$) but not consistently the most recent choice ($choice_{t-1}Xoutcome_{t-1}$: $t(19)=-1.60$, $p=0.06$). This indicates subjects flexibly assigned credit to the appropriate causal choice based on the task rules.
FMRI: We tested whether the relevant past choice's identity elicited a characteristic activity pattern across voxels when outcomes were later revealed. In condition 1 the *most recent* choice could be decoded at the time of outcome delivery in inferior occipitotemporal, perirhinal and lateral orbitofrontal cortex ($t(19)>3.6$, $p<0.001$ uncorrected). In condition 2 we found a similar network for the *previous* causal choice's identity, albeit at a reduced threshold ($t(19)>2.57$, $p<0.01$), but not for the most recent choice ($t(19)<1.2$, $p>0.1$), which could instead be decoded from dorsolateral prefrontal cortex ($t(19)>2.57$, $p<0.01$).
Conclusions
Our findings provide novel evidence that past stimulus choices are coded in inferior occipitotemporal and orbitofrontal cortex when outcomes are subsequently delivered. This suggests retrospective choice codes provide a mechanism by which the brain attributes outcomes to their likely causes.

Title: Updating impairments after right brain damage are due to inefficient exploration of hypothesis space.

Authors: *A. L. FILIPOWICZ[1], J. DANCKERT[1], E. KOECHLIN[2], P. DOMENECH[3], B. ANDERSON[1];
[1]Univ. of Waterloo, Waterloo, ON, Canada; [2]École Normale Supérieure, Paris, France; [3]Hôpital Henri Mondor, Créteil, France

Abstract: Recent research has demonstrated that patients with right brain damage (RBD) have difficulty updating their beliefs in response to environmental change. However, little is known about the functional basis of the impairment. The current study tests two potential explanations: a) RBD patients do not detect changes in their environment and therefore persist acting on old beliefs, or b) RBD patients detect changes, but fail to identify a new effective strategy due to an impaired ability to explore the hypothesis space. We administered an adaptive learning task to RBD and left brain damage patients (LBD). Participants had to learn rules about button-stimuli associations through trial and error. At unpredictable points throughout the task these rules changed (i.e., every 33-48 trials). On each trial, participants received noisy feedback (90% congruent) indicating whether or not they had pressed the correct button. We used a computational model of adaptive learning (the PROBE model) to partition the effect of change on exploratory behaviour. We found that RBD patients had more difficulty adapting to rule changes than LBD patients. These challenges, however, were not due to difficulties detecting rule switch; following a rule switch, RBD patients made changes to their responses, and persisted with old rules at a similar rate to LBD patients. Critically, RBD patients tended to detect *more* changes than were actually present. That is, RBD patients engaged in frequent and largely unguided explorations of potential new rules. We suggest that these difficulties stem from problems integrating feedback information such that RBD patients are more susceptible to

incongruent feedback. Our results suggest that the right hemisphere is specialized for the exploration of alternative options in adaptive learning tasks, and that exploratory failures contribute to the updating deficits seen in RBD patients.

Title: Decoded fMRI neurofeedback can induce bidirectional behavioral changes within single participants

Authors: *A. CORTESE[1,2,3], K. AMANO[3], A. KOIZUMI[1,3], H. LAU[4,5], M. KAWATO[1,2]; [1]Cognitive Mechanisms Laboratories, Dep. of Decoded Neurofeedback, ATR Inst. Intl., Kyoto, Japan; [2]Information Sci., Nara Inst. of Sci. and Technol., Nara, Japan; [3]Ctr. for Information and Neural Networks, Osaka, Japan; [4]Dep. of Psychology, [5]Brain Res. Inst., UCLA, Los Angeles, CA

Abstract: Studies using real-time functional magnetic resonance imaging (rt-fMRI) have recently incorporated the decoding approach, allowing for fMRI to be used as a tool to manipulate fine-grained neural activity. Because of the tremendous potential for clinical applications, certain questions regarding decoded neurofeedback (DecNef) must be addressed. Neurofeedback effects have been previously shown to last for months, but the short- to mid-term dynamics are currently not known. Specifically, can the same participants learn to induce neural patterns towards two opposite directions in different sessions? This leads to a further question, whether learning to reverse a neural pattern may be less effective after training to induce it in a previous session. Here we employed a within-participants design, with participants undergoing

DecNef training sequentially in opposite directions (up or down regulation of confidence judgements in a perceptual decision task), with the order counterbalanced across participants. For each direction, participants underwent two days of DecNef training, with behavioral tests before and after the fMRI scanning sessions (pre- and post-tests). A one-week interval separated the opposing DecNef trainings. Behavioral results indicated that the magnitude of neurofeedback effect was strongly influenced by the order and direction of neurofeedback training. We therefore applied nonlinear mathematical modeling to decompose the behavioral effect into four main consequences of DecNef: main effect of change in behavior, strength of down-regulation effect relative to up-regulation, maintenance of learning over sessions, and anterograde learning interference. Modeling results revealed that bidirectional brain manipulation successfully led to bidirectional behavioral changes in different sessions. Furthermore, up-regulation effect was more sizable, and such effect was largely preserved even after an interval of one week. Lastly, there existed a strong anterograde interference onto the next DecNef session by the first week DecNef; the consequence was a stronger effect of neurofeedback in the first week as compared to the second week. These results suggest reinforcement learning characteristics of DecNef, and provide important constraints on its application to basic neuroscience, occupational and sports trainings, and therapies.

Title: Dissociable explanations for uncertainty driven changes in neural representation across the brain

Authors: *J. W. KABLE[1], M. NASSAR[2], J. MCGUIRE[3];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Brown Univ., providence, RI; [3]Dept. of Psychologocial and Brain Sci., Boston Univ., Boston, MA

Abstract: Neural networks in rodent medial prefrontal cortex occasionally go through rapid changes in neural firing patterns. Such “network resets” tend to occur during periods of uncertainty during which animals are rapidly shifting between different behavioral regimes [1]. Currently it is unknown what the populations of neurons that participate in such phenomenon are representing. One potential explanation is that such populations represent the current behavioral regime and that rapid transitions in this representation reflect changes of mind with regard to a behavioral policy. An alternative explanation for this phenomenon is that the networks provide a fluctuating context to which newly arriving information is bound. Within this framework, gradual transitions in network activity could allow partial pooling of information collected within a stable context, whereas rapid network resets could allow information collected in one context to be effectively partitioned from that collected in the next. The critical difference between these two explanations is that the former involves a population representation that is capable of returning to a previously encountered behavioral regime whereas the latter explanation predicts a population representation that moves further and further from previous contexts, even when those contexts involved similar stimulus action mappings. Thus, testing these two hypotheses requires observing uncertainty driven network resets in the context of a task where behavioral regimes are occasionally re-encountered. Here we do this by examining the fluctuations in multi-voxel patterns of BOLD activity from human subjects making sequential inferences about the state of a partially observable and discontinuously changing variable [2]. We find that, within the context of this task, the vast majority of cortex contains representations that change more rapidly during periods of uncertainty. We find that, in some cortical areas, such as motor cortex, this phenomenon is indicative of discontinuous changes in the representation of a behavioral regime. In contrast, we identify other cortical regions, including orbitofrontal cortex, which are more consistent with the representation of a context that fluctuates more rapidly during periods of uncertainty. Finally, we show that several other cortical areas showing the basic phenomenon, such as DLPFC and ACC, are best described by an alternative explanation: encoding uncertainty itself.

Title: The network architecture of value learning

Authors: ***M. G. MATTAR**[1], S. L. THOMPSON-SCHILL[1], D. S. BASSETT[2];
[1]Dept. of Psychology, [2]Dept. of Bioengineering, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Value guides behavior. With knowledge of stimulus values and action consequences, one is able to select its actions to maximize expected cumulative reward. Prior work has identified several brain structures critical for representing stimuli and their values. It remains unclear, however, how these structures interact with one another and with other regions of the brain to support the acquisition of value-related knowledge. Here we approach this problem from a network neuroscience perspective, examining patterns of BOLD functional connectivity across the whole brain and how they change as 20 human subjects learn the values of novel stimuli in a simple two-alternative forced choice task. The monetary values of 12 shapes were learned over the course of four consecutive days, through a feedback consisting either of the value of the shape selected (10 subjects) or the correctness of the selection (10 subjects). Our results show that the overall functional networks change continuously over the course of learning, and that these changes primarily involve regions of the visual, frontal, and anterior cingulate cortices. Using a cross-validation procedure, we show that connections between visual and frontal and between visual and cingulo-opercular modules are useful predictors of a subject's learning stage, and that connections between various modules and basal ganglia structures can significantly classify the type of feedback received by the subjects. Together, these results demonstrate that functional networks dynamically track behavioral improvements in a value judgment task, and that interactions between network communities are useful biomarkers of value learning.

Title: Sequential integration of task-related dimensional components during multi-dimensional reinforcement learning task

Authors: *O.-H. CHOUNG, Y. JEONG;
Bio and Brain Engin., KAIST, Daejeon, Korea, Republic of

Abstract: We often face multi-dimensional decision making situations, in which we gather incomplete pieces of information to deduce optimal decisions. Although a few studies have been performed on reward-based learning process in multi-dimensional environments, they focused only on the reduction of unnecessary dimensions (Niv et al., 2015), competitions, or combinations of dimensions (Hunt et al., 2014); no previous study has yet investigated how the brain integrates dimensions during learning trials. In this study, we investigated how the brain integrates information in multi-dimensional reinforcement learning task using computational model based on hidden markov model (HMM) and reinforcement learning (RL) and fMRI; we observed that our brain integrates pieces of information in a sequential manner and that the frontopolar cortex is responsible for the integration process.
23 subjects participated in the multi-dimensional behavioral task. Subjects were shown pictures with multiple features—shapes, color, and patterns—and asked to collect as many points (reward) as possible; participants were not informed of the rule and were to find optimal strategies to achieve their goals. During behavioral tasks, subjects' performance and the fMRI signals were simultaneously recorded.
To examine whether subjects learned by integrating multi-dimensional information sequentially or processing concurrently, we fitted behavior data into two separate computational models—one with both HMM and RL for sequential learning and the other with only RL for concurrent learning. The comparison between two models demonstrates that the participants integrated multi-dimensional information sequentially.
After confirming that information is integrated sequentially, we examined which part of the brain was related in our behavioral task from the fMRI data. We observed that the frontoparietal cortex encoded expected reward, and the ventromedial prefrontal cortex encoded prediction error, as previously reported (Lee et al., 2014). Also, the frontopolar cortex was observed to be correlated with transition probabilities in HMM, indicating that it is responsible for multi-dimension integrating process. Psycho-physiological interaction (PPI) analysis revealed the existence of causal connections between these three areas, suggesting that the frontopolar cortex works as a meta-controller and integrator of value and error signals.
Overall, our result explains how our brain integrates multi-dimensional components sequentially during reinforcement learning. Our study, therefore, suggests how human effectively processes new information when the dimension is extended.

Title: Correlates of robot-error observation in the human EEG

Authors: *J. BEHNCKE[1], D. WELKE[1], R. T. SCHIRRMEISTER[1], L. KAHLE[1], W. BURGARD[2], T. BALL[1];
[1]Univ. Med. Ctr. Freiburg, Freiburg, Germany; [2]Dept. of Computer Sci., Freiburg, Germany

Abstract: Brain-controlled robots are a new type of assistive device for severely impaired persons. Information about the correctness of robot performance might provide a teaching signal for adaptive control algorithms and thus help reducing errors. To reach this goal, an evaluation of the correctness of the robot's action must be inferred from the brain activity of the robot user.Studies about the neural correlates during observation of robotic action are rare. Here, we present findings from two novel experiments in which subjects watched different types of robots conducting everyday-actions (i.e. pouring liquid and picking up objects). In both scenarios, actions were either performed correctly or incorrectly (Fig. 1 a-c). We recorded 128-channel high-resolution EEG during the observation tasks to train rLDA- and filterbank-CSP classifiers on varying time-intervals and frequency-components of the multivariate signal. These classifiers should either decode for the correctness of the observed action, or for the type of the observed robot (humanoid/non-humanoid). It was possible to decode both the correctness, at least in one of the investigated error scenarios (spilling of liquid), as well as the robot type significantly above chance level with decoding accuracies up to around 70% (see Fig. 1 d-f). Further on, our results indicate an effect of the frequency components used for decoding. We conclude that non-invasive recordings of brain activity elicited when observing robots can indeed provide decodable information about the correctness of the robot’s action, and also about the type of observed robot. Hence, brain signals related to robot-error observation may improve the performance of future brain-controlled devices and might reveal valuable insights into the neural bases of human-robot interaction in general.

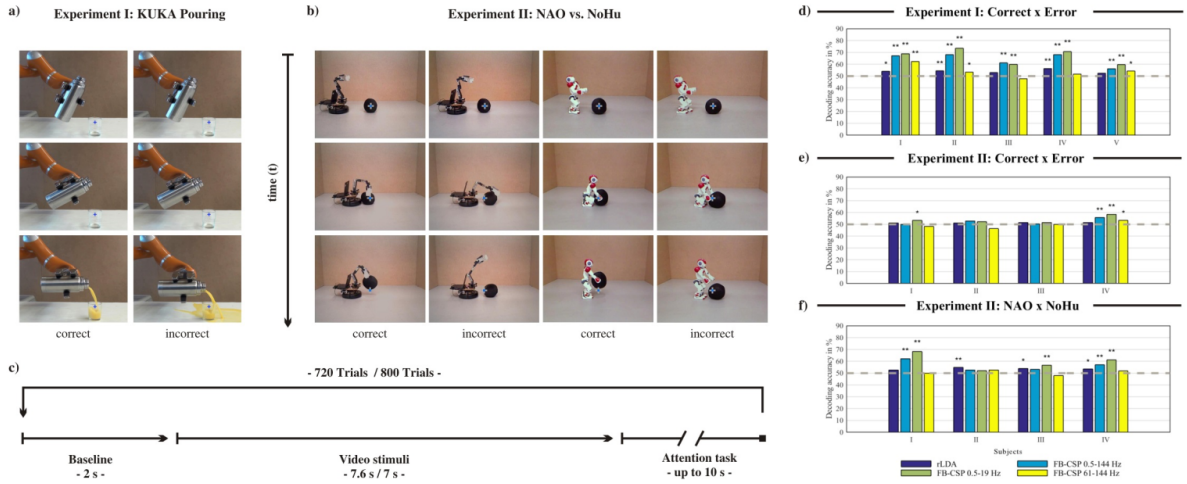

Figure 1. Experimental paradigms and decoding results: video stimuli in exp. I (a) and exp. II (b), and schematic procedure of the observation tasks (c). Best filterbank-CSP decoding results for exp. I (d), error condition of exp. II (e) and robot condition of exp. II (f). Significance is indicated by asterisks: * $p < 0.05$, ** $p < 0.01$.

Title: Prediction-error signals in the substantia nigra and the dorsal striatum for behaviorally relevant Pavlovian learning relate to performance at instrumental learning

Authors: *J. T. COLAS[1], W. M. PAULI[2], T. LARSEN[2,3], J. M. TYSZKA[2], J. P. O'DOHERTY[1,2];
[1]Computation and Neural Systems Program, [2]Div. of the Humanities and Social Sci., Caltech, Pasadena, CA; [3]Ctr. for Mind/Brain Sci., Univ. of Trento, Trento, Italy

Abstract: In natural settings, Pavlovian (or classical) conditioning and instrumental (or operant) conditioning often occur concurrently. Neural subsystems specialized for either type of learning thus often could benefit from exchanging information. Typical approaches to studying the interactions between these two systems entail presenting previously learned Pavlovian cues during instrumental performance and exploring the interactive effects on behavior (i.e., Pavlovian-instrumental transfer). Here, we were more concerned with the extent to which knowledge about the environment acquired via Pavlovian learning (i.e., conditioned reinforcement) could influence instrumental learning when the outcomes of those instrumental actions are learned about in a Pavlovian manner, and we set out to delineate the neural mechanisms underlying such effects.
For this study, human subjects performed a multi-stage learning task that required both Pavlovian and instrumental learning in parallel. High-resolution functional magnetic-resonance imaging (fMRI) data with 1.5-mm isotropic voxels were acquired using protocols optimized for the midbrain. Reinforcement-learning models accounted for subjects' behavior and were applied to model-based analyses of the fMRI data. Pavlovian states were interleaved with and related to instrumental states by design. Prediction-error signals for these Pavlovian states were identified within the dopaminergic midbrain--specifically, the substantia nigra and the ventral tegmental area--as well as in the ventral striatum, a region that has previously been implicated in Pavlovian learning. Notably, such Pavlovian learning signals were also identified within the dorsal striatum, a region that has previously been argued to have roles specific to instrumental learning. Furthermore, the magnitudes of Pavlovian prediction-error signals in the substantia nigra and the dorsal striatum were correlated with how optimally subjects performed the instrumental component of the task.
The present findings suggest that acquiring conditioned reinforcement through Pavlovian learning may depend on neural circuits hitherto implicated in instrumental conditioning--namely, in the dorsal striatum and the parts of the substantia nigra that project to the dorsal striatum. By linking the dorsal striatum to learning about conditioned reinforcers that ultimately could be used to drive instrumental actions, the present results broaden our understanding of the functions of this area in reward-related learning.

Title: Does the salience network's functional connectivity relate to individual variability in processing speed in elderly subjects?

Authors: *A. RUIZ-RIZZO[1], J. NEITZEL[2], N. NAPIORKOWSKI[1], H. J. MÜLLER[1], C. SORG[2], K. FINKE[1];
[1]Dept. of Psychology, Ludwig-Maximilians-Universität München, Muenchen, Germany; [2]TUM-Neuroimaging Center, Neuro-Kopf-Zentrum, Klinikum rechts der Isar, Technische Univ. München, München, Germany

Abstract: Visual processing speed is the rate of visual information uptake per time unit. The salience network (SN) covers bilateral frontal gyrus areas assumed to be relevant, e.g., for processing speed. While both processing speed and intrinsic functional connectivity (iFC) of the SN (SN-iFC) are reduced in healthy aging, it is not known whether and how their individual variability is related. Here, we aimed to describe this relation in a group of older (60-80 years; mean = 71; n = 29; 11 females) and, for reference, a group of younger (18-35 years, mean = 25.9; n = 26; 14 females) adults. All participants underwent resting-state functional magnetic resonance imaging for 12.5 min, with eyes closed, in a 3T scanner. In a different session, processing speed was assessed using a Theory of Visual Attention (TVA)-based whole-report task. Here, participants were presented with letter arrays for brief, variable, and individually pre-adjusted exposure durations and had to report all letters they were fairly certain they had seen. Parameter processing speed was estimated, via computational modelling of report accuracy changes with increasing exposure durations. Preprocessed functional images of all participants were used for a group independent component analysis with 20 dimensions. The SN was visually identified and further confirmed by multiple regression of a SN template. To examine the correlation between SN-iFC and processing speed values, we performed multiple regression analysis of both variables, separately for each age group. In the older compared to the younger group, we found significantly lower visual processing speed and lower average SN-iFC. Significant group differences were found in IFC in left superior frontal and middle frontal gyrus, left anterior and right middle cingulate cortex, and right angular gyrus. Within each group, we found significant correlations between individual visual processing speed values and SN-iFC in distinct frontal clusters, i.e. a left inferior cluster in the older and a right middle frontal cluster in the younger group. Our results suggest that, within the SN, frontal iFC is associated with visual processing speed across different age levels, but that the most critical frontal area within the SN might change with age.

Title: The impact of input modality on cognitive training task performance in a large online population

Authors: S. MACLEOD, *A. KALUSZKA;
Lumos Labs, Inc., San Francisco, CA

Abstract: Previous research has shown that varying psychophysical task parameters can have significant effects on performance. However, this research did not account for different input methods and their effects on cognitive task performance. We hypothesized that altering the input modalities in cognitive training tasks would affect participant performance and training strategies.
Through a wide-scale study of participants undergoing cognitive training through an online system (Lumosity), which includes millions of users, we investigated the result of input method differences between computer-based and mobile-based training. We measured performance in several different cognitive training tasks, including selective and divided attention and working memory tasks.
Performance metrics such as reaction time, error rates, and memory capacity were recorded and compared across groups completing either computer-based or mobile-based training. We observed several significant differences in behavior, such as faster response times and lower accuracy in mobile-based attention tasks compared to computer-based tasks. This study suggests that input modality is an important consideration when designing cognitive training tasks and interpreting their results.

Title: Attentional modulation of neural oscillations in the human spinal cord

Authors: *M.-P. STENNER[1], T. ZAEHLE[2], E. AZAÑÓN[4], H.-J. HEINZE[2], A. SCHOENFELD[5], L. BUENTJEN[3];
[1]Otto-von-Guericke Univ., Magdeburg, Germany; [2]Dept. of Neurol., [3]Dept. of Stereotactic Neurolosurgery, Otto-von-Guericke Univ. Magdeburg, Magdeburg, Germany; [4]Dept. of Psychological Sci., Birkbeck, Univ. of London, London, United Kingdom; [5]Leibniz Inst. for Neurobio., Magdeburg, Germany

Abstract: Neural oscillations in sensory cortex, recorded via scalp electroencephalography (EEG), are modulated by attention and expectation. In particular, cortical alpha- and beta-oscillations are suppressed in anticipation of attended stimuli, and this pre-stimulus suppression influences perception. We demonstrate a similar top-down oscillatory modulation at the level of the human spinal cord. We recorded local field potentials (LFPs) from epidural spinal electrodes implanted for pain relief in patients with different pain syndromes, simultaneous to scalp EEG, during an intermodal, somatosensory vs. visual, attentional cueing paradigm. We found a stimulus-induced decrease in the power of alpha- and beta-oscillations in spinal LFPs, similar to stimulus-induced responses in the cortical EEG. Importantly, the power of alpha- and low beta-oscillations in the spinal cord was already suppressed prior to stimulus onset, evidence of an anticipatory, top-down regulation at the level of the spine. Attention to somatosensory stimuli resulted in diminished, rather than enhanced, pre-stimulus alpha- and beta-suppression, contrary to its well-known effects at the cortical level. Taken together, first results of this ongoing study support the idea of a top-down regulation of somatosensory processing via changes in alpha- and beta-oscillations as early as the spinal cord.

Title: Intracranial cortical event-related potentials and alpha wave gating of visual consciousness.

Authors: *S. I. KRONEMER[1,2], W. R. XIAO[1,2], L. GOBER[1], R. E. SMITH[1], S. M. A. WAFA[1], A. RAJA[1], E. MORSE[1], R. E. WATSKY[1], C. L. HORIEN[1], E. SABERSKI[1], O. MORGAN[1], G. J. TOULOUMES[1], W. C. CHEN[1], D. D. SPENCER[3], J. L. GERRARD[3], H. BLUMENFELD[1,3,2];
[1]Neurol., [2]Neurosci., [3]Neurosurg., Yale Univ., New Haven, CT

Abstract: Primary questions in the study of consciousness are (1) what is the succession of neural activity linked with conscious events, and (2) how are otherwise unconscious stimuli recruited to perception? The current investigation supports the role of alpha oscillations in gating conscious perception and corroborates the neural activity progression defined by established models of visual consciousness. Nine participants with intractable epilepsy undergoing an intracranial EEG implantation (100-300 subdural intracranial electrodes; sampling rate = 1024 Hz) were recruited from the Yale Epilepsy Surgery Program. A visual threshold perception task was administered requiring participants to indicate their awareness of a face stimulus appearing on a dynamic background. Stimuli were calibrated to that participant's 50% threshold of contrast detection, confirmed by response accuracy. Electrodes located in the primary visual cortex revealed similar intracranial event-related potentials (ERPs) activity between perceived and not perceived trials during early post-stimulus onset phases (<200 ms). Diverging ERPs were observed between perceived and not perceived trials during intermediate and late post-stimulus onset phases (>200 ms). Deviations were particularly true for higher visual processing and other association cortical areas, including the fusiform face area, fronto-parietal cognitive and medial temporal memory networks. Moreover, alpha oscillations tended to be phase locked within both consciously perceived and not perceived trials, yet phase shifted relative to these trial types within subjects. Accordingly, the temporal relationship between alpha phase and the stimulus onset may gate conscious events. In summary, these results exhibit unique activity patterns for higher order brain circuits for consciously perceived versus not perceived stimuli. Furthermore, the alpha phase data suggests that pre-stimulus activity is involved in gating conscious perception. Our ERP and alpha findings predict global synaptic brain activity that may be essential for defining what stimuli become conscious and how this information is processed.

Future investigations will focus on the role of subcortical activity in conscious perception and its relationship to the temporal progression and regional specific activity for conscious stimuli as revealed in the current study.

Title: Template specificity in loss avoidance value driven attentional capture

Authors: *M. DIBARTOLO[1], B. A. ANDERSON[1], S. M. COURTNEY[1,2,3];
[1]Psychological & Brain Sci., [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]F.M. Kirby Res. Ctr. for Functional Brain Imaging, Kennedy Krieger Inst., Baltimore, MD

Abstract: Cues previously associated with reward persistently capture attention, even when rendered task-irrelevant and perceptually non-salient. This phenomenon, referred to as value-driven attentional capture (VDAC), has been studied in the context of reward, but the role of active loss avoidance in shaping attentional biases remains unexplored.
To explore the ability of negative reinforcement to support VDAC, human participants completed two behavioral tasks over the course of a single session. In an initial training phase, participants learned to associate one color with low value (3¢) and another color with high value (15¢) during visual search for a color-defined target. Correct responses were associated with the avoidance of a corresponding loss from a compensation bank. The shape of the target and non-target stimuli were only circles for 32 participants (10 male, age 21.63 $\pm$ 3.9) and only diamonds for 19 participants (10 male, mean age 20.44 $\pm$ 2.2). Following the first task, all participants completed a second visual search task during which they identified a unique shape target among colored distractors. Half of these trials included a previously value-associated color distractor, which either was or was not the shape of the trained stimuli (equally-often). Trials that included distractors in the same color and shape as the value-associated stimuli during training were considered template matches. Reaction times were compared across value conditions, separately

for distractor shape template match and non-match conditions.
Response times (RTs) differed significantly among the three test phase value conditions: distractor absent (644 $\pm$ 74 ms), low value distractor (649 $\pm$ 80 ms) and high value distractor (655 $\pm$ 76 ms) [$F(2,100) = 4.7$, $p < .05$]. High-value distractors slowed RT relative to distractor absent trials [$t(50) = 3.212$, $p < 0.01$]. When comparing across trial types, a repeated-measures ANOVA revealed an interaction between training shape and the template match of the distractors [$F(1,49) = 112.683$, $p < .001$]. The high-value distractors slowed RT relative to distractor absent trials specifically in template matching [$t(49) = 4.228$, $p < .001$], but not non-matching [$t(49) = .643$, $p = .523$] conditions.
The results indicate that, as with monetary gains, stimuli associated with loss avoidance are able to capture attention. However, unlike with monetary gains, loss avoidance VDAC is only significant when the distractor in the test phase is an exact match to both the color and shape of the stimulus for which the value association was learned during the training phase.

Title: Costs and benefits of tRNS-induced improvements in performance during an unattended feature task

Authors: *S. TYLER[1], F. CONTÒ[2], L. BATTELLI[3,4];
[1]Univ. of California San Diego, LA Jolla, CA; [2]Cognitive and Brain Sci., Univ. degli Studi di Trento, Rovereto, Italy; [3]Ctr. for Neurosci. and Cognitive Systems, Inst. Italiano di Tecnologia, Rovereto, Italy; [4]Berenson-Allen Ctr. for Noninvasive Brain Stimulation and Dept. of Neurol., Harvard Med. Sch., Boston, MA

Abstract: Attention helps selectively sensitize the brain towards important visual information. However, repetitive exposure to either below threshold or unattended stimuli can still sensitize the visual system to those features (Watanabe 2001). In our study, we investigate whether transcranial random noise stimulation (tRNS) facilitates this sensitization during an unattended feature paradigm, and whether the presence of a competing task interferes with this process. Fifty-two participants were equally divided into a “Training” or “No Training” group. Both groups completed an orientation discrimination task on Day 1 and Day 5. The task comprised of a pair of temporally offset flickering discs (black and white), with one cycle briefly presented as

a pair of oriented Gabors. Subjects were asked to judge if the orientation of the Gabors were the same. On Days 2-4, subjects in the "Training" group were presented with the same stimuli, but instead asked to attend to the temporal order of the oriented Gabor discs. The "No Training" group had no task.
These groups were further divided into one of four tRNS groups: bilateral Parietal, bilateral hMT+, bilateral Sham, and No Stim condition. Subjects undergoing active (Parietal and hMT+) or Sham stimulation were stimulated during the temporal order task on Days 2-4 for 25 minutes each day.
Parietal stimulation in the "No Training" group significantly *increased* behavioral accuracy for the orientation discrimination task on Day 5 versus Day 1. All other tRNS conditions showed no net improvement over the week. Conversely, parietal stimulation in the "Training" group caused *decreased* accuracy on the orientation task on Day 5 versus Day 1. This trend was not seen in any other "Training" stimulation groups.
These results are the first to show that tRNS over parietal cortex can selectively induce task-specific excitation for the attended task (the temporal order task) while suppressing performance on a task irrelevant perceptual task (the orientation task). tRNS can act as an exogenous boost to attentional arousal, allowing subjects to better focus on a continuous selective attention task (Mauri et al, 2015). For subjects in the "No-training" condition, this boosted state may linger into Day 5, producing a heightened state of cognitive arousal allowing subjects to better ignore competing temporal order information. However, for the "Training" group, specific parietal cortical networks involved in temporal order processing were boosted via tRNS, and that effect interfered with behavioral performance on the orientation task.

Title: Novel mobile video game and electroencephalography system to assess the neural correlates of attention

Authors: ***R. GIL-DA-COSTA**, R. FUNG, M. ZINNI, M. CASWELL, M. LOPES; Neuroverse, Inc., San Diego, CA

Abstract: In a society currently affected by a wide range of mental disorders that impose exponentially growing heavy penalties at both the individual and societal levels, there is a

concerning absence of usable and reliable systems to assess cognitive and neural function in large scale. Unlike other biosensors (i.e. cardiac, glucose, etc.), available solutions in the neural space are cumbersome, unreliable or both, and as such there is an urgent need for novel tools designed to capture, integrate and evaluate brain signals of interest in real-world monitoring settings. Here, we used Neuroverse's mobile forehead electroencephalographic (EEG) sensing system, with a software application for testing and analysis in mobile platforms (e.g. smartphones and tablets) to test the detection of well-known event-related brain potentials (ERP) correlated with attention (P300 and N2) in 25 healthy individuals during two visual oddball paradigm tasks: a) a more traditional serial visual presentation of natural images (where subjects were asked to keep a mental count of "target" images) and b) a novel action video game (where subjects were required to discriminate and selectively respond to "red" ants while simultaneously filtering and withholding a response to the more frequently presented "black" ants). Our results show statistically significant differences for brain responses to "target" versus "distractor" objects in both tasks, demonstrating the efficacy of this mobile system for efficient large scale use in the assessment of attentional neural responses. Moreover, additional advantages of the use of the video game versus more traditional testing paradigms, both in terms of additional measures and engagement levels, will be discussed. This study presents evidence of the outstanding efficacy of a novel user-friendly mobile system that can open new avenues for much needed large-scale applications ranging from clinical (i.e. neuropsychiatric deficit detection and evaluation, clinical outcome predictability and drug efficacy evaluation) to health prevention or education.

Title: Sustained spatial attention alone explains the bias in microsaccade direction

Authors: ***C. XUE**[1], A. CALAPAI[1], K. DANNHAEUSER[2], J. KRUMBIEGEL[2], S. TREUE[1,2]; [1]German Primate Ctr., Goettingen, Germany; [2]Fac. of Biol. and Psychology, Goettingen Univ., Goettingen, Germany

Abstract: Microsaccades are small eye movements while fixating. The distribution of their directions is biased towards an eccentric location indicated by an endogenous spatial cue ~300ms after the cue's presentation. Therefore, microsaccades could serve as an index for covert spatial attention. However, this use of post-cue microsaccades suffers from two major factors. First, visual spatial attention is usually entangled with saccade planning. A systematic investigation is needed, as to which extent saccade planning can influence microsaccade directions, confounding the attention-specific effect. Second, most studies of the post-cue microsaccade direction effect focused on a time window around 300ms after the onset of the endogenous cue (such as an arrow pointing at the required gaze location); and the bias reverses direction if the cue is exogenous (i.e. appears at the required location). These effects seem to indicate that the microsaccade direction bias is contingent on the cue, not necessarily reflecting a sustained attentional state. To resolve the first problem, we investigated microsaccades of human subjects while they performed a spatial attention guided match-to-sample task. The subjects had to covertly attend to a location while preparing a saccade either toward or away from the attended location. To resolve the second problem, we provided a verbal spatial cue before each experiment session, instead of before each trial, so as to exclude any cue contingent effects on micro saccades. Our data show a sustained bias of the directions of microsaccades toward the attended location, and not the saccade target. Despite the absence of cues during the trials, sustained attention alone still reliably produces the microsaccade direction effect. Overall, our findings demonstrate that sustained spatial attention, rather than saccade planning or the spatial cue per se, determines the direction bias in microsaccades. Our results also question the notion that spatial attention is functionally equivalent to a movement planning process.

Title: Investigating the relation between Stroop interference and attention capture using event-related potentials

Authors: A. J. LOWERY, R. D. WRIGHT, *J. J. MCDONALD;
Psychology, Simon Fraser Univ., Burnaby, BC, Canada

Abstract: People are faster to name the color in which a word is printed (e.g., blue) when the word itself is a congruent color word ("BLUE") than when it is an incongruent color word ("RED"). This well-known Stroop effect has been ascribed to the automaticity of word reading. That is, the Stroop words are read in an obligatory fashion (despite the fact that they are task-irrelevant), and the meanings of those words are extracted without necessarily attending to the words. However, some results suggest that the magnitude of Stroop interference depends on attention. For example, Kahneman and Chajczyk (1983) found that the Stroop effect is reduced by the concurrent presentation of a response-irrelevant stimulus, such as a string of identical letters (e.g., "XXX"). This reduction of Stroop interference was hypothesized to occur because the second stimulus interferes with attentional processing of the color word, implying further that the Stroop effect itself depends on the ability of the color word to capture attention. In the present study, we recorded event-related potentials (ERPs) to determine whether (i) task-irrelevant color words capture attention in the non-integrated variant of the Stroop task, and (ii) the magnitude of Stroop interference depends on the strength of attention capture. On each trial, a colored rectangle (red, green, or blue) was presented at fixation and was flanked by a color word ("RED", "GREEN", or "BLUE") on one side and a length-matched string of Xs on the other side of fixation. Participants were required to identify the color of the rectangle and to press a corresponding button as quickly and as accurately as possible. Consistent with previous findings, response times were slightly but significantly longer on incongruent trials than on congruent trials (18 ms difference). To determine whether the color word captured attention, we isolated lateralized ERP components associated with early attentional selection (N2pc) and later stimulus identification (SPCN). Color words were found to elicit both the N2pc and subsequent SPCN, demonstrating that the words were attended despite the fact that they were irrelevant. However, the amplitudes of these ERP components did not correlate with the magnitude of Stroop interference. These findings indicate that while the color words captured attention reflexively, such attention capture may not underlie the interference found in the Stroop task.

Title: Object-based attention acts upon degraded object representations in early visual cortex

Authors: *S. AL-JANABI[1], N. STROMMER-DAVIDOVICH[2], S. GABAY[2], A. S. GREENBERG[1];
[1]Dept. of Psychology, Uw-Milwaukee, Milwaukee, WI; [2]Univ. of Haifa, Haifa, Israel

Abstract: Previous evidence of object-based selection along the visual cortical hierarchy (V1 to V4) indicates that attention can gate visual (object) representations early in the processing stream. It is unclear, however, whether or not the strength of object percepts modulates the level along the visual cortical hierarchy at which object-based selection is evident. Here, we aimed to ascertain whether attention selects information 'early' or 'late' in the visual processing stream when object information is degraded. While acquiring fMRI data, we asked participants to identify a target preceded by a central arrow cue (60% valid) in the double-rectangle paradigm (Egly et al., 1994). Cues to objectness were strong (standard visible rectangles), reduced (occluded rectangles), or weak (illusory rectangles). Our behavioural results indicated that participants identified the target faster when it appeared on the spatially cued versus the non-cued object. This same-object advantage emerged irrespective of object strength, suggesting that both strong and weak object percepts can be prioritised for attentional selection. We independently localized retinotopically-specific regions of cortex corresponding to target locations to examine neural activation in both early and mid-level regions of the visual cortex hierarchy (V1-V3, and LOC). Consistent with our behavioral results, target-evoked BOLD activation in V1/V2 increased at locations on the cued object, but not the non-cued object; indicative of a neural same-object advantage in these regions. This effect did not differ as a function of object cue strength, and it was absent in both V3 and LOC. We, therefore, conclude that attention modulates weak object percepts at the earliest levels of the visual cortex hierarchy. This finding has implications for theories of attentional selection, supporting early selection accounts, which posit that attention serves to help bind low-level visual information into completed object percepts.

Title: Neurofeedback Informed Meditation Technique (NIMT) for modulating posterior cingulate cortex activity—proof-of concept for a novel mental-training paradigm with clinical applications

Authors: *J. F. SANTOYO[1,2], B. CULLEN[3], C. KERR[4];
[1]Providence, RI; [2]Neurosci., [3]Psychiavtry and Human Behavior, [4]Family Med., Brown Univ., Providence, RI

Abstract: I present initial evidence from two experiments for a method (NIMT) that aims to elucidate clinically-relevant causal relationships between neurophysiological and cognitive processes. Here, expert meditators use a neurofeedback display to employ a systematic procedure for discovering, formulating and refining meditation strategies (NIMTs) that modulate the chosen neurofeedback signal. NIMTs are then introduced to hypothesis-blind groups to assess the influence of the NIMT on the targeted neurophysiological signal and relevant behavioral measures. In our first experiment, we developed a NIMT for downregulating posterior cingulate cortex (PCC) activity by drawing on expert meditators' verbal descriptions of the experiential correlates of PCC activity reported previously (Garrison et al. Frontiers in Human Neurosci . 2013). We used fMRI to compare PCC activity and functional connectivity in participants with some meditation experience (n=10) during six minute blocks during which participants used either the PCC-NIMT or a control meditation (focused attention on the breath) and rest-blocks with the instructions to 'close your eyes, do not meditate and do nothing in particular'. BOLD activity in the PCC was significantly decreased during the PCC-NIMT in comparison to rest and the control meditation. In our second experiment, expert meditators (n=4) used EEG-based neurofeedback to develop NIMTs for upregulating somatosensory alpha-band (S1-alpha) power. We report the correlates of S1-alpha power in these meditators' self-reports and the cognitive processes they identified to most effectively modulate S1-alpha band activity. Initial EEG data (n=6) suggests that hypothesis blind participants using this S1-alpha NIMT demonstrate increased alpha-band power. In the next phase of this experiment, we will compare the influence of these techniques on EEG-recorded S1-alpha power and coherence, as well as on behavior that has been previously associated with S1-alpha activity—i.e. threshold levels for detection of tactile stimuli (Kerr 2011). These preliminary results suggest that the NIMT methodology may

offer neurofeedback-independent modulation of targeted neurophysiological signals with important implications for clinical treatment.

Title: Broadband gamma activity in the formation of a conscious visual experience in humans

Authors: ***W. R. XIAO**[1,2], S. I. KRONEMER[2], L. M. GOBER[1], R. E. SMITH[1], S. M. A. WAFA[1], A. RAJA[1], E. C. MORSE[1], R. E. WATSKY[1], C. L. HORIEN[1], E. SABERSKI[1], O. MORGAN[1], G. J. TOULOUMES[1], W. C. CHEN[1], D. D. SPENCER[3], J. L. GERRARD[3], H. BLUMENFELD[1,2,3];
[1]Neurol., [2]Neurosci., [3]Neurosurg., Yale Univ., New Haven, CT

Abstract: We used human electrocorticography to directly observe the temporal progression of neural activity during conscious visual events. We developed a threshold perception task paradigm using a face image held at 50% perceptual levels. We recruited 9 patients from the Yale Epilepsy Surgery Program undergoing observation for intractable epilepsy to perform our task by reporting perception of the image verified by reporting its location. Each patient was implanted with 100-300 subdural and depth electrodes sampled at 1024 Hz. We calculated the z-score of 40-115 Hz gamma power changes in each electrode as a measurement of local neuronal population spiking. Gamma power increases were observed in the primary visual cortex for all trials immediately following stimulus presentation. When perceived, however, by 300 ms post-stimulus the primary visual cortex showed gamma decreases along with strong visual association area increases. Those increases were in turn followed by sustained increases in fronto-parietal association areas as well as deactivations in some traditionally identified default mode network areas such as the precuneus, ventral medial frontal, lateral parietal, and lateral temporal cortices.

By 900 ms post-stimulus, the primary visual and orbitofrontal cortices showed reactivation. When viewed grossly, the "wave" of activity responsible for conscious visual processing moves forward from the visual cortex along the dorsal and ventral streams. Early primary visual cortex activation followed by deactivation and culminating in reactivation is a novel observation. In contrast during not perceived trials, visual cortex increases were sustained with some more low-amplitude increases radiating into the dorsal and ventral visual stream. K-means clustering of time-series produced functional brain networks: 1) primary visual and higher-order association cortex, 2) early and 3) later intermediate association cortex and memory areas and 4) default mode network in perceived trials but not in not perceived trials. All clusters have high within-network integrity demonstrated by high silhouette values. The same clusters applied to not-perceived time-series show negative silhouette value means except for the visual cortex. We observed the formation of a conscious visual experience in the human brain from intracranial electrophysiology. In consciously perceived trials, an ordered pattern of activation and deactivation in functional networks emerged whereas strong activity was only observed in the primary visual cortex for not perceived trials, suggesting that concerted network activity, however transient, is a mechanism of conscious perception.

Title: Neural correlates of auditory attention in an exogenous orienting task

Authors: *M. SCARPETTA, M. PITTS, E. CANSECO-GONZALEZ;
Psychology, Reed Col., Portland, OR

Abstract: In an exogenous orienting task, attention is increased to the target stimulus if the cue validly predicts the target's location and the cue and target occur in quick succession. With a longer interval between the cue and target, the opposite effect occurs: attention is inhibited for validly cued targets. These attentional phenomena are known as facilitation, and inhibition of return (IOR), respectively. Both effects have been extensively explored in vision but less so in the auditory domain. The visual N2pc, an attention-related event-related potential (ERP)

component has been used to examine the neural correlates of IOR (McDonald et al., 2009; Yang et al., 2012), but recently, an auditory analog of the N2pc was discovered, known as the N2ac (Gamble & Luck, 2011). To our knowledge, no previous study has explored the neural basis of exogenous attentional facilitation and IOR in the auditory modality. The present study sought to fill this gap using the N2ac as a neural marker of auditory spatial attention. Brain activity was recorded from nineteen participants while they performed a Posner exogenous auditory orienting task. We compared the ERPs elicited by the target stimulus for short (200 ms) cue-to-target intervals (facilitation), and long (700 ms) cue-to-target intervals (IOR). We observed behavioral and electrophysiological evidence of attentional facilitation, and a behavioral trend of IOR, but no apparent electrophysiological evidence of IOR. This study demonstrates that the N2ac is enhanced by exogenous attention during the facilitation phase of the cue-to-target interval, but remains unaffected during the later IOR phase. These findings suggest some similarities as well as some differences between this newly discovered ERP component (N2ac) and its visual analog, the N2pc.

Title: A decision-theoretic model of the temporal dynamics of visual priming

Authors: ***H. ZHANG**[1], Y. HUANG[2], H. LUO[1];
[1]Peking Univ., Beijing, China; [2]Shenzhen Inst. of Advanced Technology, Chinese Acad. of Sci., Shenzhen, China

Abstract: It is widely acknowledged that brain activities are intrinsically dynamic. Interestingly, recent studies also reveal rich temporal fluctuations in behavioral performances. For example, a visual priming study (Huang et al., 2015) sampled priming behavioral performances (i.e., reaction times, RT) at varied SOA with an unusually high sampling rate (50 Hz) and found that the resulting RT function could be decomposed into two components: a slow declining trend that is matched with classical priming pattern and a new theta-band (~4 Hz) periodical pattern.

Here we investigated whether the newly observed theta-band rhythm in priming behavior is hard-wired, or could be influenced by the rewarding structure of the environment. In particular, we manipulated temporal uncertainty of the target appearance after prime onset. In previous experimental studies, SOA and temporal uncertainty usually co-varied with each other. For example, at a later SOA, it is more certain that the target would come at the next moment, and vice versa. In contrast, we designed an experiment in which SOA and temporal uncertainty could be disentangled. Thus we could compare human subjects' RTs across conditions where SOAs were the same but temporal uncertainties were different, or the reverse.
We found that the manipulation of temporal uncertainty exerted prominent effects on the slow-trend component but more subtle effects on the oscillation component. Some of the effects are counterintuitive and most effects cannot be predicted by any existing theories of priming. We developed a decision-theoretic model to account for the effects of uncertainty on RT. The model also provides a new perspective for widely reported but unexplained phenomena in other fields such as attention.

Title: Machine learning to predict pupillary dynamics in conscious visual perception

Authors: *S. M. A. WAFA[1], B. KIELY[1], W. R. XIAO[1,2], Y. CHEN[1], L. M. GOBER[1], J. PRINCE[1], S. I. KRONEMER[1,2], E. SABERSKI[1], O. MORGAN[1], Z. DING[1], M. J. MCGINLEY[2], D. A. MCCORMICK[2], H. BLUMENFELD[1,2,3];
[1]Dept. of Neurol., [2]Dept. of Neurosci., [3]Dept. of Neurosurg., Yale Univ., New Haven, CT

Abstract: The neural mechanisms of consciousness are the focus of many philosophic and empiric studies. Conscious perception requires attending to transient stimuli and encoding them in short-term memory for potential subsequent report. Recent data indicates that conscious perception might be associated with cortical and subcortical attention networks and memory encoding systems. A challenge for studying consciousness is the necessity of overt responses in behavioral paradigms. To address this limitation, we explored the use of pupillometry to covertly measure conscious visual perception. Pupillary responses have been correlated with several

cognitive processes in humans and more recently have been associated with auditory signal detection in rodents. We measured pupil diameter continuously using a pupillometry system during a visual threshold perception task in which face stimuli were calibrated to each participant's 50% perception threshold, confirmed by response accuracy. Changes in pupil dilation were measured and compared between perceived and not-perceived trials. On average, perceived trials were associated with an increase in pupil diameter approximately 1-2 seconds post-stimulus and this response was not seen in the average data for the not-perceived trials. Machine learning methods suggest that pupillary responses in individual trials can be predicted with an accuracy of 76.30% ± 13.46 for perceived and 78.25% ± 13.05 for not-perceived trials. This study may offer a new paradigm to gauge awareness without overt report. In addition, the results may enhance scientific knowledge on conscious information processing and inform the diagnosis of neurological disorders.

Title: Attending to auditory targets enhances visual perceptual processing in ventral visual cortex

Authors: *K. M. SWALLOW, H. B. TURKER, R. MOYAL, B. G. LI;
Psychology, Cornell Univ., Ithaca, NY

Abstract: Although attention is limited, there is at least one circumstance under which attentional capacity appears to increase in response to increased task demands. In the attentional boost effect, encountering an auditory tone (e.g., a low tone) that requires a behavioral response (e.g., a button press) is associated with better memory for concurrently presented visual images than is encountering a tone that requires no response (e.g., a high-tone distractor). In this study we asked whether increasing attention to a target tone facilitates perceptual processing of concurrent visual information by improving the signal-to-noise ratio (SNR) within visual cortex. We measured BOLD activity while participants monitored individually presented auditory tones for pre-specified targets (auditory tone detection task) and simultaneously memorized briefly presented, masked visual images (500 ms duration). Participants pressed a button as soon as they

heard a target tone and did nothing when they heard a distractor tone (target tone pitch was counterbalanced across runs) or when they heard no tone. Univariate analyses showed that auditory target detection increased BOLD activity in visual cortex relative to distractor tones and no-tones. Of primary interest, however, was whether it also improved the SNR in visual cortical areas. In an MVPA analysis, we therefore asked whether auditory target detection improved the ability to classify which type of image was presented on a given trial based on patterns of activation within primary visual cortex, the fusiform face area (FFA), and the parahippocampal place area (PPA). If auditory target detection improves the SNR in visual cortex, classification should be better for images presented with auditory targets than images presented on their own or with a distractor in the auditory tone detection task. Consistent with our predictions, the types of images that were presented on a given trial were more accurately classified if the image was presented with an auditory target tone, rather than an auditory distractor tone or on its own. This was true for the FFA and PPA as well as for early visual cortex. In contrast to the interference effects that are typically observed during divided attention tasks, our data demonstrate that increasing attention to a behaviorally relevant stimulus in the auditory modality can improve information processing in visual areas of the brain. H.T. & R.M. contributed equally to this project.

Title: Sounds reflexively decrease the occipital alpha rhythm: disentangling voluntary and involuntary shifts of cross-modal attention

Authors: *V. S. STOERMER[1], A. T. WALLACE[2], S. A. HILLYARD[3], J. J. MCDONALD[2]; [1]Psychology, Harvard Univ., Cambridge, MA; [2]Simon Fraser Univ., Vancouver, BC, Canada; [3]Univ. of California San Diego, San Diego, CA

Abstract: A salient, peripheral sound can influence visual processing of a subsequent target at the same location. Recently, we discovered that a sound elicits activity over occipital scalp sites even in the absence of visual stimulation, suggesting that a sound activates visual cortex automatically. In particular, we found that a peripheral sound triggers a slow positive deflection over contralateral occipital cortex (the ACOP) that is accompanied by a decrease of the occipital alpha rhythm (8-14Hz) - a brain oscillation that has been linked to visual-spatial attention. Here we explore to what extend these sound-induced changes in occipital alpha activity depend on the voluntary deployment of attention. A salient noise burst was presented on the left or right side and was followed by a masked visual target 1200 ms later. In different conditions, the target always appeared at the same location as the sound (predictive cue) or at a mirror-symmetric location on the opposite side of fixation (counter-predictive cue). Participants were asked to attend to the anticipated target location and to discriminate the identity of the target as quickly as possible. Consistent with the hypothesis that sounds reflexively enhance activity in contralateral visual cortex, alpha-band activity measured over the contralateral occipital scalp dropped ~200 to 500 ms after cue onset in both conditions. While this initial alpha reduction was greater contralateral than ipsilateral for both predictive and counter-predictive sounds, these conditions showed an opposite pattern of contralateral and ipsilateral activity in the later time interval, consistent with the voluntary allocation of attention to the anticipated target location. Overall, these data show that a salient, lateralized sound triggers an initial decrease of the contralateral occipital alpha rhythm regardless of its predictive value, supporting the hypothesis that a salient sound captures attention involuntarily and enhances visual activity in a spatially specific manner.

Title: Predictions, not attention, modulate the first feedforward sweep of cortical information processing

Authors: *H. A. SLAGTER[1], J. ALILOVIC[2], B. TIMMERMANS[2], L. C. RETEIG[2]; [1]Dept. of Psychology, [2]Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Both attention (stimulus relevance) and expectation (stimulus probability) have been shown to alter information processing in primary visual cortex, suggesting that top-down

influences can modulate the very first stage of cortical information processing. However, prior work either confounded attention and expectation, rendering their specific effects unclear, or used fMRI, which has low temporal resolution, leaving it unclear if these effects reflect a modulation of the first feedforward sweep of visual information processing or later, feedback-related activity. The current study orthogonally manipulated stimulus relevance and likelihood while exploiting the high temporal resolution of EEG to investigate if attention and/or expectation can modulate initial afferent activity in V1, as indexed by the early C1 component. Because the C1 is highly variable across individuals, for each participant we first determined two spatial locations at which the C1 could be reliably measured. Next, subjects performed an attentional cuing task in which they were cued on a trial-by-trial basis to direct their attention towards one of these locations and press a button whenever a target stimulus was presented at that location. The probability of a stimulus appearing at a given location was manipulated block-by-block, such that in different blocks the likelihood that a stimulus would appear was high (75%), neutral (50%) or low (25%). ERP analyses revealed that only stimulus probability, not stimulus relevance, had an effect on the amplitude of the C1. Specifically, the C1was largest for predicted stimuli and smallest for unpredicted stimuli. These results may indicate an effect of expectation, not attention, on the first feed-forward sweep of information processing.

Title: An open-source system for EEG-neurofeedback and transcranial current stimulation control: Applications for clinical treatments

Authors: ***B. CULLEN**[1], J. SANTOYO[2], C. KERR[3], C. MCFARLANE-BLAKE[4];
[2]Neurosci., [3]Family Med., [1]Brown Univ., Providence, RI; [4]Boston, MA, Boston, MA

Abstract: We present an open-source EEG hardware and software system for neurofeedback and transcranial current stimulation (tCS) control and discuss its applications for clinical research. Neurofeedback and tCS are non-invasive neuromodulation techniques with demonstrable utility in therapeutic contexts. These techniques allow for the volitional modulation of specifically

targeted neurophysiological signals. Our open-source system offers a cost-efficient approach to EEG and neurofeedback research and allows for customizability to specific research programs. Additionally, this system provides an interface for closed-loop tCS paradigms, wherein specific changes in selected neurophysiological signals can be set to trigger tCS stimulation. This allows for rigorous experimental control and versatility in real-time EEG-based neurofeedback paradigms.This combined neurofeedback and tCS package offers a possibility of supplementing existing neuromodulation techniques and has utility in neuroscience research that seeks to use objective tools of measurement to explore the neurophysiological correlates of first-person experience, e.g. pain sensations. We demonstrate examples for these applications with data that represents successful modulation of somatosensory alpha-band power and by elucidating correlations between changes in EEG recorded alpha-band activity and expert meditators' self-report while viewing a neurofeedback display of somatosensory alpha-band activity.

Title: The neural basis of reward-driven attentional capture

Authors: *L. TANKELEVITCH[1,2], E. SPAAK[1,2], M. F. S. RUSHWORTH[1], M. G. STOKES[1,2];
[1]Exptl. Psychology, [2]Oxford Ctr. for Human Brain Activity, Univ. of Oxford, Oxford, United Kingdom

Abstract: Selective attention is the prioritization of information by relevance, which is often defined by task goals (e.g., searching for food), or by the intrinsic salience of stimuli (e.g., a bright flash). Importantly, attention can also be driven by reinforcement learning, in which stimuli with a history of reward can capture attention in contexts in which they are not task-relevant, intrinsically salient, or rewarded. Here we show that human subjects' response times and discrimination performance are affected by reward-driven attentional capture, and probe the neural dynamics of these effects.
First, subjects completed a learning task in which they aimed to maximize their monetary rewards by choosing between visual tokens, each associated with a certain reward outcome.

They then completed a visual discrimination task, in which they had to report the orientation of a lateralized target grating, while ignoring a distracter grating. Importantly, subjects also encountered the previously rewarded - but now irrelevant - tokens appearing around the gratings. A low or high value token could appear around the target (congruent trials) or around the distracter grating (incongruent trials). To investigate the timecourse of reward-driven attention, the tokens appeared at 1000, 500, or 0 ms delays relative to the gratings.
Subjects' response times were slower in incongruent and faster in congruent trials, relative to a neutral condition in which only zero-value tokens were encountered. Moreover, subjects were also worse at discriminating the target in incongruent trials. Critically, these effects were modulated by reinforcement learning, occurring only for the high value tokens, and appeared in all delay conditions.
In parallel, we used magnetoencephalograpy (MEG) to record brain activity as participants completed both tasks. Focusing on the discrimination task, preliminary results show that alpha-band (8-12 Hz) lateralization, an index of spatial attention, is modulated by the presence of task-irrelevant but previously high-value tokens. Moreover, reward history information is decodable from the brain as early as ~250 ms after stimulus onset, and dissipates ~500 ms later. These results indicate that reward-driven attentional capture can be indexed by multiple neural measures of attentional allocation, and further our understanding of the interaction between reinforcement learning and selective attention.

Title: The role of confidence in self-reported mind wandering and task engagement: an fMRI investigation

Authors: E. DENKOVA, M. KRIMSKY, A. B. MORRISON, *A. P. JHA;
Univ. of Miami, Coral Gables, FL

Abstract: Mind wandering (MW), defined as off-task thinking that is self-generated and unrelated to the task at hand, has seen a recent escalation as a topic of interest in the cognitive

neuroscience literature. Recent neuroimaging studies investigate the neural underpinnings of MW, which has typically been assessed through subjective reports collected in response to probe questions embedded in a cognitive task. Yet, very little is known about the factors that may modulate the neural correlates underlying self-reports of MW. Here, we investigated the neural correlates of self-reported task engagement *vs.* MW during an attention task by considering participants' confidence in these self-reports. We collected functional Magnetic Resonance Imaging (fMRI) data from 38 participants while they completed the sustained attention to response task (SART) with embedded experience sampling probe-questions. The first question assessed participants' experience of task engagement *vs.* mind wandering using a dichotomous judgment of 'on task' *vs.* 'off task'. The second question assessed participants' level of confidence in their self-reports of 'on task' and 'off task' using a 4-point Likert scale. In the fMRI analysis, the 6s periods preceding the participants' response to the first probe question were modeled as a function of 'on task' *vs.* 'off task' reports, while confidence ratings were considered as a parametric modulator on a trial-by-trail bases. The fMRI results revealed that level of confidence in 'on-task' *vs.* 'off-task' reports differentially modulated dorsal *vs.* ventral lateral regions of the prefrontal cortex (PFC), respectively. Particularly, higher confidence in being 'on task' was associated with greater dorsolateral PFC, while higher confidence in being 'off task' was associated with ventrolateral PFC. These findings pinpoint the importance of considering the level of confidence as a form of meta-cognitive assessment in the investigation of the neural mechanisms underlying self-reports of task engagement and MW. The present study sheds light on the engagement of brain regions associated with executive control as a function of confidence in subjective reports.

Title: Exploring markers for neurofeedback-based augmentation of effortless awareness meditation.

Authors: *R. VAN LUTTERVELD[1], E. VAN DELLEN[2], S. HOULIHAN[3], P. PAL[1], K. STAM[4], J. BREWER[1];
[1]Preventive Med., Univ. of Massachusetts, Worcester, MA; [2]Univ. Med. Ctr., Utrecht, Netherlands; [3]MIT, Cambridge, MA; [4]VUmc, Amsterdam, Netherlands

Abstract: Introduction: Meditation has shown beneficial effects for multiple psychiatric disorders. However, learning to meditate is not straightforward as there are no easily discernible outward signs of performance and thus no direct feedback is possible. Real-time neurofeedback based on signals that are associated with effective meditation practice may provide a solution to this issue. We showed in a previous study that EEG source-estimated neurofeedback corresponds with the subjective experience of effortless awareness (which is a major component of meditation). In the present study, we aim to identify additional potential neurofeedback targets by comparing EEG activity between novice and experienced meditators during effortless awareness practice. These can then be tested in further neurophenomenology experiments for their temporal association with the subjective experience of effortless awareness and potential efficacy in increasing specificity of the EEG source-estimated neurofeedback signal.
Methods: Sixteen experienced meditators and sixteen age and gender matched novice meditators participated in the study. Experienced meditators performed a self-selected meditation practice that supported effortless awareness and novice meditators were briefly trained to perform a basic meditation practice. Eyes-open EEG recordings were obtained while participants meditated. Power in the theta (4-8 Hz), alpha (8-13 Hz) and beta (13-20 Hz) frequency bands was calculated for 19 EEG sensors covering the whole head. Mean functional connectivity per electrode was assessed using the phase-lag index (PLI). Differences between groups were assessed using repeated-measures analysis of variance (ANOVA).
Results: For alpha power, a significant interaction ($p=0.10$) was observed as well as a significant between group difference ($p=0.027$). Post-hoc testing showed increased power in the F3, P4, O2 and Pz electrodes in the experienced group compared to the novice group. Visual inspection revealed that median alpha power was higher in the experienced group for all 19 electrodes (range 29 – 204%, median 80%). For functional connectivity in the alpha band, a significant group difference ($p=0.009$) was observed. Post-hoc testing showed increased functional connectivity in the experienced meditator group compared to the novice group in 15 electrodes. Visual inspection revealed that median functional connectivity was higher in the experienced group for all 19 electrodes (range 9-24%, median 17%).
Discussion: Global alpha power and functional connectivity might be explored further as potential neurofeedback targets to augment effortless awareness.

Title: Reconstructing location-selective population codes during the attentional blink

Authors: *M. MACLEAN[1,2], T. BULLOCK[1,2], B. GIESBRECHT[1,2];
[1]Inst. for Collaborative Biotechnologies, [2]Psychological & Brain Sci., Univ. of California Santa Barbara, Santa Barbara, CA

Abstract: Following the presentation of a target (T1) embedded in a rapid serial visual presentation, the ability to detect or identify a subsequent target (T2) is impaired for ~ 500 ms, an effect referred to as the attentional blink (AB; [Raymond, Shapiro, & Arnell, 1992]). Some evidence suggests that the locus of this effect is post-perceptual [Vogel, Luck, & Shapiro, 1998], such as a temporary loss of control over attention [Di Lollo, Kawahara, Ghorashi, & Enns, 2005]. In the current experiment we used an inverted encoding model to estimate location-selective channel tuning functions (CTFs) from scalp recorded EEG in the alpha-band for location information [Garcia, Srinivasan, & Serences, 2013] as a model for selective attention. If the AB affects early selectivity then the profile of the CTF should change during the AB period relative to the pre-T1 period. Participants (n = 4) observed a flickering Gabor presented in the periphery for 3 seconds. The Gabor briefly (100 ms) rotated either clockwise or anti-clockwise (T1), followed by a Gabor of a different orientation (T2) either 200 (lag 2) or 900 ms (lag 9) later. Participants reported the direction of the T1 rotation (CW/ACW), and then reported the orientation of T2 on a continuous scale. We modeled the degree of error in the T2 response [Bays & Husain, 2008; Zhang & Luck, 2009] and found that the precision of T2 report was reduced at lag 2 (k = 24°) as compared to lag 9 (k = 20°; p = .17), indicating the presence of an AB effect. We calculated average slope and amplitude of the location-selective CTF for three time points: pre-T1 (-800-0 ms), immediately post-T1 (0-200 ms), when lag-1 sparing is observed [Di Lollo et al., 2005], and during the AB (200-400 ms). We did not observe a decrement in either the slope (*pre-T1* = .02 μV^2/10°, *SE* = .002; *lag 1* = .02, *SE* = .009; *AB* = .03, *SE* = .009) or the amplitude (*pre-T1* = .14 μV^2, *SE* = .02; *lag 1* = .19, *SE* = .04; *AB* = .17, *SE* = .06) of the location-selective CTF profile during the AB. Furthermore, amplitude of the CTF was greater during the lag-1 period, relative to the pre-T1 period (p = .10). This increase fits with the theoretical account of an initial “boost” of attention following T1, also thought to cause lag-1

sparing [Olivers & Meeter, 2008]. Our results indicate that the selective representation of location information was not disrupted during the AB period.

Title: Neurophysiological correlates of deliberate and spontaneous mind-wandering

Authors: *A. MARTEL[1], M. ARVANEH[4], P. DOCKREE[2], I. ROBERTSON[3];
[2]Sch. of Psychology, [3]Trinity Institue of Neurosci., [1]Trinity Col. Dublin, Dublin, Ireland; [4]Dept. of Automatic Control and Systems Engin., Univ. of Sheffield, Sheffield, United Kingdom

Abstract: *Motivation:* Recent years have witnessed a substantial increase in the number of neuroscientific studies investigating mindwandering, i.e. selfgenerated, taskindependent thoughts. Latest findings suggest that mindwandering is a heterogenous class of mental states and many authors now argue in favor of the differentiation of mindwandering (MW) with and without awareness (Smallwood and AndrewsHanna 2013; Seli et al. 2015; Fox et al. 2015) . The former being described as an intentional, controlled or deliberate MW (dMW) and the latter as unintentional or spontaneous MW (sMW). *Aim:* The aim of the present study was to identify neurophysiological differences between sMW and dMW. *Material and Methods:* 26 subjects (12 female; 23.4 ± 3.2 years) performed two tasks, a breathcounting (BC) task and a fixed version of the SART (Robertson et al. 1997) while electroencephalography (EEG) data was recorded. MW was assessed in both tasks with 5scale selfinitiated or randomly interrupting thought probes with the following options: Attention was (1) ontask (no mindwandering), (2) on thoughts pertaining to the task, (3) distracted by internal sensations or external distractions, (4) on reminiscing or planning thoughts (dMW), (5) daydreaming (sMW). *Results :* Behavioral results revealed significant differences in response time coefficients of variability (RTCV) for grouped trials leading up to reports of focused attention, dMW and sMW during the SART. Analysis of the 64-channel EEG recorded data revealed that average α activity prior to thought probes differentiates between the ontask and sMW conditions as well as between dMW and sMW conditions. Time-frequency analysis revealed increased activity in the α band and decreased activity in the lower- ;;, ;; and lower- ;; bands between dMW and sMW for both tasks. Eventrelated potentials (ERPs) for the SART trials preceding MW reports exhibited significant differences across all conditions. P3a components gradually decreased in amplitude for SART trials leading up to

dMW and sMW reports when compared to ontask reports with the most pronounced decrease for the sMW condition. These results demonstrate that both dMW and SMW have distinct behavioral and neurocortical signatures.

Title: Interactions between prefrontal cortex and temporal lobe during selective attention in a cocktail party task

Authors: *A. DE PESTERS[1,2], P. BRUNNER[1,3], G. SCHALK[1,2,3];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [2]State Univ. of New York at Albany, Albany, NY; [3]Dept. of Neurol., Albany Med. Col., Albany, NY

Abstract: The cocktail party effect describes the ability to focus on one of several simultaneous auditory streams. Recent studies have established that cortical activity in specific frequency bands and cortical locations selectively tracks the attended auditory stream (Mesgarani and Chang, 2012; Golumbic et al., 2013), but the mechanisms that support this function have been unclear.
It is well established that the prefrontal cortex (PFC) plays a crucial role in the top-down modulation of attention, in particular during complex cognitive tasks (Zanto et al., 2012; Voytek et al, 2015). In addition, previous studies have shown that variations in oscillatory activity in the alpha band (8-12 Hz) may implement top-down modulation of cortical activity by increasing excitability in task-related areas and inhibiting it in task-unrelated ones (Klimesch et al., 2007; de

Pesters et al., 2016). Based on this evidence, we hypothesized that the PFC may be involved in selective auditory attention. Specifically, we hypothesized that the PFC receives task-relevant information from early auditory cortex and perisylvian areas, and may use this information to exert modulatory influences of cortical excitability in those same areas.
To investigate the interplay between bottom-up sensory input and top-down modulation of auditory attention, we recorded electrocorticographic (ECoG) activity from subdural electrode grids in ten human subjects during a cocktail party task. The subjects were asked to focus on one of two simultaneously presented speakers. Our results demonstrated the existence of two distinct populations of cortical locations within perisylvian areas. The first subset of locations responded mostly to the attended speaker, while the second subset responded to both attended and unattended speakers, thereby confirming the findings from previous studies (Golumbic et al., 2013; Dijkstra et al., 2015). More importantly, we found that locations from both subsets of auditory locations modulated PFC population-level cortical activity in the broadband gamma (> 70 Hz) range. In turn, cortical excitability (as measured by the power in the 8-12 Hz band) in those same subsets was modulated by population-level cortical activity in the PFC. These interactions were specific to the attended speaker.
In sum, our results suggest that the PFC receives information about the attended auditory stream from auditory cortical areas, and that the PFC in turn modulates cortical excitability in auditory cortical areas. We expect that these results help to clarify our understanding of the relationship between PFC and auditory areas during selective auditory attention in a cocktail party.

Title: Alpha desynchronization during a visual-spatial attention task in concussed athletes.

Authors: *S. GUAY[1], L. DE BEAUMONT[1], P. JOLICOEUR[2];
[1]Dept. de psychologie, Univ. Du Québec À Trois-Rivières, Trois-Rivières, QC, Canada; [2]Univ. de Montréal, Montreal, QC, Canada

Abstract: ***Objective*:** To report Alpha amplitude/power baseline and investigate event-related spectral perturbations (ERSPs) in alpha-band activity in multiply concussed athletes relative to unconcussed athletes.
Background: Event-related potentials (ERPs) have been useful to detect persistent subclinical

alterations of cognitive processes in concussed athletes. Studies interested in ERP markers of attention revealed significant N1, P2 and P3 amplitude alterations in asymptomatic concussed athletes. Pertinently, concussion effects on these ERP markers of attention and working memory were found to be exacerbated with recurrent concussions.
***Design/method*:** A total of 45 university football players were assigned to three experimental groups based on prior concussion history: Athletes with a single-concussion history (n = 15); Athletes with two or more concussions (n = 15, M = 2.8, SD = 1.32); and a control group of non-concussed athletes (n = 15). Time since last concussion was more than nine months and the average post-concussion time was two years. We studied the long-term and cumulative effects of concussion on alpha-frequency Event-related desynchronization (ERD) when performing a visuospatial attention task.
***Results**:* This study found that the baseline Alpha amplitude/power was significantly lower in the multi-concussion group compared to the control group, $F(1,29) = 4.54$, $p = .04$. After correction for baseline alpha activity, Alpha ERD was still significantly reduced among the multi-concussion group ($F(1,29) = 8.03$; $p = .009$) and the latter was negatively associated with baseline Alpha ($r(24) = -.786$, $p = .002$).
Conclusion: This finding suggests that recurrent concussions significantly alter Alpha rhythm ERD elicited by a visual-spatial attention task. Baseline Alpha activity was found to strongly predict subsequent Alpha ERD amplitude in athletes with recurrent concussions. Baseline alpha activity and Alpha ERD disruptions could underlie known attention-related ERP alterations in recurrent concussion athletes.

Title: Development of a closed-loop feedback system using eye-tracking technology to train sustained attention

Authors: *K. E. SELOFF[1], T. B. NGUYEN[2], J. L. MOSES[3], C. G. BEEVERS[3], D. M. SCHNYER[3];
[1]Inst. for Neurosci., [2]Neurosci., [3]Psychology, Univ. of Texas At Austin, Austin, TX

Abstract: Sustained attention is critical in everyday functioning and has been shown to be limited, with healthy individuals showing a decrease in sustained attention after as little as 5 minutes. Previous work using closed-loop real-time fMRI neurofeedback to improve sustained attention demonstrated that providing feedback on attentional focus by altering the display saliency was effective in improving sustained attention on a real-time Attention Training version of the Sustained Attention to Response Task (rtAT-SART). This paradigm rewarded participants for sustained attention by making the task easier and alerted participants to lapses in attention (ideally before those lapses affected task performance) by making the task more difficult. We are conducting a preliminary investigation of a closed-loop eye-tracked Attention Training version of the SART (etAT-SART) that modifies the rtAT-SART to use gaze data obtained from an eye-tracker instead of neural data obtained from rtfMRI as the basis for capturing attentional focus and adjusting feedback. Our preliminary study included 32 healthy undergraduate students, 12 of whom received real-time feedback based on whether or not they were attending to the target location during the etAT-SART and 20 of whom served as no-feedback controls. Preliminary results have shown that gaze accuracy (percentage of time on the instructed target image, as opposed to the distractor image) improves in response to feedback (mean improvement of 11.8% from the pre-training test), but does not change in no-feedback controls (mean improvement of 0.9% from the pre-training test) ($t(13.51) = 4.34$, $p < 0.001$, Cohen's $d = 1.7$). This suggests that visual search patterns are altered in the presence of gaze-based feedback. Additionally, task performance on the SART shows a trend for improvement from the pre-training test to the post-training test in the feedback group (normalized A' change score of 0.019), but not in the no-feedback control group (normalized A' change score of 0.001) ($t(17.59) = 1.44$, $p = 0.169$). This suggests that gaze-based feedback can improve sustained attention similarly to its neurofeedback predecessor. We plan to analyze the fixation and scan path data from the eye-tracking system in a post-hoc manner to determine the optimal method of classifying the attended image in the etAT-SART. We will then investigate the use of this classification method as the basis for providing feedback in our closed-loop system. Once the task has been optimized, we plan to examine whether it can be used with negative stimuli (e.g. sad faces) as distractors to decrease negative attention bias in individuals with elevated depressive symptoms.

Title: Cortical and subcortical involvement in switching between task positive network and default mode network

Authors: *R. LI[1,4], D. KLUGER[1], E. LEVINSOHN[1], Y. CHEN[1], W. XIAO[1], H. BLUMENFELD[1,2,3];
[1]Dept. of Neurol., [2]Dept. of Neurosci., [3]Dept. of Neurosurg., Yale Univ. Sch. of Med., New Haven, CT; [4]Key Lab. for Neuroinformation of Ministry of Education,School of Life Sci. and Technol., Univ. of Electronic Sci. and Technol. of China, Chengdu, China

Abstract: The human brain is organized into dynamic correlated and anti-correlated functional networks. Cognitively demanding tasks have consistently been shown to evoke activation of the brain's task positive network (TPN) and induce deactivation in the default mode network (DMN).However, the neural mechanisms underlying this switching between activation and deactivation of brain networks are not completely understood. Here, we used task functional magnetic resonance imaging (fMRI) to investigate the switch-like mechanisms in the brain that turns these networks on and off. We acquired task-fMRI data of 22 normal children (ages 11-16) completing a block-design continuous performance task (CPT). The average percent signal changes across all the blocks and subjects were calculated to examine brain changes during the switching process. In addition, we performed time course analyses for regions of interest (ROIs) extracted from the TPN and the DMN to describe the switching changes occurring with onset and offset of task. We observed significant activation of a network comprising the precuneus, anterior insula, supplementary motor area, medial thalamus, and midbrain during both onset and offset of task. Although the general view is that the TPN and the DMN are anti-correlated and have sustained activation or deactivation during task, our results suggested that some regions within the TPN and the DMN show increased activity both as a response to the onset of task and as a response to the offset of task. Moreover, we demonstrated a potential role for subcortical structures in mediating the switch between passive fixation and active task performance. Our findings provide new insights into the network switching mechanisms between brain networks involved in externally oriented attention and internally oriented mental processes.

Rotterdam, Rotterdam, Netherlands

Abstract: Research suggests that mindfulness-practices may aid smoking cessation. Yet, the neural mechanisms underlying the effects of mindfulness-practices on smoking are unclear. Response inhibition and performance monitoring are main deficits in addiction, associated with relapse. Notably, both functions are candidate targets for mindfulness-based practices. Using electroencephalography (EEG), the current study therefore investigated the effects of a brief mindfulness-practice on both functions in smokers. Participants underwent a cigarette cue-exposure, and were then randomly assigned to a group receiving mindfulness instructions or to a non-instruction control group. Then, they performed a smoking Go/Nogo and Flanker task, while their brain activity was recorded. No group differences in task performance were observed. However, EEG analyses revealed a decrease in Nogo-P3 amplitude in the mindfulness versus control group. As both groups performed equally well, the reduced P3 might indicate less-effortful response inhibition after the mindfulness-practice, and suggest that enhanced response inhibition underlies observed positive effects of mindfulness on smoking behavior.

Title: Cognition, Disinhibition and sexual risk behavior among African American adolescent females

Authors: *S. G. DALMIDA;
Capstone Col. of Nursing, UNIVERSITY of ALABAMA, Tuscaloosa, AL

Abstract: Introduction: Adolescence is characterized by immature executive function and risk taking behavior. African American (AA) girls engage in higher sexual risk behavior (SRB) and are disproportionately affected by HIV and sexually transmitted infections (STIs), yet knowledge gaps persist regarding the role of neurocognitive determinants of AA girls' SRB.

Method(s): This cross-sectional study, guided by the Biopsychosocial Model of Risk Taking, examined the: 1) neuro-psychosocial profile of girls with high SRB vs low SRB and 2) association between depression, sensation seeking/disinhibition, cognitive function and SRB in a sample of 65 AA girls ages 15-23 years. Each participant and/or parent provided written informed consent and/or assent. Girls completed CANTAB computerized cognitive function tests, including the Information Sampling Task (IST) and Cambridge Gambling Task (CGT) and demographic, psychosocial and SRB surveys. Scores >1 on a SRB index (0-6) indicated high SRB. Bivariate correlations, ANOVA and regression statistics were used.

Results: Mean age was 17.8±1.9 years. Mean age at sexual debut was 15.5±2.6. Girls with high SRB (vs low SRB) were/had significantly: older (18.6 vs 16.9) and greater mean: depression (11.58 vs 7.26), disinhibition (4.29 vs 2.77) and lower mean: coping (165.14 vs 177.73) and accuracy on IST (poorer impulse control) (6.43 vs 7.38). Higher SRB scores were significantly ($p<.05$) associated with higher: age ($r= .41$), disinhibition ($r=.34$), depression ($r=.33$), boredom susceptibility ($r=.27$) scores and poorer/lower: coping ($r=-.26$), seeking spiritual support ($r=-.29$) and impulse control: IST sampling errors ($r=.30$), IST total correct ($r=-.30$), IST mean # boxes opened/trial ($r=-.32$). Some AA girls with high reported SRB (compared to low SRB) showed greater cognitive delay aversion during reward-related risk-taking (CGT). Girls with higher disinhibition were more likely to have higher SRB [$Exp(B)=3.08$, $p=.09$], while accounting for covariates (all non-significant). Greater disinhibition was also ($Beta= .47$, $p=.001$) associated with higher SRB index scores in a model accounting for 58.7% variance ($R2=.587$), beyond covariates (non-significant).

Discussion & Conclusions: Higher SRB was associated with disinhibition and poorer impulse control and poorer decision making, in our sample of AA girls. Those interested in helping AA girls to minimize their SRB should provide tailored HIV/STI prevention efforts based on important links between psychosocial factors, including disinhibition, and impulse control. Findings can be used to facilitate future imaging, longitudinal and intervention studies.

Title: Brain signal variability in monolinguals and bilinguals

Authors: J. GRUNDY[1], *J. A. ANDERSON[2], E. BIALYSTOK[1];
[1]Psychology, York Univ., Toronto, ON, Canada; [2]Psychology, York Univ., Etobicoke, ON, Canada

Abstract: Bilinguals constantly use cognitive control to manage competition between languages that compete for selection (Green, 1998). Practice with this control might lead to domain-general enhancements in executive functioning (EF; Bialystok, Craik, & Luk, 2012). Support for this view has appeared on a range of EF tasks in both children (e.g. Barac, Bialystok, Castro, & Sanchez, 2014) and older adults (e.g. Bialystok, Craik, Klein, & Viswanathan, 2004) showing that bilinguals outperform their monolingual peers. Behavioral findings from young adults are more variable. In light of this, some have questioned whether second-language experience leads to domain-general cognitive changes (e.g. Paap & Greenberg, 2013). However, similar behavioral outcomes can emerge from quite different cognitive processes. This is especially true for young adults who often perform at ceiling on these tasks. The present study examined brain signal variability using multiscale entropy (MSE; Costa, Goldberger, & Peng, 2002) analysis. EEG was recorded while young adult monolinguals (N=20) and bilinguals (N=20) performed a task-switching paradigm. Brain signal complexity increases with development and is inversely related to reaction time (RT) variability (McIntosh, Kovacevic, & Itier, 2008). If lifelong bilingualism contributes to development of domain-general EF, then bilinguals should show greater brain signal variability while performing an EF task, even in the absence of mean RT differences. Results revealed that brain signal variability was greater for bilinguals than monolinguals in occipital, but not frontal electrode sites. Furthermore, signal variability predicted RT differently for bilinguals than monolinguals: Greater signal variability was associated with faster RTs in bilinguals but slower RTs in monolinguals. These findings suggest that bilinguals make use of brain complexity (i.e. signal variability) in a way that monolinguals do not.

Title: Perceptual difficulty and its effect on response inhibition using the modified stop-signal paradigm

Authors: *M. V. SOLOVEVA[1], S. JAMADAR[1], G. POUDEL[1], M. HUGHES[2], N. GEORGIOU-KARISTIANIS[1];
[1]Monash Univ., Melbourne, Australia; [2]Swinburne Univ., Melbourne, Australia

Abstract: The stop-signal paradigm has been widely used in behavioural research as a measure of response inhibition, a core component of cognitive control. It is known that stopping behaviour can be accounted for by assuming that a race between independent 'go' and 'stop' processes determine whether inhibition is successful or not. The interplay between the 'go' vs 'stop' processes and the quality of visual information and its impact on inhibition has also gained much interest in the literature. However, a few studies have examined how perceptual difficulty of the 'go' stimuli may indirectly affect the 'stop' process. In this experiment, we assessed how parametrically manipulating perceptual difficulty of the 'go' stimuli affects response inhibition, as measured by stop-signal reaction times (SSRTs) and probability of inhibiting (P_i). Eight healthy individuals (4 female and 4 male) (M = 30.00; SD = 6.00) underwent a modified 22-minute stop-signal task, where traditional 'go' stimuli (i.e., arrows) were replaced by images of 'Y' and 'V' letters with low, intermediate-1, intermediate-2, and high levels of perceptual clarity (levels of Gaussian blur). On 33% of trials, the stop-signal (50 ms audio tone) followed the 'go' stimuli after a brief interval (the stop-signal delay, SSD), which was individually adjusted for the participant to reach a minimum of 50% accuracy for the stop trials. Results showed that reaction times to the 'go' stimuli significantly increased with increased perceptual difficulty, $F(3, 18) = 6.07$, $p < .005$, = .50. No significant effect of perceptual difficulty on P_i and SSRTs was observed, however, a trend towards significance ($F(3, 18) = 2.51$, $p = .09$) was observed for Pi, indicating a trend towards higher probability of inhibiting as a function of perceptual difficulty. Our results indicate that 'go' and 'stop' processes are independent as assumed by the race model. These preliminary findings have implications for the relationship between the 'stop' and 'go' processes but require further validation if we are to disentangle how perceptual load may influence response inhibition.

Title: Exploring human cognition research on a large scale through the Human Cognition Project

Authors: *K. KERLAN, N. F. NG, C. M. SIMONE, E. CORDELL, M. SCANLON;
Lumos Labs, Inc., San Francisco, CA

Abstract: Our growing understanding of human cognition has been impeded by conventional research methods involving many small-scale studies with local convenience samples at individual university laboratories utilizing incomparable task designs. These methods make cognition research slow, costly, and difficult to replicate. The Human Cognition Project (HCP) is a large-scale, online science project aimed to complement traditional laboratory-based experimental approaches used in the cognitive sciences. Inspired by Lumosity's web-based cognitive training platform that includes a suite of games, assessments, surveys, and tracking metrics, the HCP advances studies of cognitive training by supporting world-wide collaborations and offering researchers access to the largest database of human cognitive performance, with data from over 80 million individuals to date.
The HCP is guided by the hypothesis that bringing together a broad network of academic scientists and clinicians will accelerate investigations of cognitive functions such as processing speed, working memory, visual attention, and flexibility, thereby advancing the field of human cognition. Since the project formally began in 2011, HCP has resulted in twelve peer-reviewed publications. Ongoing studies include investigations of population trends in cognitive changes across the lifespan, neuroplasticity associated with targeted cognitive processes, and effectiveness of cognitive training as a neurotherapeutic tool for individuals affected by mild cognitive impairment, Multiple Sclerosis, stroke, ADHD, cancer, and TBI. Here we present an overview of the HCP science model as well as several primary findings from published studies that have resulted from the project.

Title: Attentional modulation of response inhibition in a Go/No-Go task: spatio-temporal oscillatory dynamics in an anatomically constrained MEG model

Authors: J. P. HAPPER[1], L. C. WAGNER[1], L. E. BEATON[1], B. Q. ROSEN[2], *K. MARINKOVIC[1,3];
[1]Psychology, San Diego State Univ., San Diego, CA; [2]Neurosciences, [3]Radiology, UCSD, San Diego, CA

Abstract: Response inhibition is an integral aspect of cognitive control whose neural mechanisms have been studied extensively. However, the attentional aspects of response inhibition have not been fully elucidated. To investigate the effects of attentional capture on response inhibition, 22 healthy right-handed participants (10 female) performed a modified Go/No-Go task. Stimuli consisted of the letters 'X' and 'Y' where a Go stimulus was the alternation and a No-Go stimulus was the repetition of letters (20% of trials). Participants responded to Go stimuli using their right index finger. Equal numbers of Go and No-Go stimuli were altered in both size and color to be more visually salient (SAL). Participants were asked to respond in the same manner to SAL stimuli as the regular, non-modified stimuli (REG). Whole-head magnetoencephalography (MEG) data were recorded with Neuromag Vectorview (Elekta). The signal was spectrally decomposed for each trial using Morlet wavelets in the theta (4-7 Hz) and beta (15-25 Hz) frequency bands. Each participant's cortical surface was reconstructed from high-resolution anatomical MRIs and served to constrain the distributed minimum norm inverse estimates. Behaviorally, task accuracy was differentially affected by stimulus type where SAL stimuli improved accuracy on No-Go trials but hindered accuracy on Go trials. Similarly, SAL Go response times were slower than REG Go, reflecting attentional capture. Successful response inhibition elicited an event-related theta power increase, peaking at ~300 ms, in a bilateral network including the inferior frontal, anterior cingulate, and insular regions, and right lateral temporal cortex. Overall there was a greater theta band increase in response to SAL stimuli compared to their REG counterparts as well as increased theta power to No-Go compared to Go trials. However, the anterior cingulate, inferior frontal, and lateral temporal regions showed particular sensitivity such that the theta power was the greatest to SAL No-Go trials. Though the activation in the anterior cingulate and inferior frontal region was bilateral, the theta power

increase estimated to the lateral temporal cortex was strongly right-lateralized. As expected, the event-related decrease in beta power was especially marked over the left motor regions subserving right-hand response preparation and execution. The beta band decrease was greater on SAL Go trials, indicating that the attentional capture affects motor output during downstream processing. Taken together, these data suggest that attentional capture plays a crucial role in informing and invoking the response inhibition system in an interactive manner.

Title: Surprising events interrupt visuospatial working memory

Authors: ***R. D. FINZI**[1], F. MARINI[1], B. R. POSTLE[2], A. ARON[1];
[1]Univ. of California San Diego, La Jolla, CA; [2]Univ. of Wisconsin-Madison, Madison, WI

Abstract: When a surprising event, such as a car honking, occurs in daily life, we often find that our ongoing train of thought is interrupted and consequently forgotten. In the lab, this situation has been modeled using a task of verbal working memory (WM) that is disruptable by surprising events. Using this paradigm, it has been shown that the disruption of verbal WM relates to the same fronto-basal ganglia mechanism that is thought to underlie the outright stopping of action (Wessel et al., 2016). While this provides new insights into the relationship between surprising events, WM, and motor inhibitory control, and could help to explain one form of distractibility, is it unknown whether the effect was due to the fact that verbal WM uses auditory and speech-based mechanisms, which may be especially disruptable by motor inhibitory control, and if the effect is thus specific to verbal WM. Moreover, the disruption effect observed in the previous study was short lasting; therefore whether the disruption effect can be extended across time remains to be established. Here we devised a visuospatial retro-cue paradigm. Participants were shown a number of square stimuli, based on an estimate of Cowan's *k* for each participant, in succession (each square was in a different position on the screen) and were then probed to recall the location of one of the squares. The probe consisted of a number cue indicating to participants which square of the sequence they would need to remember. Prior to presentation of the probe, a

sound was played. In Experiment 1 ($N = 16$), the sound was either a standard 600 Hz sine-wave tone (80% of trials) or a novel (a unique birdsong segment, 20% of trials), each played for 200 ms. While the proportion of novel trials was the same as in Wessel et al., 2016, nearly twice as many trials were used overall. We found a significant effect of surprise on visuospatial WM (as measured by the distance from the response location to the centroid of the target square) with decreased response precision after novel versus standard tones ($t(15) = 2.98$, $p = .009$, $d = 0.46$). We then replicated this effect in Experiment 2 ($N = 16$, $t(15) = 5.00$, $p < .001$, $d = 0.66$), including two types of surprising events: unique birdsong segments and longer duration sine-wave tones (500 ms), extending our findings to a different type of auditory novel. Thus, surprise impacts not only verbal WM (as in our earlier studies), but also visuospatial WM. Additionally, we show that the effect of surprise on cognition persists twice as long as previously shown, and that multiple types of novel events can produce the effect. This experimental paradigm is a good platform for further investigation of the neural correlates of the effect of surprise on WM.

Title: Cognitive control networks route task information to other networks via intrinsic functional connectivity pathways

Authors: ***T. ITO**, D. H. SCHULTZ, L. I. SOLOMYAK, R. H. CHEN, R. D. MILL, M. W. COLE;
Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ., Newark, NJ

Abstract: Functional connectivity (FC) patterns during rest and task are highly similar, suggesting an underlying intrinsic FC architecture shared between these states (Cole et al., 2014). Despite this, recent studies have provided evidence that cognitive control networks flexibly represent a dynamic range of task information through activity patterns and widespread task-evoked FC changes (Waskom et al., 2014; Cole et al., 2013). Here, we tested the hypothesis that intrinsic FC pathways carry the flow of task activity from cognitive control networks to content-related (e.g., visual and motor) networks to help implement task demands. We collected resting-state and task functional magnetic resonance imaging (fMRI) data while subjects performed a

complex cognitive paradigm involving the learning and implementation of multiple task rules (C-PRO, a variant of the paradigm from Cole et al., 2010). Using a recently developed method that linearly maps activity flow between regions via FC modulation, we extracted trial-by-trial task-rule activity patterns and mapped activity flow between networks. To test the information content of task-rule activity in the predicted network, we trained a linear classifier on predicted data while testing the classifier on the network's real data. We found that task-rule activity patterns generated in cognitive control networks could predict activity in content-related networks via activity flow for each of the three rule types (logic, sensory, and motor). Furthermore, network-to-network activity flow mappings were specific to the predicted network's functional relevance to the decoded rule type (e.g., motor network mappings for motor rules). To validate the computational principles underlying this approach, we constructed an abstract neural network model organized with distinct network communities to verify whether task activations in specific networks could be predicted based on network topology. Indeed, we found that intrinsic functional connectivity architectures could successfully predict the channels of activity flow. These findings suggest two conclusions: (1) Intrinsic FC reflects an underlying architecture that carries task information in the form of activity flow (the spread of cognitive task activation amplitudes), as validated through both empirical fMRI data and computational network models; (2) Flexible representations of task activity patterns in cognitive control networks contain information to downstream activity patterns in content-related networks.

Title: Exploring the relationship between psychopathic traits and cognitive control performance in the context of reward

Authors: ***A. M. HOWELL**[1], T. SALO[2], P. K. PATEL[1], S. R. ASHBY[3], T. A. NIENDAM[1], T. A. LESH[1], C. S. CARTER[1];

[1]UC-Davis Imaging Res. Ctr., Sacramento, CA; [2]Florida Intl. Univ., Miami, FL; [3]Univ. of Oregon, Eugene, OR

Abstract: Although psychopathic traits (PT) are most often linked to emotional deficits, recent literature has shown PT are also linked to abnormal brain activation during cognitive control and reward processing tasks. However, the relationship between PT and cognitive control in the context of reward has not been studied extensively. We sought to explore the relationship between level of PT and engagement of cognitive control and reward networks. Specifically, we hypothesized that higher PT would relate to decreased activation in cognitive control networks and increased activation in reward systems.

Twenty-six healthy control participants completed the Incentivized Control Engagement Task (ICE-T), an incentivized version of a delayed match-to-sample task that separates reward anticipation and reward consumption in the context of cognitive control during fMRI. Participants also completed the Levenson Self-Report Psychopathy Scale (LSRPS) to determine level of psychopathy traits. Whole-brain regression analyses examined the relationship between LSRPS scores and BOLD activity during high versus low cognitive control trials as well as reward versus neutral trials. Whole-brain analyses were height thresholded at $p<.005$ and cluster-corrected at FWE $p<.05$.

LSRPS scores did not relate to participant's ability to perform more accurately or rapidly during high versus low cognitive control or rewarding versus neutral trials. Neuroimaging data indicated that higher LSRPS scores were associated with decreased BOLD during trials requiring higher cognitive control in the DLPFC, inferior parietal cortex, temporal lobe, somatosensory cortex, and cerebellum. While LSRPS did not show a significant relationship between BOLD and reward anticipation, significantly increased activity during the consummatory phase of reward compared to neutral trials was identified in DLPFC, ventral striatum, inferior parietal cortex, anterior cingulate cortex, thalamus, and supplementary motor cortex.

Neuroimaging data showed global cognitive control deficits and increased reward sensitivity in relationship to PT. Furthermore, people with increased PT engaged their attention and salience networks more during reward versus neutral trials. We hope to expand these results with further analyses differentiating the effects of affective/interpersonal (F1) and antisocial/lifestyle (F2) traits and compare individuals with unique combinations of F1 and F2 traits. Additionally, we hope to further assess the interaction of cognitive control and reward performance in these individuals.

Title: The importance of sleep quality on baseline concussion neurocognitive testing in collegiate student-athletes

Authors: *E. E. HALL[1], K. WARREN[1], L. STANDARD[1], R. HALLMAN[1], K. PATEL[2], C. J. KETCHAM[1];
[1]Exercise Sci., [2]Sports Med., Elon Universtiy, Elon, NC

Abstract: Baseline neurocognitive tests are a key component to concussion management protocols and are useful in helping make return-to-play (RTP) decisions. Previous research has shown that the amount of sleep that one has prior to neurocognitive testing may impact performance. However, the influence of sleep quality is less known. The purpose of this study was to examine the relationships between the amount of sleep and sleep quality on baseline neurocognitive performance. Ninety-seven NCAA Division I student-athletes completed the Immediate Post-Concussion Assessment and Cognitive Testing (ImPACT^{TM}) test and the Pittsburg Sleep Quality Index questionnaire (PSQI) as part of baseline concussion testing. PSQI measures sleep quality based on responses to questions based on the past month. Number of hours of sleep the night before was reported into ImPACT. Of the 97 participants, 20 of the participants were considered poor sleepers based on the PSQI. MANOVA revealed that those considered poor sleepers had slower reaction time ($p = .031$) and higher total symptom score ($p < .01$). Based on the amount of sleep the night before, participants were classified as short (< 7 hours; $n = 26$); intermediate (7 to 9 hours; $n = 44$); and long (≥9 hours; $n = 4$). MANOVA on amount of sleep revealed no significant differences on scores on the ImPACT. These findings suggest that the amount of sleep the night before neurocognitive testing may not be as important as the sleep quality that they usually get the previous month. These results suggest that sleep and sleep quality may have an influence on neurocognitive performance and should be considered when making RTP decisions.

Abstract: The impacts of excess Body Mass Index (BMI) on physical health are well known and widely studied, but little is known about the consequences of being overweight or obese on cognitive function. The aim of this study was to correlate the BMI with executive functions in overweight middle-aged women. Seventy overweight middle-aged women between 48 and 64 years of age who are otherwise healthy participated in the study. Demographic and anthropometric variables were evaluated. Four standard neuropsychological tests were applied to assess executive functions, sustained attention, selective attention, and verbal fluency. The mean BMI of the participants was 29.35 and was negatively correlated with categories reached ($r = -0.41$, $p = 0.007$) and positively correlated with the number of errors ($r = 0.43$, $p = 0.005$) of executive function test. Scores of other neuropsychological tests applied showed no correlation with BMI. These findings suggest that BMI impacts the executive functions in overweight women who do not present any signs of disease.

Title: Feasibility of at-home iPad cognitive testing

Authors: *N. NG, E. PETERSON;
Lumos Labs, Inc, San Francisco, CA

Abstract: The ability to monitor cognitive functioning across the lifespan accurately and remotely remains an essential method for understanding normal, healthy aging versus cognitive impairment and decline. Mobile, computerized neurocognitive assessments allow for less burdensome and more frequent administrations with minimal learning effects, which could potentially result in more accurate measures of an individual's performance in his natural environment and increase the reliability and the sensitivity of these assessments to cognitive change over time. For researchers, mobile assessments can aid in recruiting and running large-scale studies in a more cost-effective manner. In the clinical world, advantages of mobile cognitive assessments may enhance clinicians' ability to screen and longitudinally monitor patients' cognitive performance and with the hope of detecting decline or inconsistencies earlier. Additionally, mobile assessments make it substantially easier and cheaper to collect large samples of normative data for use in understanding how to interpret performance on mobile assessments.

While the capability of remotely administering cognitive assessments decreases burden of having a trained psychometrician or clinician present, development of these tools requires a balance between an easily understood self-guided experience and the psychometric requirements of good cognitive assessments. The mobile NeuroCognitive Performance Test (mNCPT; Lumos Labs, Inc.) is a mobile application and platform developed to remotely assess cognitive abilities in adults ages 18-90. The mNCPT is available for download on iPad and for this study was offered to a set of individuals who use Lumosity on their iPads. Individuals were guided through a battery of subtests to measure cognitive abilities, including working memory, attention and reasoning, and had the option of providing additional demographic information about themselves afterwards. To investigate the reliability of the mNCPT, a set of those who completed a first battery were asked to come back on a subsequent day to complete the same battery a second time. In this poster, we explore psychometric properties of the mNCPT and provide evidence for the feasibility and adequate reliability (average $r > 0.50$) of the mNCPT as a remote, unsupervised measure of cognitive performance.

Title: A novel design to dissociate experience- and expectation-based hierarchical control in task switching.

Authors: *C. LIU[1,2], N. YEUNG[2];
[1]Exptl. Psychology, Oxford, United Kingdom; [2]Dept. of Exptl. Psychology, Oxford, United Kingdom

Abstract: In both psychology and neuroscience, goal selection is held to be crucial to adaptive behavior. However, goals can be defined at multiple levels of abstraction: the same action can be treated as both taking a sip of coffee and refreshing oneself to work. Our work aims to study task-switching processes under these multiple levels of control. To date, some hints have suggested that hierarchical task organization might operate in task switching, in particular from studies showing that switching efficiency varies with the global probability of task switches (e.g., Monsell & Mizon, 2006). This finding suggests that contextual control information (about switch frequency) influences lower levels of control (guiding selection of specific tasks). However, an alternative interpretation of these results is that they reflect practice effects, with greater experience of switches improving their performance. To study multiple levels of top-down control, deconfounded from effects of experience, we developed a novel design to tease out pure top-down influences experience-driven adjustment.
Healthy human participants performed a standard task-switching paradigm in short blocks of trials. Importantly, participants' belief about switch probability in each block was manipulated through explicit instruction: Switch frequency instruction varied across blocks (frequent vs. rare switch) but objective frequency was matched for a subset of blocks (labeled as Fake Frequent and Fake Rare). Across these conditions, any difference in switching performance can be attributed exclusively to instruction and corresponding high-level control. Study 1 demonstrated behaviorally that instruction played a role above experience as evidenced by increased switch

costs in the Fake Rare vs. Fake Frequent condition. Study 2 manipulated reward to demonstrate that this effect was motivation-dependent. Study 3 used EEG methods to characterize the level at which instruction affected processing. We measured lateralized motor potentials to assess whether switch expectancy directly affects motor preparation for a task. On the other hand, expectancy could engage with attention system by strategically changing attentional scope as reflected in EEG alpha power. We found effects of instruction only on alpha power (Frequent Switch > Rare Switch). The results suggest that expectancy prompts the adoption of distinct control modes across blocks but not motor preparation of individual trial level.
Overall, we demonstrated that expectations uniquely contribute to adjustments in cognitive control in a task switching through hierarchical control.

Title: Global motor suppression following action errors is related to post-error slowing and also to error-related interference

Authors: ***C. M. LEWIS**[1], A. R. ARON[2], J. R. WESSEL[3];
[1]Psychology, [2]Psychology/Neuroscience, Univ. of California San Diego, La Jolla, CA;
[3]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Many studies of performance-monitoring propose that after action errors, motor execution is slowed down to avoid further errors (post-error slowing, PES). However, a major challenge to these models comes from studies showing that when time to adapt is short, PES increases while post-error accuracy decreases. Here, we propose that this happens because a mechanism for global motor suppression is invoked to effect PES, which, however, negatively affects accuracy on the next trial. In 4 experiments using a foot-pedal Simon task with a short inter-trial interval, we tested whether error commission elicits global motor suppression by quantifying motor-evoked potentials (MEPs, elicited by transcranial magnetic stimulation) in task-unrelated hand muscles. Hand-MEPs were reduced at 250-300ms following error commission, indicating global motor suppression. We then tested whether the degree of this global motor suppression related to PES. Indeed, participants with greater motor suppression

showed increased PES. However, global motor suppression was negatively correlated with post-error accuracy: in all experiments, accuracy was decreased following action errors, and participants with stronger global motor suppression showed greater post-error accuracy deficits. We propose that following error commission, when time to adapt is short, a neural mechanism for global motor inhibition is invoked to effect PES. This global inhibition system may also impact cognition, affecting current task-set, and impacting subsequent behavior.

Title: Executive functioning, academic self-efficacy, motivation, age and prior academic performance predict academic performance in university students

Authors: ***M. L. GARCÍA-GOMAR**, A. J. NEGRETE-CORTES, S. VALDEZ-HERNANDEZ, B. E. JIMENEZ-HIGUERA, D. I. ORTIZ CORTEZ, A. MONTOYA-VAZQUEZ;
Escuela de Ciencias de la Salud, Univ. Autónoma Del Estado De Baja California, Tijuana, Baja California, Mexico

Abstract: Objective: To study the relationship between executive functioning (EF), academic self-efficacy (SE), motivation, study habits and academic performance (AP) in university students. Methods: 75 students of health sciences were included in the study. EF was assessed with Modified Wisconsin Card Sorting Test (M-WCST) (Nelson, 1976), Verbal Fluency Test, Stroop Color-Word Interference Test, Symbol Digit Modalities Test (SDMT) (Smith, 1982) and Trail Making Test (TMT). Students were also assessed with Barrat Impulsivity Scale (Patton, Standford y Barrat, 1995), Academic Self-efficacy Scale (Blanco et al., 2011) and Inventory of Study Habits (Fernández-Pozar, 2014). GPA was considered as a measure of academic performance. Results: The students included in the study were 50 women and 25 men, with an average of 18.8±0.89 years old. All enrolled between first and second semester, 9.3% were medical students, 22.6% dentistry students, 18.6% nursing students and 49.3% psychology

students. Students had a GPA average of 83.2±11. Regarding EF assessment, low scores were found in EF tests. The students had an average of 4.5±1.9 categories in M-WCST (15th percentile); 5.9±6.6 perseverative errors (30th percentile); 6.8±7.6 Stroop interference score (40th percentile); 12.3±4.2 verbal fluency score (letter S) (20th percentile). The best fit linear regression model explained 37% of the variance in AP (p=0.00087) and included: prior AP (beta=0.3, p=0.02); Stroop interference score (beta=0.023, p=0.04); SE (beta=0.21, p=0.13); age (beta-0.21, p=0.05); motivation (beta=-0.20, p=0.10); communication factor in SE (beta=0.17, p=0.17); perseverative errors in M-WCST (beta=-0.16, p=0.14) and verbal fluency (beta=-0.13, p=0.24). Conclusions: The results support that prior AP, inhibition, SE, age, motivation, mental shifting and verbal fluency predict AP. Our results are in contrast with other studies in university population that found no relationship between EF and AP (Barceló-Martínez, Lewis Harb & Moreno-Torres, 2006; Vergara-Mesa, 2011) but agree with studies that found a positive relationship between EF and AP in children and adolescents (Bull, Espy & Wiebe, 2007; St Claire-Thomson & Gathercole, 2006; Latzman, Elkovitch, Young, Lee & Clarck, 2010). Our results showed that inhibition, mental shifting and verbal fluency are the EF components most related with AP, in contrast to other studies which found that working memory is the most related EF component (Da Costa Leite, 2013; Thorell, Veleiro, Siu, Mohammadi, 2013). It is important to increase the sample size, to include a working memory test and psychophysiological measures to confirm the results.

Title: Network signatures of flexible cognitive control are reflected in oscillatory MEG source connectivity

Authors: *R. D. MILL[1], A. BAGIC[2], W. SCHNEIDER[2], M. W. COLE[1];
[1]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. Newark, Newark, NJ; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The ability to flexibly adjust thoughts and behavior across diverse task domains is a fundamental feature of cognitive control. Previous fMRI research in humans has linked such control processing to the cross-domain engagement of cognitive control brain networks, which

alter their patterns of functional connectivity with domain-specific networks in response to ongoing task demands (Cole et al., 2013; *Nat Neuro*). However, fMRI imaging is limited in its capacity to resolve the fine-grained temporal signatures underlying flexible control network recruitment. Furthermore, prior functional connectivity studies using higher temporal resolution imaging methods (e.g. M/EEG) have either been confined to network analyses at the raw sensor level (rather than the underlying neural source space) or have primarily focused on the resting state (which lacks explicit experimenter control over ongoing task demands). Hence, subjects in the current study underwent MEG scanning whilst performing the permuted rule operations task (PRO) - a paradigm that iterates through 4 categories of each of 3 rule domains (4 logic x 4 sensory x 4 response rules) to present a total of 64 unique task states (Cole et al., 2010; *J Neuro*). Using adaptive linear beamforming methods of source localisation and individualized head models constrained to subjects' anatomical MRIs, we reconstructed spatio-temporally precise source activation timeseries from 264 brain regions specified from a functional atlas (Power et al., 2011; *Neuron*). The source timeseries were resolved to separate frequency bands (via band-pass filtering and the Hilbert transform), and corrected for source mixing/spread artifacts by the removal of spurious 'zero-lag' phase relationships between source pairs (Hipp et al., 2012; *Nat Neuro*). The resultant band-limited, phase-orthogonalized source power envelopes were correlated on a pairwise basis to estimate functional connectivity during performance of the PRO paradigm. Consistent with previous fMRI findings, graph theoretic analyses applied to the MEG source connectivity estimates identified flexible patterns of network engagement across multiple task states that were specific to cognitive control networks. Our results go further in segregating these flexible network signatures as a function of frequency band and the specificity of task processing (e.g. by contrasting connectivity during 'initial encoding' versus 'active performance' of the different PRO tasks). The findings provide insight into the dynamic, oscillatory brain network processes that underpin controlled cognitive processing across multiple task domains.

Title: Predicting outcome and timing of upcoming decisions using multivariate pattern analysis for event-related potentials

Authors: *S. BODE[1], H. KEAGE[2], D. FEUERRIEGEL[2], M. E. R. NICHOLLS[3], O. CHURCHES[3];
[1]The Univ. of Melbourne, Parkville, Australia; [2]Sch. of Psychology, Social Work and Social Policy, Univ. of South Australia, Adelaide, Australia; [3]Sch. of Psychology, Flinders Univ., Adelaide, Australia

Abstract: Over the past decade, multivariate pattern classification analysis (MVPA) has become a valuable tool for the analysis of human neuroimaging data. Recently, these methods have been successfully applied to spatially distributed patterns of event-related potential (ERP) data to predict upcoming decisions during the early stages of information processing (Bode et al., 2012, *J Neurosci*; Bode & Stahl, 2014, *Biol Psychol*). One important question that remains is whether this early information directly informs subsequent decision behaviour. The present study therefore investigated the extent to which decodable decision-relevant information predicted the timing of behavioural responses. ERP data was recorded from 12 participants (18-37yrs, 6 female) during a series of simple identity decisions, whereby two consecutively presented letters were shown in 12 different rotation angle conditions (0°-330°, in steps of 30°). The electroencephalogram was recorded at 1000Hz using a Quickcap (Neuroscan) system with 64 silver/silver-chloride electrodes. After standard pre-processing, decision outcomes were predicted from spatio-temporal activity patterns in 10ms analysis time windows, which were moved through each trial. We identified the first time window from which decisions could be predicted at ~200-260ms after the presentation of the probe stimulus, depending on rotation angle condition. This information preceded the average response time (RT) by ~200-250ms. To estimate the extent to which decision-information from these early time windows was related to RT, the *change* in mean classification accuracy was correlated with the *change* in mean RT for each rotation angle condition when excluding each participant once. On average, the amount of decision-relevant information that correlated significantly with RT started at 260ms after the probe stimulus, and peaked at ~400ms, which corresponded to the beginning of the response period (mean $r = -.45$; $p < .05$ Bonferroni-corrected). This suggests that when more information was represented in brain activity patterns during early time windows, faster decisions were made. These results provide strong evidence that MVPA for ERPs can reveal the accumulation of information in the brain that is directly relevant for upcoming behaviour.

Title: Human brain dynamics supporting emergence of sudden insight

Authors: *Y. J. WU[1], S. MAKEIG[2];
[1]UC San Diego, LA Jolla, CA; [2]Swartz Ctr. for Computat. Neurosci., UC San Diego, La Jolla, CA

Abstract: Sudden insight during problem solving results from enlarging or restructuring a problem solution space, allowing a previously inaccessible solution to emerge into the participant's imagination, producing an 'Aha!' experience. As the subjective suddenness of such moments suggest their precipitation by a transient brain dynamic event, much research on insight during human problem solving has focused on the second immediately preceding a participant's signal (by button press) that they have discovered a solution. In the past decade, however, a number of studies have indicated a direct relationship between brain processes occurring in earlier stages of problem solving and the subsequent 'Aha!' experience. To examine brain activities during the full time course of a solution search process, we recorded high-density EEG data as healthy adults solved 'Wheel-of-Fortune' style language puzzles. Each trial began with a series of dashes and blank spaces on a screen indicating the positions of letters in a common phrase or idiom. At randomly jittered intervals (1.5-3s), single letters in the phrase, randomly selected by the game application, replaced the dashes. Participants pressed a button as soon as they could guess the full phrase. After a cue, they spoke their solutions aloud, allowing the experimenter to check accuracy. The participants then rated the degree of sudden insight they had experienced when reaching the solution. Correct solutions were reached after presentations of two to twelve letter clues, and were later rewarded with a monetary bonus proportional to solution speed. Pre-cleaned 256-channel EEG data were decomposed into underlying source contributions by adaptive mixture independent component analysis (AMICA). Brain-based independent component (IC) scalp maps were modeled as projections of single equivalent dipoles, and event-related spectral perturbations (ERSPs) were computed for each such IC in 1.5-s epochs following each letter clue presentation. Measure Projection Analysis (MPA) identified a subspace of model brain voxels exhibiting consistent cue-onset ERSP patterns across ICs with nearby equivalent dipoles. This consistency voxel subspace was further divided into distinct domains by Affinity clustering on voxel-centered mean ERSP differences. Results revealed spectral power changes in right hemisphere cortical field activity beginning at least three letter presentations before participants articulated the correct solution. This result implies that problem solving in this task is a prolonged process with distinct brain dynamic pre-conditions.

Title: Normative foundations for value normalization in choice behavior: balancing outcomes with entropic costs

Authors: *C. K. STEVERSON, A. BRANDENBURGER, P. GLIMCHER;
NYU, New York, NY

Abstract: Barlow (1961) argued that meaningful study of neural mechanisms requires an understanding of their functional importance. In the case of the divisive normalization model of visual systems (Carandini and Heeger 2012), it has been argued that the functional importance of normalization comes through the efficient coding of stimuli (Schwartz and Simoncelli 2001, Lyu and Simoncelli 2009). More recently, the normalization mechanism has also been observed in value representation and choice behavior. Value normalization has successfully explained neuronal activity in primates (Louie et al. 2011) and experimental choice behavior in humans (Louie et al. 2013, Web et al. 2014). However, stimulus encoding is not the purpose of choice, so that efficient coding cannot explain the functional importance of normalization in choice behavior. We propose instead that value normalization plays a role in bringing about efficient choice. Specifically, we show that any behavior arising from a class of value normalization models can be rationalized as maximizing the expected value of choice minus the costs of decision making. We also establish that our class of value normalization models covers all the behaviors that can be rationalized by our model of costly decision making. We model the costs of decision making via the Shannon entropy of the choice probabilities, which is a measure of the degree of stochasticity in choice. Less stochasticity in choice requires a larger reduction in entropy and is therefore more costly. In addition, we scale the costs of decision making via a set-dependent factor that allows choice sets to vary in how hard it is to discriminate among the alternatives. For instance, choice sets might vary in the similarity or salience of the alternatives they contain. We connect our normalization model to the classic Luce model of stochastic choice which is popular in the field of economics. We show how a relaxation of the condition called independence from irrelevant alternatives, which is known to characterize the Luce model, leads to normalization. Our work provides a normative foundation for value normalization by deriving it as the class of optimal solutions to a problem of costly decision making. This normative foundation lends support to the possibility that the functional importance of value normalization lies in bringing about efficient choice behavior.

Abstract: Decision-making links cognition to behavior and is a key driver of human personality, fundamental for survival, and essential for our ability to learn and adapt. It has been well established that humans make logical decisions where they maximize an expected reward, but this rationality is influenced by their emotional state. Psychiatric patients who have dysfunctional cognitive and emotional circuitry frequently have severe alterations in decision-making where emotion hijacks logic. Unfortunately, the function of relevant neural circuits in humans is largely uncharted at fine temporal scales, severely limiting the understanding of changes underlying disruption associated with age or psychiatric diseases. In this study, we localize neural populations, circuits, and their temporal patterns *on a millisecond scale* that are critically involved in human decision-making.
Twelve human subjects, implanted with multiple depth electrodes for clinical purposes, performed a gambling task while we recorded local field potential neural activity from deep and peripheral brain structures. The gambling task consisted of a game of "high card", where the subject bets high ($20) or low ($5) on whether her card will be higher than the computer's card. We posited that each subject's decision-making system consists of a feedforward model with the playing card as the input and betting behavior as the output (e.g. how she bets and how quickly she bets). The behavior and gambling outcome is a feedback control signal to the model, which updates the internal latent state of the feedforward model. For each subject, we estimated the latent state variable from binary bets (high versus low) using maximum likelihood methods. Specifically, we modeled the probability of betting high as a function of this internal state and the player's card, and the state updates on each trial as a function of observed quantities such as

the card value, expected reward, and variance of reward.
Further, neural correlates for the internal state trajectory and components that update the internal state are present in key limbic structures suggesting that the internal state is correlated to the subject's emotions. In particular, specific oscillations in brain structures, including amygdala, cingulate cortex, and the entorhinal complex are shown to influence betting behavior (what you bet and how quickly you make the bet) in a profound way. These findings provide new insight into how humans link their internal biases (e.g. emotions) to decisions.

Title: Quality and quantity in value-based decision making

Authors: ***A. O. DE BERKER**, Z. KURTH-NELSON, R. B. RUTLEDGE, S. BESTMANN, R. DOLAN;
Univ. Col. London, London, United Kingdom

Abstract: Quality and quantity are cardinal dimensions in value-based decision-making. To make effective decisions it is necessary to combine information about both in order to estimate an integrated value for available options. This calculation requires an interaction between quality and quantity, given that the value of one additional unit of a good depends fundamentally upon the unitary value of that good; an extra car is worth more than an extra pair of socks. Here we investigate how quality and quantity are represented in the brain, and how they interact to produce integrated value. In a behavioral experiment we first assessed individual value functions

for different gift cards (e.g., supermarket, book store) using Becker-DeGroot-Marschak auctions. We then used fMRI to identify the neural representation of quality (how desirable the brand of each gift card was), quantity (how much money was on each gift card), and the interaction between these two dimensions. Activity in lateral and inferior prefrontal and temporal cortices correlated with gift card quality, while activity in intra-parietal sulcus and surrounding parietal cortex reflected the quantity. A network comprising the cingulate cortex, bilateral hippocampus, and medial prefrontal cortex encoded an interaction between quality and quantity. Conjunction analyses revealed overlapping representations of quality, quantity, and their interaction in the anterior cingulate, suggesting that this region provides the substrate for the formation of an integrated value from quality and quantity.

Title: A quantitative meta-analysis of neuroimaging studies on counterfactual thinking

Authors: *F. DE BRIGARD[1], G. STEWART[1], N. PARIKH[1], N. SPRENG[2];
[1]Psychology, Duke Univ., Durham, NC; [2]Human Develop., Cornell Univ., Ithaca, NY

Abstract: Counterfactual thinking refers to our psychological capacity to entertain thoughts about alternative ways in which past events could have occurred but did not. In the past decade, cognitive neuroscientists have explored neural activations associated with counterfactual thinking either in the context of decision-making or in the context of mental simulation. However, the extent to which both kinds of counterfactual thinking tasks engage common brain regions remains unknown. To address this question, we present here a quantitative meta-analysis of neuroimaging studies of counterfactual thinking from both the decision-making and the mental simulation literatures. After a systematic search of the scientific literature, 18 neuroimaging studies involving counterfactual thinking tasks were identified. Next, a coordinate-based meta-analysis using Activation Likelihood Estimation (ALE) was conducted. This analysis revealed seven clusters reliably activated during counterfactual thinking tasks: right lateral parietal cortex (BA39), left superior prefrontal cortex (BA 8), bilateral globus pallidus in the

basal ganglia, right hippocampus, inferior prefrontal cortex (BA 47), anterior cingulate cortex, and left precentral gyrus (BA 9). These results provide reliable and robust estimates of the neural correlates of counterfactual thinking. In addition, we believe these results add to growing evidence suggesting that the hippocampus plays a critical role during mental simulation and decision-making tasks involving thoughts about unactualized events. Finally, these results suggest further avenues to research interactions and differential contributions of basal ganglia, parietal and pre-frontal cortices during counterfactual thinking tasks.

Title: The role of reward immediacy in temporal discounting

Authors: ***U. BROMBERG**, J. PETERS, C. BUCHEL;
Dept. of Systemic Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Temporal discounting tasks require agents to engage in a trade-off between value and time, while making choices between smaller but sooner and larger but later rewards. The degree of discounting of reward-values that are burdened with a timely delay, varies considerably among individuals, giving rise to subject-specific values of the rewards. Neural correlates of subjective values in discounting can be characterized by parametric value representations (Kable & Glimcher, 2007, 2010; Miedl et al., 2012; Peters & Büchel, 2009). It has been shown that the availability of immediate rewards increase responses in brain regions involved in reward value coding (McClure et al., 2004; McClure et al., 2007; Luo et al., 2009), but it is not yet known whether parametric value representations are modulated by the immediacy of reward. Here we investigate the impact of immediate rewards on parametric value representation as well as related functional connectivity in meso-limbic circuits, that are possibly modulated by immediate rewards (Ousdal et al., 2012; Ambroggi et al., 2008). Our sample of young adults (n = 55, age 18-20 years, 30 females) performed a discounting task that included two conditions: choices with immediate rewards (now-trials = NT) and choices without immediate rewards (not-now-trials =

NNT). We tested our results in an age- and sex-matched independent replication sample (n = 55, age 18-20 years, 30 females). We report an impact of immediacy on neural subjective value representation with stronger activation in the medial and bilateral OFC for NT as compared to NNT. No differences in activation was found for NNT as compared to NT. We also report results from psycho-physiological analyses. Our results confirm a previously reported impact of immediacy on neural reward processing in temporal discounting. Specifically we show an impact on neural parametric value representation of discounting behavior. The results are discussed in relation to several discounting relevant measures such as personality and substance use.

Title: Neural mechanisms underlying speed-accuracy adjustments in the subthalamic nucleus.

Authors: *D. HERZ[1,3], H. TAN[1,3], J.-S. BRITTAIN[1,3], P. FISCHER[1,3], B. CHEERAN[1], A. L. GREEN[1,2], T. Z. AZIZ[1,2], K. ASHKAN[4], S. LITTLE[5], T. FOLTYNIE[5], R. BOGACZ[1,3], P. BROWN[1,3];
[1]Nuffield Dept. of Clin. Neurosciences, [2]Nuffield Dept. of Surgical Sci., Univ. of Oxford, Oxford, United Kingdom; [3]MRC Brain Network Dynamics Unit at the Univ. of Oxford, Oxford, United Kingdom; [4]Dept. of Neurosurg., King's Col. Hosp., London, United Kingdom; [5]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London Inst. of Neurol., London, United Kingdom

Abstract: Neurobiological models of decision-making propose that the subthalamic nucleus (STN) plays a central role when humans weigh quick but possibly erroneous decisions against more accurate but slow decisions. However, to date there is no direct electrophysiological evidence linking STN activity to such trade-offs between speed and accuracy. To address this, we recorded STN local field potentials (LFP) from eleven Parkinson patients who had undergone STN deep brain stimulation surgery. During the recordings participants performed a task in

which they had to decide whether a cloud of moving dots appeared to move to the left or to the right. The percentage of dots moving coherently in the correct direction was either high (50%) or low (8%), and participants were instructed to respond as quickly or as accurately as possible indicated by a cue presented before the onset of the moving dots. In order to relate recorded neural activity to distinct aspects of the decision-making process, we applied Bayesian hierarchical drift diffusion modelling (HDDM). HDDM computes the rate at which evidence accumulates over time (drift rate), the level of evidence at which participants respond (decision threshold) as well as the non-decision time based on participants' behaviour. For all statistical analyses, significance thresholds were set to 0.05. As expected, subjects responded slower when they were instructed to focus on accuracy, not speed. In addition, participants were slower and less accurate during trials with low compared to high coherence. HDDM revealed that these behavioural changes were related to an increase in decision thresholds following cues instructing accuracy relative to speed and a decrease in drift rates in low compared to high coherence trials. Analysis of STN LFPs showed that instructing patients to speed up responses increased low-frequency oscillatory (LFO) activity (2-8 Hz) and induced a stronger initial decrease in beta activity (13-30 Hz) between the onset of moving dots and the response. Interestingly, these two neural processes were not statistically related to each other as indicated by correlation analyses. Including the pre-response changes in STN LFO- and beta activity as predictors in HDDM regression analyses revealed that increased LFO activity predicted increased decision thresholds only after accuracy but not speed instructions, while stronger decreases in beta activity predicted decreased decision thresholds irrespective of the instruction. These findings indicate that distinct processes in the STN mediate adjustments between fast and accurate decisions by modulating how much evidence subjects acquire before committing to a decision.

Sci., Winston-Salem, NC; [5]Univ. of Washington, Seattle, WA; [6]Univ. Col. London, London, United Kingdom

Abstract: The neurotransmitters dopamine and serotonin are important modulators of neural activity and synaptic plasticity. Much work has been performed in model organisms to elucidate how these systems influence behavior and learning. However, technological limitations have hindered investigation of how these systems coordinate in real-time in humans to control behavior and influence learning. Here, we report simultaneous real-time (10Hz) measurements of dopamine and serotonin fluctuations in the striatum of 25 humans engaged in a continuous decision-making task. These measurements were made using fast scan cyclic voltammetry on carbon fiber microelectrodes acutely implanted in the striatum of patients undergoing deep brain stimulation electrode implantation for the treatment of Parkinson's disease symptoms. Penalized regression and a substantial calibration data set were used to train models for estimating dopamine and serotonin levels from non-background subtracted voltammograms. We demonstrate that this approach produces models that: (1) accurately track dopamine and serotonin fluctuations for long periods (>30min), (2) discriminate dopamine, serotonin, and pH fluctuations, while (3) overcoming the effects of electrode fouling and background drift that have plagued previous approaches. We applied these models to cyclic voltammograms collected from patients playing a sequential investment game. Sub-second dopamine and serotonin fluctuations encoding changes in expectations and evaluative feedback; further, fluctuations in one trial were predictive of actions in the next trial. These methods promise unprecedented insight into dopamine and serotonin systems in human decision-making, health, and disease.

Title: Neural correlates of temporal change point detection in the human brain

Authors: *R. ADACHI, S. SUZUKI, J. P. O'DOHERTY;
Caltech, Pasadena, CA

Abstract: Detecting changes in the timing of event occurrence is prevalent across species. Toads detect changes in the pattern of ripples on the water's surface caused by the movement of potential prey while human stock traders detect changes in the arrival of transactions to figure out shifts in investor sentiment. In this experiment, we investigated the behavioral and neural underpinnings of temporal change point detection. In the task, subjects observed a sequence of images presented on the screen while being scanned in the fMRI scanner. The sequences contained abrupt changes in the rate of image presentation and the subjects reported perceived changes by the button press. Subjects' performance was significantly better than chance and we observed considerable heterogeneity in performance across subjects. To describe subject behavior quantitatively, we developed a frugal temporal averaging model, that compared the average rate of image presentation in a moving window defined over the recent past against the average rate estimated over a longer temporal interval. We compared the performance of the temporal average model to a more computationally expensive Bayesian online change point detection model inspired by Adams and MacKay (2007). Surprisingly, we found that the simple temporal average model captured the important aspects in the behavioral data as well as the Bayesian model despite the difference in their model complexity. We then correlated the time course of the decision variable predicted by the temporal average model against fMRI data. We found that the difference in the rate of image presentation exhibited a positive correlation with BOLD activity in a region of dorsomedial prefrontal cortex. Subsequent analyses will further explore the relationship between behavioral and neural data across subjects.

Title: The effect of contextual novelty on monetary intertemporal choice

Authors: *M. SELLITTO, B. WITTMANN;
Biol. Psychology, Justus-Liebig-Universität Giessen, Gießen, Germany

Abstract: In intertemporal choice, humans often discount the value of delayed rewards, preferring immediate rewards. When the average reward rate (expected reward per time unit) increases, the cost of waiting for a future reward weighs more heavily, increasing temporal discounting. Tonic dopaminergic activity has been suggested to represent the average reward rate, and pharmacological enhancement of dopamine transmission increases discounting. Tonic dopamine is also increased in novel environments. In the present three-day fMRI study, we investigated whether exposure to novelty modulates subsequent intertemporal choice. On day 1, participants' discount rate was measured and they were familiarized with a set of images. On days 2 and 3, participants were first presented with familiar or novel images for 5 minutes. Subsequently, fMRI data were collected during an intertemporal choice task. Preliminary results (N = 10) suggest that the correlation between striatal activity and the subjective value of the chosen option is higher after exposure to novel compared to familiar stimuli, pointing to a possibility of novelty-associated modulation of intertemporal choice.

Title: Predicting individual differences in impulsivity using resting-state fMRI and machine learning

Authors: *W.-Y. AHN, N. HAINES;
Dept. of Psychology, The Ohio State Univ., Columbus, OH

Abstract: The development of objective biomarkers for addictive disorders can innovate their prevention and treatment. Abundant evidence indicates that addictive disorders are characterized by neurocognitive manifestations of *impulsivity*, one of the most viable endophenotypic markers for addiction. A promising neuroimaging-based biomarker for addiction and related traits is resting-state functional magnetic resonance imaging (rs-fMRI) connectivity. Previous studies demonstrated its association with impulsivity (e.g., Davis et al., 2013) and rs-fMRI connectivity predicted the status of addiction dependence (e.g., Pariyadath et al., 2015). However, it remains unclear if individual differences in impulsivity can be accurately predicted by rs-fMRI connectivity.
To test if rs-fMRI connectivity can predict individual differences in impulsivity, we used 926 participants' rs-fMRI data provided by the Brain Genomics Superstruct Project (GSP). The Conn toolbox was used to preprocess and perform ROI-to-ROI connectivity analysis in each subject. We tested several machine learning algorithms to predict impulsivity (total scores of the Barratt Impulsiveness Scale) using ROI-to-ROI connectivity measures in new samples. Each machine learning algorithm was fitted on the same training set (617 participants' data) using 10-fold cross validation and we tested its out-of-sample prediction accuracy in the test set (309 participants' data). Our preliminary results suggest that rs-fMRI connectivity can predict impulsivity scores in new samples and it is our expectation that this line of work may shed light on the development of biomarkers that can be used to assess individuals' risk to addiction in clinical settings.

Title: Specific impairment in integrating quantitative features of intertemporal choice in Alzheimer's disease

Authors: ***A. J. BEAGLE**[1], J. H. KRAMER[2], M. HSU[3], A. S. KAYSER[2], K. A. WOOD[2], W. CHIONG[2];
[2]Dept. of Neurol., [1]Univ. of California, San Francisco, San Francisco, CA; [3]Helen Wills Neurosci. Inst. and Haas Sch. of Business, Univ. of California, Berkeley, Berkeley, CA

Abstract: It has been proposed that economic choice involves a two-stage process in which the subjective value of each option is computed, and then these values are compared to arrive at a decision (Padoa-Schioppa, Ann Rev Neurosci 2011). Such neuroeconomic models may help explain decision-making impairments observed in neurodegenerative diseases such as Alzheimer's disease (AD) and frontotemporal dementia (FTD). We investigated whether conditions targeting different anatomic systems would have dissociable effects on neural mechanisms of decision-making in intertemporal choice. We have reported that patients with temporal lobe-predominant FTD make a greater proportion of impulsive choices than controls, while patients with AD make a similar proportion of impulsive choices to controls (Chiong et al, Brain 2016). In this analysis, we studied participants' sensitivity to quantitative and temporal features of a hypothetical two-choice delay discounting task in which the delay length and the absolute and relative magnitudes of rewards were fully crossed. Controls responded to increases in delay length, decreases in the absolute magnitude of the delayed reward, and increases in the relative magnitude of the immediate reward by more frequently choosing the immediate reward. Patients with AD had diminished sensitivity to differences in delay length ($p < 0.01$) and the absolute ($p < 0.01$) and relative reward magnitude ($p < 0.01$), though their baseline tendency to choose an immediate reward did not differ ($p = 0.45$). Patients with temporal variant FTD did not differ from controls in their sensitivity to these features ($p = 0.45$, 0.93 & 0.07), but had a greater baseline tendency to choose an immediate reward ($p < 0.01$). Patients with frontal variant FTD ($n = 12$) demonstrated an intermediate phenotype. These results suggest that impaired decision-making in AD may result from failures to integrate quantitative features of available options in subjective valuation, while in the temporal variant of FTD it may result from a systematic bias towards impulsive choice that is independent of such integration.

Title: Age differences in mutual information of electroencephalograms during value-based decision-making

Authors: *H.-Y. HUNG[1,2], P. CHEN[2], J. GOH[2,3,4];
[1]Dept. of Physics, Natl. Taiwan Univ., Taipei, Taiwan; [2]Grad. Inst. of Brain and Mind Sciences, Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan; [3]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan; [4]Neurobiological and Cognitive Sci. Center, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: The aim of this study was to evaluate age-related temporal differences in neural information transmission when young and older adults make value-based decisions. We used time-delayed cross mutual information (CMI) to measure linear and nonlinear dynamical coupling of EEG signals between electrodes. EEGs from 32 channels were recorded in 11 young (6/5 males/females; age = 24±1.9 yrs, mean±SD) and 11 older (3/8 males/females; age = 68±4.0 yrs) normal participants during a lottery choice task. All data were filtered with a band pass of 0.1-50 Hz. Participants decided to accept or reject stakes consisting of high, middle, and low levels of points magnitudes and probabilities of winning (or losing) the points. Focusing on central line electrodes (CZ, FZ), we computed CMI time courses affording onset, peak, and terminating times of waves of information transmission occurring after stimulus onset for each subject and then evaluated age differences in peak latencies. Older adults displayed more risky behavior with higher acceptance rates than the young for more costly low win probability conditions (high lose probability) (Young: 0.02±0.09; Old: 0.15±0.20 ; $p < .05$). We found significant age difference ($p<.001$) in the times of the first CMI peak such that signal in CZ was correlated with that in FZ between 88±18 - 228±54ms in the young group but between 181±60 - 354±87ms in the older group. Thus, it took less time for the first peak of neural information transmission in young than older adults. However, the effect of probability was trivial in the first peak suggesting that it reflected basic representational processes. Critically, both age and probability modulated onsets of subsequent second CMI peaks. Whereas there were no age differences during the high probability condition (310±62 - 472±77ms), the second CMI peak

times were earlier in younger than older adults in the middle (Young: 244±30 - 415±81ms; Old: 439±97 - 587±98ms) and low (Young: 240±56 - 400±95ms; Old: 385±36 - 609±88ms) probability conditions. Further, while the probability effect was not significant in the young group, the time of the second CMI peak in middle and low probability conditions were significantly later than that in the high probability condition in the older group (334±72 - 473±105ms; $p < .05$). Our findings suggest that risky behavior in older adults is associated with more temporally extended neural processing compared to younger adults. We further demonstrate that CMI between EEG electrodes captures psychologically and neurophysiologically meaningful aspects of human processing of value-based decisions.

Title: Using rapid reaching to explore the value of information

Authors: *C. S. CHAPMAN[1,2], S. HO[2], J. SAWALHA[1], I. I. GILANI[2], N. J. WISPINSKI[3], J. K. BERTRAND[1], E. B. LAVOIE[1];

Abstract: Is there a difference between knowing you will receive a reward and actually getting it? These two factors, here called information (info) and action-outcome (action), are usually intertwined, but may bias a decision in different ways. In the two reported experiments (E1 & E2) we teased apart how these two factors biased rapid reach decisions.
For both experiments, participants completed two phases. In the Value Learning (VL) phase, they learned to associate specific shapes with specific outcomes. In the Rapid Reaching (RR) phase, they were told to ignore the learned associations and hit one of two targets cued at reach onset. During VL trials, participants saw shapes at only a single target location. A first shape (info) came on the screen and served as a movement pre-cue. After a brief delay, an auditory go cue signaled that participants should reach for that shape. Upon movement onset, the first shape was replaced by a second shape (action). Participants had to successfully reach toward and hit the action target to receive reward points for that trial. In E1 info shapes predicted action shapes

100% of the time. One info-action pair produced reward 100% of the time and a second info-action pair produced reward 50% of the time. In E2 info shapes were not predictive of action shapes, but each action shape was still consistently paired with either 100% or 50% reward. During RR trials, participants were presented with two of the four VL shapes coincident with the go cue and had to rapidly initiate a movement. At movement onset one of the two shapes was selected (filled-in black) and participants had to rapidly reach to its location to receive a reward for that trial. Possible rewards for RR trials were constant and based only on rapid reach performance (e.g. shape was irrelevant).
We used functional regression techniques on RR hand trajectories to separately reveal the time evolving bias induced by two factors acquired during VL: information vs action and 100% reward vs 50% reward. In E1 we found the hand was significantly biased toward information targets and 100% reward targets. In E2, even though the information targets no longer predicted reward, we saw the same pattern of results. We hypothesize that info targets are valuable in part because they predict reward (E1) but more because they predict the upcoming action location (E1 & E2). This suggests that successfully completed actions are intrinsically and powerfully rewarding, and this reward signal plays an integral role in shaping learning and behavior.

Title: The speed-accuracy tradeoff regulates the rate of evidence accumulation, non-decision time, and decision boundary

Authors: *S. ITTHIPURIPAT[1], J. T. SERENCES[2];
[1]Neurosciences Grad. Program, UCSD, La Jolla, CA; [2]UCSD, San Diego, CA

Abstract: Manipulating the speed-accuracy tradeoff (SAT) has a significant impact on the underlying cognitive processes that support decision-making. Multiple behavioral studies in human suggest that the SAT is best explained via changes in the amount of evidence required before making a decision (i.e. the *decision boundary*). However, a recent study using non-human primates found that neural responses recorded from the lateral intraparietal (LIP) area, which is thought to track evidence accumulation, reached the same threshold under different SAT regimes. Here, we tested the generality of this result in humans by examining how the SAT impacts the cento-parietal potential (CPP), which has been shown to track evidence accumulation in human subjects in a similar manner to LIP neurons in non-human primates. To do so, we recorded electroencephalography (EEG) from human subjects while they were performing a contrast discrimination task where either speed or accuracy was emphasized across blocks of trials. Consistent with the recent monkey study, we found that the CPP reached a similar threshold before response onset across different SAT regimes. However, the slope of the CCP during decision-making was higher in the speed-emphasized compared to accuracy-emphasized blocks suggesting faster sensory evidence accumulation. Moreover, we found that the CPP peaked right at the response onset in the speed-emphasized block but that it peaked ~50-100ms before the response onset in the accuracy-emphasized block, which suggests that speed pressure reduces non-decision time. Interestingly, we also found that the CCP reached different thresholds when the data in the speed-emphasized block were sorted by short and long reaction times (RTs); however, only the slope of the CCP changed when the data in the accuracy-emphasized block were sorted by RTs. Overall these results challenge the original views on how the SAT impacts decision-making by demonstrating that the SAT regulates multiple - instead of one— components of decision-making processes, and these include the rate of evidence accumulation, non-decision time, and decision boundary.

Title: Sacrificing evidence for urgency: Tracking stratal activation during mounting urgency during decision-making

Authors: *S. MAASS[1], H. VAN RIJN[2], B. FORSTMANN[3], L. VAN MAANEN[3];
[1]Fac. of Behavioural and Social Sci., Groningen, Netherlands; [2]Exptl. Psychology, Univ. of Groningen, Groningen, Netherlands; [3]Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: As time passes in the process of making a decision, the need to give a response or perform an action increases. This "need-to-act" is defined as a sense of urgency. In the standard models of binary decision-making, noisy evidence is accumulated until a fixed threshold is reached for one of the two choices. Recent work has highlighted the striatum as the main brain region controlling this process (Forstmann, Ratcliff, & Wagenmakers, 2016). In contrast to the concept of fixed thresholds, current evidence suggests that the amount of evidence needed to give a response, might change during the process of making a decision (Boehm, Hawkins, Brown, van Rijn & Wagenmakers, 2015; Cisek, Puskas, & El-Murr, 2009). As time passes and urgency increases, the amount of evidence needed to trigger a decision seems to decrease, leading decision-makers to make a choice based on less evidence. In a first experiment, we tested three methods to induce urgency, which vary in the degree of explicit time pressure: an implicit method of slowing down the presentation of stimuli, a reward-based method in which points can be earned through fast responses and a deadline method in which participants are required to respond before a deadline. Using an expanded judgement paradigm we were able to compute the likelihood ratio of the chosen alternative to quantify the urgency effect. Results of a behavioural experiment show that all methods were able to induce urgency. The implicit method, however, was least affected by confounds such as strategy use. Looking at the neural mechanism behind the urgency effect previous research has shown the basal ganglia to be a likely source (Thura & Cisek, 2016). Our second experiment aims to describe how varying levels of urgency affect the development of activation in the basal ganglia, specifically the striatum, on a single trial level. Accordingly, the implicit urgency inducing method from Experiment 1 was employed in a 7T fMRI experiment. We hypothesize that in trials with a high level of urgency the striatum will be less active than in trials with a low level of urgency. Over time, this difference in activation could result in a lower response inhibition, and therefore responses are made based on less evidence for the chosen option.

Title: Striatal dopamine relates to information sampling in the beads task as a measure of impulsivity

Authors: *R. VICARIO FELICIANO, V. D. COSTA, J. B. CZARAPATA, D. EISENBERG, K. BERMAN, B. B. AVERBECK;
Natl. Inst. of Health/NIMH, Bethesda, MD

Abstract: Impulsivity refers to the tendency to act without forethought or consideration of action outcomes. Since decisions are most effective after collecting sufficient information to predict rewarding outcomes, information sampling tasks have proven useful as a behavioral metric of impulsivity. The beads task is a probabilistic decision making task used to study information sampling biases. Participants view sequences of bead colors drawn from hidden urns and attempt to infer the majority bead color in each urn. After viewing each bead drawn, participants chose either to seek more evidence about the urn by drawing another bead (draw choices) or to infer the urn contents (urn choices). Functional imaging of the beads task shows that the decision to stop sampling information and guess an urn activates a reward anticipation network that includes the striatum. Further, a subset of Parkinson's disease patients that develop behavioral addictions following dopamine replacement therapy and patients with schizophrenia display reduced information sampling in the beads task. This suggests that dopaminergic signaling contributes to information sampling biases. However, dopaminergic manipulations in healthy controls have not been shown to modulate information sampling behavior in the beads task. To determine if striatal dopamine is related to information sampling we measured presynaptic DA stores and synthesis with [^{18}F]-FDOPA positron emission tomography (PET) in 65 healthy participants and correlated it with information sampling behavior in the beads task. The specific uptake constant, K_i, a measure of dopamine synthesis activity, was estimated for striatal regions of interest (caudate, putamen, and ventral striatum). Striatal dopamine synthesis capacity was inversely correlated with number of beads drawn in caudate and putamen. These results implicate dopamine function in information sampling behavior and therefore implicate increased striatal dopamine in impulsivity.

Title: The feedback-related negativity encodes an information prediction error in decisions to seek information

Authors: *D. BENNETT, M. BRYDEVALL, C. MURAWSKI, S. BODE;
The Univ. Of Melbourne, Melbourne, Australia

Abstract: In a dynamic world, accurate beliefs about the environment are vital for survival, and individuals ought regularly to seek out new information to update their beliefs. This aspect of behaviour is not well-captured by rational theories of decision making, and the neural mechanisms of information seeking are poorly understood. One recent theory posits that canonical neural reward-processing circuits assign an intrinsic value to information, even when that information lacks instrumental use. We investigated this question by recording EEG from twenty-two participants performing an information-seeking task. In this task, participants could pay a monetary cost to receive advance information about the likelihood of receiving reward in a lottery at the end of each trial. Importantly, acquiring information did not alter reward probability, which was known to participants. Behavioural results showed that participants were willing to incur considerable monetary costs to acquire early but payoff-irrelevant information. Analysis of the event-related potential elicited by informative cues revealed that the feedback-related negativity (FRN), a component strongly linked to reward processing, encoded an information prediction error. Crucially, encoding of the information prediction error was orthogonal to encoding of a reward prediction error, which was also reflected in FRN amplitude. These findings suggest that information may represent a distinct dimension of valuation in decision making under uncertainty, and that information seeking might result from intrinsic valuation of information within neural reward-processing circuits.

Title: Neurons encode subjective opinion in the human prefrontal cortex.

Authors: *M. JAMALI, Z. MOSES, K. HAROUSH, S. PATEL, Z. WILLIAMS;
Neurosurg., Massachusetts Gen. Hospital/Harvard Med. Sch., Boston, MA

Abstract: Subjective opinion plays a critical role in many social, political and legal arenas, yet they can also dramatically differ between individuals even when observing the same precise situation or scene. How subjective opinions computed by neurons in the human brain is unknown. Here, we investigated neural correlate of subjective opinion in patients undergoing planned neurosurgery by recording from single units in the dorsolateral prefrontal cortex (dlPFC). During recordings, the participants were presented with visual stimuli of seven different real-world scenes, and were asked to render judgments about them. Our data from a total of 134 dlPFC neurons indicated that many neurons in the dorsal lateral prefrontal cortex (dLPFC) closely tracked the subjective opinions of the participants. Whereas certain neurons displayed responses that shifted when transitioning from one opinion to another, other neurons displayed responses that preferentially signaled their 'tipping-point' or equipoise. When grouped together, these neuronal populations provided a remarkably accurate account of an individual's voting profile. They were also predictive of their upcoming selections within less than a second after the scenes were presented. These findings identify a set of basic rules by which subjective opinions are encoded by neurons in the human dlPFC, and may help explain how humans make rapid decisions under conditions in which there are no explicit rules to guide their selections.

Title: Deciding to know: information prediction errors and value in the human brain

Authors: *C. J. CHARPENTIER[1], E. S. BROMBERG-MARTIN[2], T. SHAROT[1];
[1]Exptl. Psychology, Univ. Col. London, London, United Kingdom; [2]Dept. of Neurosci. and Kavli Inst. for Brain Sci., Columbia Univ., New York, NY

Abstract: How do we decide what to know and when to remain ignorant? Knowledge about the world is vital for informing our choice of actions. Moreover, knowledge can have an intrinsic value: humans and animals exhibit a strong preference to seek information even when that information cannot be used to guide action. Yet, the mechanisms underlying information seeking in humans are largely unknown. Here, we characterize the neural basis and computational principles of how people decide what to know. We show that the decision to receive information is driven both by the resolution of uncertainty and the likelihood of receiving good news. Participants were more eager to know about outcomes with higher expected value, a strong effect that was also modulated by outcome uncertainty. We identify two sets of Information Prediction Errors (IPE) in the human brain, which represented these two motives. One set of IPEs were independent of expectations of reward and loss (in OFC/vmPFC) and the other (in ventral striatum) were modulated by such outcome expectations. Our results identify the components that give rise to information seeking decisions and their respective encoding in the human brain.

Title: Converting from count to worth: neural mechanisms of the value-to-utility transformation

Authors: *O. A. MULLETTE-GILLMAN, Y. A. KURNIANINGSIH;
Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Choosing the ‘best’ option is not just selection of the one that is most numerous or physically largest, but requires that the options be converted from such physical measures of objective value (or count) to subjective measures of worth. Here, we demonstrate that the information necessary to perform this value-to-utility transformation is encoded within the the dorsal anterior midcingulate cortex (daMCC), using a highly specific computational model (a

270-point fit, with 15 trials per point). Specifically, for each value, enhanced daMCC activation results in reduced subjective valuation (SV), diminished activation with enhanced SV, and baseline activation with non-modulated SV.
Analyses were performed in a within-study replication design, with initial analyses focused on the gains domain and replication in the losses domain. Participants (N=30) chose between certain and gamble options with varied absolute value and probability (Kurnianingsih et al., 2015). The value-to-utility transformation of each participant was quantified using a standard measure of risk preference (alpha). Participants were on-average risk averse in the gains domain, with a wide range of preferences.
To localize the brain region responsible for the value-to-utility transformation, we identified neural regions that encode a linear value signal whose slope is determined by the direction and degree of subjective valuation each individual is performing. This was accomplished through between-subject covariate analyses, applying individual preference values upon trial-value regressors (two independently tested, both demonstrated to caputre value coding within the ventral medial prefrontal cortex). Whole-brain analyses localized this information to a single cluster of voxels within the daMCC, which replicated in the losses domain. Post-hoc ROI analyses confirmed a zero-centered negative relationship between activation of the daMCC and subjective valuation. Functional connectivity analyses indicate that this region is positively connected with lateral prefrontal cortex and negatively connected with the nucleus accumbens, which we hypothesize allows the value-to-utility transformation to be 'set' by contextual inputs and modulate reward regions.
In conclusion, we show that the daMCC encodes the information necessary to perform the value-to-utility transformation, providing a clear computational function for the daMCC.

Title: Neural pathways underlying explore-exploit tradeoffs in social and nonsocial contexts

Authors: *D. V. SMITH[1], S. WANG[2], M. R. DELGADO[1];
[1]Dept. of Psychology, Rutgers Univ., Newark, NJ; [2]Dept. of Psychology, New York Univ., New York, NY

Abstract: Many of our decisions require us to tradeoff using existing information (exploitation) and gathering new information (exploration). Previous work has suggested that exploitative decisions involve the ventromedial prefrontal cortex and the ventral striatum whereas exploratory decisions involve the frontopolar cortex and intraparietal sulcus. While these brain regions help shape explore-exploit tradeoffs, it remains unclear whether such decisions are influenced by social context. We therefore created a social variant of a conventional 2-armed bandit task. On each trial, participants were first presented with a picture of their partner (a confederate or a computer) before choosing one of two bandits where the potential payouts (1-100 points) varied across time according to Gaussian random walks. After selecting a bandit, participants were shown how many points could be won on that trial. Participants were then shown a screen indicating that their partner was playing an unrelated card-guessing game. Next, participants were asked to press a button to reveal whether their partner guessed correctly or incorrectly. If the partner guessed correctly, then the participant received the points; but if the partner guessed incorrectly, the participant did not receive the points. We found that the partner's success on the previous trial increased exploitative decisions, despite being independent from the potential payouts of either bandit. Our preliminary neuroimaging analyses (N = 11) revealed two results. First, dorsal anterior cingulate cortex responses encoded the absolute extent to which the potential points deviated from what the participants expected (i.e., unsigned prediction errors). Second, ventral striatal responses to winning points depended on the type of partner, with the confederate partner evoking more activation to winning points compared to the computer partner. Taken together, our results suggest that both behaviors (i.e., tendency to exploit) and neural pathways (i.e., ventral striatum) underlying explore-exploit tradeoffs can be influenced by social context.

Abstract: To facilitate life in social environments, we often change our decisions and judgments in order to conform to the social group. However, we also value being consistent with ourselves by conforming to our own judgments. Social influence on our behavior has been extensively studied in social psychology. However, the neural mechanisms of self-conformity and self-consistency remain unclear. In this study, we investigated the neural mechanisms underlying group and self-conformity in a sequential facial attractiveness-rating task with functional magnetic resonance imaging. One week after having given ratings of facial attractiveness in the scanner, participants were asked to rate the same faces again. At the second rating, participants were provided with the previous rating of either the "group average" or "yourself". To convey these group or individual ratings to the participants, we first manipulated each participant's previous ratings by splitting them into two conditions; true (same rating as their previous rating) or false (shift above or below their previous rating). We then randomly selected half of the ratings and used them as basis for the group opinion, whereas the other half was used as basis for the individual opinion. In line with previous research, we found that participants adjusted their judgments of facial attractiveness at the second rating to conform to the group opinion. Interestingly, participants also adjusted their judgments to conform to their own opinion stated in the initial ratings. Indeed, comparing group and individual conditions, participants tended to conform at least as much to their own ratings as to those of the normative group. In the brain, false group and false individual reminders triggered distinct activations. Direct comparisons showed stronger temporo-parietal responses for group conformity than self-conformity and stronger medial prefrontal and central orbitofrontal responses for self-conformity than group conformity. These data suggest that social conformity and self-consistency are based on different neural mechanisms.

Title: The social conformity effect uppon liking and sharing behaviors.

Authors: *N. FISCHER[1], B. E.M. DO NASCIMENTO[3], M. FIORANI, Jr.[2];
[2]Inst. of Biophysics Carlos Chagas Filho, [1]Federal Univ. of Rio De Janeiro, Rio DE Janeiro, Brazil; [3]Forebrain LLC, Rio de Janeiro, Brazil

Abstract: We are constantly asked to express our opinion. With the popularity of social networks, the expression of preferences can be measurable. However, it is still to be understood what kind of underlying process would be influencing our declared preferences. In this way, our goal is to elucidate what behavioral and neural parameters could be related to two common behaviors expressed by people in social networks: liking and sharing. The experimental design consisted in the visualization of a set of 10 seconds videos, each of them followed by the questions: (1) “How much did you like the video?”; (2) “Would you share this video with someone else?”; and (3) “Have you seen this video before?”. Subsequently, subjects visualized the whole set of videos a second time, but before the questions it was presented a feedback screen shown how that video was supposedly evaluated by others. During the whole experiment, subjects had their behavior and their electroencephalographic (EEG) parameters recorded. Regarding behavioral parameters, regression analysis showed that, at the populational level, thirds’ opinion about videos influenced strongly (p~0) participant’s evaluation. Regarding the ‘like behavior’, the subject’s second responses statistically followed the ‘others’ (feedback) evaluation showing a strong social conformity effect. The feedback also affected significantly the ‘sharing behavior’, so, downgraded videos were less shared while upgraded videos were shared more times. These results show that the conformity with third part’s opinion is an important modulator of “liking” and “sharing” behavior. Regarding EEG data, it is still under analysis.

Title: Neural correlates of conforming behavior toward a group sharing the same preference on movies

Authors: *S. LEE, D. LIM, E. SEOMOON, D. KANG, S.-P. KIM;
UNIST, Ulsan, Korea, Republic of

Abstract: Humans estimate the value of objects and make judgment based on it, which is often affected by both internal and external factors. Other's opinion is one of the external factors that can change one's decisions. Many studies have shown that individuals conform to the opinion of a reference group such as public, experts or peers, driven by a desire to belong to the reference group. In line with the previous studies, we aimed to investigate how individuals conform to a reference group sharing the same preference for movies that they frequently consume in daily life. Also, we aimed to examine neural signals modulated by such conforming behavior. In the beginning, participants assessed a list of movies they watched before and were informed that they belonged to one of the four groups based on their assessments. Next, participants performed a series of trials in which participants were shown a movie poster and asked to evaluate how much they anticipated to see the movie, then were exposed to the assessment of the assigned reference group, and finally reevaluated the movie while seeing the same poster again. EEG signals were collected while participants were informed of the assessment of the reference group. There were two behavioral patterns when participants encountered a conflict with the reference group: changing evaluation toward the reference group or keeping their initial ratings. A negative deflection in the frontal area (Fz) peaking at 300 ms, which is known as feedback related negativity (FRN), was increased when participants conformed to the reference group. It reflects a prediction error signal in the reinforcement learning model, induced by a difference between expected outcome (i.e. initial rating) and obtained outcome (i.e. assessment of the reference group). It was shown that participants' adjustment was bounded to the assessment of the reference group, indicating a possibility of the anchoring effect occurring during conformity to the reference group. Our findings suggests that a reference group sharing the same preference can lead to conforming behavior.

Title: Temporal dynamics of decision-making for oneself versus others

Authors: *A. M. HARRIS[1], C. HUTCHERSON[2];
[1]Psychology, Claremont McKenna Col., Claremont, CA; [2]Psychology, Univ. of Toronto Scarborough, Toronto, ON, Canada

Abstract: Although research on decision-making has focused largely on choosing for oneself, in our daily lives we must often select options for others: for example, preparing a meal for a child or buying lunch for a friend. In these cases, we must take into account another's preferences, even though they may differ markedly from our own. Yet, it is unclear when such attributions of others' preferences emerge in the time course of choice. Here we measured participants' brain activity with event-related potentials (ERP) while they made food choices for themselves and two partners, one with similar tastes and one with markedly different (i.e., "health-conscious") preferences. Behaviorally, participants changed their weighting of taste and health attributes depending on the intended recipient, relying most heavily on taste for themselves and on health for the health-conscious partner. As seen previously, neural value signals were visible from 500 to 650 ms after stimulus onset, and were localized to ventromedial prefrontal cortex (vmPFC), a brain region implicated in valuation. Neural activity differentiating decisions for oneself versus others emerged even earlier, from approximately 300-500 ms post-stimulus, localized to social cognition regions including posterior superior temporal cortex (pSTC). However, when individual taste and health ratings were included as covariates, early activity for oneself versus other was largely explained by the weighting on health information. In contrast, neural responses to taste emerged in the later time window associated with value, and showed no interaction with the intended recipient. Consistent with this idea, value-related brain activity showed a significant interaction of the weighting of taste and health information by the intended recipient. Whereas taste contributed most strongly to ERPs for oneself, health information was weighted increasingly with increasing partner distance (Self < Similar < Different). Together, these results provide novel insights into the time course of decision-making when others' preferences are taken into account.

Title: Altered striatal activity to wins and losses of rewards in ADHD

Authors: *C. FASSBENDER[1], P. MUKHERJEE[1], C. A. CALUB[1], J. F. DIXON[1], S. HINSHAW[2], A. E. GUYER[3], W. VAN DEN BOS[4], S. MCCLURE[5], J. B. SCHWEITZER[1]; [1]UC Davis Sch. of Medicine, MIND Inst., Sacramento, CA; [2]Dept. of Psychology, Univ. of California Berkeley, Berkeley, CA; [3]Human Develop. and Family Studies Unit, Dept. of Human Ecology, UC Davis Ctr. for Mind and Brain, Davis, CA; [4]Max Planck Inst. for Human Develop., Berlin, Germany; [5]Psychology, Arizona State Univ., Tempe, AZ

Abstract: ADHD impairments are associated with altered motivation, perhaps attributable to altered response to rewards in this group. However, many tasks used to evaluate reward processing also involve cognitive control processes, also implicated in ADHD impairment. We employed fMRI and a Numeric Guessing Game reward paradigm to examine neural responses to wins and losses in youth with ADHD compared to typically developing peers (TD). Participants consisted of 20 ADHD (mean age 14.83 yrs) Combined subtype (significant symptoms of inattention and hyperactivity/impulsivity) and 20 (mean age 14.82 yrs) age and sex-matched TD peers between the ages of 12 and 18. A Numeric Guessing Game presented participants with a single digit number between 0 and 9 and they were required to guess, by button press, if a "hidden" number was greater than or less than the presented number. The response period was followed by a variable "anticipation" period (2, 4 or 6 sec; avg. 4.13 sec). Participants were then provided feedback; a smiling face represented a correct guess and a $1 reward and a frowning face represented an incorrect guess and a loss of 50c. An entire trial was followed by a jittered ITI (4,6 or 8 sec; avg. 6.13 sec). Trials were presented in 4 blocks of 15 trials each for a total of 60 trials.
ADHD and TD groups did not differ on age, Tanners pubertal ratings or Full scale IQ. The ADHD group were significantly elevated on Conners' parent ratings of both inattention and hyperactivity/impulsivity ($p<0.0001$) compared with the TD group. AFNI preprocessed and analyzed the imaging data. Following the GLM, we performed a 2 (Condition; Win v Loss) x 2 (Group; TD v ADHD) ANOVA, which examined the Group x Condition interaction, as well as the within group Win v Loss maps. The TD Win v Loss map revealed a number of brain regions including multiple regions in the striatum (caudate, putamen, lentiform nucleus), the insula, inferior frontal gyrus (IFG) and anterior cingulate cortex (ACC). The ADHD Win v Loss map revealed two regions one in the IFG and one in the ACC. The Group x Condition Interaction map revealed two regions in the striatum and one in the ACC. We extracted percent signal change values from the striatal ROIs, due to their prior importance in the reward literature and in ADHD. The TD group displayed greater activity in all striatal regions to wins over losses whereas the ADHD group displayed equivalent activity in the striatum to wins and losses (Left Caudate and Right lentiform nucleus).
These results suggest a blunted response in the striatum to wins and losses in ADHD. This may explain why individuals with ADHD respond differently to rewards compared with their typically developing peers.

Title: Differences in brain response to anticipation for food and money rewards predicts children's intake of savory foods served at a highly palatable buffet meal.

Authors: *S. ADISE[1], A. M. CAPRIO[2], N. J. ROBERTS[3], C. N. WHITE[4], C. F. GEIER[3], K. L. KELLER[1];
[1]Nutritional Sci., [2]Biol., [3]Human Develop. and Family Studies, The Pennsylvania State Univ., University Park, PA; [4]Psychology, Syracuse Univ., Syracuse, NY

Abstract: Basic decision-making is integral for food choice. fMRI studies show that brain regions implicated in decision-making (e.g., reward and inhibitory control [IC]) respond to food cues, and increased response is associated with obesity. Thus, brain response in regions associated with reward and IC may underlie food-based decisions but how this relates to actual food intake is unknown. Previously, we found that selection of savory-fat food items (e.g., pizza, chips, etc.) over sweet and sweet-fat foods at a highly palatable buffet positively correlated with weight status. However, the neural mechanisms underlying these food-based decisions have not been determined. We hypothesized that increased intake of savory-fats and child body mass index (BMI) *z*-score would correlate with BOLD signal in regions associated with reward processing (e.g. medial prefrontal cortex [mPFC], ventral medial prefrontal cortex [vmPFC]) and IC (e.g. dorsolateral prefrontal cortex [dlPFC]) when anticipating food > money (F_a>M_a) rewards. We measured fMRI BOLD response to anticipation of food and money rewards (via a modified card-guessing task), BMI *z*-score, and *ad libitum* intake at a highly palatable buffet of savory (e.g., pizza, chips), sweet (e.g., candy), and sweet-fat (e.g., cookies) foods in 7-11-year-old children (n=26; 42% obese/overweight). Multiple linear regressions were used to predict intake with independent predictors of BMI *z*-score and BOLD activation in the regions associated with reward and IC to F_a>M_a. Results showed that intake of savory-fats was positively

predicted by BMI *z*-score (p=.046) and $F_a>M_a$ BOLD signal in the mPFC (p=.019), which explained 33% of the total variance in intake (*p*=.009). vmPFC BOLD signal for $F_a>M_a$ (p=.05) and BMI *z*-score (p=.046) positively predicted intake, explaining 28% of variance (p=.02). Savory-fat intake was also positively predicted by BMI *z*-score (p<.001) and BOLD signal to $F_a>M_a$ in the left dlPFC (p=.001) (explaining 48% of total model's variance [p=.001]) and right dlPFC (p=.02) (predicting 50% of the total model's variance in intake of savory-fats [p<.001]). There were no relationships between the aforementioned regions and intake of the total meal, sweet, or sweet-fat foods. Our results suggest that anticipation of food relative to money rewards in brain regions implicated in reward and IC predicts intake of savory-fat foods at a buffet meal. Therefore, brain regions involved in decision-making may play a crucial role in overeating, particularly for savory items. Further investigation into the mechanisms underlying brain responses to rewards are driving increased food intake is needed.

Title: Elucidating the underlying components of food valuation in the human orbitofrontal cortex

Authors: *S. SUZUKI[1,2], L. CROSS[3], J. P. O'DOHERTY[2,3];
[1]Frontier Res. Inst. for Interdisciplinary Sci., Tohoku Univ., Sendai, Japan; [2]Div. of the Humanities and Social Sci., [3]Computation and Neural Systems, Caltech, Pasadena, CA

Abstract: The valuation of food is a fundamental component of the decision-making process that all humans complete on a daily basis. Consumption of high nutrient food increases the likelihood of survival, while consumption of low quality food is deleterious for health. A dysfunctional food valuation process may play a large role in the development of obesity, diabetes, and eating disorders. The orbitofrontal cortex (OFC) is thought to be a canonical brain region for food valuation. There is accumulating evidence that the OFC and adjacent medial frontal cortex represents information about value for various classes of goods including food.

Also, the OFC receives direct projections from primary sensory areas involved in representation sensory features of food such as gustatory and olfactory cortex. Yet, little is known about how value of a food is computed in the OFC. Specifically, it remains elusive how the OFC computes a food value through integrating information about multiple nutrient factors.
To address this issue, we scanned 24 human participants by fMRI while they reported their "willingness to pay" (i.e., value) for 56 food items (Task 1), followed by a behavioral task in which they rated subjective nutrient factors of the same set of the items (Task 2). Importantly, during Task 1, the participants were not aware that they would be subsequently required to rate nutrient factors of the items. Behaviorally, we found that subjective ratings about the four nutrient factors, fat, carbohydrate, vitamin and protein, predicted subjective value of the food items. Furthermore, multivariate analyses (MVPA) on the fMRI data revealed that information about food value can be decoded above chance-level from patterns of neural activity in both medial and lateral parts of the OFC. On the other hand, information about the nutrient factors can be significantly decoded from neural activity in the lateral OFC, but not in the medial OFC. These results may suggest that food value is computed in lateral OFC by integrating information about multiple nutrient factors and sent to medial OFC to guide behavior.

Title: Effects of sex and education on trajectories of cognitive change with age in older adults

Authors: *L. K. MCEVOY[1], E. T. REAS[2], J. BERGSTROM[3], D. KRITZ-SILVERSTEIN[3], E. BARRETT-CONNOR[3], G. A. LAUGHLIN[3];

Abstract: Many cognitive abilities decline with advancing age. However, the magnitude and timing of cognitive changes, and their moderators, are not fully known. In this study we aimed to characterize sex-specific trajectories of change in cognitive performance over a 27 year follow-up period in older community-dwelling adults, and to assess the influence of education on age-related cognitive decline. Between 1988 and 2016, 2225 community-dwelling participants of the

Rancho Bernardo Study (mean age 71 years, range 31-99 years at initial cognitive assessment) completed up to seven cognitive assessments at approximately 4 year intervals. Participants completed tests of global cognition, executive function, category fluency, and verbal episodic memory. Linear mixed effects regression models were used to define sex-specific trajectories of cognitive change with age, adjusting for education and retest effects. Analyses were conducted on the full cohort, and after excluding individuals with evidence of cognitive impairment at the first or last cognitive assessment. Cognitive impairment was defined as an MMSE score greater than two standard deviations below the sex-, age-, and education-adjusted mean, based on normative data from the National Alzheimer's Coordinating Center (Shirk et al. *Alzheimer's Research & Therapy,* 2011). Significant decline was observed on all tests for both men and women, with acceleration in decline beginning around age 65 and increasing after age 80. Higher education was associated with slower decline in executive and global function for both sexes, but was not associated with rates of decline in category fluency or episodic memory. Although women performed better than men on the episodic memory test, rates of decline did not differ between men and women. Men were more likely than women to show cognitive impairment (32% vs 17%). When these 517 participants were excluded, age-related decline on all tests remained significant, and women showed steeper decline in executive function than men. This study shows that significant decline with age occurs across multiple cognitive domains in men and women, with men and women showing similar trajectories of decline in most domains. Higher education protects against age-related decline in some cognitive domains, but not in others. In future studies we will take advantage of the wealth of information available in this extremely well-characterized longitudinal cohort study to examine associations of a wide range of health and lifestyle variables with trajectories of cognitive change with age, and will investigate whether these associations differ by sex.

Title: Effects of apoe status on age-related cognitive decline in community-dwelling older adults: modulation by sex, education and lifestyle

Authors: *E. T. REAS[1], G. A. LAUGHLIN[2], J. BERGSTROM[2], D. KRITZ-SILVERSTEIN[2], E. BARRETT-CONNOR[2], L. K. MCEVOY[1];
[1]Radiology, [2]Family Med. and Publ. Hlth., UNIVERSITY OF CALIFORNIA, SAN DIEGO, La Jolla, CA

Abstract: The Apolipoprotein E (ApoE) gene is one of the strongest genetic risk factors for sporadic Alzheimer's disease, with elevated disease risk for carriers of the E4 allele. However, there is conflicting evidence about whether E4 accelerates cognitive decline in normal aging. We assessed the association between ApoE genotype and age-related cognitive decline in community-dwelling adults from the Rancho Bernardo Study, and assessed whether E4 effects were modulated by sex, education and lifestyle. Tests of global cognitive function, executive function, verbal fluency and episodic memory were administered to 1393 adults (1087 E4-; 306 E4+) aged 44-99 years at their initial cognitive assessment. Participants were evaluated up to seven times over a maximum follow-up period of 27 years between 1988 and 2016. Linear mixed effects models examined age-related trajectories of cognitive change, assessing the influence of ApoE genotype, sex, education, physical activity, alcohol consumption and smoking. There were no main effects of ApoE on cognitive function, but E4 carriers showed greater age-related decline than non-carriers on tests of executive function and verbal fluency for both men and women. Presence of an E4 allele in men, but not in women, was associated with greater age-related decline in global cognitive function. Verbal fluency decline was accelerated for those without a college education, but only for E4 carriers. E4 interacted with alcohol consumption on age-related decline in global cognitive function and memory, but did not interact with smoking or physical activity. These findings indicate that the E4 allele may increase risk for age-related decline. This risk differs between men and women, and may be modulated by education and alcohol consumption.

Title: Alzheimer's disease risk factor score is associated with cognitive performance and brain volume

Authors: *A. SAKHARE[1], W. MACK[2], J. PA[2];
[1]Biomed. Engin., [2]USC, Los Angeles, CA

Abstract: Background: Large epidemiological studies suggest there are 7 main modifiable lifestyle factors that increase the risk of developing Alzheimer's disease (AD): obesity, low education, physical inactivity, diabetes, hypertension, and depression. However, it is unknown whether the presence of these risk factors in cognitively normal individuals is associated with early changes in cognition or brain structure. The objective of this study was to create a composite risk factor score (RFS) and correlate it with performance on cognitive tests of attention, executive function, and memory in addition to brain structure across the lifespan.
Methods: Participant data (N=379, Ages 22-85) were obtained from a cross-sectional study performed by the Nathan Kline Institute. The RFS was calculated as a weighted sum of these risk factors, with weights based on previously reported relative risk values (Barnes & Yaffe, 2011); a higher RFS suggested greater AD risk. RFS was correlated to performance on the following cognitive tests: Forward and backward digit span, DKEFS Trails A and B, and RAVLT delay and immediate recall. T1 MRI images were processed using voxel based morphometry. A linear regression analysis was performed to correlate RFS with grey matter (GM) volume, controlling for age. The RFS was also split at the median; a 2 sample t-test was performed to evaluate group differences (lower vs. higher RFS) in voxel-wise brain volume across the lifespan. A subgroup analysis was performed for 3 age groups: early-life (EL) (22-39), mid-life (ML) (40-64), and late-life (LL) (65-85).
Results: The RFS distribution showed a slight leftward skew towards protection against AD across all participants. Trails A and B tests showed a positive association with RFS across all participants and in the LL subgroup analysis. A negative RFS association was seen with the forward digit span in the ML group. RFS was not significantly associated with RAVLT. Linear regression analysis showed negative associations between GM volume and RFS in the precuneus (LL), thalamus (ML), and basal ganglia (EL) ($p<.001$). The RFS median split analysis showed lower GM volume in the amygdala, medial-prefrontal area, and inferior temporal gyrus for those with higher RFS (LL only).
Conclusions: Our study suggests that these modifiable AD risk factors are associated with cognitive function and brain volume across the lifespan, even in cognitively normal older adults. Lower GM volume observed in the precuneus, medial-prefrontal cortex, and inferior temporal cortex could indicate increased vulnerability to developing AD as these are known regions of beta-amyloid and tau deposition.

Title: A role for sleep-dependent consolidation in age-related episodic memory decline?

Authors: *B. E. LEYK[1], M. C. SANDER[1], Y. FANDAKOVA[1,2], T. H. GRANDY[1], B. RASCH[3], Y. SHING[1,4], M. WERKLE-BERGNER[1];

Abstract: Sleep after learning benefits memory. With advancing age, both sleep and memory performance undergo drastic changes. However, whether the observed age-related alterations result from qualitatively different mechanisms or simply reflect quantitative changes in the reliance on a functionally comparable neurocognitive machinery remains obscure. In the current study, tracing learning histories across multiple learning-test cycles allowed for close monitoring of the strength of individual memories. Hence, we were able to disentangle the effects of overnight forgetting from active enhancement of initially labile memory traces. Particularly, we asked whether aging differentially affects forgetting and active enhancement. To address this question, we analyzed data from 29 younger (YA, 16 female, M = 23.55 years, SD = 2.58) and 36 older adults (OA, 16 female, M = 68.77 years, SD = 3.15) who completed an associative memory paradigm, comprising of a learning session with multiple learning-test cycles as well as a delayed cued-recall task on the following day. During the nights before and after learning sleep was monitored by ambulatory polysomnography (PSG). We focused on the distribution of sleep stages as well as the occurrence of sleep spindles and slow wave activity (SWA) during non-rapid eye movement (NREM) sleep. While overnight memory enhancement was comparable across age-groups, forgetting was more pronounced in OA. Despite altered sleep architecture in OA, there were no age differences in the association between sleep physiology and memory performance. Crucially, SWA and the occurrence of sleep spindles were related to overnight forgetting across the whole sample. Reduced SWA and spindle density in the elderly were paralleled by decreased overnight memory retention, most prominently expressed for pairs of poor memory strength. Contrary, no reliable association between memory enhancement and

measures of sleep physiology could be detected. The present findings suggest two distinct consolidation mechanisms that differ with regard to their relation with sleep and aging. Our results underpin the idea that functionally similar mechanisms underlie the consolidation of episodic memories in both younger and older adults. Specifically, slow oscillations and sleep spindles during NREM sleep counteract overnight forgetting. The reduction of SWA and sleep spindles in OA likely impedes the reactivation of memory traces during sleep and their redistribution to the brain's long-term store in the neocortex. Hence, while overnight memory retention in the elderly is impaired, memory enhancement remains spared from aging.

Title: Lateral entorhinal cortex hypoactivation in amnestic mild cognitive impairment

Authors: ***T. T. TRAN**[1], C. SPECK[2], M. GALLAGHER[1], A. BAKKER[2];
[1]Psychological & Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Increased hippocampal activation in the context of impaired memory function is considered a characteristic feature of the amnestic mild cognitive impairment (aMCI) phase of Alzheimer's disease. However, the entorhinal cortex, which serves as the primary relay for both input and output to and from the hippocampus, is the site of the earliest pathological changes including neuronal, synaptic and volume loss. Specifically, the lateral entorhinal cortex is also the site of significant accumulation of tau neurofibrillary tangles early in the disease progression. To assess whether functional changes can be observed in the lateral and medial entorhinal cortex in patients with aMCI, 37 healthy older adults and 42 patients with aMCI completed a forced

choice memory task designed to tax medial temporal lobe memory function while completing a high-resolution functional magnetic resonance imaging (fMRI) scan. Consistent with their diagnosis and previous studies, patients with aMCI showed a significant memory impairment compared to age-matched healthy control subjects as well as increased hippocampal activation. In this context, patients with aMCI also showed significantly decreased activation in both the left and right entorhinal cortex. The observed hypoactivation was localized to the lateral entorhinal cortex and was not observed in the medial entorhinal cortex. Decreased activation in the left lateral entorhinal cortex was correlated with poorer performance on the memory task in patients with aMCI. Finally, the volume of both the left and right lateral entorhinal cortex was significantly reduced in patients with aMCI compared to healthy control subjects while no volume differences between the groups were observed in the medial entorhinal cortex. These results show that, consistent with the locus of early disease related pathology, decreased activation and reduced volume in the lateral entorhinal cortex is observed in patients with aMCI and is associated with impaired memory function in these patients.

Title: Differential effects of hypertension status and white matter hyperintensity volume on white matter integrity in older adults

Authors: *L. A. NGUYEN[1,6,7], P. K. BHARADWAJ[1,6,7], K. A. HAWS[1,6,7], G. A. HISHAW[2], T. P. TROUARD[3], G. E. ALEXANDER[1,6,7,4,5];

Abstract: Healthy aging has been associated with a greater prevalence of vascular risk factors, such as hypertension and increased cerebral white matter hyperintensity (WMH) burden. We sought to investigate whether hypertension status and WMH volume would differentially affect regional white matter integrity in a sample of 48 neurologically healthy community dwelling older adults, 70-89 years of age, with treated hypertension (N = 25) and without hypertension diagnosis or treatment (N = 23). Groups were matched in age, gender, and education. MRI scans were acquired at 3T, including a volumetric T1, T2 FLAIR, and diffusion-weighted imaging. The volumes of WMHs were computed with a multispectral, automated lesion segmentation method to produce probability maps using Statistical Parametric Mapping (SPM12) and the lesion segmentation toolbox (LST; Schmidt et al., 2012). Diffusion-weighted MR images were processed using TRACULA with Freesurfer, which performs automated probabilistic tractography and generates estimates of fractional anisotropy (FA) and mean diffusivity (MD) for major white-matter pathways (Yendiki et al., 2011). The results indicated that hypertension status, but not WMH volume, was significantly related to FA in the forceps minor ($p < 0.001$) and to MD in the forceps major and minor ($p's < 0.001$). Additionally, WMH volume, but not hypertension status, was significantly associated with FA in the left superior longitudinal fasciculus parietal bundle, right cingulum-angular bundle, and right uncinate fasciculus ($0.021 \leq p \leq 0.049$). WMH volume was significantly associated with MD in the left inferior longitudinal fasciculus ($p < 0.01$). There were no interaction effects of hypertension status and WMH volume on the white matter diffusion measures. Together, these findings suggest that vascular risk factors common in healthy aging may have a differential regional impact on white matter integrity in older adults. Further research is needed to evaluate the longitudinal effect of these vascular factors on metrics of white matter integrity and on cognition in the context of healthy cognitive aging.

Title: Event related potentials N500 is decreased in elder people with excess of absolute theta power in a counting Stroop task

Authors: *S. SÁNCHEZ MOGUEL[1], G. ALATORRE CRUZ[2], S. CASTRO CHAVIRA[1], M. GONZÁLEZ LÓPEZ[1], T. FERNÁNDEZ HARMONY[1];
[1]Dept. de Neurobiología Conductual y Cognitiva, Inst. De Neurobiología, UNAM, Querétaro, Mexico; [2]Facultad de Estudios Superiores Iztacala, UNAM, Estado de México, Mexico

Abstract: During healthy aging, inhibitory processing is affected at sensorial, perceptual and cognitive levels. Decay in inhibitory efficiency contributes to performance decline in elderly adults observed in tasks requiring selective attention, working memory or sustained attention. Moreover, patients with mild cognitive impairment (MCI) frequently show an even more diminished control of the inhibitory processing. The Stroop task during Event Related Potentials (ERP) has been used to study age-related decline in the efficiency of inhibitory processes. The magnitude of the Stroop effect increases in late adulthood. Studies using ERP have found that the N500 amplitude is attenuated in healthy elderly adults as compared to young adults. However, inhibitory processing in older adults at the preclinical stages of cognitive decline has not yet been assessed. An excess of theta activity, as evaluated by normative Quantitative Electroencephalography (QEEG), is an excellent predictor of cognitive deterioration during aging; which enables the assessment of inhibitory processing years before the appearance of cognitive decline. The aim of this study was to evaluate inhibitory processing in older adults with excess theta Absolute Power as compared to older adults with normal EEG activity. ERP were recorded while subjects performed a counting Stroop task. We found that N500 amplitude was significantly reduced in older adults with excess theta. However, there were not differences in the number of correct answers or in response latency. Previous studies showed that reduced N500 amplitude over the midline frontocentral region during interference trials co-occurs with age-related inhibitory-processing decline. Thus, our results suggest that subjects with excess of theta EEG activity, exhibit electrophysiologically differences in inhibitory attentional processing, as evidenced by ERP. Though these results were not confirmed by behavioral assessment, the electrophysiological differences suggest hidden deterioration of inhibitory processing in subjects at preclinical stages of cognitive decline, which is consistent with previous findings of inhibitory-processing deterioration in MCI and dementia patients. Title: Neural connectivity during spatial source memory retrieval in young and old adults

Authors: *S. CANSINO[1], P. TREJO-MORALES[1], C. ESTRADA-MANILLA[1], E. H. PASAYE-ALCARAZ[2], E. AGUILAR-CASTAÑEDA[3], P. SALGADO-LUJAMBIO[3], A. L. SOSA-ORTIZ[3];

Abstract: The memory of our personal experiences is referred to as episodic memory. Personal memories include the event and contextual details, as the moment, place and the emotional state of the individual. The ability to retrieve contextual details declines gradually with advancing age, whereas the ability to remember the event without contextual information is almost unaffected in old age. The former is termed as recollection and the latter as familiarity. Several regions exhibited greater activity in young adults than in old adults during the recollection of episodic information. However, less is known about how the interaction among these regions accounts for the decline of recollection in old age. Twenty-two young adults and 22 old adults participated in the study. Functional magnetic resonance imaging (fMRI) data were recorded while participants performed a spatial source memory task. FMRI data were analyzed using dynamic causal modeling (DCM) to examine neural connectivity during successful and unsuccessful spatial source memory retrieval. DCM analyses were conducted in brain regions that showed significant activity differences between age groups in the contrast between correct versus incorrect source judgments. Only brain activity in regions from the left hemisphere was analyzed. Effective connectivity between the hippocampus and the middle frontal gyrus was reduced in old adults relative to young adults during source retrieval. The results suggest that age effects on recollection cannot be attributed only to local under-recruitment activity but also to a less functional network.

Title: Differential regional alterations of white matter integrity in healthy cognitive aging

Authors: *P. K. BHARADWAJ[1,2,7], L. A. NGUYEN[1,2,7], K. A. HAWS[1,2,7], G. A. HISHAW[3], T. P. TROUARD[4], G. E. ALEXANDER[1,2,5,6,7];

Abstract: White matter (WM) microstructural integrity assessed with diffusion weighted imaging is diminished in the context of healthy aging. Such age effects have often shown an anterior-posterior gradient and may be influenced by vascular risk factors such as hypertension. The aim of this study was to investigate regional differences in WM integrity measured by fractional anisotropy (FA) and mean diffusivity (MD) in a healthy sample of community dwelling older adults, ranging in age from 50 to 89 years. The study sample comprised 74 healthy older adults divided into four age groups (50-59, 60-69, 70-79 and 80-89 years). Only neurologically healthy participants without a clinical diagnosis of diabetes or hypertension were included. T1-weighted and diffusion weighted images were acquired at 3T and processed using FreeSurfer (Fischl et al., 2004a) and TRACULA (Yendiki et al., 2011), to create individual ROIs, perform probabilistic tractography, and compute regional values of FA and MD for 18 major WM tracts. The diffusion metrics were tested using ANCOVA with age as the between group factor and total cortical WM volume as a covariate. The results showed that FA decreased with age bilaterally in the anterior thalamic radiation (ATR, $0.011 \leq p \leq 0.021$), and the left temporal and parietal branches of the superior longitudinal fasciculus (SLFT, $p = 0.005$; SLFP, $p = 0.05$). MD demonstrated age-related increases bilaterally in the ATR ($0.003 \leq p \leq 0.014$), cingulum angular bundles ($0.002 \leq p \leq 0.042$), inferior longitudinal fasciculus ($0.001 \leq p \leq 0.006$), uncinate fasciculus ($0.0003 \leq p \leq 0.001$), and the right SLFT ($p = 0.043$). Pairwise comparisons of FA and MD in these tracts showed varying patterns of age group differences that differed between the two diffusion metrics. These results demonstrate that measures of WM microstructure assessed by FA and MD differ by age group, for select tracts, as well as by which

specific age groups are most affected. Together these findings suggest that measures of diffusivity (MD) and microstructural organization (FA) may show differences in their ability to detect age-related WM integrity changes among healthy older adults.

Title: Considering structural complexity as a measure of age-related differences in brain morphology

Authors: *C. R. MADAN, E. A. KENSINGER;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: INTRODUCTION: Different measures of cortical morphology have been shown to index distinct aspects of inter-individual differences (e.g., volume, thickness, surface area, gyrification). Here we consider the additional measure of structural complexity, as quantified by fractal dimensionality. Using several open-access MRI datasets, providing a combined sample of over 2000 adults across the adult lifespan, we examined the relationship between fractal dimensionality and other extant measures of brain morphology. We additionally examine the relationship between each measure and age-related differences in brain morphology. In a separate set of analyses we further examine the test-retest reliability of each measure using datasets where participants were scanned multiple times within a short period, either on the same scanner or at a different site (i.e., travelling subjects). METHODS: Common measures of cortical and subcortical structure were measured using FreeSurfer. We additionally calculated the fractal dimensionality of these cortical and subcortical structures using the calcFD toolbox, which we recently developed and freely distribute (http://cmadan.github.io/calcFD/). RESULTS: With respect to cortical structure, we found that fractal dimensionality captured more age-related differences in morphology than either cortical thickness or gyrification (see Madan & Kensinger, 2016, NeuroImage). Additionally, all measures have high test-retest reliability. Age-related differences in subcortical structures was explained better by fractal dimensionality than differences in volume (ICV-corrected). Complexity of ventricular structures was not improved

relative to volume differences, suggesting that the measure may only be indicative of more meaningful age-related differences in neuroanatomical structure. DISCUSSION: When examining the relationship between brain morphology and inter-individual differences, it is important to consider the most appropriate measure. For instance, it has been established that age-related differences are reflected most in cortical thickness, rather than surface area or volume. Here we found that fractal dimensionality, which incorporates shape-related properties, to be a more sensitive measure of age-related differences in cortical and subcortical structures. However, it is important to consider that more age-related variability explained may not be necessarily be desired, as this leaves less variance available to be related to other factors, e.g., performance on cognitive measures, so extant measures may still be a preferable depending on the research question.

Abstract: It is well-known that aging is associated with differences in cognitive performance among community-dwelling older adults, with executive function, memory, and processing speed often preferentially affected. Physical activity is one factor that may have an important role in influencing observed individual differences in cognitive aging. We sought to determine whether higher levels of self-reported physical sport activity is associated with better

performance on those measures of cognitive function often affected by healthy aging. In a sample of community-dwelling, neurologically healthy older adults, self-report ratings of physical sport activity were obtained from 202 participants ages 50-89 years (mean ± SD = 70.24 ± 10.5 years). Subjects who reported a high level of sport activity (n=38) were compared to those who reported a low level of sport activity (n=164). The groups did not differ in age and years of education. Regression was used to test the effects of age, physical activity, and their interaction. Results revealed significant main effects for age across all domains (p's < 0.0001), but not for physical activity (p's > 0.282). Significant age by physical activity interactions were observed for measures of executive function (WAIS-IV Matrix Reasoning, Stroop Word-Color Interference, and Trails-B; $0.004 < p < 0.032$), memory (Rey Complex Figure Test-Delay Recall; $p = 0.039$), processing speed (Finger Tapping (non-dominant hand); $p = 0.02$), visuospatial function (WAIS-IV Block Design; $p = 0.006$) and language (WAIS-Similarities; $p = 0.017$). These effects remained significant after controlling for hypertension status. The older adult group (72-89 years) with high physical activity performed better than those with low physical activity. In addition, the older adult group with high physical activity performed better than, or comparable to, the younger adult group (50-71 years) with high physical activity. These findings suggest that engagement in high levels of sport activity may be an important element for maintaining cognitive abilities in old age.

Title: Adaptive computerized cognitive training for healthy older adults

Authors: *S. RABIPOUR[1], M. PETRUCELLI[2], M. DE O. G. GERMANO[3], A. POPESCU, K1N 9A8[2], P. DAVIDSON[4];
[2]Computer Sci., [3]Mechanical Engin., [4]Psychology, [1]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Computerized cognitive training is becoming increasingly popular and practical, holding promise for both patients and healthy individuals. Nevertheless, basic questions remain about the real-world benefit of such programs and the degree to which participant expectations might influence training effects. Here we examined: i) the feasibility of a 5-week computerized

cognitive training intervention in healthy older adults; and ii) the potential effects of participant expectations on performance during training. Participants were 91 healthy older adults 59-91 years of age (M = 68.88, SD = 6.32; 69 women) randomly assigned to complete either the intervention or an active control program. The intervention, a pirate-themed web program called *Activate*, comprised adaptive computer games previously shown to improve scholastic performance in children with impulse-control impairments as well as reduce depressive symptoms and executive dysfunction in patients with geriatric depression. Participants in the *Activate* intervention completed a series of games designed to improve functions such as working memory, attentional control, pattern completion, and category sorting. The control program comprised non-adaptive computer games with no unifying theme (Sudoku and single n-back working memory exercises), which have little evidence for improving cognitive function, despite popular conceptions. We further randomized half of the participants in each group to receive information implying either high or low effectiveness of cognitive training, to manipulate their expectations of outcomes at the outset of the program. The intervention was feasible in healthy older adults, with 97% of participants completing the program. Moreover, participants provided positive feedback and reported that they would recommend the program, regardless of experimental condition (75/85 = 88%; $X^2 = 2.59$, *ns*). Analyses of performance on *Activate* revealed a trend towards greater improvement over the course of training by participants assigned to the high expectations subgroup; this trend reached significance in one of the four game types ($F_{(4, 152)} = 3.54$, $p = 0.009$, $\eta^2 = 0.085$). In contrast, we found little difference in the training patterns of those in the high versus low expectations control group. Our results suggest that the present cognitive training intervention is feasible, engaging, and enjoyable, but that high expectations at the outset may facilitate greater improvement during the course of training.

Title: Age-related changes in dopamine reduce cognitive flexibility by disrupting fronto-striatal-thalamic functional connectivity

Authors: *A. S. BERRY[1], V. D. SHAH[1], W. J. JAGUST[2];
[1]E O Lawrence Berkeley Natl. Lab., Berkeley, CA; [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, CA

Abstract: Aging is associated with reduced cognitive flexibility and dysregulation of dopamine, including elevated dopamine synthesis capacity in dorsal caudate nucleus (DCA) relative to young adults measured by 6[^{18}F]fluoro-L-*m*-tyrosine (FMT) PET. FMT is a measure of dopamine synthesis capacity similar to FDOPA, and is quantified as net tracer influx (K_i). Our previous research in young and older adults revealed an inverted U-shaped relationship between cognitive flexibility and DCA FMT K_i, such that extreme high K_i in older adults and extreme low K_i in young adults was associated with reduced flexibility indexed as larger behavioral switch cost. The influence of DCA dopamine on switch cost may be mediated by its modulation of activity within the fronto-striatal-thalamic loops supporting cognitive flexibility. Here we tested the hypothesis that non-optimal DCA FMT K_i is associated with disrupted functional connectivity during task switching in young (n = 21, mean age = 23.8) and older (n = 15, mean age = 77.4) adults. Specifically, we used fMRI and psychophysiological interaction analyses to measure task-related increases in DCA connectivity during switch trials, and examined its relationship with switch cost and DCA FMT K_i. *A priori* region of interest analyses revealed that stronger task-related connectivity between DCA and left inferior frontal gyrus was related to smaller switch cost ($r = -.45$, $p < .01$). Evaluation of the relationship between dopamine and connectivity strength revealed a significant FMT x connectivity x age interaction ($F(1,32) = 4.82$, $p < .05$) such that high K_i in the older adult group and low K_i in the young adult group was associated with reduced fronto-DCA connectivity. Complementing these findings, exploratory voxel-wise regression analysis revealed that increased DCA-thalamic connectivity was also related to smaller switch cost. Likewise, analysis of DCA-thalamic connectivity demonstrated a significant FMT x connectivity x age interaction ($F(1,32) = 5.62$, $p < .05$) such that high K_i in older adults and low K_i in young adults was associated with reduced DCA-thalamic connectivity. Together, these data provide evidence that cognitive flexibility is supported by fronto-striatal-thalamic connectivity, and that connectivity within this circuit is acutely sensitive to DCA dopamine function. We suggest that age-related declines in flexibility are mediated by the effect of dysregulated dopamine on the tuning of striatal circuits.

Title: Multitasking of young and older adults in ecologically valid scenarios- the association with executive functions

Authors: ***C. JANOUCH**[1], U. DRESCHER[2], O. L. BOCK[2], C. VOELCKER-REHAGE[1]; [1]Sports Psychology (Rehabilitation and Prevention), Univ. of Technol. Chemnitz, Chemnitz, Germany; [2]German Sports Univ. Cologne, Cologne, Germany

Abstract: Many daily and sports activities rely on our ability to perform multiple motor and cognitive tasks concurrently, e.g., when driving a car while using the car's navigation system. Multitasking skills have been shown to decrease with advancing age (e.g., Verhaegen et al., 2003). The underlying mechanisms and interplay between cognitive and motor decline are, however, still unclear. It is proposed that executive functions (EF) might contribute towards multitasking, particularly in old age (Baddeley, 1986). Thus, first, we investigated the association between the partitioned EF systems' components (task switching, memory updating, response inhibition (Miyake et al., 2000) and dual-tasking (Strobach et al., 2014)) and the performance in multitasking situations. Moreover, performance in laboratory settings seems to differ from performance in everyday life (Bock & Züll, 2013). Thus, we further aimed to investigate age-related differences in multitasking performance in realistic (virtual) scenarios, namely driving and street crossing. Therefore, executive functions of young (20-30 years) and older (65-75 years) adults are assessed with standardized laboratory tests (updating: spatial n-back task; inhibition: Simon task; task shifting: Geometric figure task; dual-tasking: visual tracking task with tone recognition). Multitasking skills in natural scenarios are assessed by use of two virtual-reality (VR) tasks (simulated street crossing and car driving) combined with a battery of realistic (cognitive) loading tasks that draw on participants' working memory, reasoning and manual skills. Data are currently collected. We expect typical age-related differences in multitasking performance between young and older adults. Age-related differences in the influence of EF on multitasking performance (street crossing and driving task) are analyzed by regression analysis. We expect a moderate effect of EF on multitasking scores in the two VR scenarios. This effect should be stronger for older than for young participants, due to the age-related increase of cross-domain associations (Baltes & Lindenberger, 1997). The understanding of age-related decline in multitasking and the potential contribution of EFs will contribute to develop optimal training programs to improve multitasking performance, particularly in older adults.

Leipzig, Leipzig, Germany

Abstract: Obesity is often discussed as being associated with primary and secondary changes in brain structure and cognition. However, previous studies yielded controversial results, especially with regard to white matter (WM) changes that might be due to differences in sample size, age, sex, and body mass index (BMI) between studies. Therefore, we aimed to assess the effect of BMI on WM microstructure and cognition using diffusion tensor imaging (DTI) in a large, well-characterized population-based sample of healthy older adults.
Analyses were conducted in 586 participants of the LIFE-cohort in Leipzig, Germany (48% females, 60-80 years, BMI 16.81-38.56 kg/m^2) who underwent DTI neuroimaging at 3T and neurocognitive testing. Voxelwise statistical analysis of fractional anisotropy (FA) as a measure of WM fiber tract orientation and density, was carried out using Tract-Based Spatial Statistics (TBSS) implemented in FSL (www.fmrib.ox.ac.uk/fsl/). Associations between BMI and WM tracts were conducted based on permutation tests adjusting for confounders (age, sex and WM hyperintensities). Potential associations with cognitive performance were assessed using partial correlations and mediation analyses controlled for age, sex, and education.
A significant negative correlation between higher BMI and lower FA was observed in

widespread areas including the entire corpus callosum (CC), corona radiata (CR) and internal capsule (IC) ($p<0.05$, FWE-corrected). FA of a BMI-associated cluster in the anterior CC was negatively correlated with BMI ($r=-0.205$, $p<0.01$), whereas it was positively correlated with executive functions ($r=0.101$, $p<0.05$). On the other hand, a higher BMI was correlated with lower scores of executive functions ($r=-0.089$, $p<0.05$). Preliminary mediation results indicated that lower executive functions would translate into lower FA via increasing BMI ($ab = 0.019$, $|BBCI| > 0$), and that BMI would again have a negative contribution to executive functions via its negative effect on FA ($ab = -0.019$, $|BBCI| > 0$).
In this large cross-sectional study we found that obesity, independent from confunders, was associated with reduced WM fiber tract orientation or density in areas including the CC, CR, and IC in healthy elderly individuals. Moreover, our findings indicate a possible role for WM dysfunction in a presumably vicious circle of lower executive functions contributing to higher BMI which in turn provokes regional WM changes, which again contribute to poorer executive functions. Future longitudinal studies are needed to further support this hypothesis and to identify possible underlying mechanisms.

Title: Comt val158met polymorphism is associated with decreased cortical thickness for val carriers in regions of the dopaminergic system

Authors: ***G. G. MIRANDA**, K. M. RODRIGUE, J. R. RIECK, K. M. KENNEDY;
Ctr. for Vital Longevity., Sch. of Behavioral and Brain Sci., The Univ. of Texas At Dallas, Dallas, TX

Abstract: Aging is associated with regionally specific decreases in cortical thickness and subcortical brain volume in healthy individuals. Cognitive aging and to a lesser extent, structural

brain aging have been demonstrated to be partly under genetic control. One common specific genetic polymorphism frequently associated with cognitive performance is the COMT Val158Met polymorphism (COMT). Individuals with the Val/Val genotype demonstrate lower prefrontal dopamine availability coupled with less efficient neural processing. Given the effects of age on brain structure in the dopaminergic pathways, we investigated the influence of COMT polymorphism on cortical thickness and subcortical volume in *a priori* determined regions of interest (ROIs) in frontal, parietal, cingulate, and subcortical areas. We further tested the resource modulation hypothesis, whereby aging is hypothesized to magnify modulation of genetic effects on brain integrity. Our sample consisted of 158 healthy participants across the lifespan for which MRI and COMT genotype data were collected (aged 20-94; Met/Met *n*=38, Val/Met *n*=77, Val/Val *n*=43). FreeSurfer pipeline with manual edits was used to extract cortical thickness and subcortical volume measures. Results indicated significant main effects of COMT genotype beyond the effects of age: we observed significantly thinner cortex for the Val/Val compared to Met/Met group in dorsolateral prefrontal cortex (inferior frontal, middle frontal, superior frontal gyri). Additionally, posterior (but not anterior) cingulate gyrus was thinner for the Val/Met compared to Met/Met group. We found no effect of COMT for orbitofrontal or parietal regions. Effects of COMT on subcortical structures ranged from small but significant (caudate, putamen) to trend-level (accumbens). Thus, individuals with suspected lower prefrontal dopamine availability (Val carriers), have thinner cortex and smaller subcortical structures selectively in regions associated with dopaminergic pathways in the human brain. Contrasting the resource modulation hypothesis, in our lifespan sample, we found no magnified modulation of brain integrity with age (i.e., Age x COMT interactions); we find the effect of COMT to be present at any point in the adult lifespan, and not limited to elderly populations.

Title: Age-related dual task-interference in visual perception while walking, standing, and sitting

Authors: J. PROTZAK, *K. GRAMANN;
Psychology and Ergonomics, Berlin Inst. of Technol., Berlin, Germany

Abstract: With advanced age, once largely automated movements like simple walking can become a challenging task that requires increased attention. Age-related deficits in mobility and sensory processing have to be corrected and possibly compensated by enhanced concentration and cognitive control. But even if an compensatory strategies lead to a more stable gait, the necessary cognitive resources might not be available. Thus, efficient and safe movement execution is more likely to interfere with simultaneously executed secondary tasks competing for cognitive resources. Little is known about the neural processes that are associated with the cognitive demands resulting from gait and posture and how these influences develop throughout adulthood. This is due to the limitations of traditional brain imaging techniques and the involved difficulties to record data in realistic test situations that include human locomotion. However, recent Mobile Brain-Body Imaging (MoBI) approaches provide feasible techniques to measure and analyze electroencephalography (EEG-) data recorded during normal movement executions. The present MoBI-study was conducted to identify and model the brain dynamics processes accompanying compensation of age-related declines in mobility and sensory processing during dual-task walking. A dual task methodology was used to measure performances variations in a visual detection task and to analyze the accompanying neural processes across three different primary motor task conditions. Two groups of younger (n = 15; age range: 19 - 31 years) and older (n = 15; age range: 69 - 80 years) adults participated in three different motor task set-ups: siting, walking, standing. They were asked to manually respond to randomly presented short visual stimuli from three different peripheral presentation angels (20°, 40° and 60° from the central field of view). EEG-data were recorded continuously with a 64-channel mobile set-up. A standard stimulus-locked event-related potential (ERP) analysis revealed two main findings. Differences in the P300-characteristic for the variation of the visual stimulation angle and motor task condition were found for both age groups. In addition, age-dependent variations in the P300 feature became prominent. These results implicate an age-related modulation of visual perception processes that vary systematically with the difficulty in the primary motor task.

Title: Age-related differences in manual dexterity and their association with executive functions, grip strength, and finger tapping.

Authors: *O. VASYLENKO, C. RODRIGUEZ-ARANDA;
Univ. of Tromsø, Tromso, Norway

Abstract: Aging is associated with declines in cognitive and motor functions, among these, declines in manual dexterity are central as dexterity is one of the most important skills in daily activities. Detailed kinematic analyses of age-related differences in dexterity are scarce and a better understanding of the contribution of cognitive functions to its decline is needed.
Objectives: a) to describe age-related kinematic differences in dexterity performance; b) to assess the relationship between dexterity, cognition, and neuromuscular hand function.
Methods: Participants were 45 young and 55 older adults, all right-handed. Dexterity performance was assessed with two subtasks of the Purdue Pegboard Test: inserting pins with the right hand, and inserting pins with the left hand. Movements analyzed were reaching, grasping, transporting, and inserting. The kinematic measures for each movement were path length, mean and peak linear and angular velocities, angles, and their coefficients of variability. The neuropsychological tests were Stroop Color-Word Test, Trail Making Test, Logical Memory, Digit Span, Grip Strength, and Finger Tapping Test.
Results: In the right-hand task older adults had lower angular and linear velocities and lower variability in angular and linear velocities during grasping and transport, but higher linear and angular velocities and their variability during inserting. The left-hand task results were similar, but in addition, older adults had lower linear and angular velocities and more variability in velocities during reaching, as well as larger angle and longer path length during transport. The largest differences were in path lengths during grasping and inserting, with older adults showing considerably longer path lengths in both tasks. Grasping path lengths in both tasks were significantly predicted by tests of executive function, grip strength, and finger tapping speed.
Conclusions: The more pronounced kinematic differences in the left-hand task indicate that even the relatively simple task of inserting pins is more difficult for older adults when performed with the non-dominant hand. Compared to the young group, older adults were slower in all movements except inserting. Higher velocities in the older group during inserting might be due to making more corrective movements. Older adults were also less precise in all movements, as indicated by longer path lengths. Executive function, grip strength and finger tapping were significant predictors of precision during grasping.

Title: Relationship between episodic memory performance, fMRI correlates of encoding and retrieval and estimates of regional brain structure in older adults

Authors: *M. JAYAKUMAR, M. DE CHASTELAINE, B. E. DONLEY, K. M. KENNEDY, M. D. RUGG;
Ctr. for Vital Longevity, Univ. of Texas At Dallas, Dallas, TX

Abstract: Episodic memory performance declines with age, as do estimates of regional brain structures. Using fMRI, we have previously reported that encoding-related functional activity in the inferior frontal gyrus (IFG) and hippocampus, and retrieval-related activity in the hippocampus, predict associative memory performance across a sample of older individuals (N=62, aged ca. 65-75 yrs.). Here we examined whether structural measures of these same brain regions explain additional variance in memory performance. Participants were scanned both while they encoded a series of word pairs and, subsequently, while performing an associative recognition task (discriminating between 'intact', 'rearranged', and 'new' pairs). Associative recognition accuracy (pR) was indexed by the difference between the proportions of intact pairs judged intact, and rearranged pairs wrongly judged intact. fMRI subsequent memory effects (intact study pairs later judged intact > intact pairs later wrongly judged rearranged) were estimated for bilateral IFG and left hippocampus, and fMRI recollection effects (intact test pairs judged intact > intact pairs judged rearranged) were obtained for bilateral hippocampus. Volume and thickness of the IFG were obtained by a semi-automated method, whereas hippocampal volumes were measured manually. Together, the three functional measures accounted for approximately 33% of the variance in pR across the 62 older subjects (adjusted $R^2 = .337$, $p < .001$). Including hippocampal volume and either left IFG thickness or volume to the regression model did not improve its fit. By contrast, each of these measures of the right IFG significantly improved the fit of the model, but without reducing the contributions of the functional variables (e.g. for right IFG thickness, adjusted $R^2 = .413$). Whereas none of the functional variables, or hippocampal volume, varied according to age (maximum $r = -.163$, n.s., controlling for performance), left and right IFG volume and thickness were highly age-sensitive (minimum $r = -.535$, $p < .001$). These findings indicate that functional and structural measures can dissociate with respect to their sensitivity to individual differences in memory performance and chronological age. This research was funded by NIH Grant 1R01AG039103.

Title: Individual differences in the neural mechanisms of superior cognitive ageing: diffusion imaging and longitudinal cognitive findings

Authors: ***C. O'DONOGHUE**[1,2], N. FILIPPINI[3], E. ZSOLDOS[2], S. SURI[2,1], M. KIVIMAKI[4], A. SINGH-MANOUX[4], K. EBMEIER[2], C. MACKAY[1,2];
[1]Oxford Ctr. for Human Brain Activity, [2]Univ. Dept. of Psychiatry, [3]Oxford Ctr. for Functional MRI of the Brain (FMRIB), Univ. of Oxford, Oxford, United Kingdom; [4]Dept. of Epidemiology & Publ. Hlth., Univ. Col. London, London, United Kingdom

Abstract: Whilst cognitive decline is common in old age, some older adults retain intact cognitive abilities, but the neural basis of this is unclear. We report preliminary direct evidence for individual differences in the neural mechanisms of superior cognitive ageing. Using literature-based brain metrics in a data-driven approach, individuals were classified as *maintainers* ('youthful' brain structure & function), *adapters* (reduced structure & increased function), or *decliners* (reduced structure & function) relative to younger adults. Cross-sectional (CS) cognitive data were compared between classified groups. Longitudinal (L) cognitive data were analysed to test whether CS differences in cognition reflect different rates of decline, or lifelong differences between groups. Group differences in diffusion (DTI) imaging measures of white matter (WM) integrity were tested, as intact WM may allow *adapters* to recruit additional functional resources.
Methods: 354 healthy older adults from the Whitehall II imaging sub-study, with L cognitive data from 1997-2013, recently completed an MRI scan (T1, DTI, fMRI) and further CS cognitive

tests. *Classification:* For each subject, grey matter (GM) volume and resting state functional connectivity (FC) were extracted from regions affected by age in an independent sample of old vs. young adults (27 vs. 27), and classified relative to the mean and standard deviation GM and FC in young adults, resulting in 118 maintainers, 56 adapters, and 47 decliners. *Cognition:* CS and L cognition was compared between groups using ANOVA. *DTI:* Fractional anisotropy (FA) maps were compared between groups using tract-based spatial statistics (FWE-corrected at $p<0.05$).
Results: *Cognition:* CS performance was significantly better in both *maintainers* and *adapters*, vs. *decliners*. Decline was observed on all L measures, except vocabulary, but there were no between group differences in amount of decline. *Decliners* performed worse across L time points on short term memory and MMSE. *DTI:* There were no group differences in FA after thresholding.
Conclusion: Better cognitive scores in *maintainers* and *adapters* suggest some cognitively superior older adults may adapt to structural decline by engaging additional functional resources, whilst others maintain relatively 'youthful' brains, although no group difference in cognitive decline suggests *decliners* poorer performance may reflect a lifelong difference, rather than a different trajectory of decline. Statistical modelling may provide more sensitive estimates of cognitive trajectories for these groups. Analysis of other WM metrics (e.g. mean diffusivity) may expand on current findings.

Title: Mindreading from the eyes is diminished in aging but independent from gender - Results from a large population-based study

Authors: *J. KYNAST[1], E. M. QUINQUE[2], A. VILLRINGER[1], M. L. SCHROETER[1]; [1]Neurol., Max-Planck Inst. For Human Cognitive and Brain, Leipzig, Germany; [2]Clin. for Psychiatry, Psychotherapy and Psychosomatic Med., Univ. Hosp. Halle, Halle (Saale), Germany

Abstract: *Background:* Theory of Mind (ToM) is an essential human quality that enables successful social interactions. The perception of social cues and their relation to another person's mental state enables individuals to predict behavior and react properly. As affective information is conveyed through eye gaze, the Reading the Mind in the Eyes test (RMET) is a frequently used tool for the assessment of affective ToM. This is the first study to investigate the effects of gender on a wide age range (19-79 years) in a large, population-based German sample. Further, we investigated the effects of item characteristics on RMET performance.
Methods: The sample comprised 1,324 participants of the LIFE study. We investigated the effect of age (12 groups) and gender (2 groups) on RMET performance by applying ANCOVA and correcting for the effect of verbal abilities. Single comparisons were calculated post-hoc. Furthermore, we investigated if gender characteristics of the RMET items (male/female) modulate mindreading ability in men and women in different age ranges (12 groups) using ANCOVA correcting for verbal abilities. Post-hoc single comparisons were calculated.
Results: Male and female performance did not significantly differ, but young adults performed significantly better than older age groups. Men and women identified mental states significantly better from female eyes as compared to male eyes. This gap becomes larger for older age groups.
Discussion: Men are as proficient as women in mindreading from the eyes. Our data suggests that affective ToM declines with increasing age, which is true for both sexes. Older adults may have problems inferring complex emotional content from limited social cues, especially in the presence of male eye gaze.

Title: White matter microstructure mediates the negative effects of amyloid on default mode network function and executive performance

Authors: *C. BROWN[1], F. A. SCHMITT[2], C. D. SMITH[2], B. T. GOLD[1];
[1]Anat. and Neurobio., [2]Univ. of Kentucky, Lexington, KY

Abstract: Executive function declines in aging have been associated with declines in default mode network (DMN) function. However, the mechanisms underlying these declines may include declines in white matter (WM) microstructure associated with normal aging and/or increasing amyloid pathology associated with preclinical Alzheimer's disease (AD). In the present study we investigated whether these mechanisms have independent or synergistic effects on DMN function and executive performance.

35 cognitively normal older adults (ages 65-93) and 29 younger adults (ages 18-34) underwent resting-state (rs-) fMRI, task (t-) fMRI, and diffusion tensor imaging (DTI). Older adults also had a lumbar draw of cerebrospinal fluid, from which $A\beta_{42}$ concentration was measured. A working memory task was used for t-fMRI. The DMN was identified in rs- and t-fMRI using independent component analysis. These components were Z-scored and combined to identify voxels showing both peak connectivity at rest and deactivation during the task. Functional connectivity at rest and deactivation during the task were measured within common regions-of-interest (ROIs) formed surrounding these peak voxels. In addition, the same ROIs were used as seeds for probabilistic tractography to identify WM pathways connecting DMN regions. Fractional anisotropy (FA) was measured within DMN WM pathways.

T-tests revealed age-related declines in task performance, DMN function, and FA. Partial correlations showed that both DMN deactivation magnitude and FA in DMN WM were negatively correlated with RT across the entire sample (r = -.39, -.40; $p \leq .002$) and within older adults (r = -.48, -.49; $p \leq .006$), after controlling for age, sex, and education. Further partial correlations showed that DMN deactivation magnitude and FA were positively correlated across the entire sample (r =.26, p = .043) and within older adults (r =.36, p =.045). Within older adults $A\beta_{42}$ was negatively correlated with RT (r = -.45, p =.01) and positively correlated with DMN deactivation magnitude (r =.35, p =.049) and FA (r =.35, p =.049) after controlling for age, sex, and education. Rs-connectivity was not related to any of the other measures across or within groups. Mediation models within older adults revealed that the effect of $A\beta_{42}$ on DMN deactivation magnitude was mediated by lower FA in DMN WM. In addition, the effect of $A\beta_{42}$ on RT was mediated by lower DMN FA and deactivation magnitude.

These findings provide the first evidence that the negative effects of $A\beta_{42}$ on DMN function and executive performance are driven by DMN WM microstructure declines. Interventions aimed at protecting DMN WM microstructure may aid in maintaining executive performance.

Title: Age-related changes in case marker processing: ERP evidence from a verb-final language

Authors: J. SUNG, B. EOM, S. OH, *S. JUN;
Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Previous research have demonstrated inconsistent evidence on whether aging-related decline emerges in online sentence processing. The current study investigated age-related changes in case marker processing of a verb-final language using event-related potential (ERP) paradigm. Korean is a verb-final language with case markers, which permits a relatively free word order as far as the verb retains in a sentence-final position. Sixteen younger adults (*mean age*=25.8, *SD*=3.1) and fifteen older adults (*mean age*=73.0, *SD*=6.0) participated in the study. Sentence stimuli consisted of plausible and case-marker violation conditions with 30 items per each. Case marker assignment was violated in the second noun phrase. Each phrase was presented for 700ms using a Rapid Serial Visual Presentation paradigm with a 200ms inter-stimulus interval during the 32-ch EEG recording. Greater negativity effects were observed in case marker violation across the groups at 300-500ms. Younger groups presented significantly stronger positivity effects at 700-900ms in the case marker violation condition, whereas the positivity effects were attenuated in elderly adults. The results suggested that Korean speakers may process a syntactic component of a case marker under the semantic frame integration, eliciting the negativity effects associated with semantic violations. Elderly adults showed attenuated effects compared to the young group, indicating age-related changes emerged during real-time sentence processing.

Title: Relating mobility to brain structure and function in older adults: A magnetic resonance imaging study of members of the Whitehall II cohort

Authors: *N. DEMNITZ[1], E. ZSOLDOS[2], A. MAHMOOD[3], N. FILIPPINI[2], A. SINGH-MANOUX[4], M. KIVIMAKI[4], C. MACKAY[2], H. DAWES[5], H. JOHANSEN-BERG[1], K. P. EBMEIER[2], C. E. SEXTON[1];
[1]Oxford Ctr. for Functional MRI of the Brain, [2]Dept. of Psychiatry, [3]Univ. of Oxford, Oxford, United Kingdom; [4]Univ. Col. London, London, United Kingdom; [5]Oxford Brookes Univ., Oxford, United Kingdom

Abstract: Mobility is a strong predictor of institutionalisations, falls, quality of life and mortality in older adults. More recently, mobility has also been linked to cognitive functioning. The association between mobility measures and brain structure, however, remains under-explored. To investigate the relationship between mobility and the ageing brain, we examined the relations between common mobility measures, cognitive functioning, and MRI measures of brain structure (white matter integrity and gray matter volumes).
The sample (n = 387) was drawn from the on-going Whitehall II Imaging Sub-Study. Participants (mean age 69, SD 5.11; 19% women) had no history of neurological illnesses. Mobility assessments (gait speed, balance test, chair stands) were conducted in 2007-2009. On a subsequent phase of data collection (2012-2015), participants underwent a 3T MRI brain scan and completed a battery of cognitive tests assessing memory, executive function, and processing speed. To examine white matter integrity, voxelwise analysis of fractional anisotropy (FA), axial diffusivity (AD), radial diffusivity (RD), and mean diffusivity (MD) data was carried out using Tract Based Spatial Statistics (TBSS). Permutation-based methods for non-parametric testing were employed for all analyses.
Results showed that older adults with better mobility had better cognitive functioning, and this relationship was evident across domains of mobility (gait speed, balance, chair stands) and cognition (executive function, memory and processing speed). Analyses of global DTI metrics showed that poorer mobility, as measured by the balance and chair stand tests, was associated with higher global AD (balance $p = 0.001$; chair stands $p = 0.043$) and RD (balance $p = 0.001$; chair stands $p = 0.043$). Only the balance test revealed a significant association with FA ($p = 0.005$). No association was found between gait speed and global DTI metrics, or between global

gray matter volume and mobility measures. In voxel-wise analyses, significant voxels were found to be widespread across the white matter. Our findings highlight the strong relationship between mobility and cognition and suggest a global decline in white matter is associated with ageing-related decline in mobility.

Title: Age-related differences in spatial memory formation and neural activations in a new virtual Morris water maze task

Authors: J. Y. ZHONG[1], *K. R. MAGNUSSON[3], M. E. SWARTS[2], C. A. CLENDINEN[1], N. REYNOLDS[3], S. D. MOFFAT[1];
[1]Sch. of Psychology, [2]Sch. of Architecture, Georgia Inst. of Technol., Atlanta, GA; [3]Dept Biomed Sci, Coll Vet Med. & Linus Pauling Inst., Oregon State Univ., Corvallis, OR

Abstract: This study applied a new virtual rendition of the Morris water maze task, which is commonly used for assessing spatial memory performance in rodents, to an examination of age-related differences in spatial memory among younger (18-30 years) and older (> 60 years) human participants. All participants were males, in correspondence with rodent studies done in the Magnusson lab. Unlike previous studies which used dependent navigational performance measures such as time spent searching for target, distance to reach target (i.e., pathlength), number of path crossings of common *xy* coordinates, and heading errors, this study was the first human study to employ a cumulative proximity to goal measure that corrected for start position using an ideal proximity length across 44 learning trials.
After controlling for age differences in the mean pathlength taken to reach the target in visible platform (control) trials, we found that older adults exhibited greater cumulative proximity to goal (i.e., more searches done away from the target platform) than younger adults. This

difference was most prominent during the first 24 place trials in which participants were uninformed that the hidden platform was fixed on every trial. The two age groups performed equally well across 19 control trials in which they moved directly to a visible platform on every trial, suggesting that age group effects detected from place trials was not confounded by age differences in visuomotor control. Importantly, older adults exhibited a learning curve that plateaued early in the second half of the learning trials (place trials 13 to 24), with significantly higher corrected cumulative proximity than younger adults in the earlier phase of these trials. These behavioral findings suggest that older adults may be poorer at accessing their newly acquired spatial memory for finding a place they reached previously in the absence of explicit knowledge of the stationary nature of that location.
All adults were subsequently informed about the stability of the hidden platform and performed the task in the fMRI scanner across 16 trials. The group-level [place - control] contrast (p = .005, uncorrected) showed that younger adults exhibited higher activation in the left middle frontal gyrus and right caudate, as well as lower activation in the anterior cingulate than poorer performers among the older adults (i.e., below the 50th percentile). The higher frontal activation implicates that younger adults may be better at planning or executing their search behavior while the lower anterior cingulate activation implicates that younger adults may expend lesser attentional resources when finding a known target.

Title: Cognitive impairment in elderly Mexicans and their association with anemia and hipozinquemia

Authors: *H. A. RUBIO-ZAPATA[1], E. SANCHEZ-AGUILAR[2], P. AGUILAR-ALONSO[3]; [1]Med. School- UADY, Merida, Mexico; [2]Sch. of Medicina, University of Yucatan, Mexico; [3]Facultad de Quimica, BUAP, Puebla, Mexico

Abstract: Cognitive impairment (CI) is a multifactorial process. The aging process is one of its most important risk factors, especially when associated with other pathophysiological conditions such as nutritional deficiencies. Iron and zinc are necessary metals in various metabolic pathways. There are reports their deficiencies associated with cognitive impairments. The aim of

the study was to determine the association between the CI and the presence of anemia and hipozinquemia in older Mexican adults. The study included 187 adults aged 65 or older, from the rural areas of southeastern Mexico (Yucatan). All people with depressive symptoms according Yesavage test were removed (n=21). For CI, we used the Minimum Mental State Examination (Minimental Test). All participants were asked to donate 5 mL peripheral blood to determine the hematocrit and hemoglobin by HemoCue® automated system, the determination of serum zinc was by the colorimetric method of Johnson et al. Chi2 statistical analysis, OR, 95% CI $p < 0.05$. All procedures were performed in compliance with the ethical standards and the School of Medicine of the University of Yucatan authorized the project. Results: 23% of the population were man and 77% women. 39.6% of the population had CI (32% mild 5% moderate, 2.6% severe); 35.4% of the population had anemia and 20% hipozinquemia. CI increased proportionally with age. There was no relation between anemia and hipozinquemia with age. The association between anemia and CI was significant ($p < 0.001$, OR 3.9, IC 1.6-8.9), while the hipozinquemia it was not ($p = 0.17$). Other variables that were associated with the CI were being female, engage in housework or fieldwork, illiterate, widowed and have metabolic and cardiovascular comorbidities. In older Mexican adults, living in rural regions the presence of anemia was associated with cognitive impairment, so it is essential the diagnosis and treat this condition to prevent or halt its progression and improve quality of life of the elderly.

Title: Subjective memory complaints associated with depression and anxiety in older women

Authors: *S. A. TREJO, L. MORADO-CRESPO, S. SOLIS-ORTIZ;
Dept. de Ciencias Médicas, Dept. De Ciencias Médicas, León, Mexico

Abstract: Introduction: Subjective Memory Complaints (SMC) are everyday forgetfulness which may cause limitations and low quality of life. These have been associated with age, cognitive impairment and Alzheimer. Older women may present symptoms of anxiety and depression as characteristic of aging. However it is not exactly known whether the subjective memory complaints are associated with the emotional state in older adults. The aim was to evaluate the association between subjective memory complaints and emotional state in older women. **Method**: 95 women participated from 60 to 80 years without chronic degenerative diseases. Were applied the Mini-Mental State Examination as a screening test of cognitive status and a questionnaire of subjective memory complaints to assess the frequency of complaints categorized in self-perception, semantic, episodic and working memory. We also applied Depression Inventory Beck to assess depressive symptoms and Trait Anxiety Inventory-State to assess anxiety. Data were analyzed using X^2, crosstabs and the relative risk was obtained. **Results**: The self-perception of changes in memory was significantly associated with depressive symptoms (X^2=10.05, p=0.01, RR=1.36) and anxiety (X^2=8.39, p=0.01, RR= 1.12). Semantic memory is associated with depressive symptoms (X^2=7.89, p=0.04, RR=1.27). Episodic memory is associated with anxiety (X^2=5.02, p=0.02, RR=1.63). Working memory for mathematical calculation was associated with depression ($X^{2=}$16.21, p=0.001, RR=1.26). **Conclusion**: These results indicate that there is more likely of finding symptoms of anxiety and depression in older women with subjective complaints of semantic, working, episodic and self-perception memory.

Title: Multivariate analysis reveals a dynamic relationship between parietal gray matter volume and anterior white matter fractional anisotropy across the healthy lifespan

Authors: *D. A. HOAGEY, J. R. RIECK, K. M. RODRIGUE, K. M. KENNEDY;
Ctr. for Vital Longevity., Sch. of Behavioral and Brain Sci., The Univ. of Texas At Dallas, Dallas, TX

Abstract: Cortical gray matter volume declines across the lifespan, most markedly in prefrontal cortex, but also in parietal and temporal association cortices. White matter integrity also shows differential regional degradation with pronounced decreases in anterior regions followed by moderate decreases in posterior white matter integrity with aging. Few studies examine these structural measures jointly; thus the relative sensitivity to age is unclear. Here we applied the data driven multivariate technique partial least squares (PLS) to examine the relationship between cortical gray matter volume and fractional anisotropy (FA) of white matter with the aim of disambiguating both the spatial and temporal properties (cross-sectional age differences) of structural brain aging. Diffusion and high-resolution T1 weighted MRI were collected from a sample of 188 healthy adults, 20-94 years of age. Gray matter cortical parcellation was performed using Freesurfer, while diffusion tensor calculation and FA maps were created using FSL. Separate data tables for gray matter volume measures and voxel-wise FA were submitted to PLS. Analysis revealed a significant principal component accounting for 82% of total variance in volumetric and FA measures ($p = .0002$). Contributing the most variance to the component was the positive relationship between white matter FA from the anterior corpus callosum, anterior projections of the genu, anterior cingulum, and fornix with gray matter volume in parietal regions. Examination of the latent variables revealed that the relationship between gray and white matter in these regions is dependent on age, such that white matter integrity decreases linearly across the lifespan, whereas gray matter volume remains relatively preserved until late life. Investigating each parietal parcel shows that within young adults (20-34) and our oldest adults (70-94), individual differences in FA were not associated with differences in volume; however, our middle adult groups (35-54 and 55-69) exhibited significant coupling between FA and volume. These findings suggest that there is a periodicity to structure-structure associations across the lifespan, with weaker dependency during the end of development/young adulthood, stronger interdependency in middle age, and weaker dependency in the oldest-old. These results partly support the last-in, first out framework of aging as frontal and parietal gray and anterior white matter have the most protracted development and are the most vulnerable to aging.

Tohoku Univ., Sendai, Japan; [5]Developmental Cognitive Neurosci., [6]Nuclear Med. and Radiology, [7]Functional Brain Imaging, Development, Aging and Cancer, Tohoku Univ., Sendai, Japan

Abstract: Microglia has been known to play an important role as remyelination, synapse pruning, memory and learning processes. It is essential to maintain normal brain function as well as condition brain environment. CX3CR1, a 7-transmembrane domain G-protein-coupled receptor, is involved in various inflammatory processes. CX3CR1 is expressed on the surface of various peripheral cells, such as T lymphocyte, macrophage, neutrophil, monocyte, NK cell, CD4 positive cell, CD8 positive T cell and mast cell, while microglia is the only CX3CR1-expressing cell in the brain. Several studies have reported that CX3CR1 plays important roles in pruning of synapses, memories and neurogenesis. It was also reported that decreases of the CX3CR1 expression was associated with the number of synapses in the brain of patients with schizophrenia. Thus, evidence suggests involvement of CX3CR1 into brain function and the pathophysiology of psychiatric diseases. On the other hand, a non-synonymous single nucleotide polymorphism (SNP) of CX3CR1, V249I (rs3732379) and T280M (rs3732378), which are located in the sixth and seventh transmembrane domains of the CX3CR1 protein, respectively. T280M is related to difference in leukocyte functions including adhesion, signaling, and chemotaxis. However, the function of V249I is unclear. These polymorphisms are associated with various peripheral diseases, they may affect brain function as well as susceptibility to psychiatric disorders, and however the associations between this SNP and phenotypes in the brain have not been investigated. The principal aim of this study was to evaluate the effect of CX3CR1 polymorphisms on the structure and function in the human brain. To investigate effect of genetic variations in CX3CR1 on the structure and function of the human brain, we evaluated association between the SNP and MRI findings, including volume of gray and white matters, diffusion tensor imaging (DTI)-based white matter integrity and arterial blood volume of cerebral blood flow (CBF) during rest using arterial spin labeling (ASL), among 1,301 healthy Japanese people. The C allele of the SNP was significantly associated with increased arterial blood volume around the precuneus. There was no major difference between brain structural indicators in any brain areas among genotypes. This finding suggests that CX3CR1-T280M and V249I may affect brain artery structures via interaction between microglia and vascular endothelial cells, and underlie relevant brain functions and susceptibilities to brain diseases.

Title: Brain cognitive networks and the related genetic components explored with three-way parallel ICA

Authors: *K. MEZEIVTCH[1], C. L. WRIGHT[2], J. LUI[5], Y. WANG[6], R. ARORA[6], J. H. CALLICOTT[7], V. S. MATTAY[3,8], D. R. WEINBERGER[4], Q. CHEN[2];
[1]Lieber Inst. For Brain Develop., Baltimore, MD; [3]Departments of Neurol., [4]Lieber and Departments of Psychiatry, Neurology, Neurosci. and The Inst. of Genet. Med., [2]Lieber Inst. for Brain Develop., Baltimore, MD; [5]The Mind Res. Network, Albuquerque, NM; [6]Johns Hopkins Univ., Baltimore, MD; [7]Natl. Inst. of Mental Hlth., Bethesda, MD; [8]Dept. of Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Multi-modal data collected for the same subjects have become common in neuroscience research. Simultaneously studying such data may yield new information that could not be observed in analyzing individual data, or enhance the common information across data modalities. In this study, we used three-way Parallel Independent Component Analysis (pICA, Vergara et al, 2014) to incorporate two fMRI tasks and genotype data extracted from the top loci reported by the Psychiatric Genetics Consortium (PGC) for schizophrenia in the same model. Data from two fMRI cognitive tasks and genotype data of 89 SNPs for 187 healthy controls were included in this study. Subjects underwent BOLD fMRI (3T) during a working memory task (NBack) and a cognitive control task (Flanker). Eighty nine SNPs ($SNPs_{pgc2\_sig}$) were selected from 108 top loci from published PGC schizophrenia GWAS study (PGC2 2014), excluding indels and SNPs on Chromosome X.
We found 9 sets of correlated components with significant pairwise correlations after Bonferroni correction. Among them, we found one of the correlated components with likely biological meaning, in which the correlation between NBack and Flanker was 0.2598 ($P_{Bonferroni}$=0.0132), the correlation between NBack and genetic data was 0.3 ($P_{Bonferroni}$=0.004), and the correlation between Flanker and genetic data was 0.27 ($P_{Bonferroni}$=0.008). Significant positively activated regions (Z>2) in NBack include BA9 (DLPFC), BA47 (VLPFC), BA32 (Anterior Cingulate). Significant negatively activated regions (Z<-2) included BA39 (Inferior Parietal). Significant positively activated brain regions (Z>2) in Flanker components included BA9, BA47, and BA32. Significant negatively activated brain regions (Z<-2) in Flanker components included BA22 (Superior Temporal Gyrus), BA13 (Insula), and BA23 (Precuneus). Index SNPs within Schizophrenia risk genes CACNA1C, TCF4, ZNF804A are among the top 5 SNPs ranked by absolute values of ICA weighting scores.

Our results show that when we examined the correlation among NBack, Flanker and genetic data simultaneously, previously identified network patterns found in individual fMRI study are also shown in the top correlated components, especially brain regions involved in both tasks, i.e. involving executive control. Previously found candidate genes for schizophrenia are ranked high based on the contribution to the correlation with fMRI data. Our results support the use of 3-way ICA to identify shared brain networks during cognitive tasks and the associated genetic components with these tasks. Further cross validation is necessary to better interpret the findings.

Title: Behavior phenotypes in mice: should single strains suffice?

Authors: *L. J. SITTIG[1], P. CARBONETTO[2], K. ENGEL[2], K. KRAUSS[2], C. BARRIOS-CAMACHO[2], A. A. PALMER[1];
[1]Psychiatry, Univ. of California San Diego, LA Jolla, CA; [2]Univ. of Chicago, Chicago, IL

Abstract: Genetically engineered mutations are a valuable tool for exploring genotype-phenotype relationships. Most such studies are carried out using inbred strain backgrounds since this allows comparison of mutant and wild type alleles on an isogenic background. These studies are predicated on the notion that genotype-phenotype relationships measured on a single inbred background will generalize to other species; thus there is an implicit assumption that they would at least generalize to other inbred mouse strains. We directly tested this assumption by examining the effects of null alleles of *Cacna1c* and *Tcf7l2*, which have been robustly implicated in schizophrenia and other complex diseases by human genome-wide association studies (GWAS). We bred C57BL/6J heterozygous males to wild-type females from 30 of the most commonly used inbred strains to generate a balanced set of heterozygous and wild-type coisogenic F_1 offspring (N=723 *Cacna1c*, N=630 *Tcf7l2*). F_1 offspring were tested for widely-used behavioral and physiological phenotypes that model aspects of schizophrenia, bipolar disorder, and depression. We found extremely strong interactions between the mutant alleles and

the different genetic backgrounds. Some F_1s were very sensitive to particular effects of the mutant alleles while others appeared completely resistant. In several cases the mutant alleles increased a given phenotype in one F_1 while decreasing the same phenotype in another. These results do not negate the invaluable contributions of mouse genetics to biomedical science; however, they do make an important contribution to the ongoing discussion of reproducibility. We conclude that genotype-phenotype relationships cannot be reliably inferred by studying a single genetic background. Therefore, we suggest that the effect of mutant alleles should be evaluated on several inbred strain backgrounds whenever possible.

Abstract: Background: Dopamine- and cAMP-regulated phosphoprotein of molecular weight 32 kDa (DARPP-32) is a central molecule that incorporates dopaminergic signal transduction into many other neurotransmitter systems, such as a glutamatergic system. Phosphorylated DARPP-32 regulates the physiological activities of various proteins. Calcineurin (CaN) is located downstream of dopaminergic and glutamatergic pathways and inactivates DARPP-32 by dephosphorylation. CaN has also been considered to be related with synaptic plasticity or neural cell apoptosis. Although the signaling pathway that contain DARPP-32 and CaN may be the one of the crucial circuit to the basic understanding of schizophrenia and other psychiatric disorders, there have been only a few postmortem brain studies of DARPP-32 and CaN in psychiatric disorders and these results were inconsistent across the studies.
Methods: In this study, the expression levels of DARPP-32 and CaN protein were measured by ELISA in two brain regions receiving dopaminergic input and implicated in schizophrenia (the prefrontal cortex [PFC], and nucleus accumbens [NAcc]) in 49 postmortem samples from subjects with schizophrenia, bipolar disorder, major depression and normal controls. We also examined the association of these expressions with genetic variants of dopaminergic system associated molecules for 129 SNPs in a much larger set of postmortem samples (85 subjects).
Results: DARPP-32 in PFC was marginally significantly decreased in schizophrenia as compared to controls ($P=0.059$). The expressions of CaN in PFC were significantly increased in schizophrenia ($p=0.02$) and bipolar disorder ($p<0.05$) as compared with normal controls. In NAcc, CaN was markedly increased in bipolar disorder ($p=1.33$ E-15), but was not changed in schizophrenia. We analysed 129 SNPs in the dopaminergic system associated molecules and found that several SNPs including the one which was previously reported to be related with schizophrenia might predict protein expression of CaN in PFC and NAcc.
Conclusion: These alternations in the pathway that includes DARPP-32 and CaN may reflect potential molecular mechanisms underlying the pathogenesis of schizophrenia and bipolar disorder or differences between these two major psychiatric disease.

Title: Facial profile principal components derived from full Procrustes analyses correlate with schizotypal inventory scores and SAT performance in sex- and side-specific manners

Authors: J. I. PERI[1], E. M. CROSS[2], B. N. KEEHAN[2], A. T. DEPEW[2], B. A. SAMONTE[2], T. M. MILEWSKI[2], P. T. ORR[1,2], *J. CANNON[1,2];
[1]Dept. of Psychology, [2]Neurosci. Prog., Univ. of Scranton, Scranton, PA

Abstract: Embryological development of the face and anterior brain occur in synchrony, are often influenced by common genes, and have the potential to be dramatically and characteristically altered by genetic abnormalities or environmental insults. Schizophrenia is thought to be caused by genetic and environmental factors that have the potential to affect the development of the brain and face. Hennesy et al. (2004) found that faces of schizophrenics showed significant morphological and sex-specific differences compared to controls. Using only frontal photographs, we previously observed relationships between facial loci and SAT/SPQ scores (Cannon et al., 2015). Here, we generated principal components (PCs) of profile facial loci in undergraduates and related those to overall and subscale scores of the Schizotypal Personality Questionnaire (SPQ) and Math/Verbal SAT scores. Other basic demographics were also assessed.

Left and right digital profile photographs were taken of undergraduates (N = 110; 74.5% female). The x-y coordinates of 37 loci were measured blind using ImageJ and processed with a full Procrustes superimposition and principal component analyses utilizing SPSS. In each case, left, right, and the average of left and right profiles resulted in 7 PCs with eigenvalues greater than 1 that typically accounted for almost 80% of variance. These PCs, listed in order of average eigenvalue strength, dealt with the following facial structures: Ear, Lips, Eyebrow/Eye, Lower Nose, Chin, Nasion/Brow Ridge, and Jaw/Face Perimeter. The PCs were correlated with the measures listed above.

The following represent the strongest correlations observed. In each case, there was a significant difference between left and right profile correlations (p = .04 to .002). For SPQ, Right Chin showed significant negative correlations in Females and Total Score ($r(66) = -.382$, $p = .002$) as well as 2 of the 3 subscales. Male correlations did not significantly differ and were in the same direction. For SAT Verbal, Left Nasion/Brow Ridge showed a significant negative correlation in Males ($r(14) = -.634$, $p = .015$). Females showed a significantly weaker, near 0, correlation. For SAT Math, Left Lower Nose showed a significant negative correlation in Males ($r(14) = -.692$, $p = .006$). Again, Females showed a significantly weaker, near 0, correlation.

Comparing these results to our earlier examination of only frontal facial landmarks, it seems clear that profile images can provide additional information relevant to both schizotypal traits and SAT Math/Verbal scores.

Title: DISC1 controls calcium transfer from endoplasmic reticulum to mitochondria

Authors: S. J. PARK, S. LEE, B. GOO, *S. PARK;
POSTECH, Pohang, Korea, Republic of

Abstract: DISC1 (*Disrupted-in-schizophrenia 1*) has emerged as a convincing susceptibility factor for the major mental illnesses including schizophrenia, recurrent major depression, and bipolar disorders, but its mechanistic links to the diseases are yet to be fully understood. The calcium plays essential roles in diverse and fundamental biological processes of a cell and an organism. This maximized functional variety of calcium is based on its fast effects and its spatially and temporally dynamic properties, which is heavily dependent on the calcium buffering function of organelles such as endoplasmic reticulum (ER) and mitochondria. Here, we identified that DISC1 localizes at the mitochondria-attached endoplasmic reticulum membrane (MAM), a specialized ER-mitochondrial contact site, and influences the calcium transfer from ER to mitochondria which is mediated by inositol-1,4,5-trisphosphate (IP3) receptors. The perturbed regulation of the calcium transfer between two subcellular organelles by DISC1 malfunction induced abnormal calcium accumulation in mitochondria upon stimulation of oxidative stress, thereby impairing mitochondrial functionalities. Our findings give a hint at the mechanistic links between DISC1 function and environmental stimuli with implications in the pathobiology of the related psychiatric conditions.

Title: Polygenic risk scores for schizophrenia of miR-137 target genes is associated with brain function during working memory

Authors: *Q. CHEN[1], C. L. WRIGHT[1], K. M. MEZEIVTCH[1], J. H. CALLICOTT[2], D. R. WEINBERGER[1,3,4,5,6];
[1]Lieber Inst. For Brain Develop., Baltimore, MD; [2]Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Psychiatry, [4]Neurol., [5]Neurosci., [6]The Inst. of Genet. Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Strong association with schizophrenia has been reported repeatedly within a region containing *MIR137HG*, the host gene encoding microRNA 137 (miR-137). Previous studies suggest that target genes of this microRNA are also involved in many schizophrenia relevant biological pathways. Therefore studying the genes regulated by miR-137 may be important in understanding the etiology of schizophrenia. Collins *et al*., 2014 reported that 420 genes were differentially expressed (DE) ($q<0.05$) at 48h following miR-137 overexpression in a human neural stem line. In our current study, we used NBack, a working memory task, to examine the effect of schizophrenia risk profile score (RPS) of miR137-regulated genes on brain activation. Two hundred and sixty seven healthy volunteers underwent BOLD fMRI (3T) during a working memory task (NBack). RPSs were calculated for each individual as the weighted sum of reference alleles of LD clumped SNPs within the total 420 DE genes (RPS_{all}), and separately within the downregulated (156) and upregulated (264) DE genes (RPS_{up} and RPS_{down}). SNPs within each gene (extended by 2K at each end) were included based on $P < 0.05$ of the PGC2 results. The PGC2 identified risk SNP, rs1702294, within *MIR137HG* was used to test for a stratification effect on the association of RPS with brain function.
Our results show no significant association of RPS_{all} with brain activation during the NBack task. However there is a significant positive correlation of RPS_{down} with IFG activation ($p=0.023$, FDR corrected in IFG) and no significant negative correlation for RPS_{down}. Whereas, there is a trend of negative correlation of RPS_{up} with brain activation in IFG ($p=0.091$, FDR corrected in IFG), but no positive correlation of RPS_{up} with brain activation. When we stratified our sample according to rs1702294 genotype, we found a strong positive correlation between RPS_{down} and IFG activation ($r=0.30$, $p=6.03e-05$) only in homozygous risk alleles carriers, but not in non-risk carriers ($r=0.14$, $p = 0.196$). There was no rs1702294 stratification effect for RPS_{up} in IFG.
Our results show that schizophrenia-associated SNPs among genes downregulated by miR-137 overexpression are associated with brain activation of the inferior frontal gyrus region during a working memory task. This association is driven by homozygous carriers of the rs1702294 risk SNP. From literature, IFG is heavily activated by the Nback and thought to compensate for abnormal dlPFC activation in patients with schizophrenia. Our current finding suggests that the *MIR137HG* gene risk SNP interacts with SNPs among putative downregulated targets of miR-137 in affecting brain function related to schizophrenia.

Title: Regulation of the serotonin 2a receptor gene (htr2a) in the mouse prefrontal cortex by early growth reponse 3 (egr3)

Authors: *X. ZHAO[1], D. REZNIK[2], A. MAPLE[3], A. MCBRIDE[3], J. LISH[3], A. GALLITANO[3]; [1]Interdisciplinary Program in Neurosci., Arizona State Univ., Tempe, AZ; [2]Barrett, the Honors College, Arizona State Univ., Tempe, AZ; [3]Univ. of Arizona Col. of Medicine- Phoenix, Phoenix, AZ

Abstract: The immediate early gene *EGR3* is associated with schizophrenia in humans and expressed at reduced levels in postmortem patients' brains. We previously found that, in addition to schizophrenia-like behavioral abnormalities, *Egr3*-/- mice have a nearly 70% decrease in prefrontal cortical serotonin 2A receptors ($5HT_{2A}$Rs). This underlies their resistance to sedation by clozapine, a phenomenon that parallels the increased tolerance of schizophrenia patients to antipsychotic side effects. These findings led us to hypothesize that EGR3, a transcription factor, directly regulates the expression of the $5HT_{2A}$R - encoding gene *Htr2a*. To test this hypothesis, we collected tissue after 8 hours of sleep deprivation (SD) from *Egr3 -/-* and wildtype (WT) mice that also carried an enhanced green fluorescent protein (EGFP) reporter construct under control of the *Htr2a* promoter (*Htr2a*-EGFP). We used antibodies against EGFP to detect $5HT_{2A}$R-expressing neurons. Our images suggest *Egr3-/-* mice had less EGFP labeling compared to WT mice, particularly in layers 4-5 of the cortex. Using bioinformatics analyses we searched for high probability EGR consensus binding sites in the *Htr2a* promoter. We identified a "distal" site located ~2800 bp upstream of the transcription start site, and a "proximal" site ~70 bp upstream of *Htr2a* transcriptional start site. To determine the expression time-course of EGR3 protein we conducted western blot analysis on prefrontal cortex tissue from WT mice at baseline, compared with animals sacrificed two hours and three hours after electroconvulsive seizure (ECS), which induces maximal expression of EGR3. These results showed that EGR3 protein levels were highest two hours after ECS. Based on these findings we conducted Chromatin Immunoprecipitation (ChIP) on frontal cortical tissue isolated from WT mice two hours following ECS to evaluate whether EGR3 directly binds to these regions of the Htr2a promoter in *vivo*. ChIP revealed significant binding of EGR3 to the distal region in the *Htr2a* promoter after ECS compare with baseline. To confirm functionality of EGR3 binding to the *Htr2a* promoter, we performed an *in vitro* luciferase-reporter assay. Results of these studies will be

presented. These findings provide information about potential regulation of the schizophrenia candidate gene *HTR2A* by the immediate early gene transcription factor EGR3.

Title: The expression levels of the genes coding for the IgLON family of neural cell adhesion molecules in the dorsolateral prefrontal cortex of schizophrenic patients

Authors: *M.-A. PHILIPS[1], K. KONGI[1], K. SINGH[1], E. LEIDMAA[2], E. VASAR[1];
[1]Univ. of Tartu, Tartu, Estonia; [2]Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: Growing evidence suggests that the family of IgLON neural adhesion molecules (OPCML, NTM, LSAMP, NEGR1) are important candidates in forming the susceptibility of schizophrenia. IgLONs have been suggested to be involved in neurite outgrowth, synapse formation and pruning and neurogenesis, all of what has been shown to be altered in the brains of schizophrenic patients. Furthermore, it has been found that the level of the LSAMP protein is approximately 20% increased in the *postmortem* frontal cortex in patients with schizophrenia. According to our recent results, there are certain tag SNP-s in the 1b promoter of the human LSAMP gene that have a strong association with the risk of schizophrenia. LSAMP gene has been in the focus of our behavioral, anatomical, association and cell culture studies in many years. As we have understood the importance of studying IgLON family as a highly regulated molecular complex, we have recently included other IgLON members as our molecular targets. Our aim was to characterize the expression levels of the genes coding for the IgLON family in the dorsomedial prefrontal cortex of schizophrenic patients by using quantitative RT-PCR. Tissue samples were obtained from from Australian Brain Bank Network. Alternative 1a and 1b promoter activities of LSAMP, NTM and OPCML were quantified separately. We found significantly higher expression of NEGR1 and NTM 1b transcript *postmortem* dorsolateral prefrontal cortex in patients with schizophrenia (n=36) compared with control subjects (n= 35).

Significant change in mRNA transcript in NEGR1 was confirmed in protein level by using western blot. Interestingly, it has been previously shown that NEGR1 transcript is significantly increased in dorsolateral prefrontal cortex of human subjects with major depressive disorder compared with non-psychiatric control subjects indicating that changes in NEGR1 levels/activity are underlying of wider spectrum on psychiatrical conditions. Furthermore, according to our preliminary cell culture experiments, NEGR1 is an important mediator in the process of neurite outgrowth. Suprisingly, we found no changes in the levels of LSAMP 1a and 1b which would be expected from previous results. However, our future research will cover wider regions in the brains of schizophrenic patients and controls, we will also continue with cell culture experiments to shed light on the exact functions of IgLON family of neural adhesion molecules and their impact in modifying neuronal substrate underlying in normal and pathological psychological/psychiatric conditions.

Title: Evidence for impaired motor learning and reduced spindle density in carriers of ZNF804A psychiatric risk alleles.

Authors: *U. BARTSCH[1], L. CORBIN[2], M. TAYLOR[2], C. HELLMICH[3], C. DURANT[4], M. W. JONES[5], N. J. TIMPSON[2];
[2]MRC Integrative Epidemiology Unit, [3]North Bristol NHS Trust, [4]Clin. Res. Imaging Ctr., [5]Sch. of Physiology, Pharmacol. and Neurosci., [1]Univ. of Bristol, Bristol, United Kingdom

Abstract: The rs1344706 single nucleotide polymorphism (SNP) in ZNF804A was among the first genetic variants associated with schizophrenia. Since then a number of studies have examined the influence of rs1344706 on cognition, brain structure and physiology. Despite this, the impact of this SNP on sleep physiology and cognitive aspects of sleep function has not been

described.
We used a recall-by-genotype design implemented in a population cohort (the Avon Longitudinal Study of Parents and Children) to investigate impacts of ZNF804A variants on sleep architecture, neurophysiology and sleep-dependent memory consolidation in healthy young adult homozygote CC (non-risk, n=11) and AA (risk, n=13). We used actigraphy with sleep diaries to assert weekly sleep wake cycles. Participants were monitored using lab-based polysomnography (PSG) on two nights. A motor sequence task (MST) was used to probe sleep-dependent memory consolidation over the second night.
Actigraphy and sleep diaries over the course of 2 weeks revealed similar rest-activity cycles between groups. We found no evidence for differences in actigraphy derived variables such as sleep latency and total sleep time between groups. PSG for both nights was scored by experts and subsequent analysis revealed no evidence for differences in PSG derived sleep latency, total sleep time or time spent in stages REM and NREM1-3 between CC and AA groups on either of the two PSG nights.
In preliminary analyses, there was evidence that the AA group performed reduced numbers of correct sequences (Mann-Whitney P value = 0.026), displayed slower average transition speed times (button press latency, Mann-Whitney P value = 0.046) and greater variance in overnight MST improvement (Levene's test, p=0.050). An automated analysis of non-REM sleep epochs provided evidence for reduced spindle densities (Mann-Whitney P value = 0.060) in AA carriers. These effects of ZNF804A on motor learning and non-REM sleep physiology provide novel insights into the genetic basis of psychiatric disorders.

Title: Molecular, functional, and pharmacological characterization of M4L, a muscarinic acetylcholine M4 receptor splice variant

Authors: D. A. SCHOBER[1], C. H. CROY[1], C. L. A. RUBLE[1], R. TAO[2], K. DEBROTA[1], *C. C. FELDER[1];

[1]Neurosci., Eli Lilly & Co., Indianapolis, IN; [2]The Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: Through bioinformatics, an open reading frame was discovered in the human, mouse and rat with a common ATG (methionine start codon) that extended the N-terminus of the muscarinic acetylcholine M4 receptor subtype by 155 amino acids resulting in a longer variant. RT-PCR experiments performed from human donor brain prefrontal cortex detected the human upstream exon and the junction of the two exons indicating the translation of the mature longer M4 receptor transcript. The predicted size for the longer two-exon M4 receptor splice variant with the additional 155 amino acid N-terminal extension, designated M4L is 69.7 kDa compared to the 53 kDa canonical single exon M4 receptor (M4S). Western blot analysis from a mammalian overexpression system, and saturation radioligand binding with [3H]-NMS (N-methyl-scopolamine) demonstrated the expression of this new splice variant. Comparative pharmacological characterization between the M4L and M4S receptors revealed that both the orthosteric and allosteric binding sites for both receptors were very similar despite the addition of an N-terminal extension. However, when both receptors were coexpressed the M4L appeared to have a dominate-negative effect on the functionality of the canonical receptor which could have implications in M4 receptor biology.

Sch., Tokushima, Japan; [4]Dept. of Bioinformatics and Genomics, Kanazawa Univ., Kanazawa, Japan; [5]Dept. of Psychiatry, Osaka Univ. Grad. Sch. of Med., Suita, Japan; [6]Mol. Res. Ctr. for Children's Mental Development, United Grad. Sch. of Child Development, Osaka Univ., Suita, Japan

Abstract: Objective Clozapine is a kind of atypical antipsychotics, which is effective for the treatment-resistant schizophrenia. DNA methylation is a major epigenetic mechanism, and it is affected by environmental factors. In this study, we examined DNA methylation changes by clozapine treatment in the patient with treatment-resistant schizophrenia by conducting a genome-wide DNA methylation profiling (485,764 CpG dinucleotides) of peripheral leukocytes. **Method** Twenty-one patients with schizophrenia (mean age: 42.1 ± 11.4 y; male: 8, female 13) were recruited from Tokushima and Osaka University Hospitals in Japan. The mean dose of clozapine was 473.8 ± 91.3 mg/day, and the mean duration of clozapine treatment was 340.8 ± 182.7 days. Peripheral bloods were collected before and after introduction of clozapine. The psychotic symptoms of patients were evaluated by Positive and Negative Syndrome Scale (PANSS) when the peripheral blood samples were collected. DNA methylation level was assessed with Infinium® HumanMethylation450 BeadChips (Illumina Inc.). A paired t-test was used to see the DNA methylation changes induced by clozapine. A single regression analysis was used to assess the relationship between the DNA methylation changes and the changes of psychotic symptoms evaluated by PANSS. **Result** Of the 435,611 CpG sites, significant DNA methylation changes after clozapine treatment were observed in 21,481 sites ($P < 0.05$ and beta difference > 0.01). Of the 21,481 CpG sites, significant correlations between % PANSS improvements and DNA methylation changes were observed at 414 sites ($p < 0.001$). **Conclusions** Our findings suggest that DNA methylation changes of the specific genes may be associated with treatment response to clozapine in the patients with treatment-resistant schizophrenia.

Title: Expression of microRNAs and inflammatory markers in schizophrenia and bipolar disorder

Authors: *S. K. AMOAH[1], B. A. RODRIGUEZ[2], N. MELLIOS[2];
[2]Dept. of Neurosciences, [1]Univ. Of New Mexico HSC, Albuquerque, NM

Abstract: Schizophrenia and bipolar disorder are multifactorial and heterogeneous psychiatric disorders, whose pathogenesis remains elusive, despite the numerous protein-coding genes potentially linked to their pathophysiology. However, the emerging consensus is that protein-coding genes inhabit only the tip of the iceberg of the mammalian transcriptome, given the plethora of actively transcribed non-coding RNAs (ncRNAs). One specific category of small ncRNAs with numerous, yet conflicting reports of aberrant expression in psychiatric disorders is that of the evolutionarily conserved small ncRNAs known as microRNAs (miRNAs). Previous approaches in miRNA profiling were hindered by their inability to appropriately discriminate between precursor and mature miRNA sequences and within members of the same miRNA families. We aimed at employing cutting-edge miRNA methodologies to determine with great accuracy the expression and potential function of schizophrenia-altered miRNAs in the human brain. To that end, we utilized NanoString miRNA expression profiling to specifically screen for differentially expressed mature miRNAs in the orbitofrontal cortex (OFC) of a large cohort of subjects with schizophrenia and bipolar disorder. Validation of mature miRNA levels was carried out for select schizophrenia dysregulated miRNAs using Taqman qRT-PCR assays. We found significant increases in a subset of miRNAs previously linked to immune activation, as well as downregulation of a small number of activity-dependent miRNAs related to synaptic plasticity, with the most prominent being miR-132. Previous studies have suggested a link between neuroinflammatory markers and psychiatric disease. Our data also revealed a significant elevation of inflammatory marker Serpina3 in the brain of subjects with schizophrenia with a trend for increase in bipolar disorder relative to unaffected control samples. Interestingly, there was an inverse relationship between Serpina3 and miR-132 expression and a significant association of both molecules (negative for Serpina3, positive for miR-132) with the age of onset of schizophrenia. Ongoing experiments are examining the developmental expression, downstream targets, and effects on neuronal structure and function of schizophrenia- and Bipolar disorder- altered miRNAs in patient-derived neuronal cultures, as well as mouse models of prenatal inflammation. In doing so, we expect to significantly advance the current understanding of the molecular mechanisms that may underlie psychiatric disorders.

Sch. of Med., Kanazawa, Japan; [5]Dept. of Psychiatry, Chiba Univ. Grad. Sch. of Med., Chiba, Japan

Abstract: The N-methyl-D-aspartate type glutamate receptor (NMDAR) are presumed to be hypoactive in brains of patients with schizophrenia. Several studies have indicated an altered proteins or mRNA expression of one of its scaffolding protein, the discs, large homolog 1 (DLG1), also known as synapse-associated protein 97 or SAP97 in the disease. The *DLG1* gene resides in the chromosomal position 3q29 where an excess of microdeletions in schizophrenia was found in multiple genome-wide analyses on copy number variations. In the present study, we have replicated the genetic association between the *DLG1* gene and schizophrenia shown in our two previous studies, using a Japanese cohort with 1808 cases and 2170 controls. We identified an unreported exon (Exon 3b) in the *DLG1* gene, and detected a significant genotypic and allelic association of the SNP rs3915512 located in the exonic splicing enhancer (ESE) sequence of this exon ($p = 0.005$ (permutation $p = 0.0164$) and 0.0032 ($p = 0.0092$), respectively). When the allele A, and not the schizophrenia risk allele T, of the SNP meets the consensus sequence of ESE, it could lead to the expression of a newly identified *DLG1* splicing variant, whose mRNA expression has been shown to be reduced in postmortem brains of early-onset (before 17) schizophrenia in our previous study. Furthermore, onset age-selective (after 18) associations with schizophrenia have been observed for the SNP. A meta-analysis of the previous and present studies of the SNP rs9843659 revealed its significant association with schizophrenia ($p = 0.033$). These findings add a support to the view that *DLG1* gene could be implicated in the onset age-associated susceptibility and/or pathophysiology of schizophrenia.

Title: Epigenetic regulation of human nicotinic acetylcholine receptor gene promoter.

Authors: *J. LICHOTA[1], M. DYRVIG[2], J. D. MIKKELSEN[3];
[1]Dept. of Hlth. Sci. and Technol., Aalborg Univ., Aalborg Ost, Denmark; [2]Aalborg Univ., Aalborg, Denmark; [3]Rigshospitalet, Copenhagen, Denmark

Abstract: The α7 nicotinic acetylcholine receptor regulates a wide variety of developmental and secretory functions in neural and non-neural tissues. The receptor is now considered a promising target for treatment of cognitive symptoms in psychiatric disorders. By using DNMT inhibitors, it has been found that DNA methylation regulates Chrna7 transcription in several human cell lines. As α7 nicotinic acetylcholine receptor ligand binding is low in human brain and binding shows high inter-individual variation, we decided to measure mRNA expression and methylation in three regions of the promoter in human brain biopsies. For all three regions we find very low degree methylation. Interestingly, for the region surrounding the promoter we find a significant correlation between transcription and methylation. It is known that nicotine itself does not induce transcriptional upregulation of the α7 nicotinic acetylcholine receptor but a strikingly high proportion of schizophrenics are smokers and also users of antipsychotics known to modify epigenetic mechanisms. Therefore, we investigated if combinations of the two resulted in transcriptional upregulation and promoter demethylation. In SH-SY5Y cells we measured low degree methylation similar to that in human brain biopsies. Interestingly, transcription was not affected by valproate or nicotine alone whereas a combination of both resulted in promoter demethylation and transcriptional up-regulation. This suggests that some types of antipsychotics may potentiate the cognitive enhancing effects of nicotine in smoking patients.

Title: Characterization of morphological changes in cleared tissue volumes using fluorescent microbead grid analysis.

Authors: *B. MARTIN, D. M. KROLEWSKI, V. KUMAR, H. AKIL, S. J. WATSON, Jr; MBNI, Univ. of Michigan, Ann Arbor, MI

Abstract: Recent advancements in tissue clearing methods and imaging techniques have provided researchers with the ability to analyze and measure intact three-dimensional structures within large volumes of brain tissue, without the use of physical sectioning of the tissue. While various clearing methods have been used successfully for this purpose, details about the expansion and contraction of the tissue caused by the clearing process are still unknown. In order to make accurate measurements and perform stereological analysis in cleared tissue samples, information is needed about overall change in tissue size. Four methods of tissue clearing (CLARITY, CUBIC, SeeDB, and 3Disco) were compared to measure changes in the size of the samples. To accomplish this, fluorescent microbeads were injected in a grid layout (100 μm gridline spacing) within pre-cleared tissue samples using a digital stereotaxic setup. Clearing was then performed on these tissue samples, and image volumes were acquired using a lightsheet microscope (CLARITY-Optimized Lightsheet Microscope). These volumes were visualized in AMIRA software and the resulting grids were measured. The results of this study will elucidate the details necessary to perform stereological analysis and measurements in tissue samples cleared by various methods.

Title: Immunohistochemistry in fresh-frozen post-fixed brain tissue using antigen retrieval techniques

Authors: *D. M. KROLEWSKI, R. A. ILAGAN, V. KUMAR, A. PARSEGIAN, B. MARTIN, H. AKIL, S. J. WATSON, Jr;
Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: Background: Cataloging fresh-frozen brain tissue in the absence of prior aldehyde fixation and cryoprotection is beneficial for preserving protein and nucleic acids (RNA/DNA) across a variety of neuroscience methods requiring long-term storage. Unfortunately, detecting brain-localized antigens via immunohistochemistry (IHC) can be more challenging, if not impossible, using post-fixation following cryosectioning and slide-mounting. The inherent effect of autolysis, particularly during the thawing process, likely contributes to such marked loss of antigenicity (Jones et al., 1992). Slowly thawing frozen human brain blocks immersed in at subfreezing aldehyde-based fixative containing cryoprotectants can retain some degree of antigenicity otherwise lost under less ideal conditions (Jones et al., 1992). However, this technique also can require long incubation times in fixative/cyroprotectant for which thorough tissue penetration can be difficult to determine.**Methods and Results:** The present study evaluates more timely IHC methods in an effort to increase antigenicity using fresh-frozen rodent and human brain tissue. The effects of aldehyde-based and non-aldehyde precipitating fixatives were compared across an array of antibodies directed at methylation markers, glial cells, neuropeptides, and other neuronal-specific molecules on slide-mounted sections. In addition, each fixative was tested alone or paired with treatment of heated antigen-retrieval buffers at varied pH. Utilizing standard diaminobenzidine/horseradish peroxidase IHC amplification methods, we show that several antibodies including those specific for glia and particular subcortical neuronal populations are clearly expressed in well-characterized topographical patterns with relatively low background. Given the successful application in thin

slices, we have begun conducting similar experiments in 1 to 2mm-thick rodent and human brain slices using transparency techniques. 3-dimensional immunofluorescence in frozen tissue processed by CLARITY (Tomer et al., 2015), CUBIC (Susaki et. al., 2014), and SWITCH methods (Murray et. al., 2015) is being performed using both confocal and CLARITY Optimized Light Sheet Microscopy (COLM) systems. The results of this study will offer additional avenues for the processing of long-term stored fresh-frozen tissue.

Title: Optimization of the tyramide signal amplification based fluorescence *In situ* hybridization in cleared thick brain tissues

Authors: *V. KUMAR, D. M. KROLEWSKI, B. MARTIN, A. PARSEGIAN, H. AKIL, S. WATSON, Jr;
Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: Tyramide signal amplification provides extraordinary detection sensitivity to fluorescence *in situ* hybridization (FISH) to visualize targets with low expression. It is based on catalyzed reporter deposition (CARD) technique where peroxidase mediated formation of highly reactive tyramide radicals result in the binding of fluorochrome-conjugated tyramide only at the site of the enzymatic reaction. This method has been successfully used for thin section FISH studies over the years, however it has been still a challenge to utilize this system with recently developed CLARITY and other tissue clearing methods for high resolution imaging and molecular characterization within intact large volumes. One of the major challenges of tyramide-based amplification in thick tissues (100 μm and more) is the rapid deposition of most of the

available tyramide on the surface, exhausting the tyramide levels for deep layers of the tissue. Recent publications show a maximum signal penetration up to 100 µm depth using the commercially available tyramide kits. We explored this issue to achieve a uniform tyramide deposition across the tissue depth by using a combination of hydrolyzed cRNA probes and homemade biotin conjugated tyramide. Homemade biotinylated TSA is not only cost effective for larger tissue volumes but also provides an opportunity to regulate the catalysis/deposition of the tyramide. We characterized this improved method in fresh frozen rat- and CLARITY perfused mice-brain sections of various thickness. We are also comparing the mRNA detection in paraformaldehyde only fixed tissues (300 µm and 600 µm) and CLARITY tissues (1 mm) with or without 1-ethyl-3-3-dimethylaminopropyl carbodiimide (EDC) fixation. We are further exploring the multi-target detection with and without TSA and were able to visualize good signal strength by using a simple immunohistochemical detection of biotin labeled probes for some of the abundantly expressed mRNAs.

Title: A simple, improved tissue clearing method with broad adaptability for high fidelity molecular interrogation in intact whole brain

Authors: *Z. WU[1], R. AZEVEDO[1], R. FARRELL[1,2], N. RENIER[1], O. OLSEN[1], M. TESSIER-LAVIGNE[1];
[1]Lab. of Brain Develop. and Repair, Rockefeller Univ., New York, NY; [2]Dept. of Biochem., Weill Cornell Med., New York, NY

Abstract: The growing interest in understanding the complexity of organ-wide cellular interactions has led researchers to develop tissue clearing protocols for visualizing molecular patterns on a more global scale. Our lab recently developed iDISCO (Renier et al., 2014) for whole-mount immunolabeling in large cleared samples followed by volume imaging. iDISCO provides advantages for profiling distinct neuronal and non-neuronal cell populations, tracing long-range axonal projections, and examining physiological status (by using molecular reporters for neuronal activity, neural proliferation and degeneration) (Richardson and Lichtman, 2015). This enables efficient investigation of complex questions that were previously difficult to address

due to technical limitations.
In order to meet more versatile and challenging demands, we have systematically engineered and optimized each step of the clearing process. A first set of improvements led to the development of iDISCO+ (Renier et al., 2016), which provides more consistent labeling and clearing, and better preserves tissue morphology for automated data registration and analysis. We have built further on those advances to: 1) improve lipid removal to achieve isotropic optical clearing, while preserving native protein conformation. This would allow us to faithfully collect fluorescence protein signal or immunolabeling signal; 2) accelerate and improve molecular labeling; 3) further preserve sample size and fine tissue morphology after clearing; and 4) be compatible with both organic and aqueous imaging systems to enable broad microscopy applications. These improvements enable easy and reliable translation of traditional histological assays from sections to whole-mount tissues while maintaining or even improving sensitivity and coverage. The new method provides a powerful platform for investigating development, plasticity and degeneration in the intact nervous system.

Title: Microscopic imaging of optically cleared brain samples: two-photon laser scanning microscopy vs. confocal laser scanning microscopy

Authors: *A. SCHUETH[1], S. HILDEBRAND[2], R. GALUSKE[4], M. VAN ZANDVOORT[3], A. ROEBROECK[2];

[1]Cogntive Neurosci., Maastricht Brain Imaging Center/ Maastricht Unive., Maastricht, Netherlands; [2]Cognitive Neurosci., [3]Genet. & Cell Biol., Maastricht Univ., Maastrcht, Netherlands; [4]Technische Univ. Darmstadt, Darmstadt, Germany

Abstract: Introduction
Our aim is a microscopic investigation of fixed, optically cleared brain tissue to visualize gray matter cytoarchitecture. To achieve this we performed comparative experimental imaging using confocal laser scanning microscopy (CLSM), as well as two-photon laser scanning microscopy (TPLSM) [1].
Methods
Formaline fixed, 3 mm thick pig brain samples were used. The clearing technique was a modified version of the FRUIT protocol (see Hildebrand et al., this conference [2]). DAPI (Carl Roth GmbH, Germany) was used for nuclear labelling. For imaging experiments a CLSM (Zeiss, AxioObserver LSM 780) was used, with a Plan-APO 10x/0.3 M27 objective. Excitation wavelength was 405 nm for DAPI. Laser power was 5-65 %. The field-of-view was 850.19 x 850.19 µm and the frame rate was 0.032 frames/sec. The TPLSM, a Leica TCS SP5 MP (Leica Mikrosysteme Vertrieb GmbH, Germany), had a HXC APO L 20x / 1.00 W 2mm working distance water immersion objective. Excitation wavelength was 800 nm and laser power 6-45%. During the examination the field-of-view was 738.10 x 738.10 µm and the frame rate 0.781 frames/sec.
Results & Conclusion
CLSM and TPLSM allowed the investigation of fixed, optical cleared brain tissue. With CLSM, cell nuclei (DAPI stained) were detected up to an imaging depth of approx. 600 µm within the sample (Fig 1c). TPLSM enabled the visualization of up to an imaging depth of more than 1 mm (Fig 1f) with showing stained nuclei (DAPI) throughout the complete sample thickness. We could show the advantage of TPLSM for neuroanatomical examinations of cleared brain samples for fluorescent labels with short excitation wavelengths. Future experiments with different optical clearing approaches could provide good imaging at depths of several millimeters.
Figures
Fig. 1: Brain samples were imaged with CLSM (A, C, E) and TPLSM (B, D, F). Imaging depths of the images are indicated in inserts. DAPI staining (nuclei, arrows) was visible up to an imaging depth of 600 µm using the CLSM (D) and up to approx. 900 µm with the TPLSM (F). Scale bars: 30 µm

Title: Comparison of fructose/urea immersion-based protocols for optical clearing of brain tissue

Authors: *S. HILDEBRAND[1], K. VON WANGENHEIM[2], A. ROEBROECK[1], R. A. W. GALUSKE[2];
[1]Maastricht Univ., Maastricht, Netherlands; [2]Technische Univ. Darmstadt, Darmstadt, Germany

Abstract: Introduction
Recently optical clearing for 3D light microscopy of brain tissue is gaining attention in neuroscience. Some protocols that show a high clearing capacity remove the lipid components, making them incompatible with lipophilic dyes like DiI [1]. Approaches that leave lipid structures intact often show only limited clearing [2]. Here we compare clearing solutions based on the FRUIT protocol [3] for their ability to clear unperfused pig brain sections while still providing compatibility with DiI.
Methods
Three pig brain hemispheres were immersion fixed in 4 % PFA. Blocked hemispheres were cut into 3 mm coronal sections on a Leica VT 1000 S vibratome. For DiI staining, dye crystals were inserted into sulci of the slices, which were incubated at 37℃ for 4 months. DAPI staining was performed by incubating each slice in 6 ml of 1 µg/ml DAPI (CarlRoth) solution for 3 d at 4℃. For clearing, stepwise (10 %, 20 %, 40 %, 60 %, 80 %, 100 %) immersion in 20 ml each was performed for all three protocols. For each 100 % solution composition was as follows (percentages given in w/v respectively): FRUIT: 0.5 % thioglycerol, 11 % urea, 100 % fructose; Thiolgycerol: 100 % thioglycerol; Variant 4: 20 % thioglycerol, 48 % urea, 38.46 % fructose, 37 % sucrose, 3 % trehalose. Samples were incubated for 1 d (10 - 40 %), 2 d (60 %) and 3 d (80 - 100 %) at RT respectively. Imaging of the samples was performed on a Zeiss AxioObserver LSM 780.
Results & Conclusions
The Thioglycerol protocol led to tissue degradation and degraded stainings. Adding non-reducing sugars while increasing thioglycerol content up to 20 % in Variant 4, reduced the Maillard reaction and provided a high refractive index of 1.497. Clearing was superior to FRUIT and enabled deeper imaging of the DiI label. Filaments were visible to a depth of at least 1.5 mm and Somata for over 1 mm (Fig. 1a-d). No difference was seen for DAPI. We conclude that our FRUIT variant allows clearing samples with less Maillard reaction while leaving DiI labeling intact.

Title: Combining CLARITY with mGRASP for brain-wide mapping of projections and synapses with light microscopy

Authors: *S.-Y. KIM[1], H.-E. PARK[1], D.-J. KOO[1], M. CHOE[1], H. LEE[2], J. KIM[2];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Complete mapping of neural connectivity across the mammalian brain (the "connectome") is a daunting and exciting prospect. Achieving this goal, even in its simplest form, requires the method that enables tracing and reconstruction of all neurites and their branches while determining the exact location and type of synapses. With relevance for this goal,

various clearing and labeling techniques for large-scale tissues are emerging, including CLARITY, stochastic electrotransport and SWITCH (Chung *et al., Nature* 2013, Kim *et al., PNAS* 2015, Murray *et al., Cell* 2015). These techniques render the tissues transparent and enable rapid and multi-round labeling, which may allow for light microscope-based imaging of all neural cell bodies, their dendrites and short- and long-range projections across the entire brain. However, the cutting-edge light microscopes optimized for the large-scale samples cannot accurately detect nanometer-scale synapses, due to the diffraction limitations of light microscopy. Therefore, the tissue clearing and labeling techniques alone do not easily lend support to synapse-by-synapse mapping of the neural circuitry. To overcome this, we aim to combine the advanced form of tissue clearing and labeling techniques with mGRASP (mammalian GFP reconstruction across synaptic partners) (Kim *et al., Nat Methods* 2012). mGRASP is the technique that enables reliable detection of mammalian synapses with light microscopy, taking advantage of the complementation of split GFP partners across the synapse. Our goal is to develop a reliable tool for the detailed mapping of neural connectivity over the millimeter-range.

Title: Visualization of adult rodent bodies at the sub-cellular level using uDISCO tissue clearing

Authors: C. PAN, R. CAI, F. P. QUACQUARELLI, A. GHASEMI, *A. ERTURK;
Inst. for Stroke and Dementia, Munich, Germany

Abstract: Optical tissue clearing approaches started to revolutionize standard histology by allowing to image intact organs and organisms. Organic solvents used in 3DISCO[1,2] including

BABB or DBE known to achieve the highest level of transparency among all reported clearing approaches. Hence, already in last 1-2 years 3DISCO has been used to study immune cells[3], stem cells[4,5], cancer cells[6,7] and transdifferentiating lung cells[8]. It has also been combined with deep tissue antibody labeling methods[9,10]. However, because 3DISCO quenches the signal from endogenous fluorescent proteins fast (half life of a few days)[1], it was not applicable to large samples requiring longer clearing procedure such as adult rodent bodies. Here, we developed ultimate (u)DISCO clearing approach, which preserves the endogenous fluorescence signal 8-10 times better compared to 3DISCO. uDISCO uses a novel tissue clearing method, which renders intact organs and rodent bodies transparent while reducing their size up to 65%, enabling standard light-sheet microscopy imaging on whole adult rodent bodies without physical sectioning. We used uDISCO to image neuronal connections and vasculature from head to toe over 7-10 centimeters and trace transplanted stem cells in an unbiased way throughout the entire bodies of adult mice. uDISCO is compatible with various labeling methods including virus tracing, antibody labeling and it is also applicable to over-fixed human tissues. Thus, uDISCO is a robust tissue-clearing method applicable to diverse biomedical purposes. 1. Erturk, A. *et al. Nat Protoc* **7**, 1983-1995, (2012). 2. Erturk, A. *et al. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Introduction: Recent advancement of laser microscopy and endogenous fluorescent tagging techniques has led to the development of many tissue clearing strategies, which render tissues optically transparent, allowing large blocks of unsectioned tissue to be visualised in 3D. Although there have been a few successful attempts at clearing of human brain tissue, challenges remain in achieving immunolabelling to a significant depth of the tissue, as well as clearing of large tissue blocks in densely myelinated brain regions. Therefore, we aim to develop an improved and simplified tissue clearing protocol for 3D visualisation of neurodegenerative pathology in the human brain. **Methods:** Fresh and formalin-fixed tissue from various regions in the human brain were processed and immunostained using CLARITY, 3DISCO and/or iDISCO. CLARITY-treated samples were immersed in different refractive index matching media before mounting and visualising under a confocal microscope. **Results:** We have optimised the CLARITY protocol for use on human tissue for the visualisation of Lewy pathology in 3D. Furthermore, by combination of different techniques, we have developed a novel tissue clearing protocol for human brain tissues, which improves immunolabeling and reduces the overall processing time from tissue fixation to immunostaining and visualisation to a minimum of 16 days. **Conclusions:** A greatly simplified and more user-friendly tissue clearing protocol has been developed for the 3D visualisations of human brain tissue. However, further work is needed for the improvement in immunolabeling and clearing of archival formalin-fixed tissue materials.

Abstract: Imaging cellular and subcellular structures in an intact organ or organism is a fundamental challenge in biology. Conventionally, this task has been approached by reconstructing immuno-labeled images taken from a series of tissue sections into a 3-dimensional structure. However, this approach is labor- and resource-intensive. A more critical limitation of this approach is that serial-image reconstructing is not accurate because physical sectioning distorts tissues and registration of two consecutive images is prone to errors. The recent advances of tissue clearing techniques allow visualization of cellular structures and neural networks inside of unsectioned whole tissue or even whole body. However, currently available protocols require long process time. Here, we present a rapid and highly reproducible ACT-PRESTO (active clarity technique-pressure related efficient and stable transfer of macromolecules into organs) method that renders tissue or whole-body clearing within a day while preserving tissue architecture and protein-based signals derived from endogenous fluorescent proteins. Moreover, ACT-PRESTO is compatible with conventional immunolabeling methods and expedites antibody penetration into thick specimens by applying pressure. Speed and consistency of this method will allow high-content mapping and analysis of normal and pathological features in intact organs and bodies.

Title: Quantitative assessment of 3D imaging for blood vessel patterns in the CNS

Authors: *J. OGAWA, G. M. PAO, I. M. VARMA;
Salk Inst. LOG-V, La Jolla, CA

Abstract: Here we describe 3D imaging of blood vessel patterning in the mouse CNS and investigate the quantitative properties of their branching pattern at different scales. A large variety of techniques have been tried for visualization of vascular structure, but with section staining, it was difficult to obtain the whole context of complicated structures. We apply a new technique to make tissue transparent which allows us to image the complicated blood vessels patterns in the CNS without losing information from sectioning. With these techniques and using confocal laser-scanning microscopy, we succeeded to image the brain to approximately 600 um in depth. The image is of enough contrast for quantitative assessment of the detailed structure of small blood vessels. We used these 3D image datasets to investigate the quantitative properties of brain blood vessels at different scales. This new assessment shows significant differences in the blood vessel patterning in different areas of the brain. Changes in total Cerebral blood flow with aging or neural stimulus has been observed using PET or MRI imaging. We will use these newly established assessment to investigate whether aging related or neural stimulus related brain state changes also induce blood vessel state differences in different areas of the brain.

Title: Three-dimensional visualization of cellular and disease markers in human brain using tissue clearing methods

Authors: Z. PARTON, L. KUKREJA, T. GEFEN, A. REZVANIAN, E. H. BIGIO, M.-M. MESULAM, *C. GEULA;
Cogn Neurol & Alzhei Dis Cent, Northwestern Univ. Med. Sch., Chicago, IL

Abstract: Recent advances in methods for optical tissue clearing have enabled 3D visualization of long-range neuronal circuitry and detailed cellular structures. These procedures remove lipid bilayers while preserving cellular proteins to ultimately render tissue transparent such that it can be fluorescently labeled and imaged. To date, few studies have applied these methods to human specimens. The Cognitive Neurology and Alzheimer's Disease Center (CNADC) at Northwestern University seeks to optimize clearing protocols for application to postmortem human tissue with the aim of conducting large scale 3D analysis of anatomic and pathologic features of neurodegenerative diseases. We have successfully applied the "CLARITY" and "iDISCO" protocols to blocks of human motor and cerebellar cortices. Each method carries relative benefits and disadvantages, and our trials have enabled us to fine-tune these procedures for relatively large human sections. CLARITY, also known as **C**lear **L**ipid-exchanged **A**crylamide-hybridized **R**igid **I**maging-compatible **T**issue-h**Y**drogel is an aqueous-based clearing method that utilizes hydrogel embedding, detergent, and/or electrophoresis followed by antibody labeling to produce the desired effects. In contrast, the iDISCO method (**I**mmunolabeling-enabled three-**D**imensional **I**maging of **S**olvent-**C**leared **O**rgans) starts with antibody labeling, followed by incubation of the tissue in a series of organic solvents to dehydrate and delipidate its content. Both methods produced 'cleared' (i.e. transparent) cortical and cerebellar tissue, with a high signal-to-noise ratio when imaged with a laser scanning confocal and multi-photon microscopes. When visualizing structures in 3D, we were able to render high resolution z-stacks that exceeded depths of 1mm. We also extended the application of our methods to brains with neurodegenerative disorders. Our immunolabeling method visualized neuronal, glial, and pathologic markers, including amyloid plaques, neurofibrillary tangles and TDP-43 inclusions. Overall, we present here methodologies for clearing human tissue that are invaluable to the study of neurodegenerative diseases. This will allow us to observe fine-scale anatomic distribution of pathology, and significantly inform systems-level understanding of intact and impaired cognitive functions.

Title: Comparison and optimization of tissue clearing techniques for whole-brain imaging of indelibly labeled memory traces

Authors: *I. PAVLOVA, S. C. SHIPLEY, R. HEN, C. A. DENNY;
Dept. of Psychiatry, Columbia Univ., New York, NY

Abstract: Whole-brain tissue clearing and microscopy imaging is a rapidly growing area of focus. We evaluated several tissue clearing and labeling approaches, such as iDISCO, CLARITY, PACT, and CUBIC, to label and visualize whole-brain memory traces in intact brains from the ArcCreER^{T2} mouse model. This model labels neural ensembles activated during memory encoding by expression of channelrhodopsin (ChR2)-enhanced yellow fluorescent protein (eYFP) and neural ensembles activated during memory retrieval by immunolabeling of Arc and/or c-Fos. Our goal was to develop a technique that allows for homogenous whole-brain clearing, immunolabeling, and imaging of both the densely expressed eYFP label and the sparser Arc/c-fos label. We first evaluated several protocols and found that the best results were achieved by iDISCO rather than CLARITY or PACT. However, using the original iDISCO protocol, uniform thick-tissue immunolabeling was achieved only for Arc/c-fos, but not for the densely expressed eYFP label. Next, we modified the original iDISCO protocol for compatibility with a GFP nanobody, a functionally similar but physically smaller alternative to a GFP IgG antibody. We found that the nanobody penetrated deep tissue better than its whole antibody counterpart, making it a potential candidate for improved eYFP iDISCO-based immunolabeling. Finally, we evaluated several clearing approaches for preservation of endogenous eYFP fluorescence and co-staining with Arc and/or c-fos. CUBIC (with reagent 1A) showed the best preservation of endogenous eYFP fluorescence, with compatibility for Arc immunolabeling in thick tissue sections. These results suggest iDISCO and/or CUBIC as the whole-brain clearing methods of choice for compatibility with the ArcCreER^{T2} mouse line. The use of these methods will provide a novel approach to studying memory traces across the entire brain and new insights into the circuits that underlie memory, cognition, and neuropsychiatric disorders.

Title: Longitudinal cellular imaging of the astrocyte response to chronically implanted neural probes

Authors: *K. MOLS[1,2,3], S. MUSA[1], B. NUTTIN[2], L. LAGAE[1,2], V. BONIN[3];
[1]Imec, Leuven, Belgium; [2]KU Leuven, Leuven, Belgium; [3]NERF, Leuven, Belgium

Abstract: Neural implants for electrical recordings or stimulation are critical for studying neural circuits, for building brain computer interfaces, and for restoring brain function. Minimizing the tissue damage and foreign body reaction is key to the success of such implants. Most knowledge about the device-tissue interface is obtained with end-point methods such as histology. However, the ability to monitor the progression of the foreign body response *in vivo* and to correlate it to implant performance would greatly contribute to our understanding of the dynamics of the device-tissue interaction.

To address this issue, we present an *in vivo* approach to (1) longitudinally image the cellular environment surrounding an implant, and (2) reliably record electrophysiological data from that implant. We used this tool to study the relation between the astrocytic reaction to a multisite single-shank silicon probe, and the stability of long-term neuronal recordings.

We combined a chronic cranial window over the visual cortex with a functional probe in a transgenic mouse, expressing the green fluorescent protein (GFP) under control of the astrocyte-specific Aldh1l1-promotor. Using a video-rate two-photon (2P) microscope, we imaged 500 μm² optical planes between 200 and 500 μm subdural weekly for 10 consecutive weeks. We corrected these images for variations in brain transparency and quantified GFP fluorescence around the probe as a measure for astrocyte reactivity. Before each imaging session, we recorded spiking activity under light ketamine anesthesia and calculated the average signal and noise amplitude in order to monitor the probe's performance. At the end of the experiment, we used confocal microscopy to image immunohistochemically labelled astrocytes (GFAP), microglia (IBA1) and nuclear DNA (DAPI) for each animal (N = 8).

We found that 2P imaging can resolve astrocytic processes at the probe's surface. The average fluorescence signal of both cell somas and processes did not show significant variation for 10 weeks (one-way univariate ANOVA, p = 1,0). Similarly, noise and spike amplitude remained constant. The noise (12 μV_{rms} on average) never reached the amplitude range of the spiking activity (123 μV_{pp} on average). Finally, the histological markers did not show a marked build-up

of inflammatory cells around the probe.
We show that our approach provides a unique look into the cellular changes at the probe-tissue interface and allows us to longitudinally monitor the foreign body response while the probe is implanted. Moreover, our results indicate that a stable astrocytic response to an implant coincides with stable electrical recordings.

Title: A novel CNS white matter preparation for electrophysiological studies of myelinated and non-myelinated axons: the isolated corpus callosum from mouse brain

Authors: ***A. A. VELUMIAN**[1,4], L. LI[1], M. SAMOILOVA[1], M. G. FEHLINGS[1,5,2,3];
[1]Toronto Western Hosp. / Neurosurg., [2]Krembil Neurosci. Ctr., [3]Krembil Res. Inst., Univ. Hlth. Network, Toronto, ON, Canada; [4]Departments of Surgery and Physiol., [5]Dept. of Surgery, Univ. of Toronto, Toronto, ON, Canada

Abstract: The axonal function in CNS white matter of laboratory animals is studied by recording compound action potentials (CAPs). In the optic nerve or dissected spinal cord white matter, reliable CAP recordings are done similar to peripheral nerves by using suction electrodes, grease gap or sucrose gap techniques for stimulation and recording of large axonal populations. The corpus callosum (CC), a major white matter structure interconnecting brain hemispheres, is extensively used for studying CNS axonal function. Unlike the optic nerve where all axons are myelinated, the CC contains also a large population of non-myelinated axons, making it particularly useful for studying both types of axons in various physiological and pathological conditions. CAP recordings in CC are typically done with extracellular microelectrodes that limit

the recordings to a limited axonal population around the electrode tip. Here we introduce a novel robust isolated "nerve-like" CC preparation that allows for suction electrode stimulation and recording similar to approaches used in the optic nerve. Unlike microelectrode CAP recordings in brain slices or in vivo, where the CC CAP peaks representing myelinated and non-myelinated axons vary broadly in size, the "nerve-like" CC CAPs show stable reproducible ratios of these two main peaks, and also reveal a third peak, suggesting a distinct group of smaller caliber non-myelinated axons. We will provide detailed characterization of "nerve-like" CC CAPs and conduction velocities of myelinated and non-myelinated axons within CC at different positions along the rostro-caudal axis of CC body. The "nerve-like" CC preparation has advantages for studying the changes in axonal conduction properties due to demyelination, which we will illustrate by comparing the CC CAPs in wild type and dysmyelinated *shiverer* mice. Similar to other nerve or nerve-like preparations, the isolated CC is useful for studying the effects of temperature, bath-applied drugs (4-aminopyridine) and ischemia (modeled by oxygen-glucose deprivation) on axonal function. Due to isolation from gray matter, the “nerve-like” CC preparation allows for studying the axonal function without "contamination" by reverberating signals from gray matter. Our analysis of "whole" CC CAPs in this nerve-like preparation reveals higher complexity of myelinated and non-myelinated axonal populations, not noticed earlier. This preparation may have a broad range of applications as a robust model for studying myelinated and non-myelinated axons of the CNS in various experimental models.

Title: Physiological basis of high frequency resting state networks in the human brain using high-speed fMRI and computer simulations of spatial autocorrelations

Authors: C. TRAPP[1], K. VAKAMUDI[1], M. O. CHOHAN[2], *S. POSSE[1];
[1]Neurol., [2]Neurosurg., Univ. of New Mexico, Albuquerque, NM

Abstract: Current studies of resting-state connectivity rely on coherent signal fluctuations at frequencies around 0.1 Hz, however, recent studies have shown that fluctuations above 0.5 Hz may exist. This may permit the observation of functional connectivity dynamics at even shorter

time scales than is currently feasible at frequencies < 0.3 Hz. The current study replicates the feasibility of measuring high frequency (HF) correlations in six healthy controls and a patient with a brain tumor in left parietal lobe, while analyzing non-physiological sources via simulation.
Resting-state data were acquired using a high-speed multi-slab echo-volumar imaging (MEVI) pulse sequence, which increases BOLD sensitivity compared to EPI (TR: 136 ms, spatial resolution: $4\times4\times6$ mm^3). Bandpass filtering of low frequency connectivity and physiological noise, in combination with a confound-tolerant sliding-window seed-based connectivity analysis (WSCA) using running mean/standard deviation was used to map HF correlations. Whole Brodmann areas (BA) and single voxels derived from peak correlations were used as seeds. Simulations of Rician noise and the underlying point-spread function (PSF) were analyzed to estimate baseline auto-correlation levels in the four networks studied (auditory, sensorimotor, visual, and default-mode).
Only the auditory and default mode networks were observed to have HF correlations significantly above baseline auto-correlation levels when observed with BA seeds. When analyzed with peak voxel seeds, auditory was the only network to show extended or bilateral correlations. All other networks were restricted to PSFs. Additionally, HF auditory correlations in the tumor patient showed a spatial displacement anterior to the tumor, corresponding with a similar displacement observed at low frequencies. When seeded within the tumor itself, there were no HF correlations outside of the PSF, in contrast with a contralateral seed.
This study demonstrates resting-state connectivity at frequencies > 0.5 Hz in the auditory and default-mode networks using sensitivity enhanced MEVI acquisition, confound tolerant WSCA and simulations of baseline autocorrelations. The displacement of high frequency correlation maps in the tumor patient as a result of the lesion further supports the physiological nature of observed high frequency correlations. While this does not rule out the possibility of visual and sensorimotor networks at high frequencies, their existence cannot be determined with the current SNR and temporal resolution limits of this study. Further studies are required to assess the origin of these high frequency correlations.

Title: Safety and EEG data quality of concurrent high-density EEG and high-speed fmri at 3 Tesla

Authors: *O. B. PAULSON[1], M. T. FOGED[1], U. LINDBERG[2], K. VAKAMUDI[3], H. B. W. LARSSON[1], L. PINBORG[1], T. W. KJÆR[4,5], M. FABRICIUS[2], C. SVARER[2], B. OZENNE[5], L. WU[3,6], V. D. CALHOUN[3,6], B. FISH[3], C. THOMSEN[1], S. BENICZKY[2,7,8], S. POSSE[3]; [1]Rigshospitalet & Univ. of Copenhagen, Copenhagen, Denmark; [2]Rigshospitalet, Copenhagen, Denmark; [3]Univ. of New Mexico, Alberqerque, NM; [4]Roskilde Hosp., Roskilde, Denmark; [5]Univ. of Copenhagen, Copenhagen, Denmark; [6]Mind Res. Network, Alberqerque, NM; [7]Aarhus Univ. Hosp., Aarhus, Denmark; [8]The Epilepsy Hosp., Dianalund, Denmark

Abstract: ***Aims:*** Concurrent EEG and fMRI is increasingly used to characterize the spatial-temporal dynamics of brain activity in neuroscience and clinical applications. However, most studies to date have been limited to using conventional echo-planar imaging. There is now increasing interest to integrate recently developed high-speed fMRI methods with high-density EEG arrays to increase temporal resolution and sensitivity for resting state fMRI and for detecting interictal spikes in patients with epilepsy. ***Methods:*** In this study we investigate radiofrequency related heating in concurrent high-density EEG and high-speed fMRI using three, clinical, 3 Tesla MR scanners from two different vendors equipped with a 64- and 256-channel MR-compatible EEG system comparing EPI, multi-echo EPI, MB-EPI and MS-EVI pulse sequences. In addition, EEG data quality was assessed on one of the scanners using a 64-channel EEG system. Data were collected in 10 healthy controls and 14 patients with epilepsy. ***Results:*** Radiofrequency heating at the surface of the EEG electrodes during 20 min scans did not exceed 1.1^{o} C. The EEG data quality during the MR scan was deteriorated compared to EEG outside of the scanner, primarily due to residual gradient artifacts and movement. The EEG quality was not significantly dependent on the fMRI method used, but a trend towards deterioration of the EEG quality with increasing short-term movement was found. ***Conclusion:*** This study demonstrates that high-density EEG can be safely implemented in conjunction with high-speed fMRI methods under the experimental conditions of this study, but deterioration of EEG quality inside the MR scanner may limit clinical applications.

Title: Resting state fMRI signals in white matter of non-human primates

Authors: T.-L. WU, F. WANG, A. W. ANDERSON, L. CHEN, Z. DING, *J. C. GORE; Vanderbilt Univ., Nashville, TN

Abstract: Neither blood oxygenation level dependent (BOLD) activation nor resting state magnetic resonance imaging (rsfMRI) signals in white matter have been well-established. However, growing evidence suggests reliable detection of white matter BOLD signals may be possible. We have reported the measurement of anisotropic resting state correlations within white matter that reveal an underlying functional structure. Recently, we introduced the concept of a functional correlation tensor (FCT) as a description of the functional architecture of white matter, purely on the basis of rsfMRI data. We find these FCTs delineate long range white matter tracts as well as short range sub-cortical fibers imaged at rest, suggesting temporal resting state signals may reflect intrinsic synchronizations of neural activity in white matter. In order to evaluate the neural basis of these correlated fluctuations, we assessed whether MRI signal fluctuations in white matter vary for different baseline levels of neural activity. Specifically, we performed imaging studies on live squirrel monkeys under different levels of isoflurane anesthesia at 9.4T. Our results showed that the power in both gray and white matter low frequencies decreased monotonically in similar manner with increasing levels of anesthesia. Moreover, the distribution of fractional anisotropy values of the functional tensors in white matter were significantly higher than those in gray matter. In addition, the functional tensor eigenvalues (i.e. greater nearest neighbor resting state correlations) decreased with increasing level of anesthesia. Overall, our results suggest that as anesthesia level changes baseline neural activity, white matter signal fluctuations behave similarly to those in gray matter, and functional tensors in white matter are affected in parallel. These findings confirm that BOLD-like signal fluctuations in white matter can be detected in a resting state, are anisotropic in nature, and consistent with underlying neural activity.

Abstract: Ultrasensitive ultrasound Doppler imaging enables fMRI-like dynamic measurement of cerebral blood volume with high-sensitivity and has recently led to the development of functional ultrasound (fUS) imaging. fUS imaging is a powerful tool for measuring brain activation and connectivity through the neurovascular coupling with high spatiotemporal sampling (100 µm, 1 ms), Here we investigated the use of fUS imaging of mice, an important pre-clinical model. First we show that ultrasensitive Doppler imaging of the entire brain is possible directly and completely non-invasively through the intact skull and skin without contrast agents in anesthetized mice, regardless of age. Using a motorized probe, we also performed non-invasive high-resolution 3D Doppler tomography in adult mice. Next, we demonstrate the feasibility of high-quality full-transcranial fUS imaging in awake and freely-moving mice in a minimally invasive setting. For this purpose we magnetically clipped a newly developed ultralight ultrasound probe to a small and flat metal frame that we fixed to the mouse skull. We have also developed a dedicated ultrasonic sequence to avoid a previously unreported specific muscle-related artifact in awake rodents. This setup allowed us to acquire full-depth high-resolution images of the awake mouse brain vasculature as well as detect the activation of the barrel cortex during whisker stimulation. These results open new perspectives for the use of fUS

imaging in imaging of behavioral studies and in non-invasive longitudinal studies of postnatal brain development.

Abstract: Many autism spectrum disorders (ASDs) have a genetic basis but it remains unclear how genetic modifications cause disease phenotypes such as social deficits and repetitive behaviors. We examined effects of mutations in ASD-linked genes on social behaviors of adult zebrafish. We focused on shoaling, a social behavior that can be elicited by visual stimuli. Using systematically modified movies, we found that attraction to shoals is modulated by skin pigmentation patterns, body size and aspect ratio. Wild-type fish and various mutants showed similar behavioral response profiles to modified fish movies. However, fish carrying mutations in shank3B and fish expressing a dominant-negative shank3B construct exhibited a sustained behavioral response to repeated stimuli, while responses of wild-type fish attenuated. To

investigate the neuronal correlates of normal and abnormal social behaviors we have established a virtual-reality environment for head-fixed adult zebrafish. This approach will be used to analyze neuronal activity patterns in the forebrain during social behaviors by multiphoton calcium imaging.

Abstract: The safety pharmacology core battery investigates the effects of pharmaceuticals on vital systems including cardiovascular and central nervous system (CNS) function. CNS evaluation includes sensory/motor reflex responses, coordination and motor activity assessments. This study was conducted to evaluate cardiovascular changes during baseline performance in neurobehavioral tests and after treatment with pharmacological agents. Animals were implanted with telemetry units capable of monitoring blood pressure (BP) and heart rate (HR). After surgical recovery, startle response, rotarod performance and locomotor activity were tested. Rats were treated subcutaneously with amphetamine (AMPH, 2 mg/kg) and MK-801 (0.2 mg/kg) and intravenously with Diazepam (DIAZ, 10 mg/kg) on separate days prior to behavioral testing. Cardiovascular data and behavior were assessed prior to treatment to serve as the control. HR increases were demonstrated with handling and during behavioral tests. In general, HR decreased with habituation to the startle and motor activity tests over time. AMPH treatment impaired startle pre-pulse inhibition and increased locomotor activity. HR was elevated during startle and rotarod performance to the same magnitude as control levels. In the motor activity test, animals showed slight habituation over time though activity remained higher than control levels. HR showed less fluctuation compared to control levels and remained elevated throughout testing. DIAZ reduced HR from baseline, control levels, and reduced performance in both startle and motor activity. HR remained elevated by the loudest stimuli for a longer duration in the startle

task compared to control levels. HR effects were reduced during rotarod testing and had an attenuated HR when initially placed into the motor activity apparatus. HR and BP were markedly increased with performance of all behavioral tests with MK-801 treatment; HR was increased by an average of 78%. However, HR spikes from handling and placement into each testing apparatus were minimized compared to control levels. MK-801 increased the magnitude of the startle response; animals were unable to perform on the rotarod, falling off almost instantly after placement. In the motor activity test, animals were ataxic and uncoordinated, and had a near complete suppression of rearing behavior. No habituation was evident with MK-801 treatment. The combined evaluation of cardiovascular and neurobehavioral testing allow for more comprehensive insight of drug effects in pharmaceutical safety testing.

Abstract: A functional observational battery (FOB) is typically performed in rodents to assess central nervous system integrity for drug safety. However, dogs and non-human primates are better models for certain drug classes. A comprehensive assay to evaluate central nervous system (CNS) integrity in the dog has not been extensively developed or used. Battelle has validated a series of approximately 32 home cage and open field tests for a rapid CNS screening in dogs. Home cage tests include looking for signs of lethargy, evaluating posture, tremor/convulsive activity, bizarre behaviors and response to handling. Open field testing consisted of evaluating gait, activity (number of squares entered on a floor grid and rearing), vocalization during the test,

as well as their ability find and consume treats in the open field. The wheelbarrow response test and visual placing test were also conducted. Dogs were tested for palpebral reflex, pupillary diameter response, nystagmus reflex response, tactile response, acoustic startle and toe pinch for pain perception. Paw flexor withdraw and limb extensor thrust response were evaluated in each dog and body temperature was collected. It was shown that the FOB could be used successfully to identify and differentiate the behavioral effects of stimulants such as amphetamine (1.5 and 8 mg/kg) and methylphenidate (0.5 mg/kg), and sedative agents such as butorphanol (0.4 mg/kg) and acepromazine (0.55 mg/kg) as compared to dogs treated with sterile water for injection. We have developed this FOB for drug screening in dogs that was based partially on an canine test battery described in the literature (Gad et al., 2003). Consistent with the Battelle rodent and NHP FOB models, data from the present study in Beagle dogs have shown an ability to discriminate the behavioral effects of different drug classes. A dog FOB testing paradigm may be a viable alternative to the NHP model for drug safety evaluation, especially for biologics.

Title: A low cost platform for large scale behavioral experiments in mice

Authors: *Y. WEISSENBERGER[1], M. C. KAHN[1], P. KEATING[1,2], A. J. KING[1], J. C. DAHMEN[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]The Ear Inst., Univ. Col. London, London, United Kingdom

Abstract: To understand the neural basis of complex behavior, animals are often trained to perform carefully controlled tasks, which is often difficult, labor intensive and costly. This limits both the complexity of behaviors that animals can be trained to perform, as well as the diversity

of environments learned behaviors are probed in. These factors can impede progress in understanding complex behavior and in turn its neural bases. To avoid these problems, we developed a low cost, high-throughput system for conducting behavioral experiments in mice, which is easy to implement and use, together with associated analysis methods. Our system is based on the Python programming language and the Raspberry-Pi series of micro-controllers. Here, we present the architecture of the system, and proof of concept behavioral data from frequency and level discrimination tasks as well as tone in noise detection. We envision that the platform will prove useful in a variety of domains: training mice to perform complex tasks, fast screening of transgenics on standardized tasks, and systematic exploration of parameter spaces of simple tasks. Together these advantages should allow us to address more effectively the mechanisms underlying learned behavior and thereby their neural bases.

Title: Functional connectivity analysis during the execution of a willed movement.

Authors: *C. KARMONIK[1], S. H. FUNG[2], M. DULAY[3], R. G. GROSSMAN[4];
[1]Houston Methodist Res. Inst., Houston, TX; [2]Radiology, [3]Neurol., [4]Neurosurg., Houston Methodist Hosp., Houston, TX

Abstract: Background: To identify, using fMRI BOLD activation maps, the brain regions and neural pathways activated during the execution of a willed movement and to quantify the functional connectivity of these regions.**Methods:**fMRI images (TR=1300ms) were obtained from 23 healthy volunteers who viewed alternately a green visual field for 50 seconds followed by a face for 10 seconds. Ten faces were presented serially in random order. Subjects were instructed to squeeze a ball with their right (dominant) hand if they perceived a face as unpleasant. BOLD activation maps were calculated using the Generalized Linear Model and brain regions activated during the execution of the willed movement were identified ($p<0.05$, AFNI software, NIH). fMRI and anatomical datasets were then loaded into the connectivity toolbox (conn, MATLAB) and functional connectivity strength (summed T-values) and number of connections were determined for these regions ($p<0<05$, FDR corrected).**Results**: In all subjects, five faces were perceived as unpleasant and elicited a willed motor response. Brain

regions with highest BOLD activation during the motor response included visual cortex (VCx), precuneus (pCun), thalamus (Thal), lentiform nucleus (Lent), caudate (Cd), cingulate cortex(ACC and PCC), fusiform gyrus (FusG), insula (Ins), supplementary motor area (SMA), sensory cortex (SCx), motor cortex (MCx) and regions in the superior frontal gyrus (SFG) (figure 1A). Functional connectivity for MCx was extensive including VCx, SMA and SCx (figure 1B). Ins and MCx showed highest connection strength (339 and 324, respectively) followed by SCx and VCc (274 and 253, respectively) (figure 1C). Number of connections correlated significantly ($R=0.84, p<0.001$) with connectivity strength for these regions (figure 1D). **Conclusion**: Execution of a willed movement in response to a visual stimulus perceived as unpleasant recruited a widespread network of brain regions. Motor cortex, sensory cortex, SMA, insula and visual cortex exhibited the largest connection strength and the greatest number of connections.

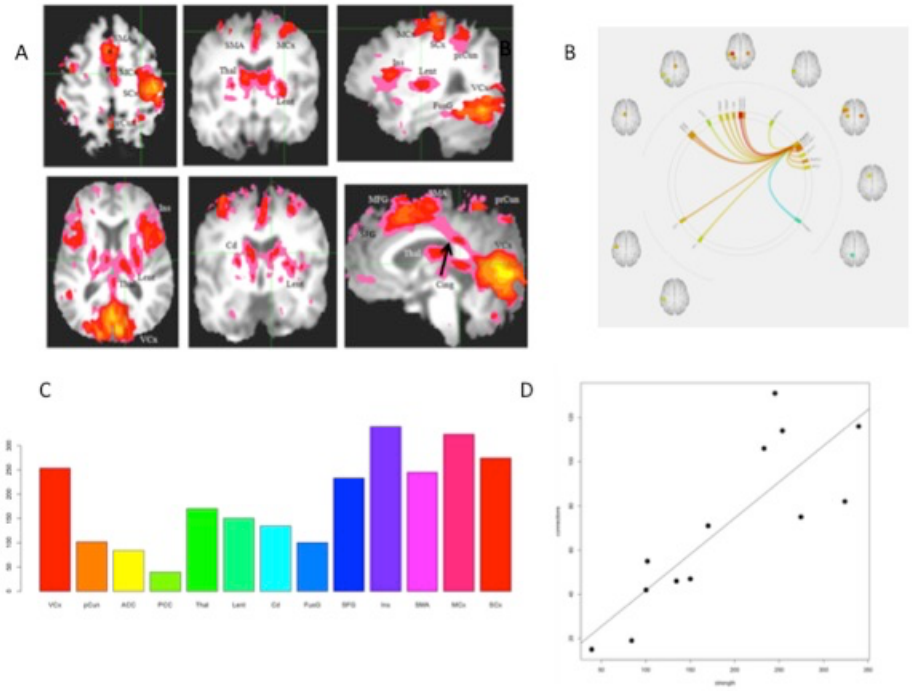

Figure 1: A: BOLD activation pattern for the execution of a willed movement as described in the text. B: Connectivity pattern for the left MCx is widespread including VCx, SMA, SCx and SFG. C: Functional connectivity strength of brain regions displayed in A. Ins, SCx, MCx, SMA and VCx exhibit largest connection strength (expressed by summed T-values). D: Number of connections and connections strength correlate significantly ($R=0.84$, $p<0.001$).

Title: Fiber analysis with scalable tensor covering from micro- to macroscopic level resolution

Authors: ***S. CHEN**, X. LI, A. LI, J. PENG, H. GONG, Q. LUO;
Huazhong Univ. of Sci. and Technol., Hubei, China

Abstract: Neuroanatomical connectivity is essential to understanding brain functions and diseases. Light microscopy and labeling methods have greatly impacted the progress of brain connectome. Quantitative analysis of fiber orientation and structural connectivity at cellular resolution have led to great challenges. Here, principal component analysis based structure tensor (pST) has been introduced for quantifying fiber architecture with tunable scale from micro- to macroscopic level. The pST method has allowed for deciphering fiber density, color-encoded orientation and fiber tractography based on developed software (e.g. DSI Studio). Tested with both Thy1-GFP and virus injection labeling mice datasets acquired with micro-optical sectioning tomography system, the proposed method enabled effective characterization of single axon/dendrite and ensemble of fibers in 3D space or even whole mouse brain. Compared with the conventional Hessian matrix based structure tensor analysis, our method exceled in accurate detection and computation efficacy. Thus, pST would be a helpful tool for fiber quantification and reliable validation of diffusion tensor imaging.

Title: Studying vocal communication of marmoset monkeys (Callithrix jacchus) in a rich, socially-interactive, captive environment

Authors: *L. ZHAO, X. WANG;
Dept. of Biomed. Engin., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Communication behaviors of non-human primates can be considered an evolutionary precursor for human social interactions and may serve as an important behavioral assay to study disorders in human social behaviors such as autism spectrum disorders. The common marmoset (*Callithrix jacchus*) is a highly vocal New World primate species that has emerged in recent years as a promising model system for studying neural basis of vocal communication. Marmosets live in social groups in their natural habitat and maintain a high level of social interactions between individuals in captivity through their vocalizations even. However, studies examining marmoset vocalizations so far have mostly focused on calls produced by individual animals or vocal exchanges between a pair of animals (e.g., antiphonal calling behavior). What has been missing is the characterization of vocal behaviors of marmosets in a richer social environment composed of a group of individuals. In order to fully understand vocal behaviors of marmosets, it is necessary to study call sequences generated by animals living in a social setting and quantify vocal exchanges among multiple animals. To tackle this problem, we have developed a behavior monitoring system in a large breeding colony that is capable of recording and analyzing vocalizations produced by multiple marmosets over a long period of time. By using parabolic microphones and miniature wireless microphones carried by individual marmosets, we are able to detect both loud and quiet calls in a noisy environment and identify individual callers when marmosets are either single-housed or group-housed. Our preliminary data demonstrate that marmosets preferentially communicate with a subset of other individuals through vocal exchanges. Such analyses enable experiments to study social interaction behaviors in this species and the neural substrates for vocal communication in a natural environment.

Title: Kernel methods for reconstructing current sources of extracellular potentials for single cells, slices, and the whole brains

Authors: *D. K. WOJCIK[1], C. CHINTALURI[1], D. CSERPAN[2], M. B. CZERWINSKI[1], M. KOWALSKA[1], Z. SOMOGYVARI[2];
[1]Nencki Inst. of Exptl. Biol., Warszawa, Poland; [2]Wigner Res. Ctr. for Physics HAS, Budapest, Hungary

Abstract: Extracellular recordings of electric potential are a popular tool for investigations of brain activity on all scales, from single neurons, through populations, to the whole brains, in animals and humans, in vitro and in vivo. The specific information available in the recording depends on the physical settings of the system (brain+electrode). The more selective smaller electrodes are used to capture local information (spikes or local field potential, LFP) while larger electrodes are used for subdural recordings (ECoG), on the scalp (EEG), but also as depth electrodes in humans (SEEG). The advantages of extracellular electric potential are the ease of recording and its stability. Its problem is interpretation: long range of electric field implies high correlations between recording sites. Thus a typical recording reflects activity of many cells, populations and regions, depending on level. To overcome this problem we may reconstruct the distribution of current sources (CSD) underlying the measurement, which is typically done on systems level from multiple LFP on regular grids.
We recently proposed a kernel-based method of CSD estimation from multiple LFP recordings from arbitrarily placed probes (i.e. not necessarily on a grid) which we called kernel Current Source Density (kCSD). In this overview we present the recent advances of this method, latest software implementations, and explain why it works. We also show two recent developments, skCSD (single cell kCSD) and kESI (kernel Electrophysiological Source Imaging). skCSD assumes that we know which part of the recorded signal comes from a given cell and we have access to the morphology of the cell. This could be achieved by patching a cell, driving it externally while recording the potential on a multielectrode array, injecting a dye, and reconstructing the morphology. In this case we know that the sources must be located on the cell and this information can be successfully used in source estimation. In kESI we consider simultaneous recordings with subdural ECoG (strip and grid electrodes) and with depth electrodes (SEEG). Such recordings are taken on some epileptic patients prepared for surgical removal of epileptogenic zone. When MR scan of the patient head is taken and the positions of the electrodes are known as well as the brain's shape, the idea of kCSD can be applied to constrain the possible distribution of sources facilitating localization of the foci.

Title: Abnormal metabolic connectivity based on ^{18}F-FDG PET image in Alzheimer's disease mouse model

Authors: *Y. CHOI, H. KANG, K. KIM, D. HWANG, D. LEE;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Analyzing the change of functional brain connectivity in cognitive impairment during the course of Alzheimer disease (AD) is essential in terms of development of new network diagnose and therapeutic monitoring for AD. In this study, we developed the diagnostic method to assess metabolic brain connectivity for AD based on integrated brain imaging technologies. To analyze metabolic network, we acquired [^{18}F] fluorodeoxyglucose positron emission tomography (FDG-PET) in the 4, 8, and 12 months old 5XFAD mice which overexpress human APP695 with the Swedish, Florida, and London mutations along with human PS1 harboring two FAD mutations. When metabolic images in AD model were directly compared with those in age-matched control, no regional differences in the brain FDG uptake was observed. Then, persistent brain network homology was applied to investigate metabolic connectivity with a threshold-free approach and the difference between two networks was compared by single linkage distances (SLDs) in all pairwise nodes. Metabolic connectivity significantly decreased between globus pallidus and entorhinal cortex/ perirhinal cortex/ amygdala, amygdala and entorhinal cortex/ perirhinal cortex in the AD mouse. In conclusion, AD mice showed reduced connectivity among memory-related brain regions such as amygdala, entorhinal cortex and perirhinal cortex. These results suggest that this multiscale and threshold-free network analysis could be used to measure abnormal connectivity in the AD animal model as an imaging-based network biomarkers.

Title: A comparison of single and multi-shell diffusion-weighted MRI imaging in the anesthetized macaque

Authors: *K. BROWN[1], P. VELASCO, 10009[2], B. PESARAN, 10009[1];
[1]Ctr. for Neural Sci., [2]Ctr. for Brain Imaging, New York Univ., New York, NY

Abstract: White-matter tractography using diffusion-weighted MRI imaging (DWI) is widely used to study anatomical connections in the primate brain. Recent interest in corticothalamocortical circuits suggests that communication across cortex depends significantly on association thalamus . As a result, correct identification of anatomical pathways depends not only on identifying cortico-cortical tracts, but constituent thalamic relay tracts as well. Advances in multi-shell imaging sequences promise greater accuracy in reconstructing anatomical pathways. However, a direct *in vivo* comparison of single and multi-shell methods for tractography in non-human primate has not been previously reported. Here, we compare the efficacy of single-shell and multi-shell acquisition schemes for *in vivo* DWI tractography. To judge the effectiveness of single-shell and multi-shell acquisition schemes, we reconstructed known thalamocortical projections using a probabilistic tracking method designed to distinguish crossing fibers, segmented the thalamus according to the most likely cortical projection target for each voxel, and compared this classification to known thalamic subdivisions in the Paxinos atlas. Data were acquired with a 3T Siemens Allegra (Erlangen, Germany) using 3 elements out of a 4-channel phased array from Nova Medical Inc. (Wilmington, MA) and 64 gradient directions. To correct for geometric distortions from field inhomogeneities caused by the non-zero off-resonance fields, data was collected with reversed phase-encode blips, forming pairs of images with distortions going in opposite directions. From these pairs the susceptibility-induced off-resonance field was estimated and the two images were combined into a single corrected one. We modeled fiber orientations for each voxel with up to two crossing fibers using a multi-shell model. We then obtained probable paths between the thalamus and each cortical target using FMRIB's probtrackx tool for probabilistic diffusion tractography. For each voxel in the thalamus seed mask, 5000 samples were drawn from the probability distribution given by a resampling procedure on the crossing fibers.
We found that single-shell acquisition underperformed the multi-shell acquisition scheme in

thalamic segmentation. Our results indicate that current *in vivo* approaches to identifying large-scale macrocircuits across macaque cortex for same-subject functional imaging and surgical targeting for electrophysiological recording can be improved using multishell DWI targeting.

Title: Brain blood vessel segmentation using local support vector machine

Authors: *H. HUI, C. HU, H. MENG, X. MA, X. YANG, J. TIAN;
Key Lab. of Mol. Imaging, CAS, Inst. of Automation, Chinese Acad. of Scienc, Beijing, China

Abstract: Introduction: Brain vessel segmentation is one of the most important tasks in image analysis for brain vasculature network study. Semi-automatic or automatic blood vessel region extraction approaches can provide useful information for image registration and three-dimensional reconstruction in image post-processing procedure. Generally, classical way is to apply vessel enhancement filtering based on Hessian matrix. However, the design of accurate and efficient vessel segmentation algorithms is still challenging, due to the variety and complexity of images, especially in brain vessel segmentation.
Methods: In this paper, the brain of new-born (5 days) C57BL/6J mouse was immunolabeled or traced tissues were cleared with BABB clearing method. The intact mouse brain was imaged by light-sheet microscope equipped with a sCMOS camera and 2x/NA 0.5, 6mm working distance dipping cap. Vessel Segmentation: In this paper, we present an approach that using the grey level of the pixel, Local binary pattern (LBP) and eigenvalues of Hessian matrix as feature vector. Support vector machine (SVM) was used to classify image pixels as background and foreground, then the outliers were removed to achieve the blood vessel segmentation. We also compared our approach with the segmentation results using Fuzzy Local Information C-Means Clustering

(FLICM) with vessel enhancement filtering. The experimental results illustrated that our approach offer more classification precision than FLICM for acquired blood vessel images by light-sheet microscope.
Conclusion: In this paper, a class-based method by combining the eigenvalues of Hessian matrix, LBP and the grey level of the pixel as feature vector was introduced. The SVM was chosen as a classifier, due to its robustness for small size, high dimensional and nonlinear samples. Only five features of the first four images were used for training sample, we have achieved more than 97% accuracy for vessel segmentation. The accuracy can be increased by adding more features, such as texture and intensity statistics features (Gray level co-occurrence matrix).

Title: Dynamic network reconfiguration during a continuous natural stimulus

Authors: ***K. TAN**[1,3], J. LU[1], J. CHEN[2], E. SIMONY[2], H. LIU[1], U. HASSON[2];
[1]Operations Res. and Financial Engin., [2]Psychology and the Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [3]Statistics and Biostatistics, Rutgers Univ., New Brunswick, NJ

Abstract: Recent advances in fMRI analysis techniques have enabled exploration of stimulus-locked network dynamics during complex natural stimuli (Simony et al., 2016). In this new method, correlations of timecourses are calculated between any two locations in the brain, exactly as in standard "functional connectivity"; however, instead of using two locations within the same brain, we use two locations in two different brains of participants viewing or listening to the same naturalistic stimulus (an audiovisual movie or auditory narrative). This modification results in a measure that is free from within-participant intrinsic noise, and locked to the stimulus input. Using this technique, termed "Inter-Subject Functional Correlation" (ISFC), we examine large-scale network dynamics in the brain during a 50-minute audiovisual movie. We assess the impact of adjusting the parameters of window size, dynamic calculation of clustering solutions as the movie storyline unfolds, and implement a mixed-membership clustering technique (Gopalan and Blei, 2013) in order to capture how the sharing of nodes between networks changes over time. All results are cross-validated in two independent groups of participants. We hope that the

development and refinement of these techniques will enhance our ability to understand how networks reconfigure across time in real-world contexts.

Title: Reconstruction of burst activity from calcium imaging of neuronal population via Lq minimization and interval screening

Authors: ***X. LIU**[1], T. QUAN[2], X. LV[2], S. ZENG[2];
[1]Huazhong Univ. of Sci. and Technol., Hubei, China; [2]Wuhan Natl. Lab. for Optoelectronics, Huazhong Univ. of Sci. and Technol., Wuhan, China

Abstract: Calcium imaging is becoming an increasingly popular technology to indirectly measure activity patterns in local neuronal networks. Based on the dependence of calcium fluorescence on neuronal spiking, two-photon calcium imaging affords single-cell resolution of neuronal population activity. However, it is still difficult to reconstruct neuronal activity from complex calcium fluorescence traces, particularly for traces contaminated by noise. Here we propose a reconstruction method that applies Lq minimization approach and interval screening (LqIS). Lq minimization approach is a widely used technique for sparse signal reconstruction. In the designed model for reconstruction, several properties of the AP train including non-negativity, sparsity, and firing rate are considered. The neuronal spike firings could be recovered from the complicated calcium fluorescence trace through Lq minimization. IS, introduced in our previous works, is used to screen out the spike interval so that the reconstruction method can only analyze the calcium trace in these effective intervals. This procedure could largely reduce the dimension of the reconstruction model. Results show that the introduction of IS vastly increases the speed of reconstruction. Compared to some available methods, like L1, Deconv and non-negative deconvolution (NNDeconv), the LqIS is superior in reconstructing neuronal burst activity from Ca2+ traces with low SNR. Moreover, we demonstrate that spikes can be automatically reconstructed from the calcium imaging data of a neuronal population with the LqIS approach.

Title: Determining dynamic couplings using Topological Causality

Authors: ***K. PAWELZIK**[1], D. HARNACK[2];
[1]Univ. Bremen, Inst. Theoretical Physics, Bremen, Germany; [2]Univ. Bremen, Inst. Theoretical Physics, Univ. Bremen, Bremen 28359, Germany

Abstract: Effective directed influences among cortical areas vary over time and may even switch their dominant direction. Since local cortical circuits can be considered to be well described by stochastic dynamical systems, previous methods for estimating causal relations that are specialized for either stochastic or deterministic dynamical systems may yield misleading and contradictory results. Here we investigate a mathematically well defined approach for describing causal interactions (by Harnack&Pawelzik, arXiv) that can be used to estimate state dependent causal influences among stochastic dynamical systems from measured time series. We apply the novel method to simulated and to electrophysiological data and demonstrate that it in fact can reliably determine direction and strength of dynamic influences and reveal their time dependence. Comparisons with other methods including Granger Causality (Granger 1969) and Convergent Cross-Mapping (Sugihara et al., Science 2012) for estimating causal influences among deterministic dynamical systems reveal the abilities and limits of this novel method.

Abstract: The program for Brain Mapping by Integrated Neurotechnologies for Disease Studies (Brain/MINDS) aims to integrate heterogeneous big neuronal data of non-human primate, the common marmoset, for comprehensive understanding of neuronal network and its relation with human neuronal diseases. http://brainminds.jp/en/ To conduct this project as collaboration among institutions, an innovative mechanism to share big data on computer networks is needed.
In this purpose, we have developed a neuroinformatics platform. It consists of two parts: one is the research platform with large-scale shared storage, HPC, VDI CLOUD and the other for data portal. In the research platform, every data is registered to and managed as metadata base. Data registration and sharing among users are operated from the research portal of the research platform. For the sake of analysis of the stored data, we designed the platform as an integrative analysis environment where analysis pipeline tools, HPC, VM and storage are directly linked though high-speed data-transfer system. This design enables to avoid troubles in big data transfer between the data server and clients. In this line, we also developed web brain atlas viewer, ZAViewer, for viewing heterogeneous images and python-base pipeline tool, SPyKGD, connecting the storage, HPC and VM. This design of the platform and tool development shall be veneficial in big data analysis not only in Brain/MINDS but also in large-scale brain projects.

Title: Analyzing functional connectivity across development in zebra finches

Authors: *K. E. SCHERTZ, E. A. LAYDEN, S. E. LONDON, M. G. BERMAN;
Univ. of Chicago, Chicago, IL

Abstract: Investigations into the dynamics and consequences of whole-brain resting-state functional connectivity (FC) have provided insights into complex neural processes. In humans, such approaches have highlighted how FC changes across the brain during different cognitive and emotional states (Berman et al., 2014). Here we aimed to understand the mechanisms by which neural maturation and experience converge to construct cognitive circuits during development, thus guiding behavior. Specifically, we implemented resting-state fMRI FC analyses on the zebra finch songbird, a model organism of vocal learning. Male zebra finches learn to sing via social interactions during a sensitive period of development, much as children acquire speech. We hypothesized that unique FC signatures would be evident during key developmental time points in which tutor song memorization becomes possible. Therefore, we acquired structural and functional MRI scans for six male zebra finches, including three birds recorded longitudinally at key time points (day 25, day 45, and day 65 post-hatch) in addition to three fully developed adult males. We used Advanced Normalization Tools (ANTs; Avants et al., 2011) to construct a custom, group-average structural template and to perform tissue segmentation and normalization. Denoising steps were completed using CONN Toolbox (Whitfield-Gabrieli & Nieto-Castanon, 2012). We conducted modularity analyses using the Brain Connectivity Toolbox (Rubinov & Sporns, 2010). Analyses for the group-averaged network identified an optimal modularity partition of six modules, which demonstrated a primarily anterior-posterior organization, as well as a pallial-subpallial organization. We compared within- and between-module FC across age groups. Regression analyses revealed increased within-module FC for module 6 ($p = .02$), a largely subpallial brain area, as a function of increasing age. Additionally, between-module FC was increased with age for modules 4 and 6 ($p = .003$), 3 and 4 ($p = .03$), and 4 and 5 ($p = .03$). These results parallel prior findings of age-related increases in modularity in humans. A larger sample size will enable us to investigate the finer scale dynamics occurring at individual developmental time points and how these relate to successful song learning. We also conducted a follow-up investigation using partial least-squares regression to predict voxel-wise functional connectivity strength via age group. This analysis

revealed a significant first latent variable ($p < .001$), wherein adult males showed increased FC in the dorsal pallium relative to the three juvenile developmental time points that parallels our modularity results.

Abstract: Stroke is the fourth leading cause of death in the United States. Advances in magnetic resonance imaging (MRI) have improved diagnostic assessment of stroke-affected brain involvement where accurate quantification is believed important in diagnosis and monitoring therapeutic options. The ischemic penumbra represents a region of hypo-perfused and functionally impaired but viable brain tissue with potential for recovery. The identification of penumbra necessitates measuring areas of reduced blood flow and lesion volume where MR perfusion-diffusion mismatch provides a measure of tissue at risk. All experiments were approved by the Institutional Animal Care and Use Committee (IACUC) of the Ohio State University. C57/BL6 mice (n=6) underwent middle cerebral arterial occlusion (MCAO) surgery. MRI was performed 30 minutes after permanent MCAO on a 9.4T magnet. Localizer scans, local shimming using Fastmap and DWI images were acquired using a spin-echo sequence. A method based on the flow-sensitive alternating inversion recovery (FAIR) and a fast rapid acquisition with relaxation enhancement (RARE) were used to acquire images. Perfusion-diffusion mismatch method was used to identify the ischemic penumbra in animals maintained on medial air (room air, RA) during stroke and those maintained on 100% oxygen (supplemental oxygen,

SO) during stroke. Importantly, SO is known to protect brain tissue from stroke-induced injury. At the acute time point of acquisition (30min post-occlusion), T2-weighted MR imaging was unable to resolve stroke-induced injury. Conversely, DWI was effective in quantitatively defining edema at this early time point in the stroke-affected brain. In post processing DWI images, thresholds were applied to delineate hyperintense regions indicative of stroke-induced injury. Compared to RA conditions, SO significantly increased the volume of the ischemic penumbra as evidenced by decreased DWI deficit without change in perfusion deficit. In the setting of ischemic stroke where "time is brain", rapid identification of the ischemic penumbra may prove critical to optimize therapeutic intervention and delivery strategies. While the clinical utility of perfusion-diffusion mismatch remains to be realized, we demonstrate in a pre-clinical setting that PWI coupled with early stage infarct quantification from DWI enables acute determination of the ischemic penumbra.
