Conclusion: Observations were made in the context of a sensory entrainment paradigm and spectral power differences between populations. However this finding provides preliminary grounds for claims that pathophysiologic mechanisms in schizophrenia can involve coupling disturbances, over and above amplitude alterations within individual bands and highlights the importance of assessing coupling alterations across a broad frequency spectrum.

Title: Functional connectivity in euthymic bipolar disorder reveals increased dynamic range

Authors: *M. C. CHAMBERS[1], C. TORGERSON[1], G. BARTZOKIS[2], L. ALTSHULER[2], J. D. VAN HORN[1];
[1]Lab. of Neuro Imaging (LONI), [2]Dept. of Psychiatry and Biobehavioral Sci., Univ. of California Los Angeles, Los Angeles, CA

Abstract: While euthymic bipolar subjects (BPE) do not experience the emotional turmoil of mania and depression, impairment of sustained attention [3], verbal memory and executive function [2] persist. Additionally recent work has shown that BPE subjects have hyper-connected cortico-limbic connections [4] during resting state. This work explores functional connectivity (FC) further by comparing whole brain FC during resting state and an emotion matching task. MPRAGE,fMRI data was carried out on a Siemens Trio 3T scanner (TR 2s) and segmented using Freesurfer. 21 control (10M, 11F) and 24 euthymic subjects (12M, 12F) were scanned during resting state and during an emotion matching/recognition task [1]. Data were motion corrected and independent components from non-grey matter voxels regressed out. FC differences between bipolar and normal subjects were controlled for motion, age, sex and brain size. False discovery rate was controlled for (fdr < 0.1). During the emotion identification task, BPEs showed greater overall connectivity (across all regions, t = 316), whereas the opposite was true for resting state (t = -154).
Functional connections most impaired during resting state includes right Jensen's sulcus (S.) with 1) right circular S. of the insula, 2) the right lingual gyrus (G.), 3) the right anterior cingulate, 4) the right postcentral G., 5) both calcarine sulci, 6) the left middle frontal S., 7) the left hippocampus, 8) the left superior frontal G., 9) the left thalamus and 10) the left inferior frontal G. (IFG). The Left Posterior-ventral cingulate was also significantly less connected to 1) the right postcentral S. , 2) the right subcallosal area, and 3) the left superior temporal G. During the task bipolar subjects showed significantly increased connectivity between the left suborbital S. and 1) the right orbital part of the IFG 2) the right lateral orbital S. 3) right medial orbital S. 4) the left orbital G./S. 5) left postcentral S. The right lateral orbital sulcus and 1) the left orbital S. and 2) the left anterior segment of the lateral S. were also significantly more functionally connected.

These results confirm that bipolar subjects continue to show dis-regulation of brain connectivity during euthymia and shows that this manifests itself as both hyper-connectivity and hypo-connectivity depending on the functional task.

Title: Slow binocular rivalry rate in patients with bipolar disorder,OCD,major depression,and schizophrenia

Authors: *X. YE[1], R. ZHU[1], K. WANG[1], S. HE[2];
[1]Dept. of Neurol., The First Affiliated Hosp. of An Hui Med. Univ., An Hui, China; [2]Dept. of Psychology, Univ. of Minnesota, Minneapolis, MN

Abstract: When two different images are presented to the two eyes dichoptically, observers usually experience a perceptual alternation between the two images. This phenomenon, known as binocular rivalry, has been used as a powerful tool to investigate mechanisms of visual awareness. It was also found that the rates of perceptual alternation are slower in patients with bipolar disorder than that in normal controls (Pettigrew & Miller, 1998). To investigate the broader clinical relevance of binocular rivalry in mental disorders, we measured the perceptual alternation rates during rivalry in normal controls (n=30) as well as patients with different types of psychiatric disorders, including bipolar disorder type I (n=30), obsessive compulsive disorder (OCD, n=21), major depression (n=46), schizophrenia (n=48), and first-degree relatives of schizophrenics (n=31). Participants viewed competing red-green images on computer monitor through red-green anaglyph glasses and pressed one of two buttons to record their alternating

perception. The distribution of normalized rivalry intervals was well described by a gamma function in all groups, suggesting that participants indeed experienced binocular rivalry. Critically, the median rate of perceptual alternation was 0.28 Hz for bipolar patients, 0.17 Hz for OCD patients, 0.23 Hz for major depression patients, 0.20 Hz and 0.24 Hz for schizophrenia patients and their first-degree relatives respectively, all significantly slower than the rate of 0.46 Hz obtained from the normal controls.
Our results show that binocular rivalry is slower in several groups of patients with mental disorders. It is possible that the abnormal temporal dynamics of binocular rivalry in patient groups may serve as a potential endophenotype for these mental disorders. However, the fact that different types of mental disorders all demonstrated similarly slower rivalry alternation suggest that the mechanism responsible for the slowdown in perceptual switching is not disease-specific. On the other hand, the current results are consistent with the possibility that these different mental disorders may have shared genetic roots. The finding that first-degree relatives of schizophrenics also had slower rivalry alternation provides further support that there might be a common genetic component in schizophrenia and in the mechanism that determines the temporal dynamics of rivalry.

Title: Effects of ketamine on resting-state and task-related neural oscillations in MEG-data

Authors: *D. RIVOLTA[1], A. SAUER[2], T. HEIDEGGER[3], K. BIRKNER[2], B. SCHELLER[3], M. WIBRAL[3], W. SINGER[2], P. J. UHLHAAS[4];

Abstract: Aberrant neural oscillations in the gamma-band range (> 30 Hz) are crucially involved in the pathophysiology of schizophrenia. A possible model for dysfunctional high-frequency oscillations involves the disrupted glutamatergic neurotransmission mediated by the N-methyl-D-aspartate (NMDA) receptor. In the current study, we examined the effects of NMDA-receptor

hypofunctioning on gamma-band activity during the administration of ketamine to healthy volunteers. Neural oscillations were recorded using a 275-sensors Magnetoencephalography-(MEG) system in a group of 15 healthy volunteers during the administration of a sub-anesthetic dose of ketamine (0.006 mg/Kg) and a placebo saline solution in a single-blinded within-subject design. For each participant, we recorded oscillations induced by sinusoidal gratings (5° of visual angle) and during rest. Data were analyzed at the sensor and source level (i.e., beamforming approach) by extracting time frequency series (1-120 Hz). Ketamine, compared to placebo, led to an increased visually-induced gamma band oscillations (45-75 Hz) over occipital sensors, with sources localized to early visual areas. Ketamine also increased gamma-activity (30-90 Hz) at rest over fronto-central sensors, with sources showing the strongest effect localized in the right hippocampus, thalamus (bilateral) and left anterior cingulate cortex. The acute administration of ketamine leads to an upregulated gamma-band activity both at rest and during visual processing. This is possibly mediated by a shift in the excitation/inhibition balance in favor of excitation of pyramidal cells due to hypofunctioning NMDA-receptors. Since the upregulation of gamma-band activity has been described in early psychosis, our results support the clinical relevance of the NMDA-receptor hypofunctioning model of schizophrenia.

Title: Reverse translation animal model of hippocampal dysfunction in Schizophrenia

Authors: *S. SOUTHCOTT, M. YANAGI, J. LISTER, I. LEE, C. TAMMINGA;
Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Animal models for psychosis have been inadequate because the cellular and molecular characteristics of the condition itself have been obscure. As the disease neurobiology is advancing, it is becoming possible to develop animal models through reverse translation, mimicking the biology of the human condition. We have focused on modeling hippocampal

pathology and its learning and memory component as it informs psychosis. In clinical studies of psychosis in schizophrenia, we show hippocampal hyperperfusion, GluN1 protein reduction, particularly in dentate gyrus (DG) and synaptic strengthening at the NIMDA receptor in CA3 along with alterations in relational memory capacity in the illness (Tamminga, et al., 2010 and 2012; Li, et al., 2012); these are the molecular and behavioral targets we have modeled in the animal. To explore a reverse translation animal model, we crossed a POMC-Cre mouse line with a floxed P-GluN1 mouse to create a DG-specific knock down of GluN1 protein in the animal. These animals have reduced levels of GluN1 restricted to DG (WT n=7; KO n=7). Behaviorally, these mice show decreased pre-pulse inhibition, reduced learning in the Morris Water Maze, increased freezing in a fear conditioning paradigm (Contextual FC p=0.04; Cued FC p=0.004) and an increased latency to respond in the passive avoidance paradigm (p=0.01). In tissue, we met the tissue phenotype of reduced GluN1 in DG but failed to generated the psychosis fingerprint of increased synaptic strengthen marker in CA3 at the NMDA receptor. However, we modified this animal model in several ways and have, in the end, been able to adapt this KO animal to show both the behavioral phenotype of psychosis (noted above) and molecular evidence reflecting both the DG GluN1 reduction and the psychosis finger-print (increased GluN2B: WT n=7; KO n=7; p=0.035) in CA3. We will include the full animal behavioral profile and the tissue bio-signature of this psychosis animal model.

Abstract: Schizophrenia has no known cellular or molecular pathophysiology, thus putting it at great disadvantage with respect to diagnostic considerations and therapeutic drug development. The most florid and unusual of its clinical dimensions is psychosis. In psychosis, the brain generates false, persistent and unpleasant perceptions (hallucinations) and false beliefs (delusions) much like psychotic memories. We have proposed a learning and memory model of psychosis, which is based on early evidence of increased perfusion in schizophrenia hippocampus, along with reduced glutamate signaling in dentate gyrus (AmJPsych 167:1178, 2010); therefore, we have been testing CA3 not only for evidence of increased *in vivo* function but also for *in vitro* tissue correlates of increased synaptic strength. The increase in CA3 function plausibly could generate vulnerability for mistakes of association and could mediate their encoding as false memories, even those with psychotic content. To test this model, we have carried out CA3-specific analyses of *in vitro* postmortem tissue using molecular markers of synaptic strength. We postulated an increase in CA3 perfusion downstream to CA1 and increase in markers of synaptic strength limited to CA3. We report an increase in GluN2B/GluN1 in CA3 ($p=0.009$) but fail to find any change in GluN2B/GluN1 in CA1 ($p=0.34$). Consistent with the increase of this protein in CA3 we also identify elevation of PSD-95, a change that is only apparent in CA3 ($p=0.01$). These changes were sustained in tissue drug-free at the time of death, confirming them as associated with disease, not medication. GAD-67 protein was unchanged in CA3 ($p=0.64$) and in CA1 ($p=0.698$). In an exploratory analysis of related synaptic proteins, we show a weak increase in GluN2A/GluN1 $p=0.05$) and a trend toward an increase in SAP-102 ($p=0.07$) all in CA3, and with the P-CREB/CREB significantly decreased in CA1 ($p=0.05$). We interpret these findings to confirm our hypothesis of an increase in synaptic strength in CA3 with increased neural activity in the Schaffer Collaterals onto CA1 neurons and suggest that this is mediated through increased number and sensitivity of the postsynaptic NMDA receptors in CA3. We propose that this increase in synaptic strength creates a risk state for psychosis which can be overwhelming in itself or can be activated by separate afferents (perhaps representing stress-related signaling) which act on high synaptic strength in CA3 to generate a ‘run away’ positive feed forward signaling within the recurrent collateral pathways in CA3. This could pervert normal associational activity in hippocampal CA3 (ProgBrainRes 169:225, 2008) and generate psychotic phenomena.

Title: Whole-transcriptome analysis of hippocampal CA3 in schizophrenia

Authors: *J. M. PEREZ, K. GLEASON, S. GHOSE, T.-K. KIM, C. TAMMINGA;
UT Southwestern, Dallas, TX

Abstract: Schizophrenia (SZ) is one of the thirty most incapacitating conditions in the world and affects over 67 million people worldwide; suicide occurs in 10% of those diagnosed with schizophrenia. Symptoms are persistent and often severe. They include hallucinations, delusions, thought disorder, and deficits in executive function and memory. Treatments available are not always efficacious. 20-40% of people with schizophrenia are resistant to treatment and less than 20% completely recover after one episode of psychosis. Due to a lack of understanding of the molecular pathophysiology of schizophrenia, its diagnosis is based on its behavioral symptomatology. Unfortunately, due to only phenomenological diagnoses, these categories are inadequate. Therefore, we are examining human tissue for molecular causes and correlates of the illness. Our lab has proposed a model of psychosis as a disorder of learning and memory. We suggest that reduced glutamatergic neurotransmission to hippocampal CA3 serves to generate an increase in CA3 basal activity and function through homeostatic plasticity changes within CA3. This increase in function may lead to the generation of inappropriate or illogical memories with psychotic content. Our lab has shown an increase in perfusion in CA3 in schizophrenia, a correlate of regional neuronal activity level. Further supporting the notion of increased activity in CA3, we have also shown an increase in spine density and dendritic complexity in CA3 as well as increased protein levels of hypothesized candidate postsynaptic molecular markers like

GluN2B and PSD-95 in CA3 of schizophrenia postmortem tissue. We are in the process of further localizing these changes using immunohistochemistry. This will help elucidate which of the different afferent projections within CA3 are involved in this increased activity level. Importantly, we are analyzing CA3 subfield transcriptome from control and schizophrenia cases, in a global and unbiased manner, using whole transcriptome (WT) sequencing to identify additional molecular changes which have not been hypothesized. We have high quality CA3 tissue from human schizophrenia and control cases, who are not being treated with antipsychotic medication. The RNA is isolated and currently being sequenced to identify alterations associated with CA3 hyperperfusion.

Inst., The Salk Institute, La Jolla, CA; [4]Howard Hughes Med. Inst., Salk Institute, La Jolla, CA

Abstract: We have previously shown that prolonged N-Methyl-D-Aspartate receptor (NMDAR) blockade during a critical period for the development of parvalbumin-positive (PV+) interneurons, leads to altered electrophysiological properties and reduced PV+ cells in adult animals, resembling alterations observed in schizophrenia models. In this study, we use this NMDAR hypofunction mouse model to monitor transcriptome changes throughout development into early adulthood. mRNA was extracted from the frontal cortex of healthy and ketamine-treated mice at 2, 6, and 10 weeks of age, in order to study the genome-wide transcriptional changes that lead to altered PV(-) phenotype. Whole genome transcript expression was obtained

using Illumina 2000 RNAseq methods. Reads were aligned to the NCBI-37 reference genome using Bowtie and Tophat, and transcript quantification was performed using Cufflinks. For differential expression at each time-point we used both Cuffdiff and EdgeR computation analyses. Finally, to uncover functional groups of related genes we employed the Ingenuity IPA system.
This analysis revealed that at P13, two days after the last ketamine injection, 69 genes remained differentially-expressed as compared to the controls. Cuffdiff and EdgeR had a strong overlap in differential expression output between saline and ketamine samples. Gene ontology mapping identified that ketamine treated mice had altered expression of gene families involved in cell-cell signaling and neural cell development, consistent with an altered trajectory of cell development which may contribute to the phenotype observed in adolescent mice. Surprisingly, we have not observed changes in parvalbumin mRNA at any time point analyzed, suggesting decreased PV immunoreactivity after ketamine may be due to post-transcriptional changes. Cell-type specificity of these transcriptional changes is being assessed using immunohistochemistry, in situ hybridization and cell-type specific quantitative PCR.

Title: Dysregulation of gene expression in a glycosylation pathway in schizophrenia

Authors: A. HELIX[1], M. SIMMONS[1], T. MUELLER[1], V. HAROUTUNIAN[2], *J. H. MEADOR-WOODRUFF[1];
[1]Dept. of Psychiatry, Univ. Alabama at Birmingham, BIRMINGHAM, AL; [2]Psychiatry, Mt. Sinai Sch. of Med., New York, NY

Abstract: Previous findings from our lab have shown alterations of N-linked glycosylation of ionotropic glutamate receptor subunits, glutamate transcripts, and most recently GABA receptor subunits in cortical regions from postmortem brains of patients with schizophrenia (SZ). N-glycosylation is the process of enzymatically adding sugars to proteins which can facilitate their

transport through the endoplasmic reticulum and Golgi. Although our work to date has focused on determining alterations in N-glycosylation in candidate proteins associated with glutamate and GABA neurotransmission, we hypothesized that there may be widespread abnormalities of glycosylation. Accordingly, this study focused on measuring the expression of genes involved in glycosylation pathways in pyramidal neurons derived from prefrontal cortex. A human glycosylation pathway PCR array was used to measure changes of 84 genes associated with encoding enzymes that add and remove sugar residues to and from proteoglycans and glycoproteins. RNA was extracted and cDNA generated from 1000 laser capture microdissected pyramidal neurons from the DLPFC of 12 patients with schizophrenia and 12 matched comparison subjects. We identified 28 genes 1.37 fold or more in SZ which clustered into 14 different functional categories associated with glycosylation. N-acetylgalactosaminyltransferases, fucosidases, mannosidases, and enzymes associated with O-linked glycosylation were among those identified. These findings contribute to the growing body of evidence that supports our hypothesis that is glycosylation is widely dysregulated in schizophrenia. We are currently extending this work to determine if these changes are specific to pyramidal neurons or are found in other cells of the prefrontal cortex.

Abstract: Schizophrenia (SZ) is a debilitating psychiatric illness with a not well understood pathophysiology. This complicated illness affects the whole brain and while many studies in postmortem brain have been published, a robust and reproducible finding has remained elusive. New and innovate tools allow the study of gene expression in defined cellular subpopulations

which may result in more specific studies in this illness. In this study, laser capture microdissection (LCM) was used to harvest medium spiny neurons in striatum from 12 pairs of subjects with schizophrenia and a matched control (Ctrl) using Affymetrix GeneChip® microarrays. Genes found to be changed in the microarray study were validated using qPCR. Genes that were altered were functionally categorized using Database for Annotation, Visualization and Integrated Discovery (DAVID) v6.7. Nucleus, transcription regulation, and plexin were among the highest scoring functional categories for genes that were changed between SZ and Ctrl in medium spiny neurons in striatum. Previous studies in our lab have been successful in finding gene alterations in other brain regions using this technique. These data add to those findings of changes in gene expression in defined cellular subpopulations of regions of the brain involved in the limbic system. These data also suggest novel pathways and potential targets disrupted in specific neuronal subpopulation in the striatum in SZ.

Title: Sequential isolation of endosome subtypes from postmortem brain

Authors: *T. M. MUELLER, J. H. MEADOR-WOODRUFF;
UAB, Birmingham, AL

Abstract: Several studies have shown alterations in the expression of proteins associated with receptor trafficking and stability in schizophrenia. Previous work from our lab has shown alterations in the subcellular localization of AMPA receptor proteins as well as aberrant gene and protein expression of molecules associated with the trafficking of both NMDA and AMPA receptors. Alterations of N-glycosylation, which is known to play a functional role in protein trafficking, have also been identified for some GABAA and glutamate receptor subunits, supporting the hypothesis that mechanisms associated with the proper trafficking and subcellular localization of signaling molecules may be deficient in schizophrenia.
In order to address this question, we are developing a method to isolate multiple specific subcellular compartments from postmortem human brain. We have previously developed techniques to separately isolate intracellular vesicles necessary for the endocytosis, sorting, and

degradation of transmembrane proteins. Our isolations of both early and late endosomes, which respectively facilitate the sorting and targeted degradation of proteins, have been validated by both western blot and electron microscopy; however, these methods require a relatively large amount of starting material, costly substrates, and multiple time-consuming processing steps. We are seeking to improve the existing method to increase the efficiency of the isolations as well as to generate more data from limited amounts of sample by isolating multiple endosomal subtypes from the same starting material using sequential isolations. Additionally, we are working to develop an effective method to specifically isolate a third endosomal subtype, recycling endosomes, from postmortem human brain which we will validate by western blot and electron microscopy.
Ultimately, we will use these techniques to measure relative abundance of GABAA receptor subunits between early, late, and recycling endosomes from the same sample to provide a more accurate picture of how these subunits are being trafficked within the cell and identify alterations to the relative abundance of subunits in each endosomal compartment in schizophrenia. This will allow us to further elucidate whether aberrant GABAergic neurotransmission in schizophrenia may be attributed to or exacerbated by functional deficits of the endocytic pathway.

Title: Altered neuregulin-1 intracellular domain dependent nuclear signaling in schizophrenia

Authors: D. SHAN[1], J. H. MEADOR-WOODRUFF[1], C. WALSS-BASS[2], *R. E. MCCULLUMSMITH[1];
[1]Univ. Alabama-Birmingham, BIRMINGHAM, AL; [2]Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Neuregulin-1(NRG1) regulates many important brain functions including synapse formation and synaptic transmission. NRG1 is a transmembrane protein cleaved into extracellular and intracellular domains (NRG-ICD) by enzymes in response to a variety of stimuli. Upon cleavage, NRG-ICD may translocate to the nucleus, where it regulates glutamateric gene expression. In the present study, we hypothesize that NRG-ICD dependent

nuclear signaling may be altered in schizophrenia attributable to changes in expression of NRG-ICD and gamma secretase which generates the intracellular domain, or disruption of NRG-ICD associated proteins, leading to abnormal glutamate levels in the synaptic cleft. We detected NRG-ICD protein in the prefrontal cortex in both control and schizophrenia subjects by Western blot analysis. Using fractionation, we found NRG-ICD is expressed in cytosol and nuclear fractions, indicating a nuclear translocation of NRG-ICD in the brain. We will also perform immunoisolation and mass spectrometry to identify NRG-ICD associated proteins. Our findings will identify the NRG-ICD associated proteins in different subcellular compartments, yielding novel candidates for probing the effects of NRG1 dysfunction in schizophrenia.

Title: Expression of AMPA receptors and their auxiliary proteins, TARPs, in isolated endoplasmic reticulum and postsynaptic density fractions from postmortem brain in schizophrenia

Authors: *J. B. DRUMMOND[1], V. HAROUTUNIAN[2], R. E. MCCULLUMSMITH[1], J. H. MEADOR-WOODRUFF[1];
[1]Psychiatry & Behavior Neurobio., Univ. Alabama, Birmingham, Birmingham, AL; [2]Psychiatry, Mount Sinai Hosp., Bronx, NY

Abstract: The glutamate hypothesis of schizophrenia suggests abnormal glutamatergic neurotransmission occurs in this illness. Recent evidence from our laboratory supports a model of altered forward trafficking and accelerated endoplasmic reticulum (ER) exit of the AMPA subtype of glutamate receptor (AMPAR) in schizophrenia. One mechanism that could lead to altered AMPAR trafficking is abnormal expression and localization of AMPAR auxiliary proteins, such as the transmembrane AMPAR regulatory proteins (TARPs). TARPs coassemble with AMPARs in the ER and traffic these receptors from the ER and Golgi apparatus to the

extrasynaptic membrane before mediating their lateral translocation to, and biophysical properties at, the postsynaptic density (PSD). Thus, TARP dysregulation may ultimately alter the expression, localization, stability and activity of AMPARs within intracellular compartments, potentially having a role in the pathophysiology of schizophrenia. We have previously reported changes in TARPs at the transcript and protein levels in homogenates of anterior cingulate cortex (ACC) in schizophrenia, suggesting altered intracellular trafficking of AMPARs in this illness. A model to explore AMPAR trafficking in postmortem brain involves examining specific, subcellular localization of these receptors and auxiliary proteins within compartments critical to AMPAR regulation. We hypothesized that these proteins are diminished in the ER in schizophrenia, consistent with our trafficking model. Utilizing a subcellular fractionation protocol optimized for human postmortem brain tissue, we measured TARP and AMPAR subunits within isolated ER from ACC in patients with schizophrenia and a comparison group. We found decreased GluA1 protein expression in the ER fraction in schizophrenia. We have recently validated a fraction enriched for isolated PSDs, and predict a subsequent reduction of GluA1 protein within this compartment consistent with our previous finding of increased GluA1 protein in an endosomal fraction in schizophrenia. Alterations in the expression and localization of AMPARs may present a new potential mechanism explaining glutamatergic dysregulation in schizophrenia.

Title: Glycoproteome of the schizophrenia brain

Authors: *J. TUCHOLSKI[1], V. HAROUTUNIAN[2], J. H. MEADOR-WOODRUFF[1];
[1]Dept Psych & Behav Neurobiol, Univ. Alabama-Birmingham, BIRMINGHAM, AL;
[2]Psychiatry, Mount Sinai Sch. of Med., New York, NY

Abstract: Protein glycosylation regulates a wide range of processes critical to development and functioning of the central nervous system; these include cell adhesion, migration, neuronal and glial differentiation as well as synaptogenesis, synaptic function and plasticity. The majority of brain glycoproteins contain N-linked glycans (glycoconjugate) that are attached to an Asn residue within the consensus peptides sequence Asn-X-Ser/Thr (X ≠ Pro). A second class of glycoproteins contains O-linked glycans attached to the polypeptide via N-acetylgalactosamine (GalNAc) or N-acetylglucosamine (GlcNAc) to a hydroxyl group of a Ser or Thr residue. We have previously observed an abnormal glycosylation of proteins in schizophrenia associated with the glutamate neurotransmitter system including EAAT1, EAAT2, GluA2, and GluK2, and the GABA system including $GABA_AR\alpha1$ and $GABA_AR\beta1$. This suggests that abnormalities in glycosylation may be involved in modulation of neuronal transmission or cell signaling events associated with schizophrenia pathophysiology. In this study, we investigated the glycosylation status of proteins in postmortem DLPFC of schizophrenia and comparison subjects using a lectin blotting approach with four different lectins: ConA recognizing glucose, or mannoses (2 or more); NPL recognizing mannose (prefers 2 or more); WGA, recognizing GlcNAc (2 or more); and SNA recognizing sialic acid attached to terminal Gal. We also identified glycoproteins altered in schizophrenia using nanoscale liquid chromatography-tandem mass spectrometry (nano LC-MS/MS). Findings from this study provide insights of identification of critical processes that are glycosylation-dependent and play a role in schizophrenia.

Title: Neural synchrony patterns and levels of GABA and glutamate/glutamine during working memory task in schizophrenia

Authors: *R. SO[1], F. STEFFEN-ALLEN[1], L. KEGELES[2], J. J. CHROBAK[1], C.-M. A. CHEN[1]; [1]Psychology, Univ. of Connecticut, Storrs, CT; [2]Psychiatry and Radiology, Columbia Univ., New York, NY

Abstract: Synchronization of neural activity with the dorsolateral prefrontal cortex (DLPFC) is thought to be related to the neural mechanisms underlying cognitive functions, including working memory. Understanding the neural basis of cognitive deficits in schizophrenia would inform the development of new targeted interventions. The present study aims to examine the synchronization patterns between ipsilateral and contralateral hemispheres that differentiate individuals with schizophrenia and healthy controls. Scalp EEG recordings were collected for patients with schizophrenia (N = 7) and healthy volunteers (N = 8) during a modified Sternberg working memory task. Each trial consisted of three stages: 1) encoding stage, an array of one of two possible set sizes (one or six upper case letters) was presented on a computer screen for 3 seconds; 2) retention stage, a blank screen was presented for 7 seconds, and 3) probe stage, a test stimulus appeared for 3 seconds at the center of the screen. Participants were asked to identify whether the probe letter matches one of the letters in the array previously presented and then to respond by a button press as quickly and accurately as possible. For each session, each set size condition had 64 trials (total = 128 trials). Only correct, artifact-free trials were analyzed. Instantaneous phases were extracted by Morlet wavelet decomposition on 89 scales from 0.5 Hz to 60 Hz. Phase locking values (PLVs; ranging from 0 [no synchronization] to 1 [perfect synchronization]) indicate synchronization of neural activity between two selected electrodes. MRS measurements of both gamma-aminobutyric acid (GABA) and glutamate/glutamine (Glx) spectra were obtained. Routine measurements in the left DLPFC and anterior cingulated cortex were made on a 3T GE MR system, using the standard volume-selective PRESS J-editing difference method with a commercial 8-channel phased-array head coil. We test the hypotheses that 1) left DLPFC electrodes will have greater PLVs with their ipsilateral electrodes than with contralateral electrodes in the temporal, parietal, and occipital lobes; 2) left DLPFC electrodes will have greater PLVs with right DLPFC electrodes than contralateral electrodes in all other lobes; 3) strength and spatial patterns of PLVs from hypotheses 1 and 2 will differ between healthy controls and patients; 4) synchronization patterns will differ depending on working memory stage, and 5) synchronization patterns will correlate with GABA and Glx levels of MRS measures.

Title: Working memory performance, oscillatory patterns and levels of GABA and glutamine/glutamate in dorsolateral prefrontal cortex and anterior cingulate cortex in schizophrenia

Authors: *F. STEFFEN-ALLEN[1], R. P. SO[1], L. S. KEGELES[2], J. J. CHROBAK[1], C.-M. A. CHEN[1];
[1]Psychology, Univ. of Connecticut, Storrs, CT; [2]Psychiatry and Radiology, Columbia Univ., New York, NY

Abstract: One of the core features of schizophrenia is impairment in cognitive functions, which depend in part on the dorsolateral prefrontal cortex (DLPFC) and anterior cingulate cortex (ACC). The present study aims to investigate the possible linkage of working memory deficits in schizophrenia with changes in neuronal oscillations and prefrontal GABAergic dysfunction by relating EEG to magnetic resonance spectroscopy (MRS). Scalp EEG recordings were collected for patients with schizophrenia (N = 7) and healthy volunteers (N = 8) during a modified Sternberg working memory task. Each trial consisted of three stages: 1) encoding stage, an array of one of two possible set sizes (one or six uppercase letters) was presented on a computer screen for 3 seconds; 2) retention stage, a blank screen was presented for 7 seconds; 3) probe stage, a test stimulus appeared for 3 seconds at the center of the screen. Participants were asked to identify whether the probe letter matched one of the letters in the array previously presented and then to respond by a button press as quickly as possible. Each set size condition had 64 trials (total = 128 trials). Only correct, artifact-free trials were analyzed. MRS measurements of both gamma-aminobutyric acid (GABA) and glutamate/glutamine (Glx) spectra in left DLPFC and ACC were also obtained. “Efficiency index” for each participant was evaluated by testing the Pearson’s correlation coefficient between gamma power (30 to 58 Hz) and cued delayed-response time of single trials in each electrode. This “efficiency index” was then correlated with GABA levels, Glx levels, and phase synchronies of different frequency bands. In our sample, diagnosis did not predict working memory performance (p values > .05). However, preliminary results show that the “efficiency index” provides an alternative classification of participants that predicted cognitive performance. A Higher “efficiency index” indicates that as neural oscillatory activities increase, reaction times decrease. Participants with higher “efficiency indexes” had better performance on the working memory task. We test the hypotheses that the “efficiency index” correlates with: 1) GABA levels in left DLPFC and Glx levels in ACC, and 2) other oscillatory patterns.

Title: OTX2 expression in the human prefrontal cortex during normal postnatal development and in subjects with schizophrenia

Authors: *K. M. ATHANAS[1], S. A. MAUNEY[2], N. K. SHASKAN[2], T.-U. W. WOO[2,3,4]; [1]Lab. for Cell. and Mol. Neuropathology, [2]Lab. of Cell. and Mol. Neuropathology, McLean Hosp., Belmont, MA; [3]Psychiatry, Harvard Med. Sch., Boston, MA; [4]Psychiatry, Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: OTX2 is a homeoprotein that is involved in the regulation of many aspects of brain development across phylogeny. More recently, studies in rodents have shown that OTX2 regulates the postnatal maturation of parvalbumin (PV)-expressing interneurons and also drives the developmental formation of perineuronal nets (PNNs), which are extracellular matrix structures that encapsulate many neurons, including PV neurons. Of interest, PV neurons and PNNs are known to be compromised in schizophrenia (SZ). In this study, we investigate the developmental changes of OTX2 expression in the prefrontal cortex (PFC), focusing on the period of adolescence and young adulthood, and its possible alteration in SZ.
Using immunohistochemistry, we quantify OTX2-immunoreactive (IR) elements in postmortem tissue of Brodmann's area 9 of the PFC in a cohort of normal control human subjects (N=16), ages ranging from 2 days to 20 years old, and in a another cohort of 15 SZ subjects demographically matched with 15 normal control subjects. Qualitative examination reveals that OTX2-IR elements comprise pyramidal neurons, interneurons and spherical-like shaped structures that morphologically resemble corpora amylacea, although the definitive identity of these structures is unknown. Quantification of the densities of OTX2-IR elements in these two

cohorts of subjects is currently underway.
Findings of this study will provide insight into the possible role of OTX2 in normal PFC development during the periadolescent period, when SZ symptomatology typically begins to emerge. In addition, they will shed light onto how OTX2 may mediate the disturbances of PFC circuitry in SZ by compromising the integrity of PNNs and PV neuronal functions and, as such, may deepen our understanding of the possible mechanisms that underlie the onset and pathophysiology of SZ.

Title: DNA-Methylation gene network dysregulation in peripheral blood lymphocytes of schizophrenia patients

Authors: *J. AUTA[1], R. SMITH[2], E. DONG[3], P. TUETING[3], H. SERSHEN[2], S. BOULES[2], A. LAJTHA[2], J. DAVIS[3], A. GUIDOTTI[4];
[1]The Psychiatric Inst., Univ. of Illinois At Chicago, Chicago, IL; [2]Natl. S. Kline institute for Psychiatric Res., New York, NY; [4]Psychiatry, [3]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Recent studies suggest that epigenetic dysregulation of the brain genome that includes brain region-specific altered DNA promoter methylation is associated with the neuropathological manifestations of SZ and related psychiatric disorders (Guidotti et al., 2011; Grayson and Guidotti, 2013, Mill et al., 2008; Huston et al., 2013). The epigenetic dysregulation of the brain genome associated with the clinical manifestations of schizophrenia (SZ) includes altered DNA promoter methylation of several candidate genes. We and others have reported that two enzymes that belong to the DNA- methylation/demethylation network pathways- DNMT1 (DNA-methyltransferase) and TET1 (5-hydroxy cytosine translocator protein-1) are abnormally increased in corticolimbic structures of SZ postmortem brain. The objective of the study is to investigate whether the expression of the DNA-methylation/-demethylation network components known to be altered in discrete corticolimbic structures of SZ patients are also altered in peripheral blood lymphocytes (PBL). Peripheral blood lymphocytes (PBL) were isolated with

Ficoll-Paque Plus method. Total RNA was extracted using the TRIzol reagent (Life Technologies) and further purified using the Qiagen RNeasy Kit. Samples were assayed with qPCR using Fermentas Maxima SYBR Green/ROX qPCR Master Mix with primers designed to cross over one intron to amplify cDNA and yield an amplicon of between 75-200 base pairs. C_T value was used for relative quantification of target gene expression and normalized to β-actin and the relative expression levels were calculated as C_T. The data show that an increase in DNMT1 and TET1 and a decrease in glucocorticoid receptor (GCortR) and brain derived neurotrophic factor (BDNF) mRNAs in PBL of SZ patients are comparable to those reported in the brain of SZ patients. Thus these finding support the hypothesis that a common epigenetic dysregulation may be operative in the brain and peripheral tissues of SZ patients. If changes in these epigenetic biomarkers can be confirmed in lymphocytes of subjects with prodromal SZ syndrome before they progress to first episode SZ, some of the underlying molecular developmental pathology leading to SZ may be uncovered objectively in living subjects opening up the possibility of preventing onset of the disease.

Title: Rare susceptibility variants for bipolar disorder: A family-based study

Authors: C. CRUCEANU[1,2], J. LOPEZ[1], A. AMBALAVANAN[1], P. A. DION[3], *N. MECHAWAR[2], M. ALDA[4], G. A. ROULEAU[3], G. TURECKI[2];
[1]Human Genet., McGill Univ., Montreal, QC, Canada; [2]Douglas Inst., Verdun, QC, Canada; [3]Montreal Neurolog. Inst., Montreal, QC, Canada; [4]Dalhousie Univ., Halifax, NS, Canada

Abstract: Bipolar disorder (BD) is a complex psychiatric condition characterized by both manic and depressive episodes. Previous studies strongly support the role of genetics in BD, with heritability estimates as high as 80%, but likely due to genetic and phenotypic heterogeneity, there has been minimal replication across studies. To address this problem we have been focusing on a well-defined sub-phenotype of BD, positive response to Lithium (Li) therapy, and shown that Li-response clusters in families. Research in BD genetics to date has consisted of

linkage and genome-wide association studies, which presume that common variants in a small subset of genes are the cause for BD. However, findings from these studies only explain a fraction of the predicted BD heritability, suggesting a causal role for highly penetrant rare variants in many different genes across the population. Our approach focuses on a well-defined clinical subtype of BD (Li-responsive) to minimize clinical heterogeneity, and we are using massively-parallel DNA sequencing to re-sequence the exomes of all affected individuals from multi-generational family units. To identify relevant BD susceptibility genes we are prioritizing rare variants that segregate with affected status within each family. To further explore the mechanisms by which these variants could lead to pathology we explore their expression in post-mortem brain samples and patient-specific lymphoblastoid cell lines. In each family we are prioritizing on average 12 potentially highly penetrant (e.g. protein-truncating, missense, or frameshift) or functionally relevant (e.g. 3'UTR, 5'UTR, splicing) variants. Some of the pathways that emerged from this analysis are involved in brain development and neurogenesis, inflammation, and epigenetic regulation - all processes that have been suggested to be dysregulated in mood disorders including BD. By focusing on rare variants in a familial cohort we hope to explain a significant portion of the missing heritability in bipolar disorder, as well as to have narrowed in on the key biochemical pathways that are implicated in this complex condition.

Title: Schizophrenia-associated alterations of microtubule associated protein 2 in human auditory cortex

Authors: *M. A. SHELTON[1], J. T. NEWMAN[1], K. N. FISH[1], P. PENZES[2], D. A. LEWIS[1], R. A. SWEET[1];
[1]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [2]Physiology; Psychiatry and Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Background: The pathology of SZ includes laminar-specific reductions in dendritic spine density in the primary auditory cortex (PAC) and other cortical regions, suggesting functional alterations in the proteins responsible for maintenance of dendritic spine architecture. Microtubule-associated protein 2 (MAP2) is crucial for establishing and maintaining both dendrite and spine structure in response to changes in neural activity. A decrease in MAP2 immunoreactivity (IR) has been reported in several areas in SZ. We therefore hypothesized a role for MAP2 in reduced dendritic spine density in the PAC.
Methods: Using quantitative fluorescence microscopy coupled with immunohistochemical markers for dendritic spines and MAP2, we examined MAP2-IR and dendritic spine density in human post-mortem tissue taken from the PAC of individuals with SZ and matched controls.
Results: MAP2-IR based on an antibody targeting the protein's c-terminal microtubule binding domain was significantly ($p<0.05$) attenuated in SZ, with 60% of SZ subjects exhibiting fluorescence values near background, below the lowest values observed in controls. Reductions in dendritic spine density were restricted to those SZ subjects with reduced MAP2-IR. Restoration of MAP2-IR was achieved through antigen retrieval. As well, MAP2-IR was detected through the use of antibodies targeting alternate epitopes along the protein. This led us to hypothesize that the decrease in MAP2-IR is due to a disease specific post-translational effect that masks the c-terminal epitope targeted by our antibody.
Conclusions and Future Directions: Altered MAP2-IR is disease-associated and the changes are correlated with dendritic spine loss in these subjects. Using a combination of quantitative microscopy, antibody-based epitope mapping, and targeted proteomics, we will generate total and domain specific measures of MAP2 to determine how changes in protein levels and epitope availability contribute to the loss of MAP2-IR in SZ. Liquid chromatography-mass spectrometry will be used in an effort to elucidate post-translational modifications as well as atypical protein interactions which could mask recognition of the c-terminal epitope.

Title: Conserved chromosome 2q31 conformations are associated with transcriptional regulation of GABA synthesis enzyme GAD1 and altered in prefrontal cortex of subjects with schizophrenia

Authors: *Y. JIANG, S. AKBARIAN;
CSM building, 9th floor, room 202, Mount Sinai Sch. of Med., New York, NY

Abstract: Little is known about chromosomal loopings involving proximal promoter and distal enhancer elements regulating GABAergic gene expression, including changes in schizophrenia and other psychiatric conditions. Here, we map in human chromosome 2q31 the 3-dimensional configuration of 200 Kb of linear sequence encompassing the GABA synthesis enzyme gene GAD1 locus, and describe a loop formation involving the GAD1 transcription start site (TSS) and intergenic non-coding DNA elements (50Kb) facilitating reporter gene expression. The GAD1-TSS-50Kb Loop was enriched with nucleosomes epigenetically decorated with the transcriptional mark, histone H3 trimethylated at lysine 4 (H3K4me3), and was weak or absent in skin fibroblasts and pluripotent stem cells as compared to neuronal cultures differentiated from them. In primary neuronal culture, Gad1-TSS-55Kb Loop and Gad1 expression became upregulated when neuronal activity was increased. In the prefrontal cortex of subjects with schizophrenia, GAD1-TSS-50Kb Loop was decreased compared to controls, in conjunction with downregulated GAD1 expression. We generated transgenic mice expressing Gad2 promoter-driven green fluorescent protein-conjugated histone H2B and confirmed that Gad1-TSS-55Kb Loop, the murine homologue to GAD1-TSS-50Kb Loop, is a chromosomal conformation specific for GABAergic neuron. We conclude that 3-dimensional genome architectures, including chromosomal loopings for promoter-enhancer interactions involved in the regulation of GABAergic gene expression, are conserved between the rodent and primate brain, and subject to developmental and activity-dependent regulation, and disordered in some cases with schizophrenia. More broadly, the findings presented here draw a connection between non-coding DNA, spatial genome architecture, and neuronal plasticity in development and disease.

Title: Case-control and family association study of early growth response gene 3 with schizophrenia

Authors: *A. L. GALLITANO[1], L. MUPPANA[2], J. CORNEVEAUX[3], A. M. AHMED[4], M. HUENTELMAN[3];
[1]Basic Med. Sci., Univ. Arizona COM PHX, PHOENIX, AZ; [2]Basic Med. Sci., Univ. of Arizona Col. of Med. - Phoenix, Phoenix, AZ; [3]Translational Genomics Res. Inst., Phoenix, AZ; [4]Arizona State Univ., Tempe, AZ

Abstract: A major obstacle in identifying genes that influence risk for psychiatric disorders is that these illnesses are determined by both genetic and environmental factors. Assessments of the genetic contribution to the risk of developing schizophrenia, one of the most severe of the mental illnesses, range from 50-80%. Environment accounts for the remaining influence. In the current study we have addressed this issue by examining a family of immediate early genes that are activated in response to environmental stimuli, such as stress, and in turn regulate the expression of genes involved in numerous biological processes that are disrupted in schizophrenia. The Early Growth Response (EGR) family of genes includes four members, EGR1, EGR2, EGR3, and EGR4, which encode transcription factors. Studies in the Japanese, Korean, and Han Chinese populations have reported significant associations between single nucleotide polymorphisms (SNPs) in EGR3 and schizophrenia. In the current study we used a case-control analysis to examine whether SNPs in EGRs 1- 4 were associated with schizophrenia. We then employed a novel Next-Generation Sequencing approach to screen the EGR3 locus for SNPs that varied in minor allele frequency between pooled samples of cases and controls in two racial populations. This analysis allowed rapid identification of promising SNPs, one of which was selected for follow-up genotyping in a larger cohort. In addition, we performed a family association study examining a SNP in EGR3 for preferential inheritance in a group of 244 family trios. We will present findings showing that a SNP in the EGR3 gene was preferentially inherited by probands with schizophrenia. Case-control studies revealed a nominally significant association between the minor allele of this SNP and schizophrenia in the white population that did not survive Bonferroni correction for multiple comparisons. No significant difference in the prevalence of this SNP was found in the black cohort. SNPs in the EGR1, EGR2, and EGR4 genes did not display any significant associations with schizophrenia in this study.

Title: Convergent in silico analysis of genes for interneurons and hypoxia response under the neurodevelopmental hypothesis of schizophrenia

Authors: *R. SCHMIDT-KASTNER[1], M. JOSEPH[1], K. MCKAIN[1], J. W. NEWCOMER[1], J. VAN OS[2,3], B. P. F. RUTTEN[2,3];
[1]Florida Atlantic Univ. (FAU), Boca Raton, FL; [2]Sch. for Mental Hlth. and Neuroscience, Dept. of Psychiatry and Psychology, Fac. of Health, Med. and Life Sciences, Maastricht Univ. Med. Ctr., Maastricht, Netherlands; [3]European Grad. Sch. of Neurosci. (EURON), Maastricht, Netherlands

Abstract: We have proposed that schizophrenia (SCZ) candidate genes may interact with hypoxia in neurodevelopment under a gene x environment interaction model (Schmidt-Kastner et al., Mol. Psychiatry 2012). Neuroanatomical and functional studies suggest an impairment of GABAergic, cortical interneurons in the manifest stage of SCZ. Decreased cortical inhibition may be related to the NMDA-receptor hypofunction hypothesis of SCZ (Olney et al., J. Psychiatr. Res. 1999) which gained fresh support from exome sequencing of GRM5 (Timms et al., JAMA Psychiatry 2013). We here suggest that interneurons may be particularly vulnerable to metabolic and other environmental stresses, including hypoxia and ethanol, during or after their complex, tangential migration from the ganglionic eminence to the cortex. This data mining study examines convergence between SCZ candidate genes, genes related to developing interneurons and hypoxia response. Candidate genes for SCZ were retrieved from the SzGene database (n=360). Genes reported to be involved in the neurodevelopment of cortical interneurons (INTDEV; n=416) were compiled from literature, based on transgenic mice with interneuron-specific reporters, cell sorting and gene expression profiling. To annotate INTDEV, we used our databases for ischemia-hypoxia response (IHR) genes, HIF-1 regulated genes, and vascular genes. Databases for copy number variations (CNVs) in neurodevelopmental delay were

studied for links to INTDEV. In total, n=147 (35%) of INTDEV genes were annotated with our databases. Thereby, n=94 INTDEV genes matched with the IHR gene database (22% observed vs. 9% random; chi-square test, p = 0.0001). Enrichment among INTDEV genes was found for vascular genes (x2.3), but not for astrocytic genes (x1.3). N=29 (7%) of SCZ candidate genes were on the INTDEV list. N=12 genes were found in the convergent analysis [SCZ x INTDEV x IHR genes], including CACNA1C, CCKAR, DLX1, GRM5 and NPY. Using data mining of CNVs and protein interactions, a novel link from haploinsufficient, hypoxia-responsive genes to glutamate receptor function, including GRM5, was developed. In conclusion, we suggest than an early hypoxic hit during critical phases of tangential migration could impair cortical interneurons, inducing long-lasting glutamate receptor dysfunction. Our convergent analysis proposes genes related to both development of interneurons (assuming specificity of the selection process) and hypoxia response for future studies, including epigenetics. The overlap between vascular genes and INTDEV genes supports recent reports of pleiotropic gene function.

Title: Disruption of AKT alters dopamine sensitivity to inhibitory synaptic transmission in the rat prefrontal cortex

Authors: *Y. LI, W.-J. GAO;
Drexel Univ. Col. of Med., PHILADELPHIA, PA

Abstract: AKT, also known as PKB, is a serine/threonine kinase that has been found dramatically reduced in the prefrontal cortex (PFC) of patients with schizophrenia. AKT1 deficiency causes abnormalities in the PFC
function, particularly working memory function in the AKT mutant mice. However, how AKT deficiency affects the PFC function is not well studied. Dopamine (DA) as a major neurotransmitter in the brain plays an important role in normal prefrontal function and

neuropsychiatric disorders. Although AKT is known important for dopaminergic transmission to maintain normal function of PFC, whether and how impairment of AKT affects dopaminergic modulation of synaptic transmission in the PFC is not clearly understood. In this study, we try to mimic AKT deficiency by bath application of AKT inhibitors in the in vitro whole-cell clamp recording of inhibitory postsynaptic currents (IPSC) in the rat PFC and then examine the DA modulation. We found that either bath application of 10 μM 10-DEBC which is a permeable AKT inhibitor or 5 μM AKT inhibitor VI , an impermeable AKT inhibitor, significantly shifted dopaminergic modulation of GABAa receptor-mediated IPSCs in PFC layer V pyramidal neurons, suggesting an reduced sensitivity to DA. The desensitization of DA to inhibitory transmission caused by inhibition of AKT is likely involved in both pre- and postsynaptic mechanisms although paired-pulse ratio was not altered. Interestingly, inhibition of AKT significantly disrupted both D1R- and D2R-mediated dopamine effects on IPSCs although it had stronger effects on D2R-mediated action. The effect of inhibiting AKT on DA modulation of evoked IPSCs, however, disappeared after inhibiting β-arrestin2, a protein integrator important for G protein-coupled receptor desensitization. Consistently, the protein level β-arrestin2 was significantly increased whereas the protein level of D2 receptors on synaptic membranes was significantly decreased by co-application of AKT inhibitor and DA in the prefrontal cortical slices. Take together, our data suggest that that AKT deficiency leads to reduction of DA sensitivity to inhibitory synaptic transmission through β-arrestin2 dependent DA receptor desensitization.

Title: Chronic haloperidol enhances amphetamine-induced conditioned reward: Contributions of the dorsal and ventral striatum

Authors: *C. EL HAGE[1], J. GUILLEMETTE LAFONTAINE[1], A.-M. BÉDARD[2], A.-N. SAMAHA[1];

[1]Univ. of Montreal, Montreal, QC, Canada; [2]Inst. de gériatrie de l'Univeristé de Montréal, Montréal, QC, Canada

Abstract: Drug abuse and addiction are excessively common in schizophrenia. It has been proposed that chronic exposure to antipsychotics might contribute to this co-morbidity by altering the reward system. Indeed, we have shown previously that rats withdrawn from continuous haloperidol (HAL) treatment (via a sub-cutaneous minipump) pursue reward cues more vigorously than HAL-naive rats following an intra-peritoneal amphetamine (AMPH) injection. AMPH-induced potentiation of conditioned reward is mediated in great part by the drug's actions in the nucleus accumbens (NAc), and to a lesser extent, in the caudate-putamen (CPu).

Our aim here was to determine the contributions of the NAc and CPu in the ability of HAL to augment AMPH-induced potentiation of conditioned reward. Rats were trained to associate a light-tone cue with water and then treated with a clinically relevant dose of HAL via osmotic minipump for 15 days. Following antipsychotic withdrawal, we assessed lever pressing for the light-tone cue (now a conditioned reward) after intra-NAc or intra-CPu AMPH injections (0 to 20 µg/hemisphere).

Across a range of doses and in both control and HAL rats, intra-CPu AMPH did not alter lever pressing for conditioned reward. In accordance with the literature, intra-NAc AMPH enhanced operant responding for the conditioned reward in control rats. However, there was no effect in the HAL-treated rats, at any AMPH dose tested. These findings suggest that continuous HAL modifies reward circuitry such that stimulation of the NAc with AMPH is no longer sufficient to increase the operant pursuit of reward cues. Our objectives now are two-fold: first, to determine whether the NAc remains necessary for the ability of HAL treatment to augment AMPH-induced potentiation of conditioned reward and second, to determine whether this effect of AMPH remains amenable to disruption by D1 and D2 receptor antagonists in HAL-treated rats as it is in control animals. The hope is that this work might shed new light on the neurobiological substrates by which antipsychotic treatment alters reward function.

Title: mRNA and miRNA expression profiling of pyramidal, parvalbumin-containing and dopamine neurons in schizophrenia and Parkinson's disease

Authors: *T.-U. WOO[1,2,3], K.-C. SONNTAG[2,3];
[1]Lab. of Cell. Neuropathology, McLean Hosp/Harvard Med. Sch., BELMONT, MA; [2]McLean Hosp., Belmont, MA; [3]Harvard Med. Sch., Boston, MA

Abstract: The human brain is an extraordinarily complex structure consisting of heterogeneous subsets of neurons that mediate distinct aspects of information processing. Disturbances of these neurons compromise the functional integrity of the connectional architecture of the brain, resulting in various psychiatric and neurologic disorders. In order to explore how the molecular integrity of various neuronal subtypes might be compromised in schizophrenia (SZ) or Parkinson's disease (PD), we combined laser capture microdissection, microarray and TaqMan-based miRNA profiling technologies to determine the convergence and specificity of the gene networks and signaling cascades that are altered in these disorders. In pyramidal neurons from the prefrontal cortex in SZ, we found differentially expressed mRNAs that belong to the transforming growth factor beta and the bone morphogenetic proteins signaling pathways, and in the parvalbumin (PV)-immunolabeled neurons from the same region differentially expressed transcripts were associated with WNT, NOTCH and PGE2 signaling, in addition to genes that regulate cell cycle and apoptosis. In the dopamine neurons from the substantia nigra in PD, there was a predominant down-regulation of genes that are involved in PD pathogenesis, such as members of the PARK gene family and genes associated with programmed cell death, mitochondrial dysfunction, neurotransmitter and ion channel receptors, as well as neuronal survival mechanisms. In addition to the gene expression profiles, we identified a set of differentially expressed miRNAs in both SZ and PD. Enrichment analysis of their predicted targets revealed signaling pathways and gene networks that were also found by the microarrays to be dysregulated raising an interesting possibility that dysfunction of these neurons in SZ or PD may in part be mediated by a concerted dysregulation of gene network functions as a result of the altered expression of miRNAs. In conclusion, our data show mostly distinctive, but also some overlapping dysfunctional gene and miRNA networks between SZ and late stage PD, and provide a platform for future downstream analyses aiming to understand the molecular processes of individual neuronal dysfunction in psychiatric and neurological disorders.

Title: Abnormal phospholipids distribution in the postmortem brains from patients with schizophrenia revealed by matrix-assisted laser desorption/ionization imaging mass spectrometry: Usefulness of antemortem psychiatric clinical information in postmortem brain study

Authors: *J. MATSUMOTO[1], Y. KUNII[2], T. HAYASAKA[3], M. HINO[2], A. WADA[2], H. AKATSU[4], Y. HASHIZUME[4], T. YAMAMOTO[4], S. SATO[5], H. YABE[2], M. SETOU[3], S.-I. NIWA[2];

Abstract: Background
Since lipid metabolism plays an important role in the functioning of the brain, the hypothesis that lipid abnormalities are involved in schizophrenia is important to clarify the molecular mechanism of schizophrenia. Nevertheless lipid analysis using postmortem brain samples is not enough. Also, in the previous psychiatric postmortem studies there were little ones which effectively used antemortem psychiatric clinical information, although most researchers performed case-control studies to detect disease specific alternations. Imaging mass spectrometry (IMS) can be used to more precisely analyze the postmortem brain samples from patients with schizophrenia. In this study, we have analyzed the results from imaging IMS utilizing antemortem psychiatric clinical information.
Methods
We performed IMS-based lipid analysis by using brain samples from 12 patients with schizophrenia and 10 control subjects. The postmortem brain tissues from patients with schizophrenia were obtained from the Postmortem Brain Bank of Fukushima for Psychiatric Research. We analyzed the gray and white matter of the frontal and temporal lobes, as these lobes tend to become atrophic in patients with schizophrenia. We examined the average intensity

of the phospholipid detected by IMS and we reanalyzed the above results using structured retrospective review of psychiatric records, DIBS (Diagnostic Instrument for Brain Studies) 1.
Results
The schizophrenia and control groups did not differ with respect to the average expression of phosphatidylcholine, sphingomyelin, galactosylceramide, phosphatidylethanolamine, phosphatidylserine, and sulfatide. The phosphatidylinositol (PI) content was decreased in patients with schizophrenia. We found that the psychiatric symptoms were severer in the group which indicated higher or lower intensity of the PI detected by mass spectrometry compared to the group which indicated middle intensity. These tendencies were also observed narrowing analysis down to the positive symptoms.
Conclusions
The decreased expression of PI observed in the prefrontal cortex of schizophrenia would indicate evidence of abnormality of phospholipid metabolism in the prefrontal cortex of schizophrenia. We also reanalyzed the results utilizing antemortem psychiatric symptoms and found some interesting results, which may lead to new significant findings in the relevant research areas.

Title: Is this really schizophrenia?

Authors: *L. ISLAM[1], L. ROMITO[2], G. TISI[3], M. CARBONI[3], S. SCARONE[4], O. GAMBINI[5];
[1]Psychiatry, Ospedale San Paolo, Milan, Italy; [2]Nurologia I, Inst. Neutologico Carlo Besta, Milan, Italy; [3]Psychiatry, Univ. of Milan Med. Sch., Milan, Italy; [4]Psychiatry, Univ. of Milan Med. school, Milan, Italy; [5]Psychiatry, Univ. of Milan medical school, Milan, Italy

Abstract: _
Introduction: A 34 year old man was referred to our unit for psychiatric evaluation, due to

suspected catatonic schizophrenia. His psychomotor development was normal until the age of 12 , when he started showing progressive loss of cognitive skills, fine motor skills and finalized motor activity. Symptoms rapidly worsened, and by the age of 20 his language and motor skills were severely compromised (he needed repeated verbal stimulation to initiate motor activity or speech, and could only sustain them for a few minutes). Starting at age 17 he had been treated with both 1st and 2nd generation antipsychotics, which did not lead to any changes in symptoms. Family history was negative for neurological disorders. His mother was diagnosed with alcohol abuse disorder and the younger sister was diagnosed with generalized anxiety disorder and borderline personality disorder.

_

Method: At the time of our evaluation the patient was receiving 10 mg of Olanzapine. He was vigilant and passively cooperative to examination; he displayed physical immobility, echopraxia, waxy flexibility, stereotyped behaviour, camptocormia, echolalia, blunted affect and automatic obedience. Thought content was difficult to evaluate, but he denied hallucinations or delusional thoughts. Cranial nerves, strength, tone, reflexes were normal, there were no signs of cerebellar dysfunction, and the only abnormality noted on neurological exam was parkinsonian gait.

_

Results: Blood panel was normal, as were thyroid and adrenal function, prolactin levels and B12. The patient was screened for Wilson's and hemochromatosis and no abnormalities were found. Sreening for metabolic disease was performed, suspecting Nieman Pick type C, and was also negative (normal aminoacidaemia and aminoaciduria). Genetic testing revealed a normal male cariotype and was negative for fragile X syndrome. Brain resting state MRI, PET scan, EEG and DAT scan were also performed and showed no abnormalities. Antipsychotic medication withdrawal didn't lead to any changes in his psychiatric or neurological exam. He was prescribed Lorazepam which didn't improve his symptoms.

_

Conclusions: The patient's symtoms fulfill the criteria for Catatonic Schizophrenia. However the early onset of symptoms, the rapid deterioration of cognitive abilities, the early and extensive motor imparment and the complete resistance to drug treatment make this an interesting case for discussion about differential diagnosis. We are currently screening for Huntigton's Chorea.

Title: Actin cytoskeleton dysregulation in schizophrenia and bipolar disorder: Relevance to dendritic spine pathology

Authors: *G. T. KONOPASKE, S. SUBBURAJU, J. T. COYLE, F. M. BENES;
McLean Hosp., Belmont, MA

Abstract: Schizophrenia is a severe and persistent mental illness affecting 1% of the population worldwide. Previously, dendritic spine density associated with pyramidal cells was found to be reduced in the deep half of layer III in the dorsolateral prefrontal cortex (DLPFC) in schizophrenia. Since the actin cytoskeleton plays a central role in the development, maintenance, and function of dendritic spines, we sought to determine if dysregulation of the actin cytoskeleton might account for the observed dendritic spine pathology. By analyzing microarray data obtained previously using DLPFC tissue from subjects with schizophrenia (n=19), bipolar disorder (n=18), and unaffected control subjects (n=25), we identified 5 candidate genes (IFG1R, MARCKS, PPP1R9A, PTPRF, and ARHGEF2) that regulate both the actin cytoskeleton and the formation or maintenance of dendritic spines. Using a microarray-based analysis of gene expression, IFG1R, MARCKS, PPP1R9A, and PTPRF exhibited increased expression in schizophrenia subjects relative to controls. However, ARHGEF2 exhibited decreased expression in subjects with schizophrenia relative to controls. The expression of all five genes did not differ between the bipolar disorder and control subjects. The microarray data were validated using quantitative real-time PCR in a second cohort of subjects with schizophrenia (n=19), bipolar disorder (n=17), and unaffected control subjects (n=18). In the DLPFC, the expression of IGF1R and MARCKS was significantly increased in both the schizophrenia and bipolar disorder subjects relative to the controls. In addition, PPP1R9A expression was significantly increased in bipolar disorder subjects relative to both schizophrenia and unaffected control subjects. The expression of PPP1R9A did not differ between schizophrenia and control subjects. Moreover, PTPRF and ARHGEF2 expression levels did not differ among the groups. Post hoc analyses correlating gene expression with dendritic spine density measurements from the same subjects will also be presented. Overall, the regulation of the actin cytoskeleton and dendritic spines appears to be altered in both schizophrenia and bipolar disorder and may possibly reflect neuropathological changes in layer III of the DLPFC.

Title: Differential distribution of the GABA synthesizing enzymes in somatostatin containing boutons of the monkey prefrontal cortex-implications for schizophrenia

Authors: B. ROCCO, D. A. LEWIS, *K. FISH;
Dept Psychiatry, Univ. Pittsburgh, Pittsburgh, PA

Abstract: In the prefrontal cortex (PFC) of subjects with schizophrenia, the density of neurons detectable by GAD67 mRNA is reduced by ~30%. This deficit occurs without a change in total neuron number, suggesting that the affected GABAergic neurons are present but contain severe reductions in GAD67 expression. In contrast, mRNA expression for GAD65 is unchanged in schizophrenia. We recently showed in non-human primate PFC that boutons belonging to cannabinoid 1 receptor-expressing basket cells contained only GAD65, those of parvalbumin (PV)-expressing chandelier cells (PVChC) contained only GAD67, and PV basket cell boutons contained both GAD isoforms. Previous findings suggest that the density of PVChC boutons is reduced in schizophrenia, whereas the density of GAD65 boutons is unchanged, which led us to hypothesize that boutons containing only GAD67 are uniquely vulnerable to GAD67 deficits in the illness.
In schizophrenia, both the density of somatostatin (SST) mRNA-positive neurons in the PFC gray matter and the expression of SST mRNA per neuron are lower. In addition, lower expression of SST mRNA is positively correlated with lower levels of GAD67 at both the tissue and cellular levels. In order to determine the possible vulnerability of SST boutons to reduced GAD67 expression, we used quantitative fluorescence microscopy to measure their relative GAD65 and GAD67 content. We found that SST neurons give rise to boutons that contain only GAD65, only GAD67, or both GAD isoforms. Considering that the majority of SST boutons

contained only GAD67, we hypothesize that a significant reduction in GAD67 expression in SST neurons could result in a loss of SST boutons. As a first step in testing this hypothesis, the density of non-PV, GAD67 only boutons was assessed in PFC tissue sections from five matched pairs of schizophrenia and comparison subjects. In schizophrenia, the mean density of non-PV, GAD67 only boutons was significantly reduced 70% compared to control subjects ($P = 0.05$). In addition, the average volume and total GAD67 fluorescence intensity of the remaining non-PV, GAD67 only boutons were significantly less ($p = 0.02$ and 0.03, respectively). Considering that PVChC boutons were excluded from our assessment and a subsequent experiment found that the vast majority of boutons arising from calretinin expressing neurons contain GAD65, our results suggest that the density of SST boutons containing only GAD67 is significantly lower in schizophrenia. SST neurons are important for synaptic integration and deficits in SST neuron signaling may result in alterations in the proper input/output functions of neuronal ensembles in the PFC.

Title: The effect of reboxetine and haloperidol on P50 suppression in healthy volunteers

Authors: *L. M. WITTEN[1,2], B. Y. GLENTHØJ[2], A. MØRK[1], B. STEINIGER-BRACH[1], J. F. BASTLUND[1], B. ORANJE[2];
[1]H. Lundbeck A/S, Valby, Denmark; [2]Ctr. for Clin. Intervention and Neuropsychiatric Schizophrenia Res. (CINS) and Ctr. for Neuropsychiatric Schizophrenia Res. (CNSR), Copenhagen Univ. Hospital, Psychiatric Ctr. Glostrup, Glostrup, Denmark

Abstract: Introduction: Disruptions in filtering of sensory information have frequently been observed in patients with schizophrenia. Successful sensory gating prevents sensory overload of higher brain functions by filtering out irrelevant stimuli before they can reach the higher brain areas. Deficits in sensory gating may therefore result in an overload of irrelevant information

reaching the higher brain areas, which in turn might contribute to the formation of psychotic symptoms. One well established paradigm to assess sensory gating is P50 suppression. In this paradigm, patients with schizophrenia score significantly lower than healthy controls. In schizophrenia both a reduction in prefrontal dopaminergic activity and an increased noradrenergic activity have been suggested to be involved in the disease. In the current study we aimed to further investigate the involvement of these neurotransmitters using the norepinephrine reuptake inhibitor (NRI) reboxetine and the dopamine antagonist haloperidol, to increase noradrenergic as well as decrease dopaminergic neurotransmitter activity, respectively.
Material and methods: The design of the experiment was a double-blind, placebo-controlled, cross-over study, where a dose of either reboxetine (8 mg), haloperidol (2 mg), their combination or placebo was administered to 21 healthy male subjects at four separate visits with a minimum of two weeks apart. The subjects were subsequently tested in The Copenhagen Psychophysiological Test Battery (CPTB) which, amongst others, measures P50 suppression using electroencephalography (EEG).
Results: We found a significant reduction in P50 suppression following separate administration of either reboxetine or haloperidol as well as following their combined administration compared to placebo.
Conclusion: The current study aimed to help clarify the neurotransmitter systems involved in sensory gating. Based on the results obtained it appears that both an increased noradrenergic and a decreased DA activity is involved in P50 suppression. However we did not observe a synergistic effect of the combination of the compounds, which might indicate a ceiling effect or a drug/drug interaction. Since sensory gating in schizophrenia patients is usually found to be reduced compared to controls our results may indicate similar underlying neurotransmitter activity.

Title: An orthosteric mGluR 2/3 Agonist, but not a Positive Allosteric Modulator, enhances acoustic startle response in rodents

Authors: *R. WILLEMS, L. VER DONCK;
Neurosci., Janssen Res. & Development, A Div. of Janssen Pharmaceutica NV, Beerse, Belgium

Abstract: The acoustic startle response (ASR) in rodents is a useful model to study the plasticity of sensorimotor information processing in mammals, including habituation and sensitization of startle and prepulse inhibition. The ASR is a relatively simple response characterized by a rapid contraction of skeletal muscles following an unexpected and intense acoustic stimulus. Changes in startle amplitude through repeated stimulus presentation or pharmacological intervention represent the simplest form of learning and have been used to identify the neural basis of learning in invertebrates. Since glutamate appears to be a prominent neurotransmitter in the auditory system, modulation of its receptors might impact the ASR.
OBJECTIVE: To compare the orthosteric mGluR2/3 agonist LY-404039 (LY) and a novel selective mGluR2 Positive Allosteric Modulator (JNJ-PAM, JNJ-40411813) on modulation of ASR.
METHODS: Male mice (NMRI and C57BL6J (BL6)) and rats (Wistar (WI) and Sprague Dawley (SD)) were treated with LY, PAM or vehicle, thirty min before testing. ASR was measured using the Acoustic Startle Reflex System (San Diego Instruments, US) producing a random mix of white noise sound pulses (70-120 dB vs. 65 dB background, pulse length: 40ms).
RESULTS: In a series of independent studies in NMRI mice, the mGluR2/3 agonist LY increased ASR at 2.5 and 10 mg/kg compared to control, from 90 dB pulse intensity onwards, ($p<0.05$ and $p<=0.001$ respectively, RM-ANOVA) whereas JNJ-PAM was without effect. In contrast, the LY-induced increase in ASR was not observed in BL6 mice. The reason for this strain difference is unclear. Increased responses were also measured in both rat strains with LY at 10 mg/kg ($p<0.001$) while no effects were found with JNJ-PAM.
CONCLUSION:
1/ Increased ASR was demonstrated in rodents by the orthosteric mGluR2/3 agonist LY-404039 but not by the mGluR2 PAM JNJ-40411813. This might indicate that modulation of the ASR is driven by mGluR3 stimulation.
2/ Continued receptor activation by an agonist may over stimulate the system, while a PAM avoids this by only modulating in the presence of physiologically released glutamate.
3/ Effects of an orthosteric mGluR2/3 agonist in behavioural tests involving startle response should be interpreted with caution.

Title: Chronic ketamine administration induces enhanced mismatch and novelty detection in rats

Authors: *A. SCHUMACHER, E. C. TOLLEDO, L. FERGUSON, R. ITO;
Psychology, Univ. of Toronto Scarborough, Toronto, ON, Canada

Abstract: Chronic ketamine administration has been widely used as an animal model of schizophrenia. Furthermore, some recent work indicates that it may has superior face validity as it can induce both positive-, as well as negative-like symptoms, and cognitive deficits in rats. This is most likely due to the fact that ketamine's primary mechanism of action is upon the glutamatergic system, and yet it can also induce alterations in the mesocorticolimbic dopamine system. The present study investigated the effect of repeated ketamine pre-treatment upon novelty detection, which is associated with reduced hippocampal recruitment in schizophrenics, and other indices of negative symptoms of schizophrenia such as anhedonia and locomotor activity. Male Long Evans rats received repeated intra-peritoneal injections of ketamine or saline. After a withdrawal period of 10 days, rats were tested in an associative mismatch detection task to examine their ability of detecting familiar audiovisual stimuli appearing in novel configurations. Rats were exposed to two audiovisual sequences over four training days, and exhibited an orienting response (OR) to the visual (light) stimulus as a behavioral index of novelty detection, which habituated across the training days. On the final test day, the two audiovisual pairings were scrambled, such that rats were presented with novel stimulus configurations, alongside familiar stimulus configurations. Furthermore, rats underwent a novel object detection task. Rats were habituated to four objects presented in each arm of a plus maze. Subsequently, one of the 4 objects was replaced by a new object, and the spatial locations of two familiar objects were switched. Additionally, rats underwent a sucrose preference test, and locomotor tests involving administering a challenge dose of amphetamine. Ketamine pre-treated rats showed significantly better mismatch detection and an enhanced ability of distinguishing spatially novel objects compared to saline rats. Furthermore, ketamine-treated rats exhibited a state of heightened hedonia, and higher spontaneous locomotor activity than saline rats. These data implicate that repeated ketamine administration can induce behavioural alterations that are indicative of a hyperdopaminergic state.

Abstract: Schizophrenia pathophysiology involves neural dysconnectivity between the prefrontal cortex and posterior areas, likely related to oligodendrocyte and myelin impairments. Moreover, redox dysregulation induced by a glutathione synthesis deficit has been reported in the disease. As oligodendrocytes are highly vulnerable to oxidative stress, we investigated the interplay between glutathione levels and myelin in prefrontal cortex. In control subjects, multimodal magnetic resonance imaging revealed a positive correlation between glutathione levels in the anterior cingulate cortex and both white matter integrity (Pearson correlation r=0.52,

p=0.01) and functional connectivity of the cingulum bundle (Pearson correlation r=0.47, p=0.02). This correlation was disrupted in early psychosis patients. To substantiate the relationship between glutathione and myelin, we investigated myelin-associated proteins in mice with genetically impaired glutathione synthesis (*GCLM*-KO mice). Immunoreactivity of myelin markers was decreased by -44% in their anterior cingulate cortex at peripubertal age. At molecular level, a glutathione deficit induced by shRNA toward glutamate-cysteine-ligase catalytic subunit (GCL: key glutathione synthesis enzyme) reduced oligodendrocyte progenitor cell (OPC) proliferation by -26% and increase OPC early differentiation. The latter was mediated by an increase of Fyn kinase activity. Consistently, fibroblasts of patients having impaired glutathione synthesis presented an abnormal regulation of Fyn expression in response to oxidative stress. All together, these data indicate a critical role of glutathione and redox dysregulation in myelination processes and white matter tract maturation in the prefrontal cortex of rodent and human, a mechanism disrupted in schizophrenia.

Title: A single minocycline administration suppresses methamphetamine-induced behavioral sensitization in mice

Authors: *T. A. KATO[1,2], S. KANBA[1], M. YAMATO[2,3], T. SHIBA[3], M. TAKARA[3], Y. SEKI[1], M. OHGIDANI[1], N. SAGATA[1], Y. YAMAUCHI[1], Y. MIZOGUCHI[4], K.-I. YAMADA[3], A. MONJI[4];

Abstract: Introduction
Methamphetamine (METH), a functional dopamine agonist, is one of the most common abused

drugs, and METH abusers show various psychiatric symptoms especially psychosis. Repeated administration of METH produces a phenotype with enhanced locomotor activity, and these rodents show a behavioral sensitization to the locomotor enhanced by METH, which has been used as a model of stimulant psychosis. Minocycline, a tetracycline antibiotic, is known to have powerful anti-inflammatory and neuroprotective properties in animal models of various neurological disorders. In addition, minocycline has been highlighted as a potent psychotropic drug for schizophrenia.
Purpose/Methods
There are limited pharmacological treatments for METH-induced psychiatric symptoms. Thus, we herein examined the ability of minocycline to alter METH-induced behavioral sensitization. Behavioral sensitization is characterized by an enhanced locomotor response to METH after chronic administration has ceased. In this study, mice (adult male C57BL/6) received 5 mg/kg METH intraperitoneally (i.p.) for seven days. On Day 14, mice were challenged with 0.5 mg/kg METH to test for sensitization. Mice were placed in the center of an open field, and the number of line crossings was recorded as an index of locomotor activity.
Results
Mice were assigned randomly to three groups, each of which was designated as Control, METH and METH+ Single Mino. A seven-day repeated administration of METH significantly enhanced locomotor activity induced by METH challenge (0.5 mg/kg) on Day 14, signifying that METH sensitization had established. Surprisingly, a single-shot administration of 40 mg/kg minocycline i.p. immediately before METH challenge significantly inhibited locomotor activity.
Conclusion
This is the first report to show the inhibitory effect of single-shot minocycline on established methamphetamine (METH)-induced behavioral sensitization. Previous reports have shown that minocycline rescues METH-induced sensitization only when treated during the initial METH treatment period. Our novel finding further indicates that minocycline may be beneficial for the treatment of established METH-induced psychotic symptoms. Further investigations should be conducted based on our novel preliminary findings.

Title: Modelling the cognitive function of the confirmed psychosis risk gene ZNF804

Authors: *J. E. HADDON, J. EDDY, T. AL-JANABI, M. O'DONOVAN, M. OWEN, L. WILKINSON;
Cardiff Univ., Cardiff, United Kingdom

Abstract: ZNF804A was found to be a top hit for association with schizophrenia (SZ) in a recent Genome-Wide Association Study1 with the strength of association increasing when bipolar cases were added to the affected sample. The association between ZNF804A and SZ has since been replicated. Murine Zfp804a is orthologous with the human gene and thus lends itself to mouse models. Using ENU mutagenesis we have generated two mutations in Zfp804a, which we are studying on a number of behavioural tasks designed to reflect symptoms of SZ. Previous work has shown effects of the mutations on aspects of emotional and motivational function, including evidence consistent with anhedonia. We are now examining the effects of the mutations on murine analogues of the Stroop paradigm, a task requiring the use of contextual information to resolve response conflict, which SZ patients have difficulty with.
In Experiment One, C57BL/6 mice were trained concurrently on two discriminations, auditory and visual, in two discriminable contexts A and B, (e.g. A: Tone→Left lever, Clicker→Right; B: Flashing light→Left, Steady light→Right, counterbalanced between animals). Correct responses were rewarded with pellets in one context and sucrose in the other. Following acquisition, mice received test presentations of audiovisual compounds of the training stimuli in both contexts. The elements of these compounds required either the same (e.g. Tone and Flashing→Left) or different lever press responses (e.g. Tone and Steady→Left/Right) during initial training, termed congruent and incongruent stimulus pairs respectively. Mice demonstrated correct responding to the congruent stimulus pairs. Responding to the incongruent stimulus pairs was dependent upon the relationship between the elements of the audiovisual compounds and the test context, such that rats responded preferentially to the stimuli previously trained in the test context. For example, when tested in context A they responded based on the auditory cues (e.g. Tone and Steady→Left, Clicker and Flashing→Right) but in context B their responding was in accordance with the visual stimuli (e.g. Tone and Steady→Right, Clicker and Flashing→Left).
Previous evidence suggests that damage to the prefrontal cortex impairs the contextual control of response conflict, a region that might be influenced by these mutations. Experiment Two examined whether mutations to ZFP804a influence the ability to respond appropriately to response conflict in a manner similar to the cognitive impairments observed in patients with Schizophrenia performing the Stroop task.

Title: Abnormal high frequency oscillations in the nucleus accumbens in the MAM developmental rat model of schizophrenia

Authors: *S. ANTHARVEDI GODA, S. KASICKI, M. J. HUNT;
Nencki Inst. of Exptl. Biol., Warsaw, Poland, Poland

Abstract: We have shown previously that spontaneous high frequency oscillations (130-180 Hz, HFO) were recordable from the nucleus accumbens (NAc) of awake rats and that NMDAR antagonists increase their power and frequency. Here, we examined whether HFO recorded in local field potentials (LFPs) of the NAc were altered in the MAM-E17 developmental rat model of schizophrenia. We found that the power and frequency of spontaneous HFO were significantly higher in MAM rats versus sham controls. In contrast the power of delta (<4 Hz) and broadband gamma (30-100 Hz) were not different between the groups. Injection of MK801 (0.05, 0.15, 0.3 mg/kg) dose dependently increased the power of spontaneous HFO in both groups. When we controlled for the larger HFO power at baseline, MK801 produced comparable magnitude of change in power for both group of rats. In contrast, MK801 did not affect the frequency of HFO in MAM rats but dose-dependently increased the frequency of HFO in the sham group. Additionally, we also found that MK801 increased the power of high gamma (70-90 Hz) in MAM rats alone. Taken together, these results suggest that abnormal spontaneous HFO are a characteristic feature of the MAM developmental model of schizophrenia.

Title: Neuroreceptor mechanisms of antipsychotic sensitization and tolerance

Authors: *S. CHOU, M. LI;
Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Chronic antipsychotic treatments often induce long-term alterations in their behavioral efficacy, termed antipsychotic sensitization and tolerance. Our previous studies indicated that repeated administration of olanzapine causes a sensitization effect in the conditioned avoidance response model, while clozapine causes a tolerance effect. However, molecular mechanisms underlying these lasting behavioral alterations are currently unclear. In the present study, we investigated the involvement of dopamine D2 receptors in antipsychotic sensitization and tolerance in a heterogenous group of animals. Male adult Sprague-Dawley rats born from dams treated with either saline or polyinosinic:polycytidilic acid during pregnancy to induce immune activation were first repeatedly treated with clozapine or olanzapine and tested daily for avoidance response for five consecutive days. Two days later the expression of antipsychotic sensitization and tolerance was examined in a challenge test in which all rats were injected with a lower dose of either drug. Finally, amphetamine was used to assess locomotor activity in all rats. We expected rats to display olanzapine sensitization and clozapine tolerance during both the repeated drug test days as well as the challenge test. We also expected rats previously treated with antipsychotics during the repeated drug test days to display significantly higher motor activity levels during the amphetamine-induced hyperlocomotion test compared to those treated with vehicle during the same period. We suggest that repeated antipsychotic treatment may stimulate dopamine D2/3 receptor up-regulation that induces lasting modulations of behavioral sensitivity to these drugs. Thus the results of this study shed light on possible receptor mechanisms involved in the long-lasting sensitization and tolerance effects caused by chronic antipsychotic treatment.

Title: Endocannabinoid-mediated modulation of neuronal correlates of social interaction in saline- and PCP-treated rats

Authors: *J. MATRICON, A. SEILLIER, A. GIUFFRIDA;
Pharmacol., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: The negative symptoms of schizophrenia (SCZ), which include anhedonia and social withdrawal, are resistant to pharmacological therapy. Experimental evidence suggests a link between negative symptoms and dysfunctional endocannabinoid transmission in the brain. Studies carried out in drug naïve schizophrenics have shown that the levels of the endocannabinoid anandamide (AEA) are inversely correlated to the severity of negative symptoms, suggesting that increased AEA production may be beneficial in SCZ. In line with this hypothesis, we previously showed that the social withdrawal observed in the sub-chronic phencyclidine (PCP) rat model of SCZ results from deficient stimulation of the cannabinoid CB1 receptor, and that AEA elevation induced by the fatty acid amide hydrolase inhibitor URB597 reverses this deficit via a CB1-mediated mechanism.

To identify the brain areas lacking CB1 stimulation during social interaction, we carried out an extensive analysis of c-Fos expression as a marker of neuronal activity in 28 cortical, limbic and subcortical regions relevant to SCZ and social behavior. Brain samples were collected from rats treated with PCP (5mg/kg, i.p., 2 injections/day for 7 days followed by 1-week wash out) or saline tested for social interaction in the presence (or absence) of URB597 (0.3mg/kg, i.p.). Rats exploring the social interaction arena alone were used as controls.

PCP treatment produced a social withdrawal, which was reversed by URB597. The same drug, however, produced social deficit in saline-treated rats. The behavioral phenotypes observed in these experimental groups matched the pattern of c-Fos activation in 2 out of the 28 cerebral regions studied. Specifically, social interaction produced neuronal activation in the orbitofrontal cortex of saline-treated rats, but not in PCP-treated animals. URB597 administration prevented the activation of this brain area in saline-treated rats, whereas it restored neuronal activation in the PCP-treated group. We found a reciprocal activation pattern in the central amygdala, suggesting a critical contribution of these 2 areas to the behavioral changes observed in our model.

To determine whether the c-Fos activation pattern reflects possible alterations of CB1 function, we are currently assessing changes in CB1 expression, activity and signaling in the orbitofrontal cortex and the amygdala using biomolecular techniques and subcellular fractionation.

These results will provide valuable information on the brain regions engaged during social

interaction in normal and schizophrenia-like conditions, and on the CB1 contribution to the neuronal activity of the underlying circuits.

Title: Working memory deficits in adult rats after acute elevation of brain kynurenic acid are alleviated by co-administration of the α7 nicotinic positive modulator galantamine

Authors: *S. A. VUNCK[1], K. SUPE[1], R. SCHWARCZ[2], J. P. BRUNO[1];
[1]The Ohio State Univ., Columbus, OH; [2]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Schizophrenia (SZ) is a debilitating psychiatric disorder that affects ~1% of the world's population. Core cognitive deficits in thought processing, attention and working memory (WM) remain largely unresolved by current drug and behavioral interventions. While traditional pharmacotherapy has focused on dopamine antagonism, interactions among several cortical-subcortical neurotransmitter systems are dysregulated in SZ and offer potential targets for adjunctive drug therapy. Elevated kynurenic acid (KYNA) levels in the brain of patients with SZ may contribute to cognitive impairments through KYNA's negative allosteric modulation of α7 nicotinic acetylcholine receptors (α7nAChRs). This hypothesis has prompted the use of experimental elevations in brain KYNA to study the cognitive impairments seen in SZ. The present study used the operant delayed non-match to position (DNMTP) task in adult, male rats to determine the impact of acutely elevated KYNA on WM) and the ability of galantamine, a positive allosteric modulator (PAM) of the α7nAChR, to alleviate performance deficits. The DNMTP task has three behavioral components: sample, retention, and choice phases. The daily sessions consisted of 120 trials; delays were 5, 10 and 15 sec. Rats received 50 min pretreatment injections (i.p.) of 0, 25 or 100 mg/kg kynurenine (the bioprecursor of KYNA), with 48 hour

intervals to assure complete return of brain KYNA to baseline levels between doses (order randomized). Reduction of the deficits produced by 100 mg/kg kynurenine was attempted by systemic co-administration of galantamine (3 mg/kg, i.p.). Elevation of KYNA via acute administration of kynurenine resulted in significant main effects of dose and delay, with an interaction between the two factors. Compared to vehicle treatment, 25 mg/kg kynurenine significantly reduced accuracy (by 12%)) only at the longest delay (15 sec), while 100 mg/kg significantly reduced accuracy overall (17%) as well as at 5 sec (11%) and 10 sec (14%), with the 15 sec delay (33%) dropping to chance levels. The deficits following 100 mg/kg kynurenine were fully prevented by a 45 min pretreatment with galantamine. Our results show that the systemic administration of kynurenine results in significantly reduced, delay-dependent performance in the DNMTP WM task. This deficit appears to result from KYNA's negative allosteric modulation of α7nAChRs, as performance accuracy was normalized by galantamine. Further research using more selective α7nAChR agonists and PAMs will clarify the mechanisms of KYNA-related cognitive deficits in WM and may provide support for the continued focus on the α7nAChR as a target for cognition enhancement in SZ.

Title: Chronic prenatal kynurenine elevation in rats: A naturalistic model of schizophrenia with biochemical abnormalities and deficits in hippocampal-mediated learning and memory

Authors: *A. POCIVAVSEK[1], M. A. R. THOMAS[1], G. I. ELMER[1], J. P. BRUNO[2], R. SCHWARCZ[1];
[1]Maryland Psychiatric Res. Center, Dept of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Departments of Psychology and Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Schizophrenia (SZ), a catastrophic psychiatric disorder, results from a combination of genetic and environmental factors. Kynurenic acid (KYNA), an endogenous antagonist of α7 nicotinic acetylcholine (α7nACh) and NMDA receptors, has been implicated in the pathology of SZ (elevated brain and CSF KYNA levels in SZ; genetic links to KYNA metabolism; role of

both α7nACh and NMDA receptors in neurodevelopment and cognition; etc.). The prominent neurodevelopmental hypothesis of SZ etiology is often studied in animals where the developmental period has been manipulated experimentally. In the present study, we increased KYNA levels prenatally, from gestational day (GD) 15 to GD 22, by adding the KYNA precursor kynurenine (kyn)(100 mg/day) daily to the chow fed to pregnant mothers (control: ECon; kyn-treated: EKyn). On the last day of treatment, KYNA levels in the brain of embryos were significantly elevated (ECon: 1344 ± 233 fmoles/mg protein, EKyn: 7654 ± 656 fmoles/mg protein, n=7 litters/group). Upon termination of the treatment, all rats were fed normal rodent chow until the animals were evaluated in adulthood, i.e. on postnatal days (PD) 56-80. KYNA levels were significantly elevated in the brain of EKyn offspring (ECon: 47 ± 4 fmoles/mg protein, EKyn: 104 ± 24 fmoles/mg protein, n=4-6 litters/group), and this was paralleled by a significant reduction in the activity of kynurenine 3- monooxygenase (KMO), a pivotal kyn pathway enzyme that controls the production of KYNA (ECon: 38 ± 8 pmoles/h/mg protein, EKyn: 6 ± 5 pmoles/h/mg protein, n=4-6 litters/group). To evaluate possible differences in de novo KYNA production, adult animals were acutely challenged with kyn (50 mg/kg, i.p., 90 min). This led to a significantly higher KYNA content in the brain of EKyn animals (ECon: 474 ± 22 fmoles/mg protein, EKyn: 702 ± 77 fmoles/mg protein, n=5-7 litters/group), possibly as a consequence of the low cerebral KMO activity. In separate animals, we tested hippocampus-dependent behaviors [passive avoidance paradigm (PAP) and Morris water maze (MWM)]. Prenatal kyn treatment caused significant PAP deficits, evidenced as decreased avoidance latency during the retention trial (ECon: 157 ± 32 s; EKyn: 43 ± 10 s; n=7 litters/group), and increased escape latency to find the hidden platform across days in the MWM (n=7 litters/group). Additional studies revealed that these delayed behavioral impairments are not seen when brain KYNA levels are raised experimentally in late adolescence (PD 42-49). Collectively, our results suggest that increases in brain KYNA during a vulnerable period in early brain development may play a significant role in the pathophysiology of SZ.

Title: Prenatal kynurenic acid elevation alters cortical development and prefrontal glutamate release, corresponding to cognitive inflexibility in adults

Authors: *M. L. PERSHING[1], D. BORTZ[1], A. POCIVAVSEK[2], P. J. FREDERICKS[1], B. LEUNER[1], C. V. JØRGENSEN[3], R. SCHWARCZ[2], J. P. BRUNO[1];
[1]Psychology, The Ohio State Univ., Columbus, OH; [2]Maryland Psychiatric Res. Center, Dept. of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Neurobio. Res. Unit, Copenhagen Univ. Hosp., Copenhagen, Denmark

Abstract: Schizophrenia (SZ) is a debilitating neuropsychiatric disorder arising from neurodevelopmental alterations in brain circuitry. These changes underlie core deficits in cognitive control that are predictive of functional outcome yet are ineffectively treated with current pharmacotherapies. We have studied the effects of chronic elevations of kynurenic acid (KYNA) as a developmental model of SZ. KYNA, an endogenous antagonist of α7 nicotinic acetylcholine (α7nAChR) and NMDA receptors, is elevated in the brain of SZ patients and may contribute to cognitive deficits. We have reported that administration of KYNA's bioprecursor (kynurenine) from gestational day (GD) 15 through weaning produces deficits in hippocampal- and prefrontal-mediated tasks when offspring are tested as adults (Eur J. Neurosci., 35, 1605-1612, 2012; Neuroscience, 238, 19-28, 2013). In the present experiments, we attempted to further define the sensitive period for elevations in KYNA by limiting the dam's exposure to kynurenine (100 mg/day in mash) to the last prenatal week (GD15-22) (EKyn rats). KYNA levels were determined on GD21 and postnatal day (PD) 56. Cognitive flexibility was assessed between PD56-80 using an attentional set-shifting task (ASST). Given the role for prefrontal glutamate in set-shifting, animals from each litter were also used to determine the expression of mGluR2 receptor mRNA, the density of dendritic spines on cortical pyramidal neurons (layers II/III), and the mesolimbic control of prefrontal glutamate release using a glutamate-sensitive biosensor. EKyn rats had elevated brain KYNA levels, relative to controls (ECont), on GD21 (~5 fold) and PD56 (~1.5 fold). In adulthood, EKyn rats showed altered prefrontal glutamate transmission and exhibited deficits in the ASST at the first reversal and extra-dimensional shift stages. Relative to ECont, EKyn rats showed reduced expression of mRNA for mGluR2 receptor at GD21
(28%) and PD56 (27%) as well as reductions in apical (11%) and basal (14%) dendritic spine density of pyramidal neurons in layers II/III. Finally, the mesolimbic activation of prefrontal glutamate release following intra-accumbens infusion of NMDA seen in ECont rats (3.58 ± 0.40 µM increase at 0.15 µg NMDA) was nearly eliminated (0.43 ± 0.22 µM) in Ekyn rats. Thus, prenatal elevation of KYNA produces long lasting molecular and neuronal changes that are associated with disruptions in prefrontal development, cortical excitability, and cognitive flexibility. These results support a focus on elevated KYNA levels and altered cortical excitability as a mechanism underlying cognitive deficits in SZ.

Title: Mesolimbic regulation of prefrontal glutamate release is blocked by local kynurenic acid and restored with oral administration of a kat ii inhibitor

Authors: *D. M. BORTZ[1], R. SCHWARCZ[2], J. P. BRUNO[1];
[1]The Ohio State Univ., Columbus, OH; [2]Maryland Psychiatric Res. Ctr., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Schizophrenia (SZ) is caused by a disruption between cortical and sub-cortical brain regions. Deficits in cognition, a core symptom cluster of the disease, are mediated by dysregulations in glutamatergic transmission in the prefrontal cortex (PFC). We have reported, using a glutamate biosensor (sampling frequency of 2 Hz; less than 1 sec to maximal response), that an infusion of NMDA into the rat nucleus accumbens (NAc) shell stimulates glutamate release in the PFC (Bortz et al, SFN 2012). Cognitively, this mesolimbic activation alleviates the performance deficits seen in rats during the distractor portion
of a sustained attention task (St. Peters et al, J. Neurosci., 225: 574-583, 2011). As glutamate levels in the PFC are reduced by increased levels of the neuromodulator kynurenic acid (KYNA; J.
Mol. Neurosci., 40: 204-210, 2010), and as brain KYNA levels are increased in individuals with SZ and result in cognitive deficits in animals, we tested the ability of KYNA to affect the stimulation of PFC glutamate by an intra-NAc NMDA infusion. As expected, local infusion of NMDA (0.15 µg) caused an elevation of glutamate in the PFC, with a mean amplitude of 4.27 ± 0.71 µM. Acute injections of
kynurenine (25, 50 or 100 mg/kg, i.p.), the bio-precursor of KYNA, 2 hr prior to the NMDA infusion dose-dependently suppressed the glutamate signal (mean % reduction of NMDA amplitudes: 71%, 86% and 94%; N=7, 3 and 3, respectively). As increased brain KYNA levels may play a causative role in the pathophysiology of SZ (Schiz. Bull., 36: 211-218, 2010), drugs designed to reduce brain KYNA formation represent a potential treatment approach. We

therefore targeted KAT II, the enzyme primarily responsible for the conversion of kynurenine to KYNA in the brain, in our paradigm. Oral administration of the
selective KAT II inhibitor BFF-816 (200 mg/kg), which readily crosses the blood-brain barrier (Wu et al., SFN 2012), delivered 2 hr prior to the NMDA infusion into the NAc, inhibited the suppressive effects of 50 mg/kg kynurenine (mean = 75 ± 11%) on the glutamate signal in the PFC by 37 ± 4% (N=5). These results provide further evidence that acute elevations in brain KYNA represent a good experimental model of SZ-like, behavioral deficits, and that KAT II inhibition may hold promise for future drug treatment of cognitive impairments in SZ.

Title: Two-hit model of schizophrenia: combining viral and glutamatergic insults

Authors: C. SCHIFANI, M. KLEE, B. JANSON, A.-L. RELO, *C. KLEIN, A. Y. BESPALOV;
Neurosci. Discovery Res., AbbVie, Ludwigshafen, Germany

Abstract: Schizophrenia is a multifactorial disorder involving both genetic and environmental factors. A theoretical model was developed which describes the onset of the disease as an interplay of at least two “hits” during development. The present study focused on modeling this “two-hit hypothesis” to investigate potential compounding effects of maternal immune activation during pregnancy (polyinosinic-polycytidylic acid, Poly I:C, infusion on gestation day 15) and neonatal exposure of offspring to glutamatergic insult (repeated treatment with an NMDA receptor antagonist phencyclidine, PCP, on postnatal days 7, 9 and 11). Controls were treated with saline and left undisturbed before weaning. Several batches of male rats were used in the experiments and the most robust findings in the “two-hit” animals were increased locomotor activity when exposed to novel environment that persisted after habituation, reduced metabolic activity in dorsal and ventral hippocampus as well as in the prefrontal cortex (measured by [14C]2-deoxyglucose uptake), higher levels of pyruvate in the cerebrospinal fluid and enlarged

ventricles. In addition, various parameters of play behavior in juvenile rats were correlated to behavioral and neurochemical findings in the adulthood (e.g. animals that were less likely to engage in play behavior displayed higher activity in the open field). Furthermore, hippocampal metabolic activity was found to correlate with behavioral readouts in the 'two-hit' animals but not in controls (e.g. stronger glucose uptake in the hippocampus was associated with more activity in the open field). Taken together, combination of the perinatal poly I:C and PCP treatments results in robust and reproducible changes in behavioral, neurochemical and neuroanatomical parameters and therefore supports the two-hit hypothesis. Perhaps, most intriguing are the changes in the metabolic brain activity that correlate with behavioral measures that may be explored as a target for novel therapies of schizophrenia and related disorders.

Title: Comparison of Valproate acid and Haloperidol effects on excessive dopamine release in the amygdala in response to conditioned fear stress: Methamphetamine-sensitized rats

Authors: *H. MURAOKA, M. KAWANO, K. INADA, T. KAWANO, H. OSHIBUCHI, J. MIYAGI, A. KASAI, M. YAMADA, J. ISHIGOOKA;
Psychiatry, Tokyo Women'S Med. Univ., Tokyo, Japan

Abstract: Patients with schizophrenia may exhibit emotional hypersensitivity; therefore, it is meaningful to study dopamine dynamics in the amygdala. In our series of studies, we found that dopamine release in the amygdala was significantly increased in methamphetamine (MAP)-sensitized rats compared to control animals during a conditioned fear stress paradigm. Excessive dopamine release is considered a biochemical marker
of vulnerability to psychosis, and it is known that antipsychotic drugs antagonize dopamine signaling in the mesolimbic system. However, it is unclear how antipsychotic drugs affect

amygdalar function. In contrast,
mood-stabilizing drugs are used for augmentation therapy of schizophrenia and other emotional disorders, but there is no biochemical evidence that they exert different pharmacological effects on psychological stress. Therefore, we examined the differential effects of conditioned stress on basal dopamine release and response among control (saline; SAL), antipsychotic drug (haloperidol; HAL), and mood-stabilizer (valproic acid; VPA) groups.
Male Sprague Dawley rats received 2 mg/kg/day of MAP for 10 days to sensitize them to the drug, and a fear conditioning paradigm was conducted to model psychological stress. Dopamine changes in response to conditioned fear stress in the amygdala were measured by microdialysis and high-performance liquid chromatography.
Compared with SAL, both the HAL and VPA groups showed inhibition of excessive dopamine release in the amygdala. HAL elevated the number of dopamine vesicles in MAP rats, but VPA did not. These results suggest that VPA-mediated alteration in the number of dopamine-containing vesicles is one of the reasons why VPA is effective in ameliorating schizophrenia symptoms.

Title: The effects of phencyclidine on self-administration of nicotine: A novel hypothesis for the comorbidity of schizophrenia and nicotine abuse

Authors: *N. SWALVE[1], S. PITTENGER[2], C. CHOU[2], M. LI[2];
[1]Univ. of Nebraska- Lincoln, Lincoln, NE; [2]Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Patients with schizophrenia smoke cigarettes at a disproportionately higher rate than the general population but the behavioral and neurobiological mechanisms underlying the comorbidity between schizophrenia and nicotine abuse remain unclear. The present experiment used preclinical means to test a novel hypothesis for this comorbidity: patients with schizophrenia are more sensitive to the reinforcement-enhancement effect of nicotine (i.e. the enhancement by nicotine of the reinforcing effects of other stimuli). This experiment

investigated this hypothesis by testing rats in an animal model of schizophrenia using a nicotine self-administration paradigm. Self-administration of nicotine is significantly increased when a cue light is presented concurrent with the nicotine infusion, which has been suggested as evidence for the reinforcement-enhancement effect of nicotine. Phencyclidine (PCP) was used to induce behavioral changes resembling symptoms of schizophrenia in rats and cue lights were either concurrently presented with the nicotine infusion during the self-administration session or absent from sessions. Forty male Sprague-Dawley rats were initially trained to lever-press for sucrose and then underwent catheter implantation surgery. They were then randomly assigned into four groups based on the drug injected prior to self-administration sessions and cue light availability: SAL-CUE, SAL-NO CUE, PCP-CUE, PCP-NO CUE. PCP (or the corresponding saline group) was administered every day before placement into the chamber. After responding stabilized, they underwent extinction and reinstatement with PCP and yohimbine, an alpha-2 adrenoreceptor antagonist, to determine what effect prior exposure to PCP would have on reinstatement of nicotine-seeking behavior. There were significant differences between groups on lever-pressing, suggesting that both cue exposure and previous administration of PCP contribute to changes in nicotine self-administration.

Title: Early lifetime treatment with phencyclidine induces interneuron dysfunction and cognitive deficits in rats

Authors: *N. PLATH[1], B. V. BROBERG[2], C. KJÆRBY[1], A. S. KARLSEN[3], J. RIISE[3], P. H. LARSEN[1], J. P. REDROBE[1], L. LERDRUP[1];
[1]Lundbeck A/S, Copenhagen, Denmark; [2]Ctr. for Neuropsychiatric Schizophrenia Res., Psychiatric Ctr. Glostrup, Glostrup, Denmark; [3]Res. Lab. for Stereology and Neurosci., Bispebjerg Univ. Hosp., Copenhagen, Denmark

Abstract: Pharmacological inhibition of the NMDA receptor (NR) has been shown to induce psychosis-like symptoms in healthy controls and exacerbate psychotic symptoms in schizophrenia patients. Consequently, perturbation of rodents with NR antagonists, e.g. phencyclidine (PCP), has become a popular means to mimic schizophrenia-like symptomatology

in animals. One such approach, the neonatal (aka perinatal) PCP (neoPCP) model, additionally incorporates the neurodevelopmental dysfunction hypothesis of schizophrenia. We applied this model to address the effects of early life NR antagonism on cognition as well as a range of neuronal functions suggested to mediate cognitive processing.
To generate neoPCP rats, male Lister Hooded rats were treated with 20 mg/kg (s.c.) on postnatal days (PND) 7, 9 and 11 and underwent phenotypical assessment during early adulthood (PND 50 - 100).
As reported earlier, neoPCP treatment produced hypersensitivity to an acute NR antagonist challenge, as evidenced by increased locomotor activity and phMRI responses. Moreover, neoPCP rats displayed deficits in episodic memory (novel object recognition) and executive function (attentional set shifting) tasks, but not in classical conditioning and reversal learning tasks (touch screen visual discrimination). These cognitive deficits could partially be reversed with pro-cognitive agents shown to be efficacious on some cognitive domains in schizophrenia patients (e.g. Modafinil). On a cellular level, neoPCP treatment led to a 25% decrease of spine numbers in pyramidal neurons of the medial prefrontal cortex (mPFC), as well as an approximate 20% reduction in mRNA expression of the presynaptic marker SNAP25 in the hippocampal CA4 region. Furthermore, neoPCP animals presented an estimated 20% signal reduction for the interneuronal marker, parvalbumin. This result was mirrored by a significant decrease in miniature inhibitory postsynaptic potential (mIPSP) frequency in the mPFC layer II/III, but not layer V. Thus far, we did not see spontaneous recovery of any of these observations within the time frame studied.
In summary, the rodent neoPCP model is suggested to represent a valid perturbation to mimic some of the cognitive deficits related to schizophrenia, mediated at least in part by an impairment of interneuron functionality.

Title: Maternal immune activation causes age-specific increase in the number of microglia in offspring in rats

Authors: *K. SUZUKI, T. TAKAHASHI, K. YAMADA, Y. IWATA, N. MORI;
Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: Background: Converging evidence from epidemiological, brain imaging, and neuropathological studies has suggested that at least in part of schizophrenia is a neurodevelopmental disorder, in which a brain abnormality is sustained early in life, but is not fully expressed until early adulthood. Among environmental factors that may destructively affect neurodevelopment, prenatal exposure to viral infection has been implicated by several large epidemiological studies, indicating that such exposure increases the risk of schizophrenia. However, it remains unknown the mechanism by which viral insults during prenatal period can cause latent development of schizophrenia. Based on post-mortem analysis showing an increased number of activated microglia in patients with schizophrenia, we hypothesized that these cells contribute to pathogenesis of the disorder.
Methods: Poly I:C injection of pregnant rats was used as an animal model of schizophrenia, and the number of microglia were assessed in the offspring at two developmental periods, prepubertal (four weeks after birth) and adulthood (eight weeks after birth), using anti-Iba1 immunohistochemistry.
Results: Eight- but not four-week-old offspring of pregnant dams exposed to 20 mg/kg of Poly I:C at embryonic day 12.5 showed significantly higher number of microglia in the hippocampus, frontal cortex, and striatum as compared to those of dams exposed to saline.
Conclusion: The result suggests that maternal immune activation during the prenatal period contributes to microglial activation after puberty in the offspring, and support the hypothesis that microglia is a contributing factor to the pathogenesis of schizophrenia.

Title: Effects of decreasing cortical GABA transmission on decision-making in rats

Authors: *A. O'HARA[1], B. PLAUT[2], D. C. LOWES[2], T. A. PAINE[2];
[2]Neurosci., [1]Oberlin Col., Oberlin, OH

Abstract: Background: Schizophrenia is associated with a number of cognitive deficits including deficits in executive function and decision-making. These cognitive functions rely, in part, on the prefrontal cortex (PFC). Notably, pathology within cortical GABA interneurons that results in reduced GABA synthesis and release (i.e., reduced expression of the GABA synthesis enzyme GAD67 and increased expression of GABAA receptor subunits) is commonly observed in post-mortem analyses of the brains of people diagnosed with schizophrenia. Thus, the goal of this experiment was to determine if decreasing cortical GABA function leads to schizophrenia-like changes in decision-making in rats.
Methods: Male Sprague-Dawley rats were trained on a rodent gambling task (rGT) until they reached stable levels of individual performance and then were implanted with bilateral guide cannulae aimed at the medial prefrontal cortex (PFC). Following recovery, rats were trained until their individual performances restabilized and then tested following infusions of the GABAA receptor antagonist bicuculline (BMI; 0, 25, 50 ng/μl) or the GABA synthesis inhibitor L-allylglycine (LAG; 0, 10, 20 μg/μl).
Results: Blockade of GABAA receptors with BMI impaired decision-making. Following BMI (50 ng/μl) infusions, rats chose the most advantageous hole less frequently and made fewer total advantageous responses than vehicle (0 ng/μl) treated rats. In addition, BMI (50 ng/μl) infusions increased omissions relative to vehicle infusions. In contrast, inhibition of GABA synthesis with LAG (20 μg/μl) did not affect decision-making (there was no change in advantageous responding) but did increase impulsive behavior as indicated by an increase in premature responding.
Summary: Blockade of GABAA receptors, but not blockade of GABA synthesis, impaired decision-making as measured by the rGT. These data suggest that reduced GABA synthesis is not sufficient to explain the decision-making impairments observed in schizophrenia; instead they suggest that reductions in GABAA receptor activation may explain this cognitive deficit. Future research is aimed at determining why blocking post-synaptic GABAA receptors negatively impacts decision-making while decreasing GABA synthesis and release does not.

Title: Chronic inhibition of cortical GABA synthesis does not impair attention

Authors: *T. A. PAINE;
Neurosci., Oberlin Col., Oberlin, OH

Abstract: Background: Attention deficits are a core feature of schizophrenia. Pathology of GABA interneurons within the prefrontal cortex (PFC), a brain region involved in optimal attention, is frequently observed in post-mortem analyses of brains from people with schizophrenia. It has been proposed that the net outcome of the pathological abnormalities is a reduction in GABA synthesis and release. The goal of the current experiment was to determine whether chronically reducing GABA synthesis within the rat medial PFC is sufficient to cause attention deficits as measured by the 5-choice serial reaction time task (5CSRTT). Because alterations in locomotor activity can have non-specific effects on 5CSRTT performance, we also examined the effects of chronically decreasing cortical GABA synthesis on locomotor activity in an open field.
Methods: Male Sprague Dawley rats were trained on the 5CSRTT until they reached criterion performance (>60% accuracy, <20% omissions for 5 consecutive days) and then were implanted with a bilateral cannula aimed at the medial PFC. Each cannula was connected to a osmotic mini pump that chronically infused the GABA synthesis inhibitor L-allylglycine (LAG, 3.2 μg/0.5 μl/hr) for 13 days. Following surgery rats were allowed to recover for 4 days and then were tested on the standard 5CSRTT for 5 consecutive days. Rats were then tested on a version of the 5CSRTT in which the stimulus duration was shortened (increasing attentional demands) and one in which the stimulus duration was lengthened (decreasing attentional demands). Finally, locomotor activity was measured assessed using an open field and then the rats were sacrificed. Brains were rapidly extracted and flash frozen for later analysis.
Results: Chronic LAG infusions did not affect accuracy of responding on any version of the task, but did increase omissions on both the standard and the short discriminative stimulus versions of the 5CSRTT. In addition, chronic LAG infusions increased premature responding on the standard version of the task. Finally, chronic LAG infusions slightly increased locomotor activity.
Summary: Chronic inhibition of GABA synthesis within the medial PFC, despite increasing impulsive behavior and locomotion, is not sufficient to impair attention per se. These data support our previous research in which acute inhibition of GABA synthesis within the medial PFC did not affect attention, yet increased locomotor activity. These data do not support the

hypothesis that disruptions in cortical GABA synthesis cause attentional impairments in schizophrenia.

Title: Comparison of scopolamine and MK801 effects on touchscreen based cognitive tasks in rats

Authors: *T. M. BALLARD, R. WYLER, T. BURNS;
Neurosci. DTA, Pharma Res. & Early Development, F. Hoffmann-La Roche AG, Basel, Switzerland

Abstract: The touchscreen is a computer-automated behavioural test system which provides the opportunity to set up cognitive tests that are virtually identical to human and non-human primate tests and thus is highly relevant for translational research in schizophrenia. For the current study, separate cohorts of 12-16 male Lister Hooded rats were trained in Med Associates operant chambers equipped with touchscreens controlled by K-Limbic (Conclusive Solutions) to either: (1). Visual discrimination (VD) task using the IMI NEWMEDS protocol and conditions; (2). Paired associate learning (PAL) task (Talpos et al, 2009). In the VD task rats learnt to discriminate between two visual stimuli (spider vs. plane) and by 10-14 daily sessions had achieved a stable baseline level of >85% correct responses. PAL is a visual-spatial memory task in which rats were trained to associate spatial location (left, middle or right of screen) with the correct visual stimulus (spider, plane or flower), and required at least 60 daily sessions to reach a criterion of 85% correct responses. Once animals had achieved a stable baseline level of performance in each task, compounds were assessed using a full cross-over design. The basis of any touchscreen task requires successful discrimination of the visual stimuli and so the VD task was used to pre-screen compound effects and to select an appropriate dose-range for testing in the PAL task. In the VD task, scopolamine at 0.1 mg/kg s.c. significantly reduced percent correct responses and the number of trials completed during the session and increased the latency to make a correct response. MK801 at 0.1 mg/kg s.c. significantly reduced percent correct responses, total completed trials, and increased the latency to make a correct response, whilst 0.025-0.075 mg/kg significantly reduced the latency to collect the food pellet. In the PAL task,

scopolamine dose dependently reduced percent correct responses and number of trials completed at 0.05 and 0.075 mg/kg. Moreover, the same doses significantly increased the latency to make a response and to collect the food reward. In the PAL task, MK801 dose dependently reduced percent correct responses without affecting the number of trials completed at 0.025 mg/kg. At 0.075 mg/kg there was a significant increase in latency to make a response, whereas at 0.025-0.05 mg/kg there was a significant decrease in latency to collect the food reward. Scopolamine impaired memory at doses which did not have an impact on discrimination of the visual stimuli, but did impair performance of the task. However, MK801 at doses which did not affect performance of the task selectively impaired visuo-spatial memory in the PAL task.

Title: Impairments in attentional performance and visual discrimination in the rat MAM model of schizophrenia

Authors: *D. YOUNG, W. M. HOWE, R. GRAF, S. M. O'NEILL, T. A. LANZ, R. KOZAK; Pfizer Inc, Cambridge, MA

Abstract: Schizophrenia is associated with a wide range of neurobiological and cognitive-functional abnormalities. However, identifying how disruptions across these domains specifically contribute to the etiology of the disease and may also serve as targets for treatment has been hindered by a lack of animal models that capture such broad symptomology. The gestational methylazoxymethanol (MAM) rodent model of schizophrenia is one that reproduces many of the structural, neurochemical, neurophysiological, and behavioral aberrations observed in schizophrenia (Lodge, 2013). We investigated the performance of MAM rats on two separate behavioral tasks that assess perceptual and attentional capacity: the visual discrimination task (VDT) and the sustained attention task (SAT). In the VDT, animals are presented with two stimuli and must press the correct image on a touchscreen in order to receive a food reward. MAM and sham controls were not significantly different in the time to acquire the task or on any performance measure. Once an animal reached criterion, the rules of the task were reversed, i.e.

the animal would need to press the opposite stimuli to receive reward; a total of two reversals were conducted. On trials that resulted in an incorrect response, MAM animals showed a significant increase in the latency to respond as compared to shams following a reversal. In the SAT, animals learn to press one of two levers which correspond to the presence or absence of a visual signal. MAM and sham controls displayed comparable levels of performance on the standard task. During the distracter version of the task (dSAT), in which a house light flashes on and off continuously at a rate of 0.5 Hz for a portion of the session, both groups were impaired similarly by the attentional challenge. However, MAM animals displayed a significant impairment in signal trial accuracy in the post-distracter recovery period of the session as compared to sham animals. These results suggest that the rat MAM model reproduces the impaired perceptual and attentional abilities observed in patients with schizophrenia. Studies are ongoing to assess the circuit bases of the behavioral disruptions observed here, with a particular focus on control of GABAergic and glutamatergic cortical circuitry by ascending dopaminergic and cholinergic systems. Together, the available evidence suggests that the MAM model can inform pre-clinical studies aimed at developing pharmacotherapies for the treatment of schizophrenia.

Title: Perineuronal nets protect fast-spiking interneurons against oxidative stress

Authors: *P. STEULLET[1], J.-H. CABUNGCAL[1], H. MORISHITA[2], R. KRAFTSIK[3], M. CUENOD[1], T. K. HENSCH[4], K. Q. DO[1];

Cell. Biol., Harvard Univ., Cambridge, MA

Abstract: A hallmark of schizophrenia pathophysiology is the dysfunction of cortical inhibitory GABAergic neurons expressing parvalbumin, a type of interneurons that are essential for coordinating neuronal synchrony during various sensory and cognitive tasks. High metabolic requirements of these fast-spiking cells may render them susceptible to redox dysregulation and oxidative stress. Using mice with a genetic redox dysregulation (*Gclm* KO mice with a reduced capacity of glutathione synthesis), we demonstrate that a specialized polyanionic matrix (perineuronal nets) enwrapping most of these interneurons as they mature, plays a critical role in the protection against oxidative stress. These nets limit the impact of genetically impaired anti-oxidant systems and/or excessive reactive oxygen species produced by severe environmental insults. A six-month redox dysregulation (as in 6 month-old *Gclm* KO mice) impairs many parvalbumin interneurons and their associated local neuronal synchrony, but spares those parvalbumin interneurons bearing well-formed perineuronal nets. We also observe an inverse relationship between the robustness of the perineuronal nets around parvalbumin interneurons and the degree of intracellular oxidative stress they display. Enzymatic degradation of the perineuronal nets renders mature parvalbumin interneurons (not calbindin and calretinin cells) and fast rhythmic neuronal synchrony more susceptible to oxidative stress. In parallel, parvalbumin interneurons enwrapped with mature perineuronal nets are better protected than immature parvalbumin interneurons surrounded by less condensed perineuronal nets. Thus, the high susceptibility of parvalbumin interneurons to oxidative stress during postnatal development is due in part to the yet incomplete maturation of this specialized extracellular matrix. While perineuronal nets act as protective shield, it is however itself sensitive to excess of oxidative stress. The protection might therefore reflect a balance between the oxidative burden on perineuronal net degradation and the capacity of the system to maintain the nets. Abnormal perineuronal nets as observed in *post mortem* brains of schizophrenia patients may thus underlie the vulnerability and functional impairment of pivotal inhibitory circuits in schizophrenia.

Title: A double-dissociation between the effects of MK-801 and Scopolamine in two touch-screen based tasks of hippocampal dependent spatial memory

Authors: *J. C. TALPOS, III, J. OLLEY, T. STECKLER;
Neurosci., Janssen Pharmaceutica NV, Beerse, Belgium

Abstract: A cognitive test battery now exists for use in touch-screen equipped operant boxes. While this approach holds promise, an important consideration is the ability of these assays to detect distinct and dissociable profiles after discrete regional (e.g. lesion), transgenic, or pharmacological manipulations. Here we report the affects of glutamatergic and cholinergic receptor antagonists on performance of the trial unique non-match to location (TUNL) task, as well as a touch-screen based automated search task (AST).
Rats (male Lister-Hooded, Harlan) were trained in TUNL or AST performed in Med Associates operant boxes run by K-Limbic software (Conclusive Solutions). In TUNL, a sample location would be displayed on the screen and the rat was required to poke at it. After a delay of 1 or 20s the rat had to choose between the original location and a new location displayed on the screen (96 trials per session). Effects of delay and spatial separation between the stimuli on performance were considered. In AST, a rat had to acquire the position of a specific location on the screen to obtain reward. The rewarded location would remain the same for 10 trials and then shift, requiring the rat to again find the rewarded location (80 locations per session). Both tests have previously been shown to be sensitive to lesions of the hippocampus, but their underlying neuropharmacology is unexplored. Once steady state performance had been achieved in TUNL or AST, MK-801 (0.025-0.075 mg/kg) or scopolamine (0.025-0.05 mg/kg) was administered. MK-801 impaired percent correct at all doses in TUNL, with delay dependent effects at 0.025 mg/kg and delay-independent effects at higher doses. A significant separation dependent effect was not observed in TUNL, although a tendency for such an effect was seen at 0.025 mg/kg. Scopolamine impaired percent correct at all doses tested; however 0.05 mg/kg also decreased responding. In AST, MK-801 impaired performance across all doses tested, while 0.025 mg/kg interacted with trial number, causing no impairment on the initial trial, but impairing performance on subsequent trials. In contrast, scopolamine only impaired performance on the first trial of a block.

In summary, MK-801 and scopolamine were capable of inducing impairments in primary cognitive measures in TUNL as well as in AST, however the pattern of impairments differed between drugs and tasks. These data indicate that these tasks have unique neuropharmacological underpinnings, and likely measure different cognitive processes. When used together TUNL and AST provide an effective means to separate the overlapping processes of attention, working memory, and spatial pattern separation.

Title: Mice carrying chromosomal microdeletions relevant to schizophrenia and performances on touchscreen tasks of learning and executive functioning

Authors: S. R. O. NILSSON, *L. M. SAKSIDA, T. W. ROBBINS, T. J. BUSSEY;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Chromosomal microdeletions at locations 22q11, 15q13 and 1q21 are among the largest known genetic risk factors for schizophrenia (Stone et al. 2008, Stefansson et al. 2008) and other psychopathologies. The current experiments tested transgenic (TG) mice carrying analogous microdeletions at chromosomal locations 22q11, 15q13 and 1q21 on touchscreen based tasks tapping learning and executive functioning. These tasks included the 5-choice serial reaction time task (5-CSRTT), used to assess attention and impulsivity, and two-choice visual discrimination and reversal learning, used to assess learning and cognitive flexibility.
15q13 TG mice showed attentional deficit in the 5-CSRTT with decreased accuracies at shorter stimulus duration. 1q21 TG mice showed impulsive responding in the 5-CSRTT with increased premature responses at longer delays. Although the genotype effect in the 1q21 TGs diminished with repeated testing, it could be restored with systemic amphetamine. 22q11 TG mice showed improved performance in visual discrimination, reversal learning, and the 5-CSRTT.
These data suggests that chromosomal microdeletions in mice affects cognitive functions relevant to schizophrenia.

Title: Modafinil fails to improve neonatal PCP-induced cognitive deficits in rats

Authors: S. J. SUKOFF RIZZO[1], T. A. LANZ[1], G. LU[2], A. SHAO[2], X. YU[2], S. M. O'NEILL[1], *R. KOZAK[1];
[1]Neurosci. Res. Unit, Pfizer, Cambridge, MA; [2]WuxiAppTecWuxiApptec Inc, Shanghai, China

Abstract: Recent clinical and preclinical evidence has implicated a role for modafinil in the treatment of cognitive impairments associated with schizophrenia. We evaluated the ability of modafinil to reverse cognitive deficits induced by treatment of neonatal rats with the NMDA receptor antagonist phencyclidine (PCP) that have been shown to induce schizophrenia-like symptoms including cognitive impairment. The neonatal PCP model is a neurodevelopmental model of schizophrenia based on resulting biochemical, synaptic, and behavioral changes observed within subjects in adulthood (Wang et al 2001; Broberg et al 2008). Briefly, newborn Long-Evans rat pups were treated with PCP (20 mg/kg, s.c.; neoPCP) or saline vehicle (neoSHAM) on postnatal days 7, 9, and 11. On PND ~56, male neoPCP and neoSHAM treated controls were assessed in a habituated locomotor activity test after acute challenge with PCP (5mg/kg, s.c.). neoPCP subjects demonstrated a significant increase in locomotor activity after acute PCP administration relative to neoSHAM treated controls ($p<0.05$). neoPCP rats were identified as low and high responders to acute PCP challenge, as defined by those individual subjects whose data for total distance traveled were below and above the group mean, respectively. One week following acute PCP challenge, subjects in the high responder group

(n=25) were selected for evaluation of spatial learning and memory in the widely used water maze task. neoSHAM and neoPCP rats were randomized into treatment groups (10 or 32 mg/kg modafinil or vehicle control, p.o.). Daily pretreatment with modafinil (30 min prior to first acquisition trial) did not improve escape latency or distance traveled to reach the hidden platform during the acquisition phase of the task. As expected, neoPCP rats demonstrated impairments in spatial memory retention during the probe trial relative to the neoSHAM group. This deficit was not reversed by modafinil. Furthermore, a significant reduction in GABAergic transcripts (parvalbumin, GAD1, GAD2) in neoPCP rat were observed in frontal cortex compared to the neoSHAM controls. Taken together these data demonstrate that neonatal PCP treatment results in long term neuronal and behavioral changes including hypersensitivity to acute PCP challenge and cognitive deficits that are not reversed by modafinil treatment.

Title: Dissecting the perceptual and cognitive profile of subchronic phencyclidine (PCP) administration in the rat using novel touchscreen-based assays

Authors: *A. C. MAR[1], S. BARBER[2], R. WOOLLEY[2], L. M. SAKSIDA[2], T. J. BUSSEY[2], T. W. ROBBINS[2];
[1]Behavioural and Clin. Neurosci. Inst., [2]Psychology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Schizophrenia patients show disruption in a variety of domains including sensory perception, attentional processing and executive function. Administration of N-methyl-D-aspartate (NMDA) receptor antagonists in rodents has been proposed as an animal model of cognitive dysfunction in this disorder. We examined the effects of sub-chronic phencyclidine

(sPCP) treatment (5mg/kg, twice daily for 7 consecutive days) in touchscreen-based behavioural assays for rodents - including a novel continuous performance test (rCPT) in which subjects are required to continuously attend, identify and touch briefly-presented target stimuli but to withhold responding to non-target stimuli. Twenty-eight Lister hooded rats were allocated to two experimental conditions: one group was pretrained and matched for baseline rCPT performance prior to sPCP or vehicle treatment, and the other trained and evaluated on rCPT only following sPCP or vehicle treatment. After an eight-day minimum washout period, the groups were reassessed or trained under baseline conditions, respectively, and further examined on a series of probe tests involving alteration of the perceptual and/or cognitive difficulty. Across both experimental conditions sPCP-treated rats showed comparable rCPT performance to vehicle-treated controls on measures of attention and inhibitory control. However, sPCP-treated rats exhibited significantly decreased target hit rate and response criterion when stimulus contrast levels were reduced (e.g., 12.5-25%). This highly selective pattern of results suggests that sPCP might provide a model of perceptual deficits in the visual magnocellular pathway that have been proposed as a putative endophenotype in schizophrenia. The discovery of such perceptual abnormalities may better frame some of the diverse behavioral effects observed in the sPCP model and aid in the identification of novel neural substrates for therapeutic intervention. These findings highlight the flexibility and sensitivity of the novel rCPT paradigm and related measures as well as the utility of the touchscreen method for translational research in psychiatry.

Title: Down-regulation of mGluR2 and mGluR6 receptors in the frontal cortex of neonatal phencyclidine(PCP)-treated adult rats, a developmental model of schizophrenia, reflects decreased promotor methylation at histon H3K4me3

Authors: M. J. MILLAN, B. CHANRION, *E. SCHENKER, B. P. LOCKHART, C. MANNOURY-LA COUR;
Inst. De Recherches Servier, Croissy Sur Seine, France

Abstract: Epigenetic mechanisms are strongly implicated in neurodevelopmental disorders like autism and schizophrenia (1), but the precise changes and functional consequences remain poorly defined. A recent study demonstrated large-scale changes in neuronal trimethylated histone H3-lysine 4 (H3K4me3) remodelling occur in early childhood (2) highlighting the importance of the H3K4me3 mark in mechanisms of neurodevelopment. We used the neonatal phencyclidine (PCP) neurodevelopmental model of schizophrenia to analyze whether epigenetic changes during development may contribute to altered gene expression characteristic of schizophrenia. Rats were injected during neonatal days 7, 9 and 11 with 10 mg/kg s.c. PCP. The mRNA expression of 50 target genes in PCP-treated adult rats (8 weeks) was studied and significant (ca. 30%) decreases in mGluR2 and mGluR6 mRNA expression seen in frontal cortex (FCX) and hippocampus. In parallel, levels of H3K4me3, a chromatin mark associated with transcriptional activation, was significantly decreased at mGluR2 and mGluR6 promoters in these structures in PCP-treated *versus* control adult rats. PCP treatment also was found to decrease mGluR2 protein levels in the FCX. Interestingly, we also found that the H3K4me3 mark progressively increased at mGluR2 and mGluR6 promoters in the FCX of control rats from a juvenile age (8 weeks) adulthood, while no increase was seen in PCP-treated rats. Finally, we checked the level of H3K4me3 in neuronal and non-neuronal nuclei of the PFC, and the reductions in H3K4me3 seen in PCP-treated adult rats at the mGluR2 promoter were restricted to neurones, with H3K4me3 unchanged in non-neuronal nuclei. These findings suggest that epigenetic mechanisms, specifically a loss of H3K4me3 recruitment, contribute to reduced neuronal mGluR2 and mGluR6 mRNA expression in a neurodevelopmental rat model of schizophrenia.

Title: Tackling behavioural variability: A case study with the MAM E17 rodent model of schizophrenia

Authors: *N. N. MALIK, F. GASTAMBIDE, M.-C. COTEL, B. EASTWOOD, S. FITZJOHN, J. LI, F. PASQUI, K. PHILLIPS, J. SHERWOOD, M. J. O'NEILL, G. GILMOUR, M. TRICKLEBANK;
Lilly Ctr. For Cognitive Neuroscience, Eli Lilly & Co Ltd, Surrey, United Kingdom

Abstract: One of the major challenges in schizophrenia research has been the development of suitable models for the cognitive aspects of the disorder. In this regard, one model that has been studied in some detail is the methylazoxymethanol (MAM) neurodevelopmental model. Our findings and those of other laboratories confirm that the MAM E17 model offspring exhibit several neurodevelopmental and pathological changes that bear similarities to schizophrenia. These include reductions in cortical thickness and hippocampal size, and enlargement of ventricles. Electrophysiological properties and sleep physiology are also affected, shown by changes in ES-coupling, sleep bout length and delta power. Behavioural consequences of MAM administration, largely emergent after puberty, include increased locomotor responsiveness to psychostimulant administration, pre-pulse inhibition and cognitive flexibility deficits.
However, the robust neuropathological and neurophysiological findings found in the MAM E17 model do not always translate into behavioural deficits and we have found them to be highly variable. This is of critical consequence for model validation and use in discovery research. In the present study we decided to tackle some of these issues by assessing key neuroanatomical (hippocampal volume, cortical thickness and ventricular enlargement), neurophysiological (electrophysiology, sleep and EEG) and behavioural outcomes (prepulse inhibition, reversal learning and fear conditioning) in a large pool of 240 rats coming from 66 different litters. This design allowed us to perform a correlation analysis to assess if deficit in one assay could predict a deficit in another assay and also to assess within litter correlations. The variability in behaviour effects will be discussed as well as study design, litter effects and statistical analysis.
Overall, our data suggest that maternal treatment with MAM on embryonic day 17 leads to persistent alterations in the adult offspring of Sprague Dawley rats that are relevant for modelling aspects of schizophrenia - but revised methods for study design and statistical analysis are crucial to avoid misinterpretation of findings.

Title: Attentional deficits following postnatal NR1 knock-out in corticolimbic interneurons

Authors: M. HVOSLEF-EIDE[1], L. LYON[2], A. C. MAR[2], K. NAKAZAWA[3], L. M. SAKSIDA[2], *T. J. BUSSEY[1];
[1]Dept. of Exptl. Psychology, [2]Deparment of Exptl. Psychology, Univ. of Cambridge, Cambridge, United Kingdom; [3]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Mouse models that focus on simulating the cognitive deficits observed in patients with schizophrenia are increasingly becoming available. Thorough understanding of the nature of the deficits displayed is essential both for validation of the models as well as for pre-clinical drug screening. Recently it has been shown that postnatal (but not adult) knockout (KO) of the NR1 subunit of the NMDA receptor in 40-50%
of corticolimbic interneurons of mice is sufficient to produce post-adolescent schizophrenia-related phenotypes (Belforte et al., 2009). The extent to which these mice display further cognitive impairments, and the degree to which such impairments relate to those observed in patients, is currently unknown. Using touchscreen-equipped operant chambers, the ability of NR1 KO mice to acquire a visual discrimination and reversal was investigated. Additionally, attentional capacity was probed using the 5-Choice Serial Reaction Time Task (5CSRTT) and a novel rodent version of the continuous performance task (CPT). Compared to littermate controls, NR1 KO mice were significantly impaired on the CPT. This impairment in CPT performance could not be explained by simple discrimination impairments, as standard visual discrimination and reversal did not differ from controls. Furthermore, only a mild deficit could be detected in

the 5CSRTT, suggesting a specific deficit when required to attend to a single location involving the detection of a visual signal against noise. The specificity of the impairment in a task highly relevant to schizophrenia suggests that the manipulation of corticolimbic interneuron functionality at a critical developmental stage could be a valuable model of schizophrenia-like cognitive dysfunction.

Title: Sex differences in the role of brain corticotropin releasing factor (CRF) and norepinephrine (NE) in drug seeking during initial abstinence

Authors: *A. M. CASON, A. BOURREZA, M. W. FELTENSTEIN, G. ASTON-JONES; Med. Univ. South Carolina, CHARLESTON, SC

Abstract: Brain locus coeruleus NE (LC-NE) and CRF neurons are involved in stress responses, including the ability of stress to drive drug relapse. Previous animal studies indicate that female rats exhibit greater drug seeking than male rats during initial drug abstinence. Moreover, females are more sensitive to the effect of stress to drive drug seeking than males. Finally, brain LC-NE neurons are more sensitive to the stress peptide CRF in females compared to males (Curtis et al., 2006). We hypothesized that this increased drug seeking in females on extinction day one (ED1) is due to an increased response to the stress of early withdrawal (initiation of abstinence) and is dependent upon the increased response of LC in females to CRF. Therefore, we tested the

hypothesis that pretreatment with CP 154,526, a CRF receptor antagonist, would decrease drug seeking on ED1 as measured by responding on an active lever previously associated with cocaine self-administration. Male and female rats were trained to lever-press for iv cocaine in an operant chamber in 2-h daily sessions. After 10 self-administration sessions in which they earned ≥ 10 infusions, rats underwent a 90-120 min test for extinction responding by measuring lever pressing in the absence of cocaine reward (ED1). Twenty min prior to this extinction session, rats were injected (ip) with vehicle or CP 154,526 (CP), to measure effects of CRF antagonism on drug seeking during early abstinence. Pretreatment with the CRF1 receptor antagonist CP (10-20 mg/kg) decreased cocaine seeking on ED1 to similar levels in male and female rats. These findings indicate that signaling at CRF receptors are involved in the increased drug seeking during initial abstinence.
Following the ED1 cocaine seeking test, rats were killed and their brains were processed with immunohistochemistry to identify NE and CRF neurons that were Fos-activated during the ED1 cocaine seeking test. Our preliminary findings indicate that there is increased Fos expression in LC-NE neurons in vehicle treated female rats (n=4) compared to male rats (n=3) rats on ED1. Ongoing studies are examining the effects of pretreatment with CP on Fos expression in LC and NE neurons in other brain areas of male and female rats.

Title: Role of oxytocin neurons in mediating the behavioral response to early extinction from cocaine self-administration: Comparisons between female and male rats

Authors: *M. E. SMITH, A. M. CASON, G. ASTON-JONES;
Dept Neurosci, MUSC, CHARLESTON, SC

Abstract: Several studies find that drug seeking on the first day of extinction (Extinction Day 1, ED1), after a period of cocaine self-administration, is substantially greater in female compared to male rats. Moreover, stress responses, and drug relapse propensity, is greater in women than in men. The first day of extinction is important as it represents the initiation of abstinence, which is

stressful due to absence of chronic drug. The hypothalamic neuropeptide oxytocin (OT) is involved in reward and "anti-stress" processes; for example, OT release is stimulated by stress (Plotsky 1987). Therefore, it is possible that OT cells are affected by the stress of initial abstinence, and may contribute to male-female differences in early drug seeking.
Male, Sprage-Dawley rats were implanted with indwelling jugular catheters and trained to self-administer cocaine iv (daily 2 hr sessions, 0.2mg/kg/ infusion). Following 10 days of stable FR1 responding (>25 infusions/session) rats were placed in the self-administration chamber for an initial extinction session (2 hr, no cocaine infusions given) or remained in their home cages. Rats were then deeply anesthetized, transcardially perfused with saline and 4% paraformaldehyde, and the brains were removed and processed for immunohistochemical localization of Fos and OT.
Preliminary results indicate that the expression of Fos in OT neurons is decreased in male rats subjected to ED1 training compared to similar animals that instead remained in their home cages. Such a decrease in the activity of OT neurons may contribute to the negative effects of the period of initial abstinence; experiments with females are underway to evaluate these results with males because of known sexual dimorphisms. Given the role of norepinephrine (NE) and corticotropin releasing factor (CRF) systems in stress responses, and interactions of these systems with OT neurons, we will also examine Fos in NE and CRF neurons on ED1 and test whether NE or CRF neurons play a role in the response of OT neurons on ED1.
We hypothesize that treatments that modulate OT transmission during the early withdrawal from cocaine abuse may facilitate initiation, as well as subsequent maintenance, of abstinence, particularly in female addicts.

Title: Dopamine DREADDs: Chemicogenetic control of midbrain dopamine activity during reinstatement of cocaine seeking

Authors: *S. V. MAHLER, E. M. VAZEY, G. ASTON-JONES;
Neurosciences, Med. Univ. of South Carolina, CHARLESTON, SC

Abstract: Ventral Tegmental Area (VTA) is crucial for many reward-related behaviors, and both dopamine and non-dopamine neurons there play complex roles in reward and motivation. Although VTA dopamine neurons are clearly involved in reward, a lack of specific tools to selectively manipulate dopamine neurons has limited our ability to test their specific functions in behaving animals.
Designer receptors exclusively activated by designer drugs (DREADDs) are synthetic G-protein coupled receptors that are inert, except in the presence of their agonist, CNO (which is otherwise pharmacologically inert). DREADD-expressing neurons can therefore be experimentally controlled in a highly selective, "lock-and-key" manner. DREADDs can be targeted to VTA or substantia nigra dopamine neurons via local microinjections of viral vectors containing a floxed DREADD gene into transgenic rats, whose dopamine neurons express Cre recombinase (TH::Cre rats). This approach allows "remote control" of dopamine neuron activity via systemic injections of CNO.
Here, we use viral vectors to express DREADDs in VTA dopamine neurons, and in their inputs from ventral pallidum, in TH::Cre transgenic rats. We expressed excitatory or inhibitory DREADDs (Gs, Gq, and Gi-coupled) in midbrain dopamine cell populations, and examined effects on cue-induced or cocaine-primed reinstatement of cocaine seeking, and on VTA cell firing patterns. We also examined effects of manipulating the reinstatement-related inputs from ventral pallidum to VTA dopamine neurons on reinstatement and VTA cell firing. Results reveal that VP is a critical input to VTA for cued reinstatement of cocaine seeking.

Title: Specific roles of hippocampal and lateral septal neurons in context- vs. cue-induced reinstatement of cocaine seeking: Fos and DREADD studies

Authors: *E. M. MCGLINCHEY, G. ASTON-JONES;
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Drug relapse often occurs when addicts are re-exposed to drug-associated contexts or discrete drug cues. In a rodent model of addiction, this is modeled by context- or cue-induced reinstatement of extinguished drug seeking. The dorsal hippocampus has been found to be necessary for context-, but not cue-induced reinstatement, suggesting different circuits may mediate these two modalities. Recent evidence from our lab revealed a functional circuit between the hippocampal CA3 neurons to the ventral tegmental area (VTA), via a relay in the caudal-dorsal lateral septum (cdLS). As the CA3 region is important for contextual processing and the VTA in reward processing, this circuit indicates the cdLS may be important for linking contextual information with reward seeking. It is clear from early self-stimulation studies in both humans and rodents that the lateral septum plays a role in reward-driven motivation; however, this brain region has been largely understudied in drug abuse and relapse. This study aims to understand the role of the hippocampus-lateral septum circuit in the context- vs. cue-induced reinstatement of cocaine seeking. A modified self-administration model of addiction was designed to dissociate between the drug-associated contextual environment and the discrete light/tone cues paired with cocaine infusions during training. All rats trained to self-administer cocaine with light/tone cues in one context, extinguished this behavior in an alternative context (without light/tone cues), and either reinstated in the training context without the light/tone cues (context reinstatement, ABA) or in the extinction context using the light/tone cues (cued reinstatement, ABB). Fos expression was used as a marker of neuronal activation in the hippocampus (CA3, CA1, and dentate gyrus) and lateral septum (cdLS, caudal LS, rostral LS) following context or cued reinstatement tests. Fos expression was greater in all lateral septum and dorsal hippocampal sub-regions for context- compared to cue-induced reinstatement. Furthermore, preliminary data indicate that inhibition of LS neurons using Designer Receptors Exclusively Activated by Designer Drug (DREADD) technology may attenuate context-induced, but not cue-induced reinstatement. Together these findings indicate that the hippocampal-LS circuit may be important for drug reward-environment associations that drive addicts to relapse.

Title: Oxytocin reduces the motivation to self-administer methamphetamine in a novel within-session behavioral-economic paradigm: Male-female comparisons

Authors: *B. M. COX, B. S. BENTZLEY, C. M. REICHEL, R. E. SEE, G. ASTON-JONES; Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Human and animal studies indicate that females have greater motivation to use methamphetamine (meth), which may contribute to enhanced relapse vulnerability. Women initiate meth use at a younger age and transition faster to dependence than men. Similarly, female rats acquire meth self-administration at higher rates and exhibit greater meth intake than males. Under a progressive ratio schedule of reinforcement, female rats show more motivation to seek meth. However, factors that influence the desired levels of intake (e.g., tolerance, sensitization) must also be considered when measuring motivation for drug, and the progressive ratio test does not account for intake differences associated with such factors. Behavioral-economic (BE) models have been designed to assess changes in consumption as a function of effort and provide separate measures of meth intake (Q_0) and motivation normalized to intake (α, a measure of demand elasticity). These measures have been shown to predict relapse in both human and animal studies, indicating that BE models will further our understanding of the relationship between motivation to seek drug and relapse behavior, and facilitate screening novel pharmacotherapies for treatment of addiction. Thus, utilizing a within-session BE paradigm, we used these measures to directly compare males and female rats during meth self-administration. We also tested oxytocin, a potential antirelapse medication, for its ability to attenuate meth seeking in both sexes. Females showed greater motivation to seek meth (lower α) compared to males and higher meth intake (higher Q_0). Oxytocin decreased motivation to seek meth in both sexes, but did not alter their intake at null price. Correlations between behavioral-economic and reinstatement measures, and determination of whether oxytocin during the within-session BE paradigm can predict attenuation of subsequent reinstatement, will also be presented. Overall, this novel paradigm will help to delineate sex differences observed in motivation to seek meth and may predict the efficacy of pharmacotherapies to treat meth addiction.

Title: Adaptive demand: DREADD mediated stimulation of locus coeruleus during a within-session behavioral economics procedure

Authors: *Z. A. COPE[1], B. S. BENTZLEY[1], E. VAZEY[1], B. L. ROTH[2], G. S. ASTON-JONES[1];
[1]Neurosci., Med. Univ. of South Carolina, Charleston, SC; [2]Pharmacol., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Modern theories of behavioral control posit a pivotal role for locus coeruleus-norepinephrine (LC-NE) neurons in appropriately directing attention according to utility and task demands. The Adaptive Gain Theory (AGT; Aston-Jones and Cohen, Ann Rev. Neurosci 2005) states that when task utility (reward value) is high it is adaptive to focus attention on task completion, and that such focused attention is facilitated by low tonic (baseline) LC activity with high phasic (bursting) responses associated with decision completion preceding a behavioral response. Conversely, when the utility of an ongoing behavior wanes, it becomes adaptive to disengage from the task to seek out other tasks with possibly greater reward. The AGT proposes that phasic firing of LC decreases and tonic activity increases to facilitate task disengagement in the face of sustained low utility. Behavioral-economic methods measure dynamic changes in demand as a function of price, i.e. the effort required of a rat to obtain a reward. Here, we employed a within-session behavioral-economic procedure to assess changes in demand for cocaine as a function cocaine price (lever responses/mg cocaine). At high prices, the utility of performing the behavior wanes, and motivation no longer supports the increased effort needed to obtain reward. The maximum price that maintains increases in response rate is known as Pmax. We hypothesize that high tonic discharge of LC-NE neurons causes attention to be disengaged from a task at a lower Pmax than lower tonic LC-NE activity. LC-NE neurons were tonically activated using the excitatory hM3Dq DREADD receptor (Designer Receptors Exclusively Activated by Designer Drugs). This DREADD was selectively expressed in LC-NE neurons with in vivo microinjections of a viral vector containing the synthetic dopamine beta hydroxylase

promoter, PRSx8. Morphological and electrophysiological studies showed this vector to be effective in transducing and activating LC-NE neurons (see Vazey and Aston-Jones, this meeting). After cocaine self-administration training, animals were randomized to receive one of three doses of the selective DREADD agonist, clozapine-N-oxide (CNO; 0, 1, or 10 mg/kg, ip) 30 min prior to testing in the within-session behavioral economic procedure. A decrease in Pmax in response to CNO would provide evidence for a causal role of LC in modifying behavior in response to changing task demands and utility. Further results and conclusions will be discussed. Supported by PHS grants R01-MH092868, R37-DA006214 and F30-DA035065.

Title: Inactivation of the subthalamic nucleus decreases the economic essential value of cocaine

Authors: *B. BENTZLEY, G. ASTON-JONES;
Med. Univ. of SC, Charleston, SC

Abstract: Economic essential value of a drug has been shown to correlate with several clinical measures of addiction. In an animal model of relapse, essential value predicts cue-induced reinstatement of methamphetamine and cocaine seeking. The current study determined the role of the rat subthalamic nucleus (STN) in driving the economic essential value of cocaine. Consumption of cocaine was measured at 11 ascending cocaine prices (lever responses/mg cocaine) in a single 110-min session. Rats were pretreated with bilateral microinjections (0.3 μL) into STN of either vehicle (artificial cerebrospinal fluid) or the $GABA_A$ receptor agonist muscimol (0.2 mM) immediately prior to sessions in a within-subjects crossover design. Muscimol pretreatment significantly attenuated the essential value of cocaine compared to vehicle or injections of muscimol immediately dorsal to STN. In contrast, muscimol pretreatment

did not reduce cocaine consumption when the price of cocaine remained low throughout the session (e.g., FR1 schedule), indicating that STN inactivation results in price-dependent changes in cocaine consumption. Further, muscimol treatment did not alter locomotor activity in a novel environment. Given the clinical promise of economic measures of drug use, these results support a possible clinical utility of STN inactivation in treating cocaine abuse - akin to STN deep brain stimulation for treatment of Parkinson's disease, obsessive-compulsive disorder and major depression. Title: Conditioning with highly palatable food rewards: A role of orexin on attention?

Authors: *L. R. FREEMAN, G. ASTON-JONES;
Neurosciences, Med. Univ. of South Carolina, CHARLESTON, SC

Abstract: Orexin neurons provide a well-known link between regulating vital functions and body energy status, but they are also known for their major input to arousal and reward centers. In fact, lateral hypothalamic orexin neurons have widespread connections throughout the brain. In the current study, orexin neurons and the effects of their projections to the medial prefrontal cortex (mPFC) were evaluated for conditioned responding to highly palatable food rewards. Male Sprague-Dawley rats were divided into two groups; one group was trained to lever-press for standard chow pellets ("Chow") and the other group was trained to lever-press for a high-fat, sucrose pellet ("HFS") on a fixed-ratio 1 schedule (FR-1). Subsequently, all rats were switched to a Go/No-Go paradigm with a new, highly palatable reward: chocolate-flavored sucrose. Preliminary results reveal no change in Go trial success in either group, but increased success on No-Go trials for HFS-conditioned rats. These results reveal a potential improvement in attention for food-motivated tasks after HFS training. In a recent study by Figlewicz et al. (2013), moderate high fat diet consumption increased sucrose self-administration compared to chow-fed control rats. The Sclafani group reported that lateral hypothalamus (in the area of orexin neurons) is involved in flavor-nutrient conditioning (2002), and another study has shown that infusions of orexin into mPFC can improve attention of rats (Furudono et al. 2006). From these and other results, we hypothesize that rats previously trained with HFS exhibit greater attention and/or motivation during subsequent Go/No-Go training due to elevated orexin transmission. We are currently testing this hypothesis by examining Fos induction in orexin and mPFC neurons. Future studies will further test the role of orexin utilizing an orexin antagonist with this paradigm. Title: Palatable food entrainment: A model of food addiction in rats

Authors: *S. GONZALEZ-GARCIA[1], S. BLANCAS[2], G. ESTRADA[2], M. HERNANDEZ[2], L. UBALDO[2], C. ESCOBAR[2];

Abstract: Recent reports suggest that consumption of palatable food induces similar neuroadaptive responses as drugs in the reward system. ΔFosB is a stable, long lasting protein believed to be involved in these changes. When 5g. of chocolate are offered daily at the same hour for up to 3 weeks rats exhibit anticipatory activity expecting chocolate access and this behavior persists for many days after the protocol is interrupted. The aim of this study was to determine if this behavior can reflect a process of addiction. Therefore we assessed whether rats would exhibit effort to obtain chocolate and determined changes of ΔFosB expression in the reward system. We also determined anticipatory changes in general activity and body temperature. Methods. Male Wistar rats (250 g) were housed in individual cages in a 12/12 cycle, fed with chow and water ad libitum. Intraperitoneal iButtons programmed to collect temperature were implanted. Rats assigned to chocolate entrainment received for 21 days 5g. of chocolate at 13:00. Brains were obtained of rats after chocolate ingestion or during chocolate anticipation and were compared with control undisturbed rats. Brains were prepared for immunohistochemistry for ΔFosB. We designed a wire box cube in which we put the 5 g piece of chocolate. This allowed the animals to see and smell the chocolate but could not touch, scratch or bite it. The aim was to determine the effort of rats to obtain the snack. After 3 weeks of chocolate entrainment rats exhibited anticipatory activity in behavior and body temperature and exhibited increased expression of ΔFosB in the nucleus accumbens, basolateral amygdala and prefrontal cortex. They also exhibited significant effort events to obtain chocolate. Conclusion: Scheduled access to chocolate entrains the circadian system and produces changes at the neuronal and behavioral level similar to those observed in drug abuse.

Title: Operant intraoral self-administration of high fructose corn syrup in laboratory rats

Authors: *A. LEVY[1,2], C. LIMEBEER[2], J. FERDINAND[2], U. SHILLINGFORD[2], L. PARKER[2], F. LERI[2];
[1]Psychology, [2]Univ. of Guelph, Guelph, ON, Canada

Abstract: The similarities between obesity and drug dependence suggest the hypothesis that "addiction" can develop to food. The current studies investigated whether principles of behavioral pharmacology that regulate intake of drugs of abuse also apply to intake of sweets. Rats implanted with intraoral cannulas were allowed to self-administer sweet solutions directly in their oral cavity. High fructose corn syrup (HFCS) was selected because of its association with overeating and obesity.
First, it was determined that intraoral self-administration (IOSA) was concentration-dependent. That is, intake was higher when the concentration of HFCS was lower (25% vs 50%). At an intermediate concentration (8%), responding was more variable, and tests using the progressive ratio schedule indicated a positive linear relationship between concentration and break points achieved. Second, self-administration of HFCS was regulated by the nutritional consequences of IO infusions. In fact, animals adjusted intake when the concentrations were altered. Third, taste/palatability also played a role in IOSA. In fact, higher concentrations engendered higher hedonic reactions measured by taste reactivity tests. This role, however, was significantly modulated by the caloric value of the reinforcer because when rats self-administered a concentration of saccharin that produced hedonic reactions similar to those induced by 25% HFCS, self-administration was very low. In addition, rats trained on 25% HFCS stopped responding when 0.1% w/v saccharin was substituted for HFCS.

The sensitivity of IOSA to differences in concentrations and schedules of reinforcement makes it an ideal procedure to investigate features of addictive-like behaviors engendered by voluntary intake of sweets.

Title: Prefrontal cortical neuroadaptations following self-administration and reinstatement of highly-palatable food: The role of brain-derived neurotrophic factor

Authors: *S. M. BARRY[1], M. N. HUIZENGA[2], G. SADRI-VAKILI[2], J. F. MCGINTY[1]; [1]Neurosci. Inst., Med. Univ. of South Carolina, Charleston, SC; [2]MassGeneral Inst. for Neurodegenerative Dis., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Obesity has become an increasingly prevalent public health problem in the United States. Recently there has been a shift in understanding obesity and studies are now focused on the psychological factors involved in the development of the disease. Brain-derived neurotrophic factor (BDNF) has an integral role in glucose regulation, satiety, and control of food consumption. There is extensive evidence that altered BDNF signaling plays a role in chronic overconsumption of food to the point of obesity. Selective BDNF knockdowns have further implicated BDNF in selectively enhanced palatable food intake. We used an operant model of animal food self-administration to examine the differences in food self-administration and reinstatement between groups of Sprague Dawley rats lever pressing for either standard chow pellets or palatable chocolate pellets with an enhanced sucrose content. Our results indicate that BDNF protein levels in the dmPFC, an area highly implicated in control of reward seeking behavior, was decreased immediately following 7 weeks of self-administration of palatable chocolate pellets. Additionally, preliminary evidence indicates a possible down regulation in total mRNA of BDNF's activity dependent exon IV transcript in dmPFC. In a separate cohort, we found that rats will escalate their lever pressing to receive palatable pellets but not standard chow pellets over the last 5 weeks of self-administration. Following extinction of lever pressing, both groups of rats reinstated with a cue and pellet prime. However rats that self-administered standard chow pellets reinstated to a greater degree than those that self-administered the chocolate pellets. Furthermore, pellet and cue primed reinstatement of palatable food seeking produced greater activation of the prelimbic (PrL) cortex than reinstatement of standard chow seeking. These data provide both a role for BDNF and the PrL in palatable food self-administration and seeking, respectively.

Title: Context-induced reinstatement to alcohol seeking after punishment is associated with activation of nucleus accumbens shell projections to lateral hypothalamus

Authors: *N. J. MARCHANT, R. RABEI, J. M. BOSSERT, A. BONCI, Y. SHAHAM;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Background: Alcoholics typically abstain because of negative consequences associated with excessive drinking. During abstinence, relapse is often triggered by exposure to contexts previously associated with alcohol use. To model this condition, we developed an animal model of context-induced relapse where alcohol seeking is suppressed by adverse consequences (punishment; Marchant et al., 2013). Here, we identify activated projections from nucleus accumbens (NAc) shell to lateral hypothalamus (LH) during relapse after punishment.
Methods: We injected the retrograde tracer cholera toxin subunit B (CTb) into LH of alcohol-preferring (P) rats to label NAc shell neurons projecting to LH. Next, we trained rats to lever-press for 20% alcohol in context A, followed by mild-shock punishment of alcohol self-administration in context B. After punishment, we tested rats under extinction conditions without shock in either context A (ABA) or context B (ABB); a third control group (ABO) was not tested. After testing, we anesthetized, perfused, and extracted brains of rats to measure Fos (neuronal activity marker) and CTb+Fos in NAc shell.
Results: Alcohol seeking (lever-presses) was higher in group ABA than group ABB, demonstrating context-induced relapse after punishment. This relapse was associated with higher Fos expression in LH neurons, as well as a higher percentage of LH projecting NAc shell neurons (Fos-Ctb double-labeled neurons).
Summary: Context-induced relapse to alcohol seeking after punishment is associated with activation of both LH neurons and NAc shell neurons that project to LH. We are currently examining the causal role of NAc shell to LH projections in this relapse.

Title: Effects of amphetamine exposure during adolescence or adulthood on reward devaluation

Authors: *E. R. HANKOSKY[1], N. M. KOFSKY[1], C. HONG[1], J. M. GULLEY[2];
[1]Psychology, [2]Psychology & Neurosci. Program, Univ. Illinois Urbana-Champaign, Champaign, IL

Abstract: Drug use typically begins in adolescence, which is a period of ongoing neurobiological development that may confer heightened vulnerability to develop drug dependence. Previously, our lab has shown that amphetamine (AMPH) exposure during adolescence alters orbitofrontal cortex (OFC)-sensitive behaviors, such as behavioral flexibility and reversal learning. Here, we investigated the sex- and age of exposure-dependent effects of AMPH on an OFC-sensitive outcome devaluation task. Male and female Sprague-Dawley rats, born from breeders maintained in our facility, were injected (i.p.) with saline or 3 mg/kg AMPH every other day between postnatal day (P) 27-45 and P85-103. On P125, rats were trained twice daily for 10 days on a Pavlovian conditioning task where a conditioned stimulus (CS; tone or flashing lights) was paired with a specific reward (orange- or grape-flavored sucrose). Subsequently, one of the two rewards was devalued (via 2 hours of free access) and rats were then given a devaluation test session consisting of 5 presentations of each CS delivered under extinction conditions. Twenty minutes prior to the devaluation test, rats were injected with vehicle or 1 mg/kg SB 242084 (5-HT2C antagonist). Our preliminary data suggest that females and adolescents treated with AMPH continue to exhibit conditioned responses to the CS paired with a devalued outcome, suggesting their behavior is driven by reward-associated cues rather than the value representation of the reward. This may be due to alterations in 5-HT signaling as pretreatment with SB 242084 partially restored outcome devaluation in these groups. Overall, our preliminary results suggest that AMPH exposure impairs OFC-sensitive cognitive flexibility in females and rats exposed during adolescence via deficits in 5-HT2C receptor function.

Title: Amphetamine exposure during adolescence alters synaptic plasticity in young adulthood via adaptations in dopaminergic signaling

Authors: *S. KANG[1,2], C. L. COX[2,3,4], J. M. GULLEY[2,5];
[2]Neurosci. Program, [3]Dept. of Mol. and Integrative Physiol., [4]Dept. of Pharmacol., [5]Dept. of Psychology, [1]Univ. of Illinois At Urbana Champaign, Champaign, IL

Abstract: Our previous studies suggest that repeated exposure to amphetamine (AMPH) during adolescence induces long-lasting changes in dopamine receptor function in the medial prefrontal cortex (mPFC). Given the key role of dopamine in regulating synaptic efficacy, we hypothesized that adolescent AMPH exposure would have enduring effects on neuronal plasticity in the mPFC. To test this, we treated male Sprague-Dawley rats with saline or 3 mg/kg AMPH (i.p.) every other day from postnatal day 27 to 45 (10 injections total). Three to four weeks later, rats were sacrificed and tissue slices containing the mPFC were prepared for field potential recordings. In saline-treated rats, we found high frequency stimulation (HFS) at 50 Hz induced long-term depression (LTD). Application of the D_1 antagonist SCH23390 (10 µM) blocked the induction of LTD. In these slices, the same tetanic stimulation produced long-term potentiation (LTP) in the presence of low- concentration $GABA_A$ receptor blockade (bicuculline methiodide, BMI; 0.1 µM). In AMPH pre-treated rats, HFS led to LTP without BMI, suggesting that adolescent AMPH exposure induces a long-lasting impairment of inhibitory modulation in the mPFC. To investigate the role of altered D_1 signaling in this effect of AMPH exposure, we performed whole-cell path recording of deep layer pyramidal cells in the mPFC. In slices from controls, we found a significant increase in the frequency of spontaneous inhibitory post-synaptic currents (sIPSCs) following activation of D1 receptors by SKF38393 (10 µM) application; this effect was not observed in slices from AMPH exposed rats. Taken together, our data suggest that adolescent AMPH exposure impairs D_1-mediated modulation of inhibitory transmission in the PFC, which in turn has a long-lasting disruptive effect on synaptic plasticity. This drug-induced predisposition to LTP may alter normal cognitive functioning as the PFC network would be expected to be relatively more “noisy” and unable to filter and process information appropriately.

Title: Repeated oxycodone exposure impairs reversal behavior when contingencies change rapidly

Authors: *K. M. SEIP-CAMMACK, M. SHAPIRO;
Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Persistent drug seeking in drug-abstinent individuals may reflect a general problem with behavioral inflexibility, a difficultly disengaging from ongoing behavior. This inflexibility may be caused by inaccurate encoding of reward history and thereby disrupts organized, goal-directed behaviors. While exposure to illicit drugs is associated with inflexible responding, less is known about the effects of prescribed opiate analgesics, such as oxycodone, on flexible, adaptive responses. The present study investigates the degree to which prolonged exposure to oxycodone alters sensitivity to reward history when contingencies change frequently or infrequently. We hypothesized that oxycodone-exposed rats would be impaired at updating reward representations, regardless of how often contingencies changed, and predicted that this impairment would slow learning and increase perseverative responding for previously rewarded stimuli. Adult male rats were trained to enter a specific goal arm on a radial arm maze to find food. After reaching a criterion of eight consecutive correct trials, they were given 24 additional trials to establish stable performance. The next day, the rats were exposed repeatedly to oxycodone (3mg/kg, 2x/day) or vehicle for five days. On the first drug-free day (Day 6), stable performance on the initial task was confirmed. On Days 7-8, the goal arm was changed at different frequencies. During low-frequency reversals (LFRs), rats were trained to a criterion performance of eight consecutive correct trials, followed by an additional 12 trials, before the goal arm was changed. During high-frequency reversals (HFRs), the goal arm changed after the rat made three consecutive correct choices. Before drug exposure, all rats rapidly acquired the initial task; after drug exposure, all rats learned new stimulus-reward associations (reversals) during the LFR task and showed equivalent stable performance on each new goal arm. In contrast, during the HFR task, oxycodone-exposed rats required more trials to learn rapid reversals and made more perseverative errors than controls, especially on the first reversal. The effect of oxycodone exposure varied with training history, so that rats trained first in the HFR task were not impaired in either HFR or LFR tasks. Thus, oxycodone exposure may impair rats' ability to update response strategies when they have a history of stable reward contingencies. In rats given a relatively stable reward history, this impairment may contribute to persistent responding for previous rewards, including drugs of abuse. **Support:** F32-DA030831 to KSC and R01-MH073689 to MS

Title: L-type calcium channel blockade in the VTA disrupts cocaine-associated contextual memory

Authors: *M. DEGOULET[1], C. E. STELLY[1], K.-C. AHN[2], H. MORIKAWA[1];
[1]Waggoner Ctr. For Alcohol and Addiction Res., Austin, TX; [2]Dept. of Psychiatry, Brain Res. Ctr., University of British Columbia at Vancouver, BC, Canada

Abstract: Development of drug addiction involves a maladaptive form of learning and memory in which drug-related experiences are remembered powerfully, resulting in persistent and uncontrollable drug seeking behavior even when the drug becomes unavailable during abstinence or extinction. We have shown previously that long-term potentiation (LTP) of NMDA receptor-mediated glutamatergic transmission onto dopamine (DA) neurons in the ventral tegmental area (VTA) is an important substrate for such learning and memory processes. L-type Ca2+ channels (LTCCs) control synaptic plasticity in different brain regions. Indeed, systemic/intracerebroventricular administration of LTCC antagonists has been shown to suppress the development of conditioned place preference (CPP) induced by psychostimulants and other drugs of abuse. Although CaV1.2 LTCCs are the predominant subtype in the brain, recent studies indicate important roles of CaV1.3 LTCCs in DA neuron Ca2+ signaling and psychostimulant-induced neuroadaptations. Therefore, we investigated the effects of CaV1.2 and CaV1.3 LTCC antagonists, applied directly into the VTA, on different phases of cocaine-induced CPP (10 mg/kg, i.p., three conditioning sessions) in male Sprague Dawley rats. Intra-VTA injection of the CaV1.2/CaV1.3 LTCC antagonist isradipine (0.6 pmol/0.3 µl/side) before each cocaine conditioning session completely abolished the acquisition of CPP. To test the effect of isradipine on CPP expression, rats were first subjected to CPP conditioning and 1st post-conditioning test (i.e., CPP expression test), then intra-VTA isradipine injection was made before the 2nd posttest. Although isradipine had no effect on CPP expression, CPP was completely extinguished when 3rd and 4th posttests were performed on the next two days without isradipine injection. Furthermore, previously isradipine-treated animals displayed no cocaine-induced

reinstatement when cocaine was injected before the 5th posttest. Intra-VTA injection of the newly developed selective CaV1.3 LTCC antagonist "compound 8" (6 pmol/0.3 µl/side; provided by Dr. Jim Surmeier at Northwestern University) also facilitated CPP extinction and prevented cocaine-induced reinstatement. In VTA slices, we found that isradipine (2 µM) had no effect on NMDA EPSCs or NMDA-dependent burst firing in DA neurons, consistent with the ineffectiveness of isradipine on CPP expression. We hypothesize that LTCC antagonists might interfere with the acquisition and maintenance of drug-associated contextual memories by affecting induction and reversal processes of NMDA LTP in the VTA.

Title: Modafinil rescues methamphetamine-Induced cognitive deficits in object recognition memory in mice: Role of ERK1/2 phosphorylation in prefrontal cortex

Authors: B. GONZALEZ[1], M. RAINERI[1], N. COLETTIS[2], J. CADET[3], E. GARCIA-RILL[4], F. J. URBANO[2], *V. BISAGNO[1];

Abstract: Chronic use of methamphetamine (METH) leads to long-lasting cognitive dysfunction in humans and animal models. Modafinil is a wake-promoting compound approved for the treatment of sleeping disorders and is being prescribed off label for the treatment of METH dependence. In the present study, we evaluated deficits in visual memory and ERK1/2

phosphorylation in the prefrontal cortex of mice treated chronically with METH; we also tested the ability of modafinil to rescue METH-induced cognitive and biochemical impairments in mice. After METH treatment (1mg/kg, sc, once daily for 7 days), mice performed the Novel Object Recognition (NOR) task, which evaluates visual memory and is sensitive to METH treatment. After the last METH injection, mice performed the NOR task which consisted of 3 habituation sessions to the open field (5 min a day, 3 consecutive days), training session (10 min, day 4), and a retention session (5 min, day 5). One hour before the training session, mice were given a single acute dose of modafinil (90 mg/kg, ip) or vehicle, and were exposed to two identical objects. After a 24 hr delay, mice performed the retention session where one of the objects was replaced by a new object. Sessions (time spent with objects and locomotor activity) were analyzed using an automated video tracking system (Ethovision XT7, Noldus). A preference index was calculated as the time spent exploring the novel object/total exploration time. Control and modafinil mice showed elevated preference indices compared to METH-treated mice ($p<0.05$). Acute modafinil increased the preference index in the NOR in METH-treated mice to values comparable to control ($p<0.05$). We also measured ERK1/2 phosphorylation in medial prefrontal cortex of METH- and saline-treated mice that were exposed to novel objects in the training session, compared to mice placed in the open field without objects. The same modafinil/vehicle acute dose was given 1 hr before testing and mice were sacrificed immediately after the 10 min session. Elevated ERK1/2 phosphorylation was found in medial prefrontal cortex of control mice exposed to objects ($p<0.05$), which was absent in METH-treated mice. Acute modafinil treatment had no effect by itself, but was able to restore the ERK1/2 phosphorylation induced by novelty in METH-treated mice to values comparable to controls ($p<0.05$). We demonstrated that modafinil induced a compensatory effect against METH-induced cognitive impairments, possibly by normalizing ERK1/2 signaling pathways in prefrontal cortex. Our results are of translational value since modafinil may be a valuable pharmacological tool for the treatment of cognitive deficits observed in human METH abusers.

Title: Rewarding drug-induced activation of the VTA elicits a long-lasting preferential use of procedural learning strategies

Authors: M. HUSSON[1], M. BAUDONNAT[2], J.-L. GUILLOU[1], M. CORIO[1], D. BÉRACOCHÉA[1], R.-M. VOUIMBA[1], *V. DAVID[3,1];

Abstract: The multiple memory systems hypothesis posits that different neural circuits function in parallel and may compete for information processing and storage. For example, instrumental conditioning depends on the striatum, whereas spatial memory is processed by a circuit centered on the hippocampus. However, the nature of the task itself is not sufficient to select one system over the other. As compared to aversive events, the impact of rewards on interactions between memory systems remain poorly understood. We have implemented an experimental set-up to compare the long-term effects of food (crisps) and drug (intra-VTA morphine) rewards on various forms of memory. This paradigm is based on a Y-maze discrimination task which can be acquired using either a cued or a spatial learning strategy. Subsequent use of cued and spatial learning strategies were further assessed using a competitive version of the Morris water-maze task. Behavioral testing was completed with brain analysis of the phosphorylated form of cAMP Response Element Binding (pCREB) protein, and recording of field potentials evoked by stimulation of the amygdalo-striatal and amygdalo-hippocampal, CA1 / Dentate Gyrus (DG) pathways in freely-moving mice. Synaptic plasticity was measured before or 1, 15 and 60 min after completion of sessions 1, 5 and 10 of the Y-maze task. We found that drug-induced activation of the reward system impaired spatial but not cue-guided learning. This spatial impairment was related to a dramatic decrease in pCREB expression within the dorsal hippocampus (mainly CA1 subfield) and the prefrontal cortex. This learning profile was related to a learning- and reward-dependent long-term potentiation (LTP) of neuronal activity in the amygdalo-striatal pathway, and a long-term depression (LTD) within the amygdalo-hippocampal pathways (dorsal CA1 and DG). Both food and drug rewards activated CREB in the nucleus accumbens. In contrast, only drug reward persistently upregulated CREB expression within the dorsal striatum for 72h. At the same time point (72h after the last Y-maze session), we observed a preferential use of cued-learning strategy in the water-maze. Decreasing CREB activity by infusing Rp-cAMPS into the dorsal striatum re-established a balanced expression of cued and spatial learning strategies. We conclude that drug-induced activation of the VTA persistently

configures memory systems interactions to promote the control of behavior by conditioning processes. This drug-induced cognitive bias could play a critical role in the instatement of addictive behaviors.

Title: Characterization of Arc expression in corticolimbic areas associated with cocaine-induced conditioned locomotor activity

Authors: *Y. ALAGHBAND, J. F. GUZOWSKI, J. F. MARSHALL;
Neurobio. and Behavior and Ctr. for the Neurobio. of Learning & Memory, Univ. of California, Irvine, Irvine, CA

Abstract: Environmental cues associated with drugs of abuse cause relapse among addicts. Conditioned activity (CA) refers to a Pavlovian paradigm in which repeated, non-contingent pairings of an activating psychostimulant drug with a particular environment produce enhanced locomotion upon exposure to this environment in subsequent drug-free tests. Previously, we used the conditioned place preference (CPP) model to show that the retrieval of a cocaine-context associated memory results in enhanced activity-regulated cytoskeletal-associated (Arc) expression in distinct corticolimbic regions. While the CPP model is frequently used to examine the molecular mechanisms underlying cocaine-cue memories, few studies have examined cocaine CA memories. Here, we examine *Arc* induction during the retrieval of a cocaine-context association, which is *not* based on preference. Male Sprague-Dawley rats were subjected to a contextual conditioning protocol in which they received cocaine (12 mg/kg; i.p.) or saline (1 ml/kg) paired with either the activity chamber or the home cage. Animals in the cocaine-paired context group were given cocaine prior to placement in the activity chamber for thirty minutes and saline two hours later in their home cage, for seven trials in each environment. Animals in the cocaine-unpaired context group received saline prior to placement in the activity chamber and cocaine in their home cage. Two days after conditioning, both groups were exposed for six minutes to the activity chamber in a drug-free state. A second paired group, activity-yoked

paired, was used to control for the amount of locomotion on the test day as a factor contributing to *Arc* induction; these animals were allowed to locomote in the activity chamber only until they matched the average distance traveled by the unpaired group. Forty-five minutes after the start of exposure, all animals were euthanized for Arc immunohistochemistry. The paired and activity-yoked paired groups did not differ in their Arc levels across brain regions, and both groups had greater levels of Arc expression in regions of the nucleus accumbens, amygdala, and frontal cortex, compared to the unpaired control group. Thus, elevated Arc expression depends upon the association between the activity chamber and cocaine administration. Overlapping corticolimbic regions of enhanced Arc expression after retrieval of a cocaine-context memory (established using either the CPP or CA model) likely signify that these regions (i) are activated during these memories irrespective of preference-based decisions, and (ii) undergo neuroplasticity in order to update information about cues previously associated with cocaine.

Title: Impulsive behavior induced by cocaine is ameliorated by the alpha2A noradrenergic agonist guanfacine in animals performing the 5-choice serial reaction time task

Authors: *P. M. CALLAHAN[1,2], R. SCHADE[2], A. V. TERRY, Jr[1,2];
[1]Dept. of Pharmacol. and Toxicology, Georgia Regents Univ., Augusta, GA; [2]Small Animal Behavioral Core, Augusta, GA

Abstract: Increases in impulsivity are clinical symptoms associated with the development and maintenance of drug abuse and considered a major risk factor for drug relapse. Similar inhibitory control issues are experienced by individuals diagnosed with attention deficit hyperactivity disorder (ADHD) and medications successfully used to treat this clinical population may have beneficial effects in substance abuse individuals. One such drug successfully used in the treatment of ADHD is the noradrenergic (NA) alpha2A agonist guanfacine which has a good safety profile and low abuse potential. Additionally, given the importance of the noradrenergic system in drug abuse, drugs acting at this neurotransmitter site represent a promising therapeutic strategy. In the present study, we evaluated the effects of guanfacine (0.1-1 mg/kg, ip) in

combination with cocaine (15 mg/kg, ip) using the 5-choice serial reaction time task (5-CSRTT). Male Wistar rats were trained to stable 80% accuracy levels using a standard protocol of 1 sec stimulus duration and 5 sec limited response hold. Administration of cocaine (3.5-15 mg/kg, ip) dose-dependently increased inhibitory control measures (premature and time out responding) with a dose of 15 mg/kg producing the greatest effect on impulsivity. Guanfacine (0.1-1 mg/kg, ip) in combination with cocaine (15 mg/kg, ip) dose-dependently and significantly reduced the impulsivity measures (premature and timeout responding) without affecting task accuracy. Despite these positive effects, some of the behavioral task indices (i.e., omissions and latency to retrieve reward) were slightly altered in comparison to cocaine performance, but not to vehicle performance. These data (in a rodent model) suggest that novel noradrenergic alpha2 agonists (like guanfacine) may have therapeutic potential for controlling impulsive behavior (and possibly, drug replase) in individuals suffering from drug addiction.

Title: Neuropsychological evaluation of attention and working memory in addicts submitted to psychotherapy and pharmacotherapy

Authors: *J. E. PANDOSSIO, S. C. MARQUES;
Univ. of Brasilia, Brasília, Brazil

Abstract: Chemical dependency (CD) is characterized by a cluster of symptoms related to maladjusted substance use. The Psychosocial Care Center for Alcohol and Drugs (CAPSad) is a reference to the treatment of CD. This study evaluated the influence of psychotherapy and pharmacotherapy on executive functions such as attention and working memory of addicts in treatment on CAPSad of Ceilandia (DF, Brazil), through psychometric scale (WAIS III - Digits and Sequence of Numbers and Letters subtests). This study also compared the performance of addicts and individuals without history of CD (control group) on the same functions. On this study, there were 60 participants, 30 addicts in the experimental group and 30 in the control group. The experimental group was divided in two, according to the treatment: addicts submitted to the association of psychotherapy and pharmacotherapy (n=21) and only psychotherapy (n=9).

This methodological schedule is in accordance with local and international ethical parameters. The results for the subtests weighted score indicated that the addicts showed no losses in these functions, according to independent t test (t=3.17, p=0.02). However, the experimental performance (M=9.20, SEM=0.48) was found below the control (M=11.03, SEM=0.30), suggesting impairments in cognitive functioning due to drug use history. The results showed no difference between the combination of pharmacotherapy and psychotherapy (M=11, SEM=0.88) and the control - no treatment (M=12.73, SEM=0.33) but, compared to only psychotherapy (M=9.67, SEM=0.80), there was a difference, according to ANOVA One-Way, followed by Tukey test (F(2,46)=6.51, p=0.007). The findings of this study also indicated that the specific interaction of benzodiazepines and anticonvulsants with naltrexone (n=6, M=4.83, SEM=0.60) or with selective serotonin reuptake inhibitors (n=5, M=4.40, SEM=0.60), used in pharmacotherapy of some participants, improved the addicts performance in working memory subtests, compared to only psychotherapy (M=3.88, SEM=0.51), according to ANOVA One-Way, followed by Tukey test (F(3,59)=5.10, p=0.01), similar to the combination of pharmacotherapy and psychotherapy. Taking together, these results confirm that the best treatment strategy for CD is the combination of pharmacotherapy and psychotherapy, focusing on executive functions.

Title: Memory-enhancing function of drug reinforcers: A solution to the cocaine puzzle?

Authors: *F. LERI[1], N. RKIEH[2], B. WINTERS[2], J. CLOKE[2];
[1]Psychology, Univ. Guelph, Guelph, ON, Canada; [2]Univ. of Guelph, Guelph, ON, Canada

Abstract: It has been proposed that the reinforcing properties of drugs of abuse are due, in part, to their ability to enhance memory formation. This hypothesis is primarily supported by evidence of enhanced recall in animals and humans treated with d-amphetamine immediately after training on memory tasks. The aim of the current study was to test this hypothesis using cocaine, a drug that clearly reinforces behavior in many species.
Cocaine (1 - 20 mg/kg, IP) was administered to male Sprague-Dawley rats immediately after

training on “win-stay” tasks in an automated eight-arm radial maze. In win-stay, animals are reinforced with sucrose for entering one specific arm that is illuminated by a cue light. In Experiment 1, post-training cocaine dose-dependently impaired acquisition. The impairment, however, was attributed to an interference with performance caused by some acute side effect of cocaine (i.e., anxiety and/or taste avoidance). In Experiments 2 & 3, rats received a sensitizing regimen of cocaine exposure prior to administration of cocaine during learning of different versions of the win-stay task. Although cocaine sensitization attenuated performance impairments, no clear memory enhancing effect was observed. In Experiment 4, co-administration of diazepam (2 mg/kg) also failed to reveal cocaine-induced memory enhancement. As a matter of fact, diazepam augmented the performance deficit caused by cocaine, and probe tests attributed the deficit to impaired motivation. Finally, Experiment 5 tested the effect of post-training cocaine on a spontaneous object recognition task. In this task, rats are required to discriminate novel from familiar objects and, importantly, performance is not driven by sucrose. Here, post-training cocaine administration caused a clear dose-dependent enhancement of retention.
Taken together, these data suggest that post-training cocaine administration can alter performance on memory tasks by a process that is independent from memory consolidation. The process appears to be associative, and to involve a link between the stimulus that motivates task performance (i.e., sucrose in the win-stay task) and acute side effects of the drug. In tasks were the nature of the stimulus is different (i.e., novelty in object recognition), the memory enhancing effects of cocaine are revealed.

Title: Self administration of oxycodone by adolescent and adult mice differentially affects gene expressions in hippocampus

Authors: *Y. ZHANG[1], A. J. BROWNSTEIN[1], K. NIIKURA[1], S. D. SCHLUSSMAN[1], A. HO[1], J. OTT[2], M. KREEK[1];

[1]Rockefeller Univ., NEW YORK, NY; [2]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China

Abstract: Prescription opioid abuse in adolescence is a pressing public health issue. We aimed to determine whether oxycodone self-administration differentially affects gene expression in the hippocampus of adolescent compared to adult C57BL/6J mice. Groups of adolescent mice (4 weeks old, n=12) and of adult mice (11 weeks old, n=11) underwent surgery during which a catheter was implanted into their jugular veins. Mice were placed in self-administration chambers for acquisition of oxycodone self-administration or were yoked saline control after recovering from surgery. Mice self-administered oxycodone (0.25mg/kg/infusion) 2 hrs/day for 14 consecutive days. Mice were sacrificed within one hour after the last self-administration session and the hippocampus was isolated for mRNA analysis. Gene expression was analyzed with real time PCR using a commercially available PCR array. We found that adolescent mice self-administered less oxycodone than adult mice over the 14 days. Adolescents and adults significantly differed in Calcium/calmodulin-dependent protein kinase, Glutamate receptor, AMPA2 and metabotropic 5 mRNA levels in the absence of oxycodone exposure. 14-day oxycodone self administration increased Proviral integration site 1 and Thymoma viral proto-oncogene 1 mRNA levels compared to controls in both adults and adolescents. More genes in the hippocampus of adult changed in response to oxycodone self administration compared to controls than in adolescent mice. Overall, this study demonstrates for the first time that repeated oxycodone self-administration differentially altered gene expression in the hippocampus of adolescent versus adult mice.

Title: Extinction of opiate reward reduces dendritic arborization and dendritic spines in the nucleus accumbens core but not shell

Authors: *G. B. KAPLAN[1], K. A. LEITE-MORRIS[1], K. L. KOBRIN[1], S. C. HEINRICHS[2], O. A. MOODY[2];

[1]Psychiatry and Pharmacol., Boston Univ. Sch. Med/VA Boston Healthcare, Boston, MA; [2]Res., VA Boston Healthcare, Boston, MA

Abstract: Recurrent opiate administration paired with environmental cues leads to conditioned drug reward and cue-induced drug craving and relapse. This study characterizes structural plasticity associated with extinction of conditioned opiate reward. We modeled the morphine reward process in C57BL/6 mice using acquisition and extinction of conditioned place preference (CPP). Extinction learning reduces conditioned responding to drug cues by creating a new memory associated with changes in neuroplasticity. In this study, changes in dendritic plasticity were examined in the nucleus accumbens (NAc) of morphine CPP and extinction-trained mice. Mice were trained to associate morphine injection with a paired chamber. Mice conditioned with different doses of morphine (1, 2.5, 5, and 10 mg/kg, SC) acquired dose-dependent CPP after four morphine exposures as evidenced by difference scores that were significantly higher than saline controls. Other mice were divided into three groups: morphine CPP (10 mg/kg) followed by extinction training, morphine CPP followed by sham extinction training, and saline controls. After acquisition of CPP, mice underwent three extinction training sessions, Extinction I (Days 11-14), Extinction II (Days 16-19), and Extinction III (Days 21-24). Mice underwent Post-Extinction or Post-Sham Extinction training preference tests on days 15, 20, and 25 and then on day 25 brains were used for Golgi-Cox staining. Mice extinguished their preference for the morphine associated compartment within the first extinction session consisting of two paired chamber exposures. Medium spiny neurons from mice were traced for dendritic length, dendritic count, dendritic intersections, dendritic spine density, and spine numbers. Mice in the morphine CPP extinction group (compared to morphine CPP sham extinction group) showed a decreased distribution of spines per neuron in the nucleus accumbens core but not shell. Morphine CPP extinction also reduced the number of dendritic intersections in the core but not shell as demonstrated by Scholl analyses. The extinction group also had decreased total dendritic length per neuron and total dendritic count per neuron in comparison to the other groups. These findings are consistent with others demonstrating that repeated exposure to opiates reduces dendritic arborization and spines in the NAc. Such dendritic changes regulate the the strength of synaptic transmission and may mediate extinction learning relevant to opiate addiction.

Title: Prior morphine exposure blocks oxytocin excitation of nucleus accumbens shell neurons

Authors: *M. MOADDAB[1,2], B. HYLAND[2], C. BROWN[1,2];
[1]Ctr. For Neuroendocrinology, Dunedin, New Zealand; [2]Dept. of Physiology, Univ. of Otago, Dunedin, New Zealand

Abstract:
Drug addiction is a chronically relapsing disorder that involves compulsive and uncontrolled drug-seeking and drug-taking. The nucleus accumbens (NAc) shell is particularly associated with reward-related behaviours, including those associated with drugs of abuse. Recently, the neuropeptide, oxytocin, has been shown to modulate reward-related behavioural responses to drugs of abuse. Hypothalamic oxytocin neurons project to many forebrain regions, including the NAc shell. We have found that intracerebroventricular (ICV) oxytocin administration enhances the expression of morphine-induced conditioned place preference (CPP). So, we used in vivo single-unit extracellular recording in urethane-anesthetized male Wistar rats to investigate the effects of ICV oxytocin on the firing rate of NAc shell neurons in morphine-naive rats and morphine-treated rats (three daily injections of morphine, with the last injection 24 h before recording). In morphine-naive rats, ICV saline (2 µl) administration did not change the firing rate of NAc shell neurons (1.3 ± 0.2 to 1.2 ± 0.3 spikes s^{-1}, n = 29; $P = 0.74$, one-way repeated measures ANOVA), whereas ICV oxytocin (0.2µg/2µl) increased NAc shell neuron firing rate (2.4 ± 0.6 to 3.2 ± 0.8 spikes s^{-1}, n = 29; $P < 0.01$). The basal firing rate of NAc shell neurons in morphine-treated rats (1.1 ± 0.2 spikes s^{-1}, n = 70) was similar to that in morphine-naive rats (1.8 ± 0.3 spikes s^{-1}, n = 80; $P = 0.06$, unpaired *t*-test). In morphine-treated rats, neither saline (1.0 ± 0.2 to 1.2 ± 0.2 spikes s^{-1}, n = 23; $P = 0.58$) nor oxytocin (1.7 ± 0.5 to 1.6 ± 0.4 spikes s^{-1}, n = 21; $P = 0.56$) affected the firing rate of NAc shell neurons. These results show that three daily injections of morphine block the excitation of NAc shell neurons by subsequent ICV oxytocin, suggesting that morphine-induced adaptations reduce the excitability of NAc shell neurons to oxytocin administration. Hence, the oxytocin enhancement of the expression of morphine-induced CPP on the test day appears unlikely to be due to acute modulation of the baseline firing rates of NAc shell neurons. Rather, morphine-induced adaptation, including the abolition of the NAc response to oxytocin, might enable oxytocin-induced modulation of other neuronal circuits to influence the expression of morphine-induced CPP.

Natl. de Recherche Scientifique/Institut Natl. de la Santé et de la Recherche Médicale/Université de Strasbourg, Illkirch-Graffenstaden, France

Abstract: A non-invasive insight into the brain's intrinsic connectional architecture of functional networks (FN) has only become possible since the development of resting-state functional magnetic resonance imaging (rsfMRI). In humans, the default mode functional networks and their alterations in pathologies are intensively studied. Moreover, when combined with diffusion tensor magnetic resonance imaging (DT-MRI) and fiber tracking investigations [1], recent studies demonstrate the structural connectivity features underlying the FN and their remodeling mapped by rsfMRI [2]. However, the intrinsic connectional architecture of functional and structural networks in the mouse brain remains a significantly underexplored research area. The goal of the present study was to bridge this gap by unifying and adapting the rsfMRI/DT-MRI techniques for studying the functional and structural connectivity pattern in mouse models of brain disorders. We focused our investigation on mapping the brain connectional networks of mu-opioid receptor (MOR) knock-out mice (Oprm1-/-), an extensively used model of drug addiction and reward [3].
Mouse brain MRI was performed with a 7T small bore animal scanner and a mouse head adapted cryogenic surface coil (Bruker Germany) both allowing for high signal-to-noise ratio and short acquisition times at high resolution. rsfMRI and DT-MRI data was acquired from 8 weeks old wild type (n=14) and Oprm1-/- (n=14) male mice using single shot Gradient Echo Echo Planar Imaging (GE-EPI) and 4 shot DT-EPI sequences. Group Independent Component Analysis (ICA) of rsfMRI data allowed the identification of elementary functional clusters of the Oprm1-/- mouse brain. Their connectional relationship was tested with partial correlation and graph theory providing a comprehensive picture of Oprm1-/- brain functional connectivity. As a step forward, the identified functional clusters were subsequently used as regions of interest in a fiber tracking algorithm, for mapping structural connectivity. We focused our analysis on brain

networks involving areas known for their clustered expression of MOR such as striatum, amygdala and thalamus. Our experiment broadens the knowledge about functional and anatomical connectivity in mouse models of brain disorders uncovering also the involvement of the mu opioid receptor in brain networks remodeling. This non-invasive study design forms also the basis for longitudinal investigations, opening a perspective towards testing therapeutic compounds and their influence on the progress of disease patterns.

Title: Novel mechanism for opioid drug action: Implications of Redox/Methylation signaling

Authors: *M. S. TRIVEDI[1], N. HODGSON[2], J. SHAH[3], R. DETH[4];
[1]Neuro-Pharmacology, Northeastern Univ., Boston, MA; [2]Northeastern Univ., BOSTON, MA; [3]Northeastern Univ., Brighton, MA; [4]Dept of Pharmaceut. Sci., Northeastern Univ., Boston, MA

Abstract: Drugs of abuse, including opioids, act upon molecular mechanisms which support attention, awareness and consciousness. Attention is closely linked to learning and memory, & frequent drug use results in persistent behavioral changes, including withdrawal syndromes, indicating that neuronal systems have adapted to repeated drug use. Mounting evidence indicates that epigenetic changes, specifically alterations in patterns of DNA and histone methylation, can produce long lasting alterations in gene expression, affecting learning, memory and behavior. Thus, the activities of methylation-related metabolic pathways in neuronal cells could help explain at least some molecular aspects of the acute and longer-term effects of opioid class of drugs of abuse. We investigated acute and long-term effects of selected opioid drugs and their mechanism of influence on pathways of sulfur metabolism, redox and DNA methylation status in cultured neuronal cells. We found that morphine dose dependently inhibited EAAT3, which transports cysteine, a precursor for glutathione (GSH) synthesis. Subsequent decreases in

GSH/GSSG and SAM/SAH ratios were also observed with prolonged morphine treatment. Mechanistic investigation suggested involvement of PI3-Kinase and Protein Kinase A (PKA) for short-term, and MAP-Kinase signaling pathways for long-term inhibition of cysteine uptake. Global DNA methylation, measured as an index of 5-methylcytosine levels, correlated to the observed changes in SAM/SAH ratio. To further confirm these observed results, qRT-PCR analysis was performed for mRNA levels of enzymes and transporters involved in antioxidant and methylation pathways. In particular, an increase in mRNA levels of LINE-1 retrotransposon, induced by prolonged morphine treatment was observed, indicating a decrease in global DNA methylation. Lastly, redox and methylation responses were also investigated upon removal of morphine after a prolonged exposure (i.e. in vitro wash out). There was a prompt increase in cysteine uptake after in-vitro washout. Similarly, intracellular GSH and cysteine were also increased. Corresponding changes were also observed in global DNA methylation.These results indicate a novel epigenetic signaling pathway for opioid drugs, involving changes in cellular redox status and methylation capacity, mediated by multiple signaling pathways. These findings have implications for drug tolerance and withdrawal, and may lead to development of novel therapeutic interventions. Additionally, this redox-methylation signaling pathway might also be implicated as a mechanism for other classes of drugs of abuse, such as amphetamines and alcohol.

Title: Opiate exposure state controls a novel, CaMKIIα/ ERK1/2-dependent molecular opiate reward memory switch in the basolateral amygdala-prefrontal cortical pathway

Authors: *L. G. ROSEN[1,2], W. J. RUSHLOW[1,2,3], S. R. LAVIOLETTE[1,2,3];
[1]Anat. and Cell Biol., [2]Dept. of Neurosci., [3]Dept. of Psychiatry, Western Univ., London, ON, Canada

Abstract: The potent rewarding effects of opiate class drugs facilitate the formation of strong associative memories linked to the drug experience and play a key role in triggering relapse. The basolateral amygdala (BLA) is involved in the encoding of acute opiate reward memories. We have reported recently that the localization of associative opiate memories anatomically and temporally shifts from the BLA to the medial prefrontal cortex (mPFC) for long-term storage between these two interconnected areas (Gholizadeh et al., 2013). Interestingly, intra-BLA processing of opiate-related reward memories is independently controlled by dopamine D1 and D2 receptor signaling as a function of opiate exposure state. Transmission via D1 receptors is required for acute opiate memory formation in the previously drug-naïve state, whereas D2-mediated signaling is implicated in memory formation following the transition to opiate dependence and withdrawal. However, the underlying molecular substrates controlling memory formation within the BLA>mPFC pathway are not presently understood. Here, we show that opiate reward memories are processed via an ERK-dependent, D1-mediated mechanism in the naïve state, but through a CaMKIIα-dependent, D2 mediated mechanism in the dependent/withdrawn state. Using an unbiased place conditioning procedure combined with protein analyses of BLA and mPFC tissue, we report that intra-BLA associative opiate-related memory formation depends upon ERK1/2 signaling in the drug-naïve state, but switches to a CaMKIIα-dependent signaling substrate in the dependent/withdrawn exposure state. Consistent with our behavioural findings, BLA western blotting protein analyses demonstrated a reduction in both phosphorylated ERK1/2 as well as total and phosphorylated CaMKIIα in opiate dependent/withdrawn animals. Interestingly, protein analysis in the mPFC has revealed a functionally opposite pattern of ERK1/2 and CaMKIIα protein expression, with an increase in both CaMKIIα and ERK1/2 in the dependent/withdrawn state, demonstrating a functional dissociation in molecular memory pathways across the BLA and mPFC controlled by opiate exposure state and withdrawal. Our results further demonstrate a functional interaction between the BLA and mPFC during the processing and storage of opiate-related associative memories and the switch from the non-dependent, to dependent/withdrawn opiate states. Using an unbiased conditioned place preference paradigm paired with local microinfusions of ERK1/2 and CaMKIIα inhibitors into the mPFC, the behavioural significance of these molecular changes are currently being examined and will be presented.

Title: A role of Regulator of G protein signaling 9-2 (RGS9-2) in the Nucleus Accumbens in opiate addiction and analgesia

Authors: *S. GASPARI[1], M. PAPACHATZAKI[1], M. E. TSIMBANOULI[1], K. DEISSEROTH[2], M. LOBO[3], V. ZACHARIOU[4];
[1]Dept. of Basic sciences, Univ. of Crete, Heraklion, Greece; [2]Dept. of Bioengineering, Stanford Univ., Stanford, CA; [3]Anat. and Neurobio., Univ. of Maryland, Baltimore, MD; [4]Neurosci. and Pharmacol. and Systems Therapeut., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Regulator of G Protein Signaling 9-2 (RGS9-2) is a multifunctional signal transduction protein with high levels of expression in the striatum. RGS9-2 plays a major role in the modulation of several GPCR responses in the striatum, and has been shown to potently modulate dopaminergic and opioidergic transmission. We recently identified RGS9-2 complexes in the striatum associated with the acute and chronic actions of different mu opioid receptor agonists. We have also developed viral mediated gene transfer approaches to investigate the actions of RGS9-2 in particular brain regions of adult animals. Using adenoassociated viruses (AAV) expressing RGS9-2 or a dominant negative form of the protein (DEPless RGS9-2) we explored the brain specific actions of this molecule in a series of behavioral paradigms for opiate reward and analgesia. Our studies reveal that RGS9-2 actions in the nucleus accumbens (NAc) negatively regulate the rewarding actions of morphine and they also affect the development of physical dependence. In addition, RGS9-2 in the NAc plays a key role in morphine analgesia and tolerance in paradigms of acute and chronic pain. These findings are further supported by optogenetic studies, in which subpopulations of dopamine D1 or dopamine D2 receptor enriched neurons were activated following morphine administration. Activation of D1 receptor enriched neurons leads to an increase in RGS9-2 levels and accelerates the development of analgesic tolerance. These findings point to RGS9-2 complexes in the NAc as novel targets for the treatment of addiction and reveal the influence of RGS9-2 in the NAc in morphine analgesia and tolerance.

Title: Exploring morphine reward and changes in opiate-related signaling molecules in the Wistar Kyoto rat

Authors: *T. S. DENNIS[1], K. D. BECK[2], T. P. COMINSKI[2], S. A. MORRIS BOBZEAN[1], R. J. SERVATIUS[2], L. I. PERROTTI[1];
[1]Psychology, Univ. of Texas at Arlington, Arlington, TX; [2]Neurol. and Neurosciences, Stress and Motivated Behavior Inst., UMDNJ, Newark, NJ

Abstract: The Wistar-Kyoto (WKY) rat has been proposed as a model of anxiety vulnerability as it exhibits pronounced behavioral inhibition, passive avoidance, exaggerated startle response, enhanced HPA axis activation, and active avoidance that is resistant to extinction. Accumulating evidence suggests that WKY rats respond differently to rewarding stimuli when compared to outbred strains of rat. A recent study from our laboratory shows that WKY rats are more sensitive to higher doses of cocaine than Sprague Dawley (SD) rats. The present study was designed to extend our previous findings and characterize morphine conditioned place preference (CPP) in WKY rats. The equipment used to quantify CPP consisted of a three-chambered apparatus. Two visually and contextually distinct compartments are separated by a small shuttle compartment. Fifteen infrared photobeam detectors were used for automated data collection. Adult male WKY and SD rats were subjected to a CPP paradigm, which included a preconditioning test, a conditioning phase, and an acquisition test. The preconditioning test was performed to identify any initial bias for either side of the CPP apparatus. All rats were conditioned with one of six doses of morphine (0, 0.5, 1.25, 2.5, 5, or 7.5.mg/kg) and saline on alternating days for a total of six conditioning days. The acquisition test began 24 hours after the last conditioning session. In this test, rats were allowed free access to all chambers for 30 minutes in a drug-free state. The increase in time spent in the morphine-associated compartment was considered a measure of conditioned preference. SD rats displayed morphine-induced CPP to each of the five doses of morphine tested. The WKY rats displayed a preference only at the 1.25, 2.5, and 5mg/kg doses but showed an aversion at the 7.5mg/kg dose. This study shows that WKY rats display a greater sensitivity to higher doses of morphine. While it is clear the WKY rat has a distinctive response to drugs of abuse, more research is needed to fully elucidate the mechanisms that drive this unique behavioral profile. Studies are currently underway to further characterize alterations in the reward neurocircuitry of these rats.

Title: Enhanced protein phosphatase 2A (PP2A) activity drives SK2 channel mediated impairment of long term potentiation (LTP) in the hippocampus after context-dependent morphine

Authors: *A. K. FAKIRA[1], G. S. PROTUGAL[1], Z. MELYAN[1], D. S. SULZER[2], J. A. MORON CONCEPCION[1];
[1]Anesthesiol., [2]Neurol., Columbia Univ. Med. Ctr., New York, NY

Abstract: Learned associations between drugs of abuse and context can have powerful effects on drug craving and relapse. Context-dependent locomotor sensitization and conditioned place preference (CPP) occur with escalating doses of morphine paired with a novel context and are associated with impaired long term LTP in the hippocampus. Our studies demonstrate that Ca^{2+} permeable glutamate receptors, AMPA and NMDA, are inserted into the synapse after morphine treatment. Small conductance Ca^{2+} activated potassium type 2 (SK2) channels have been shown to modulate LTP. Dephosphorylation by PP2A increases Ca^{2+} sensitivity of SK2 thus increasing the channel function. Since Ca^{2+} is known to increase PP2A activity Ca^{2+} influx from AMPA and NMDARs may activate PP2A and potentiate SK2 channel function. Our studies show that mice that display locomotor sensitization have increased SK2 channel function and PP2A activity. Ultimately, inhibition of either PP2A and SK2 channels restores LTP to normal levels. Future studies will determine if these mechanisms are involved in LTP impairment following morphine CPP. Additionally, using 2-photon imaging of dendritic spines we plan on investigating if pairing morphine with a novel context results in increases in AMPA and NMDAR-mediated Ca^{2+} transients in the spine. . Altogether, our data highlight new mechanisms underlying context-dependent drug seeking behavior and may lead to development new therapeutic approaches to preventing relapse.

Title: Orexin/hypocretin in the ventral tegmental area is necessary for morphine-induced synaptic plasticity of dopamine neurons

Authors: *C. BAIMEL[1], S. L. BORGLAND[2];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Dopamine neurons in the ventral tegmental area (VTA) are a key target of addictive drugs and neuroplasticity in this region may underlie some of the core features of addiction. All drugs of abuse induce an LTP-like potentiation of excitatory inputs to VTA dopamine neurons, but it is not well understood how these drugs, despite chemical diversity and differences in molecular targets, bring about a common synaptic change. Orexin (hypocretin) is a lateral hypothalamic neuropeptide released into the VTA that promotes drug-seeking behaviours and potentiates excitatory synaptic transmission in the VTA. Inhibition of systemic orexin signaling blocks both cocaine-induced plasticity and drug seeking behaviours. However, it is unknown how orexin gates drug-induced plasticity in the VTA. We determined if orexin action in the VTA was necessary for morphine-induced strengthening of excitatory synapses onto VTA dopamine neurons. We used whole cell patch clamp electrophysiology in midbrain slices taken from male Sprague Dawley rats 24 hours following a single in vivo injection of morphine (10 mg/kg) or saline to assess excitatory synaptic strength. Morphine potentiated glutamatergic synaptic transmission onto VTA dopamine neurons by a presynaptic increase in glutamate release and by a postsynaptic change in AMPAR number or function, likely including a switch in subunit composition. Systemic or intra-VTA administration of SB 334867, an orexin receptor type 1 antagonist, blocked a morphine- induced increase in the AMPAR/NMDAR ratio, morphine-induced increases in AMPAR mini excitatory postsynaptic current frequency and amplitude, as well as morphine-induced AMPAR subunit redistribution measured by a change in rectification. These results support a role for orexin signaling in both pre-and postsynaptic potentiation of glutamatergic transmission in the VTA by morphine. Because orexin signaling is required for

plasticity induced by both morphine and cocaine, orexin may function as a gatekeeper for drug-induced plasticity of glutamatergic inputs to dopamine neurons.

Title: Chronic morphine and morphine withdrawal dynamically regulate the rpS6 multiple phosphorylation in a brain region-specific manner

Authors: A. CICCARELLI[1], A. CALZA[2], F. SANTORU[2], A. CONCAS[2], *M. SASSOE-POGNETTO[1], M. GIUSTETTO[1];
[1]Dept. of Neurosciences, Univ. Torino, Torino, Italy; [2]Dept. of Life and Envrn. Sci., Univ. Cagliari, Cagliari, Italy

Abstract: The activation of the extracellular regulated kinase (ERK) is a necessary step for several cognitive processes such as learning and memory formation, and is also involved in the onset of addiction caused by drugs of abuse. In the context of opiate abuse, it is still unclear how ERK signaling is recruited by morphine administration and what are its downstream effectors. One target of ERK activation is the ribosomal protein S6 (rpS6), a component of the 40S ribosomal subunit whose phosphorylation levels correlate with the rates of protein synthesis and that is regulated also by the AKT/mTOR pathway. In a previous study we showed that while ERK signaling is down-regulated in neurons of the nucleus accumbens (NAc) and lateral septum (LS) after chronic morphine treatment, naloxone-precipitated withdrawal activated ERK pathway in these brain areas. In this work we found that chronic morphine produces a decrease of the number of neurons showing phospho(p)-rpS6 immunoreactivity (both for ser 230/235 and 240/244 sites) in the LS, while an increase was found in the dorsomedial striatum. Interestingly, naloxone-precipitated morphine withdrawal produced a robust increase of rpS6 phosphorylation both in the LS and the NAc, as well as in the somatosensory cortex. Moreover, the analysis of double labeling experiments revealed that phospho-ERK and p-rpS6 are co-localized in LS neurons of withdrawal rats. These data underscore the importance of rpS6 in the modulation of

morphine effects in the brain and suggest that withdrawal may produce its negative effects through an increase of translational activity mediated by the activation of both ERK and mTOR pathways. Moreover, the heterogeneous and dynamic activation of phospho-rpS6 unveils a complex and parallel activation of multiple brain regions following opioid treatment.

Title: Differential effects of hydrocodone, oxycodone, and morphine on the response of D2/D3 dopamine receptors in adolescent mice

Authors: *M. A. EMERY, M. L. S. BATES, P. J. WELLMAN, S. EITAN;
Psychology, Texas A&M Univ., College Station, TX

Abstract: Oxycodone and hydrocodone are prescribed analgesics for children and adolescents. In addition, these prescription opioids are frequently abused among adolescents. The adolescent brain is still developing, thus exposure to opioids in both pain relief and abuse contexts might have different long term outcomes in this population than in adults.
Our recent studies demonstrate that morphine exposure differentially modulates the dopaminergic system in adolescent and adult mice. We observed that adolescent mice exposed to morphine exhibited behavioral supersensitivity of the D2Long/D3 postsynaptic receptors. This effect of morphine was extremely pronounced in adolescents but was hardly observed in adults. We have also demonstrated that buprenorphine and methadone, opioids used for maintenance treatment, differentially alter the responses of the dopaminergic system in adolescents. In the current study, we compared hydrocodone, oxycodone, and morphine for their effect on D2L/D3 receptor activity.
Adolescent mice were orally administered oxycodone, hydrocodone, morphine, or saline for 6 days. Twenty four hours after the last opioid dose, mice were examined for their locomotor response to quinpirole, a D2/D3 receptor agonist. Additionally, the effect of exposure to the various opioids on modulating D2 receptor-induced signaling molecules was explored using Western blot.
Quinpirole (10 mg/kg) reduced locomotor activity in drug-naïve adolescent mice, in line with the

literature demonstrating that the predominant effect of quinpirole on motor activity is suppressive in mice. Consistent with our previous findings, in the opioid-treated adolescent mice, initial suppression of locomotor activity was observed, but was followed by enhanced locomotion. However, the extent of this effect differed across the various opioids. The most profound effect was observed after exposure to oxycodone, followed by significantly less effect of hydrocodone. The least effect was observed following exposure to morphine. Additionally, differential effects on downstream signaling molecules were observed following exposure to the various opioids.
These findings suggest that exposure to various opioids carry differential risks in altering the highly sensitive neurochemistry of adolescents' brain, especially in regards to the D2L receptor system. These results call for more research to reveal individual differences between different adolescents recreationally using (misusing/abusing) various opioids. Additionally, these studies strongly indicate potential age-dependent and drug-dependent risks in administering opioids to adolescents for pain management.

Title: Hypocretin-2 receptor antagonism dose-dependently reduces compulsive-like self-administration of heroin in rats allowed extended access

Authors: *B. E. SCHMEICHEL[1], L. F. VENDRUSCOLO[1], K. K. MISRA[1], J. E. SCHLOSBURG[1], C. CONTET[1], D. E. GRIGORIADIS[2], G. F. KOOB[1];
[1]The Scripps Res. Inst., La Jolla, CA; [2]Neurocrine Biosci., San Diego, CA

Abstract: Animal models of drug dependence indicate that extended access to the drug produces escalation of intake over time, compared with stable levels of intake observed in animals maintained on a limited access schedule. Importantly, escalation of drug intake has been suggested to model the transition from controlled drug use to compulsive-like drug seeking/taking. Recently, the hypocretin/orexin (HCRT) neuropeptide has been associated with

both drug reinforcement and reinstatement, implicating HCRT-1 receptor signaling, in particular, in drug-related behaviors for all major drug classes, including psychostimulants, nicotine, alcohol and opiates. However, to date there are limited studies investigating the role of HCRT-2 receptor signaling in drug seeking, especially under extended access self-administration conditions. The current study examined the effects of administering the HCRT-2R antagonist, NBI-80713, on heroin self-administration in rats allowed short- (1 hour; ShA) or long- (12 hour; LgA) access to intravenous heroin self-administration. Results indicate that systemically administered NBI-80713 dose-dependently decreased heroin self-administration in LgA, but not ShA, animals. These observations suggest a functional role for HCRT-2 receptor signaling in compulsive-like heroin self-administration with extended access and indicate HCRT-2R antagonism as a potential pharmacological target for the treatment of heroin dependence.

Title: Enhanced heroin self-administration is associated with deficit of CREM in NAc core of an animal model of impulsivity

Authors: *Y. REN, C. V. MORRIS, H. SZUTORISZ, Y. L. HURD;
Neurosci. & Psychiatry, The Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: There is a strong association between trait impulsivity and addiction in humans. However, the neurobiology of impulsivity and its relationship to addiction vulnerability is poorly understood. This experiment was designed to study a common molecular basis between impulsivity and addiction vulnerability. Heroin self-administration (SA) was studied in spontaneously hypertensive rats (SHR), an impulsive animal model, with Wistar Kyoto rats

(WKY) as a control. In vivo dopamine in NAc core was measured using microdialysis. Expressions of genes of DA system as well as synaptic plasticity were studied by a customized PCR array. Compared with WKY, SHR took more heroin during the maintenance, showed higher resistance to extinction and enhanced heroin-seeking upon cue-reinstatement. In drug naive animals, SHR were more impulsive than WKY as characterized by intolerance-to-delay (ITD) task. In vivo DA increased to a greater extent in SHR NAc core in response to an acute heroin, but no differences in basal DA level between two strains. Gene expressions of DA receptors were not different between two strains. However, a significant decrease of CREM gene expression was detected in SHR NAc core but not shell, which was associated with less enrichment of 3meH3K4 and H3Ac at CREM gene. These data suggest that the impulsivity of SHR involves in CREM deficit regulated by histone lysine methylation, which might contribute to their heroin vulnerability.

Title: Expression of the superoxide generating NADPH oxidase Nox2 gene in the nucleus accumbens is required for morphine conditioned place preference

Authors: *M. J. GLASS[1], E. OGORODNIK[1], P. ZHOU[1], R. L. DAVISSON[2,3], C. IADECOLA[1];
[1]Brain and Mind Res. Inst., [2]Cell and Developmental Biol., Weill Cornell Med. Col., NEW YORK, NY; [3]Col. of Vet. Med., Cornell Univ., Ithaca, NY

Abstract: Although reactive oxygen species (ROS) like superoxide have traditionally been viewed as deleterious byproducts of oxidative metabolism, recent evidence indicates that they can also act as important signaling molecules generated by specific and highly regulated enzymes in the brain. Although ROS have been recently implicated in neural processes critical for addiction, including the modulation of glutamate signaling, synaptic plasticity, and learning and memory, there is little direct evidence that specific ROS producing enzymes are involved in

opioid addictive behaviors. We provide evidence that the superoxide-generating NADPH oxidase (NOX) plays a role in the expression of classically conditioned behaviors associated with opiate exposure. Mice with a constitutive knockout (cKO) of the catalytic Nox2 NOX subunit showed deficits in a morphine (10 mg/kg) conditioned place preference (post-training difference scores (sec): +160±40 versus +50±30, $p<0.05$, wild-type compared to Nox2 cKO mice, respectively). The reduction in morphine CPP was not simply the result of a generalized deficit in place learning, since separate groups of wild-type and Nox2 cKO mice made dependent on morphine and trained to express a naloxone withdrawal conditioned place aversion showed comparable aversive learning (wild-type: -230±110 sec versus Nox2 cKO: -210±71 sec, $p>0.8$). Wild-type and Nox2 cKO mice did not differ in morphine analgesia (tail-flick latency (sec) at 52.5º C; wild-type: 5.1±0.6 versus Nox2 cKO: 4.7±0.7, $p>0.1$), indicating that these differences were also unrelated to genotype-dependent effects on morphine pharmacokinetics. Compared to wild type mice, Nox2 cKO's showed reduced immediate early gene expression in the nucleus accumbens (Acb) in response to exposure to a morphine paired environment. Spatial-temporal gene knockdown produced by microinjection of an adenovirus expressing a small interfering Nox2 RNA (siNox2) in the Acb impaired the expression of morphine place preference compared to mice receiving administration of a control (siCnt) vector (siCnt: +245±60 sec versus siNox2: +80±30 sec, $p<0.05$). These results provide the first evidence that Nox2 expression in the Acb plays a critical role in classically conditioned behaviors associated with opiate exposure; this information may enhance our understanding of opiate action by identifying novel free radical mediated intracellular signaling pathways involved in opioid addiction and provide novel targets for the development of future pharmacotherapy.

Title: Girk3 in the ventral tegmental area (VTA): A key determinant of sensitivity to opioid reward-related behavior

Authors: *L. A. KOTECKI[1], M. B. MUNOZ[2], P. A. SLESINGER[3], K. WICKMAN[1]; [1]Pharmacol., Univ. of Minnesota, Minneapolis, MN; [2]The Salk Inst., La Jolla, CA; [3]Dept. Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The ventral tegmental area (VTA) and interconnected brain regions including the nucleus accumbens and medial prefrontal cortex comprise in part, the mesocorticolimbic dopamine (DA) system. The mesocorticolimbic DA system mediates the reward-related behavioral effects of all drugs of abuse, including opioids. Opioids stimulate dopaminergic neurons in the VTA indirectly, via direct inhibition of GABAergic neurons located in the VTA and/or rostromedial tegmental nucleus (RMTg). Indeed, GABAergic input to VTA DA neurons represents a critical regulator of DA neurotransmission in the reward circuitry. VTA DA neurons express a unique subtype of G protein-gated inwardly-rectifying K+ (Girk/KIR3) channel - a heterotetramer containing Girk2 and Girk3 subunits. The Girk2/Girk3 heterotetramer in VTA DA neurons mediates the postsynaptic inhibitory effect of GABAB receptor stimulation, which potently suppresses VTA DA neuron output. Interestingly, the residual Girk channel in VTA DA neurons from Girk3-/- mice (presumably a Girk2 homotetramer) is more sensitive to GABAB receptor stimulation than the Girk2/Girk3 heterotetramer expressed in VTA DA neurons from wild-type mice. Previous work from our group has identified Girk3 as a key determinant of the sensitivity of mice to the analgesic effects of opioids, cannabinoids, and clonidine. Girk3 has also been implicated in withdrawal from barbiturates, ethanol, and opioids, and the reinforcing effect of cocaine. Here, we show that Girk3-/- mice are less sensitive than wild-type counterparts to the acute motor-stimulatory effect of systemic morphine. Importantly, lentiviral-mediated expression of Girk3 in the ventral midbrain of Girk3-/- mice restored the normal sensitivity of the Girk channel in VTA DA neurons to GABAB receptor stimulation, and the normal sensitivity of Girk3-/- mice to the motor-stimulatory effect of systemic morphine. These data support the contention that increased sensitivity of VTA DA neurons to inhibitory input is a key and perhaps titratable determinant of sensitivity to the reward-related behavioral effects of drugs with abuse potential.

Title: Memory consolidation processes engaged by relapse to heroin seeking: Role of noradrenergic locus coeruleus complex

Authors: *E. L. CUMMINS, E. BOUGHNER, J. GRANT, K. KENT, T. MACDONALD, D. KWIATKOWSKI, F. LERI;
Univ. Guelph, Guelph, ON, Canada

Abstract: It is thought that relapse to drug taking involves new learning characterized by memory consolidation. These studies were designed to explore the role of the noradrenergic (NA) cell groups of the locus coeruleus (LC) complex in the memory consolidation process engaged by relapse. To do this, we used a conditioned place preference (CPP) reacquisition model of relapse in male Sprague-Dawley rats. This involved 7 phases: habituation, place conditioning (1 mg/kg heroin or 20 mg/kg cocaine, and vehicle; 4 place pairings each), test of conditioning (Test I), extinction (vehicle only; 4 place pairings each), test of extinction (Test II), reconditioning (heroin or cocaine, and vehicle; single place pairing each) and test of reconditioning (Test III). Rats received systemic (vehicle, 10, 40 or 100 ug/kg) or intra-LC infusions of clonidine (vehicle, 4.5 or 18 nmol), an alpha 2-receptor agonist, following drug reconditioning with the goal of disrupting the memory consolidation process underlying reacquisition of CPP. To establish the role of NA input to the basolateral amygdala (BLA), an LC projection site important for associative memory, on heroin reacquisition, rats received intra-BLA infusions of a prazosin/propranolol mixture (alpha 1-receptor antagonist/non-selective beta receptor antagonist respectively; vehicle or 2.4/34 nmol) after reconditioning. The effect of intra-LC clonidine on cellular activity within the BLA was assessed using an immunohistochemical stain for the immediate early gene c-fos. We found that post-reconditioning, systemic or intra-LC clonidine dose dependently blocked heroin reacquisition when given immediately or 4h after, but had no effect when given 8h after reconditioning (systemic data only) or 4h before Test III. Post-reconditioning clonidine also blocked cocaine reacquisition, suggesting that the effect of clonidine is not due to a diminution of heroin withdrawal symptoms. Further, we show that activation of alpha 1- and beta NA receptors in the BLA is critical for the consolidation of a drug memory, as blocking these receptors also abolished heroin reacquisition (pending BLA histological analysis). We speculate that the disruptive effect of clonidine on memory is at least partially due to reduced NA activity in the BLA. In fact, BLA c-fos activity was dose-dependently reduced following intra-LC clonidine, further relating the essential involvement of LC activation and NA release within the BLA on heroin reacquisition. Together, these data suggest that relapse involves a memory consolidation process sensitive to manipulations of the noradrenergic LC complex.

Title: Pro-opiomelanocortin mRNA expression is selectively altered by ethanol exposure in the rat brain

Authors: *K. HERNANDEZ FONSECA, E. CABRERA-MUÑOZ, C. REYES, M. MENDEZ; Neurochemistry, Inst. Nacional De Psiquiatría Ramón de La Fuente, Mexico city, Mexico

Abstract: The endogenous opioid system is associated with a variety of functions, including ethanol reward and reinforcement. Ethanol reinforcement and high alcohol drinking behaviour may be partially mediated by the ethanol-induced activation of endogenous opioid systems. Ethanol and opiates share numerous pharmacological properties and exhibit similar behavioural effects in animals and humans. Low ethanol doses produce psychomotor activation and euphoria, whereas high doses induce locomotor inhibition and sedation. Ethanol may alter opioidergic transmission at different levels, including the synthesis, processing, release and/or ligand binding to opioid receptors. The aim of this work was to investigate the effects of different doses of ethanol on Pro-opiomelanocortin (POMC) mRNA expression in different brain areas. Male Wistar rats were administrated with saline or different doses of ethanol (0.5, 0.75, 1.0, 1.5, 2.0, 3.0 g/kg i.p.) and 30 min later distinct brain areas were dissected: prefrontal cortex (PFC), nucleus accumbens (NAcc), anterior-medial (amCP) and medial-posterior (mpCP) regions of the caudate-putamen (CP), amygdala, hypothalamus and hippocampus. POMC mRNA levels were quantitated by real time PCR. POMC mRNA expression was increased by high ethanol doses in the PFC, while moderate to high doses (1.5 and 2.0 g/kg) decreased POMC mRNA levels in the hypothalamus and hippocampus. Ethanol induced biphasic effects in the NAcc, amygdala and CP. Moderate ethanol doses increased (amCP and mpCP) or decreased (NAcc and amygdala) mRNA expression, while high doses produced the opposite effect in these regions. Our results indicate that ethanol-induced changes in POMC mRNA expression are dose-dependent and region-specific. Ethanol-induced changes in POMC mRNA expression could be involved in both the stimulant and sedative effects of the drug.

Title: Confocal microscopy reveals shrinkage of dopaminergic cell bodies in the ventral tegmental area after access to morphine, but not endomorphin analogs

Authors: *M. R. NILGES[1], J. E. ZADINA[1,2,3];
[1]Grad. Neurosci. Program, [2]Dept of Med. and Pharm, Tulane Univ. Sch. of Med., New Orleans, LA; [3]SE LA Veterans Hlth. Care Syst., New Orleans, LA

Abstract: We have previously demonstrated that endomorphin (EM)-derived analogs are mu-opioid receptor agonists that inhibit pain behaviors with fewer side effects than morphine. For example, side effects from morphine include respiratory depression, tolerance, motor impairment, glial activation, and reward potential. By comparison to morphine and appropriate controls, we have shown that all 5 of these side effects are substantially reduced in rats injected with EM analogs. Abuse of morphine and heroin is pervasive and has a major socio-economic impact. By comparing equi-antinociceptive doses of morphine and EM analogs, we have shown that EM analogs do not elicit significant reward potential in the conditioned place preference model and have reduced self-administration (SA) rates under 12 hour/day/7 day sessions. The rewarding effects of morphine are thought to occur via disinhibition of dopaminergic cells located in the ventral tegmental area (VTA). After chronic morphine usage, the surface area of dopamine (DA) cell bodies in the posterior VTA decrease and may contribute to the reward tolerance associated with morphine. The decreased soma size in the VTA is interesting because it reliably occurs in rodent models of morphine or heroin reward and in post-mortem brains from heroin-dependent humans. In this study, we have directly compared tyrosine hydroxylase-containing DA neurons in the VTA of rats that previously self-administered vehicle, morphine, or EM analogs for 12 hours/day/7 days. Using immunohistochemical techniques and a Leica

confocal microscope with resident software for determining soma surface area, we compared DA soma sizes from the VTA of these rats. Consistent with previous reports, VTA soma sizes were significantly reduced in rats that self-administered morphine compared to controls. However, the surface area of DA neurons in the VTA from rats with access to EM analogs was not different from controls. Together with our previous conditioned place preference and self-administration data, the results provide evidence that 1) EM analogs produce significantly less reward behavior than morphine under identical conditions, and 2) VTA dopamine morphology is not altered by access to EM analogs in a paradigm where morphine is self-administered and reduces DA soma size in the VTA. The results support our hypothesis that the analogs have better safety profiles than morphine.

Title: Impairments of chromatin remodeling and gene expression in the striatum of human heroin abusers

Authors: *G. EGERVARI[1], E. KELLER[2], Y. L. HURD[1];
[1]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Forensic and Insurance Med., Semmelweis Univ., Budapest, Hungary

Abstract: Heroin abuse continues to have a detrimental impact on the individual and society in the United States and worldwide. Knowledge is, however, still lacking regarding neurobiological disturbances in human heroin abusers that could better guide treatment interventions. Abnormal gene transcription has been noted in opiate users, but no information currently exists regarding related epigenetic mechanisms, key regulators of transcription, in human drug users. As such, we studied the human striatum to characterize the state of epigenetic marks and genes related to synaptic plasticity, dysregulation of which is a core feature of addiction disorders.
We used a homogeneous postmortem collection of human heroin abusers to explore expression of genes in the striatum (microarray, Nanostring, quantitative real-time polymerase chain reaction) directly related to synaptic plasticity and glutamatergic neurotransmission, and to assess associated epigenetic mechanisms (Western blot, chromatin immunoprecipitation).

We observed marked perturbations of glutamatergic gene expression and epigenetic regulation in the striatum of human heroin abusers. In the nucleus accumbens, we found heroin-related transcriptional changes of chromatin remodeling enzymes and of genes involved in synaptic plasticity and glutamatergic neurotransmission. In the dorsal striatum, we found a significant increase in nuclear coactivator 1 (NCOA1) histone acetyltransferase and global histone H3 acetylation (AcH3) that correlated with years of heroin use, and showed negative correlations with heroin toxicology. In addition, we also observed a significant increase in AcH3 at the gene body and promoter region of selected glutamatergic genes. Other marks examined such as tri- or dimethylation of histone H3 lysine-9 (H3K9me3/2) related to transcriptional repression were not significantly altered.
Overall, the data to date suggest that epigenetic perturbations, particularly the hyperacetylation of histone H3, and thus the resulting more open chromatin configuration, might be intimately involved in the regulation of heroin-induced striatal synaptic plasticity. In addition, our findings indicate that molecular mechanisms are differentially affected by acute drug toxicity versus the chronic pathologic state of substance abuse.

Title: The effects of repeated morphine exposure on metabotropic glutamate receptor activity in adolescent mice

Authors: K. E. SELOFF, M. A. EMERY, M. S. L. BATES, P. J. WELLMAN, *S. EITAN; Dept of Psychology, Behavioral & Cell. Neurosci Program, Texas A&M Univ., College Station, TX

Abstract: Adolescent mice exhibit marked changes in D2/D3 dopamine receptor activity following administration of certain opioids. Thus, the present study examined whether repeated exposure to morphine would also modulate the activity of metabotropic glutamate receptors (mGluRs) in the dorsal striatum of adolescents. Administration of a group I-specific mGluR agonist, S-3,5-dihydroxyphenylglycine (DHPG), induces face-washing behavior in adolescent mice. Since this behavioral effect has been shown to be mediated by mGluR1, this behavior was used as an indicator of mGluR1 activity in the dorsal striatum.

Adolescent mice were first examined for their behavioral response to unilateral administration of DHPG directly into the dorsal striatum. Morphine (20 mg/kg, s.c.) was then administered once daily for 6 days. The response to DHPG was re-examined at one of three times, i.e., 2, 4, or 24 hours following administration of the final dose of morphine.
A significant increase in face-washing behavior was observed in drug-naïve animals following microinjection of a low dose (10 nmol) of DHPG into the dorsal striatum. Importantly, no differences were observed between the experimental groups, either at baseline or post-DHPG. Thus, differences between the various groups observed following repeated morphine administration are not due to pre-existing differences prior to the morphine administration. Morphine administration did not alter baseline face-washing behaviors in any of the experimental groups. Additionally, there were no significant differences in baseline face-washing behaviors between the various experimental groups following the repeated morphine administration. Thus, morphine per se and the withdrawal from morphine have no direct effects on face-washing behavior. Accordingly, differences in DHPG-induced face-washing behaviors between post- and pre-morphine administration are likely due to the effects of morphine administration on mGluR1 activity rather than locomotor activity or stereotyped behaviors in general.
Notably, this study demonstrated that repeated exposure to morphine does have an effect on the DHPG-induced increase in face-washing behaviors. Our results suggest that repeated morphine administration causes a decrease in mGluR1 activity in the dorsal striatum of adolescent mice, which could affect long-term neural activity. This is significant because it contributes to a more complete understanding of the factors that contribute to development of opioid addiction during adolescence.

Title: IP271973 a novel nonselective mglur7 agonist

Authors: *A. PILC, P. P. BRAńSKI, A. BOJARSKI, A. STANKIEWICZ, G. BURNAT, B. CHRUśCICKA;
Inst. of Pharmacol., 31-343 Krakow, Poland

Abstract: **Background:** Available data indicate on the important of mGluR7 receptor in psychiatric disorders. However, the results are misleading. The only known selective agonist for $mGluR_7$, N,N'-dibenzhydryl-ethane-1,2-diamine dihydrochloride (AMN082) was active in preclinical test of depression and anxiety. Concomitantly similar properties were observed for negative allosteric modulator of $mGluR_7$ (MMPIP). This discrepancy may be a result of a rapid internalization of mGluR7 in the presence of agonist and may result an in inhibition of signaling via mGlu7 receptor, as a net effect. Therefore, we need novel agents with
agonistic properties for mGlu7 receptor to evaluate if the activation of the receptor would produce antidepressant- and anxiolytic-like activity. **Aim:** Identification novel chemical scaffold possessing $mGlu_7$ positive allosteric modulation activity by interaction with transmembrane region of $mGlu_7$ receptor. **Methods:** Human GRM7 was cloned into genome of HEK-293 cells contained T-Rex expression system
(Invitrogen). Expression of the receptor was analyzed by means of qRT-PCR and Western blot in both: cells before and after stable transfection with GRM7. The screening study and activity of potential PAM was determined using forskolin-induced cAMP accumulation, in a HEK-293 T-Rex cell line stably expressing $mGlu_7$ or mock transfected HEK-293 T-Rex cell line. For the functional characterization of $mGlu_7$
we measured level of cyclic AMP (cAMP) by cAMP dynamic2 (CisBio) kit according to manufacture instructions. The concentration response curves were fitted using the non-linear regression analysis program, GraphPad Prism (GraphPad Software). All liquid handling operations were performed using EVO 2000 system (Tecan). **Results:** Via *in vitro* screening of compound collection we have identified
chemical scaffold possessing $mGluR_7$ potential PAM activity. Active compound have been characterized: induce a leftward-shift of the glutamate concentration-response curve (8,6 fold in 0,3 uM concentration of IP271973). - Activate $mGluR_7$ as a partial agonist (EC_{50} = 0,3 uM) - Is not selective, activate both $mGluR_4$ and $mGluR_8$

Abstract: Dehydroevodiamine·HCl(DHED) has been reported to prevent memory impairment and neuronal cell loss in a rat model with cognitive disturbance. We investigated the effect of DHED on memory impairment and behavioral abnormality caused by stress. We demonstrated that DHED can improve stress-induced memory impairments and depression-like behaviors by using open-field test, Y-maze test and forced swimming test. DHED treatment significantly recovered the decreases in the levels of neural cell adhesion molecule (NCAM) proteins caused by stress and the decreases in cell viability and NCAM levels by staurosporine treatment. Our results suggested that DHED is a potential drug candidate for neuronal death, memory impairment and depression induced by stress.

Title: Triple tracer receptor occupancy for 5-HT_{1A}, 5-HT_{2A} and D_2 using LC-MS/MS based method in rats

Authors: *G. BHYRAPUNENI, V. KANDIKERE, J. THENTU, D. AJJALA, R. ALETI, R. NIROGI;
Discovery Res., Suven Life Sci., Hyderabad, India

Abstract: Measuring the extent to which the test compound occupies target receptor plays a critical role in prioritizing compounds in CNS drug discovery. Thus, measuring in-vivo

occupancy simultaneously for compounds having affinity towards multiple receptors will be of great interest. Utility of multiple non-radiolabelled tracers to measure their distribution for occupancy at various receptors was accomplished in a single animal using LC-MS/MS mode of analysis. Current research on novel antipsychotics focus interactions with range of receptors, including serotonin and dopamine receptors, the mechanism of action different from typical and atypical antipsychotics. In this report, we developed simultaneous in-vivo receptor occupancy assay for 5-HT_{1A}, 5-HT_{2A} and D_2 using three different non-radiolabelled tracers, WAY 100635, MDL 100,907 and raclopride, respectively at 3 µg/kg, i.v. dose. The tracers used in this study were chosen based on information from the literature describing their use as occupancy tracers. Individual assays for each target were set and then a "triple tracer" assay was established where all three tracers were administered simultaneously. Assay was validated with various doses of selective and non-selective antipsychotics (pindolol 0.1 - 10 mg/kg, i.v, ziprasidone 0.01 - 6.0 mg/kg, i.v or olanzapine 0.1 to 10 mg/kg, p.o) in rats. The ED_{50} vales were similar when tested alone or in triple tracer assay. This is the first reported method to simultaneous determine the occupancy of these receptors in the same animal. The method can be employed in screening the novel compounds at lead optimization phase.

Title: Amygdala-specific phosphodiesterase 2 knockout controls hippocampal remodeling and fear memory

Authors: *Y. XU, C. ZHANG, L. RUAN, T. SHAO, H. ZHANG, J. O'DONNELL;
Dept. of Behavioral Med. and Psychiatry, West Virginia Univ., Morgantown, WV

Abstract: Impaired regulation of emotional memory is a feature of stress-related disorders, such as anxiety and fear memory impairment. Such regulation occurs, in part, by interactions between two stress-sensitive brain regions, the basolateral complex of the amygdala (BLA) and its downstream target the hippocampus. Extensive findings indicate that inactivation of the ipsilateral, but not the contralateral, BLA blocks the expression of genes involved in hippocampal synaptogenesis and hippocampal responses to stress, further indicating an

interaction between the BLA and hippocampal function. However, the molecular and cellular mechanisms supporting the influence of the amygdala on fear memory and hippocampal synaptic plasticity remain unknown. The high expression of phosphodiesterase 2 (PDE2) in the hippocampus and amygdala makes it an attractive target for regulation stress-related emotional memory. Activation of the secondary messengers (cAMP and cGMP) by inhibition of PDE2 appears to be a viable and tractable means of enhancing neuronal communication between these two brain regions. The current PDE2 inhibitor Bay 60-7550, though very potent, is not completely selective over other PDEs. Efforts have been made for the creation of a complete PDE2 knockout mouse, which only led to embryonic lethal pups. Creating conditional PDE2 knockout mice of the brain will provide great research merit in explaining the role of PDE2 in remodeling of impaired neuronal circuits induced by stress. In this study, an amygdala-specific PDE2 knockout mouse will be created to elucidate the involvement of PDE2 in chronic stress, and its function in controlling the remodeling responses of neuronal connections in the hippocampus to emotional input from the ipsilateral BLA. Successful completion of this study will reveal the role of PDE2 in shaping emotion-associated neuronal networks during stress. Characterizing the role PDE2 plays in amygdala-hippocampal associated fear-memory performance could result in a breakthrough in the PDE research area, and possibly identify PDE2 as a potential target for the treatment of stress-related neuropsychiatric disorders.

Title: Translational drug discovery at the University of Sussex

Authors: *J. R. ATACK, S. E. WARD;
Translational Drug Discovery Group, Univ. of Sussex, Sch. of Life Sci., Brighton, United Kingdom

Abstract: Big Pharma companies (for example GSK, Astra-Zeneca, Sanofi, Novartis, Merck) are decreasing their drug discovery efforts within neuroscience, especially for psychiatric disorders (ECNP Summit, Eur. Neuropsychopharmacol., 2011, 21:495-9). However, there is little doubt that there remains a need for improved treatments for a variety of CNS disorders,

which raises the question of from where will such new therapies emerge (Schoepp, 2011, Nat. Rev. Drug Discov., 10:715-6)? The onus therefore falls upon academic drug discovery which takes advantage of the fact that academic groups with a deep knowledge of the pathophysiology of disease processes are best-placed to identify novel targets or understand existing targets. Accordingly, the University of Sussex (UoS) recently set up the Translational Drug Discovery Group (TDDG). Our aim is to establish a portfolio of targets within the oncology and neuroscience therapeutic areas that will attract external funding (Wellcome Trust, MRC, CRUK, Pharma or whoever), with the ultimate goal being to provide preclinical candidate molecules suitable for clinical development.
The TDDG comprises a core group of medicinal chemists and biologists that are supplemented by personnel funded by external funders to deliver on specific projects. We can provide our research partners with pharmacological tools to better validate novel targets as well as identify and optimise screening hits against the target of interest. Rather than high-throughput screening, the TDDG has chosen an alternative approach to hit-finding, namely fragment-based drug discovery. Following this strategy, a relatively small number (c.2,000) of low molecular "fragments" are screened using either biochemical or biophysical assays with hits being confirmed using X-ray crystallography, thereby exploiting the UoS's world-leading structural biology expertise. Further limited exploration of novel chemotypes is used to develop an early understanding of the structure-activity relationship in order to support applications to external funding bodies. Our oncology targets are based around UoS expertise in DNA damage whereas the neuroscience portfolio is currently being assembled and we welcome the opportunity to collaborate with any interested academic or industrial partners.

Title: Centrally acting antitussives, possessing inhibitory action on GIRK channels, increase the c-Fos and TH double-immunopositive cells in the ventral tegmental area and locus coeruleus

Authors: *R. HAMASAKI[1], F. SOEDA[1], K. TAKAHAMA[1,2];
[1]Dept. of Envrn. and Mol. Hlth. Sci., Grad. Sch. of Pharmaceut. Sci., Kumamoto, Japan;
[2]Kumamoto Hlth. Sci. Univ., Kumamoto, Japan

Abstract: We previously reported that the centrally acting antitussives inhibited inwardly rectifying K^+ (GIRK) channel currents to induce neuronal firing of the neurons in the dorsal raphe, ventral tegmental area (VTA) and locus coeruleus (LC) in rats. Furthermore, we reported that the antitussives at antitussive-effective doses elevated extracellular monoamine levels in rat brain and ameliorated symptoms of the animal models of various psychiatric disorders including intractable depression without causing undesired effects like psychostimulants. According to our previous behavio-pharmacological studies, the multiple pharmacological effects of the antitussives may be produced at least partly by activating catecholaminergic neurons via inhibition of GIRK channels. Then it is essential for validation of our own working hypothesis to confirm whether the antitussives at antitussive-effective doses activate catecholaminergic neurons in vivo, because it is reported that dopaminergic neurons in VTA may be not homogeneous in neurochemical properties and pharmaco-physiological roles. In this study, using double-immunohistochemical technique, we investigated the effects of tipepidine (TP) and cloperastine (CP) on the number of double-immunopositive cells for c-Fos and tyrosine hydroxylase (TH) in VTA and LC of rats minutely. TP and CP (40 mg/kg, i.p.) commonly increased the number of TH(+)/c-Fos(+) cells in the LC(Bregma -6.84 mm), and in the restricted region of VTA (Bregma -5.88 mm), but not in other regions of the VTA (Bregma -6.24 mm and -6.84 mm). Then CP but not TP increased TH(+)/c-Fos(+) cells in the VTA (Bregma -5.16 mm). Furthermore, CP and TP also increased TH(-)/c-Fos(+) neurons in the VTA (Bregma -5.88 mm, -6.24mm, -6.84 mm). Then, CP but not TP increased TH(-)/c-Fos(+) cells in the VTA (Bregma -5.16 mm). Subnuclei (paranigral nucleus, PN; parabrachial pigmented nucleus, PBP; parainterfascicular nucleus, PIF; interfascicular nucleus, IF) analysis of the VTA (Bregma -5.88 mm) is now in progress. The increment of TH(-)/c-Fos(+) cells by TP and CP might suggest that TP and CP also activate GABAergic interneurons, because it is greatly known that there are numerous GABAergic interneurons expressing GIRK channels in the VTA, which may put a brake on excessive excitation of dopaminergic cells. Although further studies are required, the current data suggest that the antitussives possessing inhibitory action on GIRK channel currents, may activate noradrenergic neurons in LC, and dopaminergic neurons of the restricted region in VTA, which may contribute to the multiple pharmacological effects in experimental animals.

Title: Evaluation of novel drug targets for schizophrenia treatment using a model of cortical and basal ganglia circuitry

Authors: *P. D. ROBERTS[1], H. GEERTS[2], A. SPIROS[1];
[1]In Silico Biosciences, Inc, Portland, OR; [2]In Silico Biosciences, Inc, Philadelphia, PA

Abstract: Novel targets for treatments of psychiatric diseases may lead to unexpected outcomes such as underestimated efficacy in humans and adverse side effects. Although animal models may reveal some aspects of clinical outcome, computational models of brain circuitry can integrate disparate data to augment predictions of potential clinical success. We present a computational model that is calibrated for improving the positive and negative symptoms of schizophrenia (PANSS) scale and extrapyramidal symptoms (EPS) to demonstrate an evaluation of phosphodiesterase-10 inhibitor (PDE10-I) as a treatment for schizophrenia.
We have developed a biophysical model of the cortex, thalamus and basal ganglia loop to simulate the neural activity patterns associated with healthy and pathological conditions in the human brain. The schizophrenia pathologies are implemented by altering dopamine levels, NMDA and GABA currents, and background noise. Modulatory effects of dopamine, serotonin, and other modulators are incorporated throughout the circuitry by implementing the changes in membrane and synaptic currents caused by receptor activation in each neuron type. Model readouts include firing rates, frequency band power, and information measures of the circuit activity.
The model was calibrated to represent the effects of drugs in human patients by adjusting modulator parameters to optimize the correlation between model readouts and clinical data. We calibrated the model to predict the efficacy of 72 antipsychotics-dose combinations on the PANSS clinical scale and the liability for EPS using historical clinical trials.
We then implemented the effects of PDE10 inhibition in the medium spiny neurons of the striatum by simulating the intracellular signaling pathway effects on dopamine receptor activation mediated modulation of membrane currents and downstream activity changes in the

cortico-striatal-thalamic loop. The simulated results demonstrate the unexpected dystonia motor effects and lack of efficacy as observed in recent clinical trials, while opposite effects are obtained with the rodents. Combination therapy with appropriate doses of dopamine antagonists is shown to improve the clinical profile of PDE10-I if the correct balance between D1- and D2-type receptors is obtained.

Title: Nicotinic receptor ligand reduces anxiety and depression-like behaviors after withdrawal from voluntary ethanol drinking in mice

Authors: *M. A. RONI, S. RAHMAN;
Pharmaceut. Sci., South Dakota State Univ., Brookings, SD

Abstract: We have shown that brain nicotinic acetylcholine receptor (nAChR) ligand lobeline decreases anxiety and depression like-behaviors after withdrawal from nicotine self-administration. The present study has determined the effects of lobeline on anxiety and depression-like behaviors after withdrawal from voluntary ethanol drinking. C57BL/6J male mice were allowed to drink 10% ethanol for four weeks. Mice were tested after 24 h and 14 days of ethanol withdrawal. In forced swim test (FST), a measure for depression-like behavior, acute lobeline treatment (1 mg/kg, s.c.) significantly reduced immobility time compared to control after 24 h of withdrawal (control: 124 ± 14 sec, lobeline: 69 ± 5 sec; $p < 0.05$). In elevated plus-maze (EPM), a measure for anxiety-like behavior, lobeline significantly increased open arm entries (control: 11 ± 3%, lobeline: 34 ± 4%; $p < 0.01$) after 24 h of withdrawal. Likewise, after 14 days of ethanol withdrawal, acute lobeline treatment significantly reduced immobility time in FST (control: 108 ± 8 sec, lobeline: 49 ± 12 sec; $p < 0.01$); increased open arm entries (control: 5 ± 2%, lobeline: 20 ± 2%; $p < 0.01$) and open arm times (control: 0.5 ± 0.2%, lobeline: 3 ± 1%; $p < 0.05$) in EPM. Furthermore, the effects of chronic lobeline on anxiety and depression-like behaviors after withdrawal from voluntary ethanol drinking and associated neuroadaptive

changes are being investigated. Overall, these results suggest that lobeline reduces anxiety and depression-like behaviors in mice likely by targeting brain nAChRs and nicotinic cholinergic mechanisms may play a critical role during withdrawal from ethanol dependence.

Title: SUVN-911, α4β2 antagonist shows antidepressant like activity and addresses the limitation of current antidepressant therapy

Authors: *V. BENADE, R. PONNAMANENI, G. BHYRAPUNENI, P. JAYARAJAN, V. GOURA, I. BHATIA, S. TELLA, V. GOYAL, S. PANDEY, S. JANA, A. MOHAMMED, S. VEERAMALLA, R. NIROGI;
Suven Life Sci. Ltd, Hyderabad, India

Abstract: Mental illnesses are leading cause of disability globally. Depression alone affects almost 121 million people worldwide. About one in every 10 persons is expected to present at least one depressive episode during his/her lifetime. Projections for economic expenditure place depression near the top of the list for the year 2030. Currently available antidepressants have a number of limitations. Some of these include low response and remission rates, delayed onset of action, sleep disturbances, cognitive dulling and sexual dysfunction. SUVN-911 is a potent and selective $\alpha_4\beta_2$ antagonist. SUVN-911 demonstrated more than 500 fold selectivity for $\alpha_4\beta_2$ receptors (NovaScreen selectivity panel). SUVN-911 showed good brain penetration and receptor occupancy following oral administration, with good oral bioavailability in all preclinical species. SUVN-911 was evaluated in animal models of depression like the DRL-72s, dominant submissive assay and forced swim assay. The minimum effective dose of SUVN-911 was found to be less than 1 mg/kg, *p.o.* At behaviorally effective doses, SUVN-911 produced a significant increase in cortical serotonin levels. SUVN-911 showed good margin of safety in toxicity studies and is non-mutagenic. The pharmacology, pharmacokinetic, metabolic, biopharmaceutical and toxicity profiles of SUVN-911 makes it promising candidate for clinical development. Above observations provide strong support to develop SUVN-911 for the management of mood disorders. The compound is ready for clinical evaluation.

Title: Scopolamine and ketamine attenuate parachlorophenylalanine-induced behavioral despair in a stress-sensitive rat strain

Authors: *W. A. ECKERT, III, G. CHEN;
Neurosci., Janssen Res. & Development, L.L.C., San Diego, CA

Abstract: Parachlorophenylalanine (PCPA), an inhibitor of tryptophan hydroxylase, interrupts the chain of synthesis of the important neurotransmitter, serotonin. PCPA administered systemically to humans can cause depression relapse in recovered patients under treatment with antidepressants. The relapse lasts for 4 to 7 days after PCPA withdrawal. Previous rodent studies showed that PCPA treatment can reduce serotonin levels in the brain, increase immobility and evoke anhedonia-like behaviors. Here, we conducted a series of experiments to refine and validate the PCPA paradigm. We found that 3 daily doses of PCPA in stress-sensitive Wistar Kyoto (WKY) rats can induce a long-lasting despair-like behavior using the active avoidance test (AAT). PCPA-treated rats failed to escape or avoid escapable foot shock up to 22 days after the last PCPA treatment. By contrast, vehicle-treated rats escaped or avoided shock on each day tested. There was no significant difference between groups in hot plate responses suggesting that the deficits of PCPA-treated rats in the AAT were not likely confounded by an altered pain threshold. Intravenous infusion of the muscarinic receptor antagonist, scopolamine, and the *N*-Methyl-D-aspartic acid (NMDA) antagonist, ketamine, each have been reported to rapidly reduce the severity of depression in patients. Both scopolamine and ketamine significantly attenuated the PCPA-induced increase in escape latencies in WKY rats in the AAT in a temporal manner similar to those observed in depression patients. These data support the administration of PCPA in stress-sensitive WKY rats to produce a model of depression that may be useful for mechanistic research and drug discovery and development.

Title: Activity of serotonin 5-ht1a receptor biased agonists in rat models of depression and syndrome: Superior profile of the post-synaptic preferential agonist, f15599

Authors: M. J. O'CALLAGHAN[1], W. C. LI[1], *R. A. MCARTHUR[2], M. VARNEY[3], A. NEWMAN-TANCREDI[3];
[1]Cerca Insights, Penang, Malaysia; [2]McArthur & Assoc GmbH, Basel, Switzerland;
[3]Neurolixis,Inc, San Diego, CA

Abstract: BACKGROUND: Serotonin 5-HT1A receptors have been extensively investigated in the mechanism of action of antidepressants. Indeed, 5-HT1A agonists are active in animal models of depression. However, previous drugs targeting 5-HT1A receptors, such as buspirone and its analogues, have yielded disappointing clinical antidepressant efficacy, possibly due to poor receptor selectivity and weak partial agonism. In addition, previous drugs did not distinguish between sub-populations of 5 HT1A receptors in different brain regions. This is important because activation of post-synaptic cortical 5 HT1A receptors is considered pivotal to antidepressant and pro-cognitive activity, whereas desensitization of pre-synaptic inhibitory somatodendritic 5 HT1A autoreceptors is a limiting factor in the onset of therapeutic efficacy. Recently, a highly-selective and efficacious 5-HT1A receptor "biased agonist", F15599, has been described that preferentially activates cortical post-synaptic 5-HT1A receptors. Its congener, F13714, displays the opposite profile, preferentially activating pre-synaptic 5 HT1A receptors. The prototypical 5-HT1A agonist, 8-OH-DPAT activates both pre- and post-synaptic 5-HT1A receptors. Here we compared the activities of these drugs in the rat FST, in tests of "syndrome" (induction of flat body posture, FBP, fore-paw treading, FPT, and lower lip retraction, LLR), and in measures of body temperature.
RESULTS: F15599 and F13714 both potently and completely abolished immobility in the FST (MEDs 0.08 mg/kg IP) as did 8-OHDPAT (MED 0.09). F13714 also elicited LLR (MED 0.16), FBP (0.63) and FPT (2.5) as did 8-OHDPAT - LLR (MED 0.1), FBP (MED 0.09.) and FPT (MED 1.78). In contrast, F15599 elicited these behaviors at higher doses (MEDs: LLR 0.63; FBP

0.63; FPT 10). In addition, F15599 showed little propensity to elicited hypothermia (MED 0.63). CONCLUSIONS: these data show that the post-synaptic preferential “biased agonist” F15599 shows potent antidepressant-like activity with a decreased propensity to elicit syndrome. Similar data have been previously reported by another laboratory [1] and the present results constitute their first independent confirmation. Preferential targeting of post-synaptic 5 HT1A receptors may be promising strategy for improved antidepressant therapy.

Title: Antidepressant and anxiolytic profiles of newly synthesized arginine vasopressin V1b receptor antagonists: TASP0233278 and TASP0390325

Authors: *M. IIJIMA, T. SHIMAZAKI, K. FUKUMOTO, S. CHAKI;
Mol. Function and Pharmacol. Labs., Taisho Pharmaceut. Co., Ltd., Saitama,Saitama, Japan

Abstract: Arginine vasopressin (AVP) has been presumed to be involved in stress-related disorders such as depression and anxiety. We revealed that both TASP0233278 and TASP0390325 are potent, selective and orally effective antagonists for an AVP receptor subtype 1b (V1bR). In the present study, we investigated antidepressant and anxiolytic profiles of TASP0233278 and TASP0390325 in animal models of depression and anxiety. Oral administration of TASP0233278 or TASP0390325 exerted the antidepressant effects in two models of depression (forced swimming test and olfactory bulbectomy model). Moreover, TASP0233278 improved depressive-like behavior induced by repeated treatment with corticosterone, a model which has been shown to disrupt hypothalamic-pituitary-adrenal axis function and to be resistant to treatment with currently prescribed antidepressants. In addition to

depression models, TASP0233278 and TASP0390325 exerted anxiolytic effects in several anxiety models (social interaction, elevated plus-maze, stress-induced hyperthermia, separation-induced ultrasonic vocalization). Of note, TASP0233278 counteracted anxiety-like behavior induced by swim stress in the elevated plus-maze test, consisted with anti-stress effects of V1bR antagonists. Moreover, TASP0233278 counteracted sodium lactate-induced panic-like responses in panic prone rats. The present results provide further evidence that V1bR is related to stress-induced changes in behaviors, and that V1bR antagonists may be useful for the treatment of depression and anxiety disorders.

Title: *In vitro* and *Ex vivi* profiles of newly synthesized arginine vasopressin V1b receptor antagonists: TASP0233278 and TASP0390325

Authors: *T. YOSHIMIZU, T. SHIMAZAKI, K. TOKUGAWA, S. CHAKI;
Taisho Pharmaceut. Co., Ltd., Saitama, Japan

Abstract: Abnormalities of the hypothalamic-pituitary-adrenal (HPA) axis activity have been observed in patients with stress-related disorders such as depression and anxiety. Arginine-vasopressin (AVP) has been considered the primary factor in the regulation of HPA axis activity through its receptor subtype, V1b receptor (V1bR) and many studies have shown the potential utility of V1bR antagonists for the treatment of depression and anxiety. Here we show pharmacological profiles of TASP0233278 and TASP0390325, novel and potent non-peptide V1bR antagonists. TASP0233278 and TASP0390325 showed high affinities for V1bR, and exhibited much lower affinities for other receptors and enzymes, including V1aR, V2R, or OXTR. TASP0233278 and TASP0390325 also potently attenuated AVP-induced [Ca2+]i increase in CHO cells expressing V1bR, while they did not change basal [Ca2+]i levels in the cells, indicating that both compounds are antagonists for V1bR. Furthermore, we examined antagonism to dDAVP (a synthetic replacement for AVP)-induced potentiation of the effect of corticotrophin-releasing factor (CRF) on ACTH release in rats. Oral administration of TASP0390325 significantly inhibited the CRF/dDAVP-induced plasma ACTH increase in rats. These results show that both TASP0233278 and TASP0390325 are potent, selective and orally

effective V1bR antagonists, and that these compounds can be used as tools to explore pharmacological significance of blockade of V1bR.

Abstract: Annona senegalensis is used in combination with other herbs in folkloric medicine for the management of psychosis. The hypnotic, effects on phenobabitone induced sleep and behavioural effect of A. senegalensis were investigated in wistar rats. A. senegalensis did not induced sleep in experimental animals, but it was observed that the methanolic extract sedated and attenuated behavioural activity in rats. The results from the study also revealed that A. senegalensis prolonged phenobarbitone induced sleep. The calming effects observed with A. senegalensis may be the basis for its use with other herbs for the management of psychosis.

Title: The Tortoise and the Hare: Fast vs. very slow corticogeniculate axons differ in visual response properties

Authors: *C. R. STOELZEL[1], Y. BERESHPOLOVA[1], J. ZHUANG[1], J.-M. ALONSO[1,2], H. A. SWADLOW[1,2];
[1]Dept. of Psychology, Univ. of Connecticut, Storrs, CT; [2]Dept. Biol. Sci., SUNY-Optometry, New York, NY

Abstract: The lateral geniculate nucleus (LGN) projects to both layers 4 and 6 of the visual cortex (V1), with layer 6 providing a feedback projection back to the LGN. This feedback is thought to shape receptive field properties and influence spike timing of thalamic neurons. Layer six corticogeniculate (CG) neurons display a wide range of axonal conduction times (40 ms, Swadlow and Weyand, 1987), and little is known how such variations are related to receptive field tuning and visual responding. To examine this question, we studied the receptive field properties of CG neurons in the awake rabbit, mapping their tuning properties with drifting gratings and other stimuli. CG neurons of layer 6 were identified by antidromic activation. Our preliminary results consist of 25 visually responsive corticogeniculate neurons. All of these cells had "simple" receptive fields and had antidromic latencies of 2.5 to 35 ms, median = 18.0 ms). Both fast and slow CG neurons had similarly low rates of spontaneous firing (median = 0.14 spikes/s, range = 0.01 - 2.5). However, fast CG neurons differed in their visual response properties from those with slowly conducting axons in several ways: (1) Fast CG neurons were more responsive (higher F1) during optimal drifting grating stimulation ($r = -.71$, $p < .001$). (2) Fast CG neurons had shorter response latencies to a flash stimulus ($r = .56$, $p<0.01$). (3) Fast CG neurons had shorter interspike intervals during visual stimulation ($r= .69$, $P<0.01$). (4) Fast CG neurons were more sensitive to contrast (C-50) ($r= 0.54$, $p<0.02$), and (5) fast CG neurons preferred higher velocity stimuli ($r= -0.51$, $p<0.02$). Additionally we recorded from 19 corticogeniculate neurons which were identified by antidromic activation, yet exhibited little to no spontaneous activity and were not responsive to visual stimulation by either drifting or flickering grating, more slashing bars of light. These "Silent" cells had longer antidromic latencies (9.4 to 48 ms (mean = 28 ms, t-test $t = 3.34$, $p = 0.002$) than corticogeniculate neurons which responded to visual stimuli. Taken together these results indicate that the diversity in CG axonal delays is strongly related to the diversity in the visual response properties of this system.

Title: Layer 4 in primary visual cortex of the awake rabbit: Contrasting properties of simple cells and putative feed-forward inhibitory interneurons

Authors: *J. ZHUANG[1], C. R. STOELZEL[1], Y. BERESHPOLOVA[1], J. M. HUFF[2], X. HEI[1], J.-M. ALONSO[3,1], H. A. SWADLOW[1,3];
[1]Dept. of Psychology, Univ. of Connecticut, Storrs, CT; [2]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA; [3]Dept. of Biol. Sci., SUNY Col. of Optometry, New York, NY

Abstract: Extracellular recordings were obtained from two cell classes in layer 4 of the awake rabbit primary visual cortex (V1): putative inhibitory interneurons (suspected inhibitory interneurons, SINs) and putative excitatory cells with simple receptive fields. SINs were identified solely by their characteristic response to electrical stimulation of the lateral geniculate nucleus (LGN, 3+ spikes at > 600 Hz), and simple cells were identified solely by receptive field structure, requiring spatially separate ON and/or OFF subfields. Notably, no cells met both criteria, and we studied 62 simple cells and 33 SINs. Fourteen cells met neither criterion. These layer four populations were markedly distinct. Thus, SINs were far less linear (F1/F0 < 1), more broadly tuned to stimulus orientation, direction, spatial and temporal frequency, more sensitive to contrast, had much higher spontaneous and stimulus-driven activity, and always had spatially overlapping ON/OFF receptive subfields. SINs responded to drifting gratings with increased firing rates (F0) for all orientations and directions. However, some SINs showed a weaker modulated (F1) response sharply tuned to orientation and/or direction. SINs responded at shorter latencies than simple cells to stationary stimuli, and the responses of both populations could be sustained or transient. Transient simple cells were more sensitive to contrast than sustained simple cells and their visual responses were more frequently suppressed by high contrasts. Finally, cross correlation between LGN and SIN spike trains confirmed a fast and precisely timed monosynaptic connectivity, supporting the notion that SINs are well-suited to provide a fast feed-forward inhibition onto targeted cortical populations.

Title: V1 corticogeniculate input to LGN is sustained

Authors: *Y. I. BERESHPOLOVA[1], C. R. STOELZEL[1], J. ZHUANG[1], J.-M. ALONSO[1,2], H. A. SWADLOW[1,2];
[1]Dept. of Psychology, Univ. of Connecticut, Storrs, CT; [2]Dept. Biol. Sci., SUNY-Optometry, New York, NY

Abstract: Layer 6 of primary visual cortex (V1) receives direct input from the lateral geniculate nucleus (LGN), and is also an important output layer, from which descending corticothalamic projections arise. In the rabbit, LGN concentric neurons are bimodally distributed into sustained and transient populations with distinct response properties (Swadlow and Weyand, 1985; Bezdudnaya et al., 2006; Cano et al., 2006) and each of these cell types provide input to cortical layers 4 and layer 6 (Stoelzel et al., 2008). Examinations of the responses of simple cells and putative inhibitory interneurons (suspected inhibitory interneurons, SINs) in layer 4 to stationary, maintained stimuli have also revealed classes of cells that respond in a sustained or transient manner to maintained stimulation of the receptive field center (Zhuang et al., 2013). Here we extend this analysis to layer 6. Corticogeniculate (CG) neurons were identified by antidromic activation. SINs of layer 6 were identified by their characteristic response to electrical stimulation of the LGN (3+ spikes at > 600 Hz), and had short-duration spikes. As in our previous studies, testing for sustained/transient responding was performed when awake rabbits were in an alert EEG state. We found that visually responsive CG neurons displayed a very broad range of axonal conduction delays (2.5 to 35 ms) and all had simple receptive fields, consisting of one or more spatially separate ON and/or OFF subfield. Remarkably each of the 22 CG neurons that we studied responded in a sustained manner to static stimulation of the receptive field center. This contrasts to our results in layer 4, where simple cells respond in a sustained (43%), transient (26%) or intermediate (31%) manner to maintained stimulation of the RF center (Zhuang et al., 2013). By contrast, SINs of layer 6 were similar to those of layer 4, in yielding predominantly transient responses to static stimulation (6 of 18 layer 6 SINs were sustained, compared to 8 of 34 layer 4 SINs). We also measured the latency of the response to flashing stationary stimuli. CG cells showed significantly longer latencies to visual stimuli (median: 64.6 ms) than layer 6 SINs (median: 33.8 ms; $p<0.001$, K-S test), layer 4 SINs (median: 28.2 ms; $p<0.001$, K-S test) or layer 4 sustained simple cells (median: 37.5 ms, $p< .001$, K-S

test). Thus, our results indicate that the layer 6 feedback to the LGN is overwhelmingly sustained across the broad spectrum of axonal conduction delays seen in this system.

Title: The rapid emergence of direction selectivity across all layers of ferret primary visual cortex

Authors: *N. RITTER[1], A. ROY[1], J. OSIK[2], S. D. VAN HOOSER[2];
[1]Biol., [2]Brandeis Univ., Waltham, MA

Abstract: In ferret visual cortex, direction selectivity develops in the days and weeks following eye opening through a process that requires visual experience (Li et al 2006). Direction selectivity can be induced rapidly in visually naïve, isofluorane-anesthetized animals by 3-12 hours of visual stimulation with a moving but not a flashing stimulus (Li et al 2008). This rapid emergence of direction selectivity has been characterized with intrinsic signal imaging and two-photon calcium imaging, techniques that target layer 2/3 neurons and do not give a direct readout of spiking activity.
Naturally emerging direction selectivity has been measured at the level of spiking across all layers (Clemens et al 2013). It was found that layer 4 neurons exhibited direction selectivity earlier in development than layer 2/3 neurons. Additionally, the increase in direction selectivity was initially due to an increased response to motion in the preferred direction, and later increases in selectivity were due to a decreased response to motion in non-preferred directions.
Here we characterize the progression of events during the rapid emergence of direction selectivity that occurs upon exposure to a motion stimulus for several hours. We monitor emerging direction selectivity in all layers with a linear array of electrodes. Data will be presented regarding the direction tuning of V1 neurons from all cortical layers over the course of training. We will compare the progression of cortical tuning during rapid emergence of direction selectivity with the natural progression of cortical tuning in the days after eye opening.

Title: Flexibility of cortical tuning during development: Insights from training with unnatural motion stimuli

Authors: *A. ROY[1], J. J. OSIK[2], N. J. RITTER[2], S. VAN HOOSER[2];
[1]Brandeis Biol., Waltham, MA; [2]Biol., Brandeis Univ., Waltham, MA

Abstract: Neurons in ferret V1 not only respond preferentially to bars of specific orientations, but also to one direction of motion orthogonal to the preferred orientation. This direction selectivity (DS) of response, like orientation selectivity (OS), expresses first at the level of cortex and neurons with similar DS are organized into distinct direction columns. But unlike OS, DS develops through normal visual experience during an early critical period (P28-35). In ferrets of this age, neurons in superficial layers of V1 can rapidly gain DS following a few hours of exposure to bidirectionally moving gratings. How does visual experience interact with the genetically specified mechanisms of cortical development to shape DS? There are two fundamentally distinct ways in which the experience-dependent and -independent processes can interact in cortex. According to one view, the genetically specified processes lay out the basic circuit required for DS already before eye opening and subsequent visual experience simply helps the completion of those processes leading to mature DS. In this scenario cortical neurons in P28-35 ferrets should be seeded for their eventual DS. Consistent with this idea, V1 neurons in P28-35 ferrets with limited visual experience exhibit very small biases in direction tuning that strongly predict the tuning outcome following directional training. Alternatively, genetic mechanisms might only establish the OS circuit, leaving visual experience to exert a more instructive role in shaping DS. Consistent with this idea, training with unidirectional grating stimuli shows that the quality of training stimulus also exerts a strong effect on neurons' DS fate. To disentangle the distinct roles played by experience-dependent and -independent processes in DS development, we have developed two types of unnatural motion stimuli that are unlikely to be represented in the form of small biases in the naïve cortex of a normal ferret. One such

stimulus consists of luminance-alternating counter-phase gratings, which is the sum of two gratings moving in opposite directions simultaneously. The second stimulus consists of gratings with arbitrary phase sequences resulting in non-smooth motion. Using in vivo two-photon imaging of calcium signals in P28-35 ferrets we are testing the results of 3-6 hours of training with these stimuli. Data will be presented regarding the directional tuning of layer 2/3 neurons before and after such training. The nature of the selectivity that arises in response to these different training patterns will reveal the degree to which cortex is primed to learn motion selectivity per se versus any arbitrary spatiotemporal pattern.

Title: Reward modulates the task-related hemodynamic signal in primary visual cortex (V1) of alert macaques

Authors: M. M. B. CARDOSO[1,2], M. BEZLEPKINA[1], B. R. LIMA[1], Y. B. SIROTIN[3], *A. DAS[1];
[1]Neurosci, Columbia Univ., NEW YORK, NY; [2]Champalimaud Fndn, Lisboa, Portugal; [3]Rockefeller Univ., New York, NY

Abstract: V1 imaging signals recorded from subjects performing visual tasks contain prominent non-visual information such as task timing (Donner et al., 2008; Pestilli et al., 2011). The neural and behavioral correlates of such non-visual signals, and their relation to visually evoked signals,

are poorly understood. By recording simultaneous imaging and electrode signals from V1 in alert monkeys we earlier reported a task-related signal that entrains to task timing and is not predicted by local spiking (Sirotin & Das 2009). When the task is stereotyped this signal can be linearly separated from the stimulus-evoked signal that is, by contrast, strikingly well predicted by local spiking (Cardoso et al., 2012).
Here we report that the task-related signal is modulated by reward (juice) amount, but in a manner that remains poorly related to local spiking. The experiments were structured as in our earlier work (Sirotin & Das, 2009). We recorded electrode signals simultaneously with intrinsic-signal optical imaging (local blood volume) signals from V1 of rhesus macaques performing a periodic fixation task in essentially complete darkness. Here, however, we systematically varied the reward schedule, with the animal receiving alternating blocks of high and low reward for correct trials.
Alternating the reward size led to a consistent change in the task-related signal, with higher peak-to-peak signal amplitude but asymptotically lower trial-averaged mean blood volume for the blocks of high vs. low reward.
Notably, the V1 spiking recorded during dark-room fixation also had a distinct trial-linked fluctuation (which is not due to stray visual input, as established through controls). However, this spiking appears independent of the task-related hemodynamic signal or its changes with reward size. The spiking signal poorly predicted the task-related signal when convolved with visually stimulated hemodynamic response function (HRF) kernels calculated for the same recording site (c.f. Cardoso et al., 2012). HRF kernels obtained by fitting the spikes to the dark-room signal directly gave better predictions; but the kernels were highly variable, both across sites, and for high vs. low reward at the same site, suggesting that they reflect just a fortuitous fit.
To conclude - we show a prominent reward-related modulation of the (hemodynamic) neuroimaging signals recorded from V1 in task-engaged macaques. However, this reward signal appears to be driven by a neural mechanism that remains distinct from mechanisms underlying any local spiking responses. These results will help provide insights for understanding the neural basis of brain imaging.

Title: Spiking activity and not LFP best predicts stimulus-evoked hemodynamics in V1

Authors: *B. R. LIMA[1], M. M. B. CARDOSO[1,2], Y. B. SIROTIN[3], A. DAS[1];
[1]Dept. of Neurosci., Columbia Univ., New York, NY; [2]Champalimaud Fndn., Lisboa, Portugal;
[3]Rockefeller Univ., New York, NY

Abstract: Neuroimaging techniques based on measuring hemodynamics, such as Functional Magnetic Resonance Imaging (fMRI) are widely used for studying human brain activity. Our lab has shown that the hemodynamic signal measured in V1 of alert monkeys performing periodic tasks can be linearly separated into two components: 1- a task-related part that entrains to trial onset and is not predicted by local neural activity and, 2- a stimulus-evoked part which can be well predicted by local spiking activity. In this study we systematically investigate which neural signal (i.e. spiking, vs. different components of local field potential - LFP) best predicts stimulus-evoked hemodynamics.

We performed simultaneous intrinsic-signal optical imaging (a high-resolution, optical analog of fMRI) and electrode recordings in V1 of alert macaque monkeys engaged in passive fixation tasks (N = 91 sites, 5 hemispheres in 3 monkeys). Hemodynamics, LFP and MUA (multi-unit spiking activity) were simultaneously acquired while presenting gratings of a full range of contrasts (typically 6.25-100% in 2x steps, and a blank). The LFP spectrograms were separated into frequency bands comprising 4-12 Hz, 12-30 Hz, 30-90 Hz or 110-200 Hz which our data showed as having distinct functional relationships with the imaging signal. Stimulus-evoked responses were obtained by subtracting away the blank (0% contrast) response from each signal. Response linearity between aggregate neural and hemodynamic signals was estimated by linear regression as well as by fitting the signals using a gamma-variate hemodynamic response function.

Spiking activity was the neural signal that best correlated with stimulus-evoked hemodynamics. LFP power at frequencies greater than 100 Hz was the second best neural correlate, possibly due to spectral leakage of spiking into high LFP frequencies. Power at the gamma band (30-90 Hz) was characterized by weak induction at low contrasts, and strong induction at intermediate and high contrast stimulation compared to spiking or hemodynamics. This resulted in a non-linear relationship with hemodynamics making it a consistently weaker predictor compared to spiking.

Power at low LFP frequency bands (4-12 Hz) was inversely related to hemodynamics for a subset of the recorded sites. However, population results for the low frequencies, despite showing the same trend, were highly variable. The beta frequency band (12-30 Hz) behaved in a manner similar to the gamma band, but its correlation with hemodynamics was consistently weaker. Evoked LFP trace, as well as its square (net LFP power), correlated well with hemodynamics for a few sites but population results revealed them as poor predictors.

Title: A relativistically-invariant gabor-like filter for receptive field representation in the mammalian visual cortex

Authors: *S. G. ODAIBO[1,2];
[1]Quantum Lucid Res. Labs., Arlington, VA; [2]Ophthalmology, Howard Univ. Hosp., Washington, DC

Abstract: The retina is the functional interface between light from a visual scene and the brain's visual cortex, where spatiotemporal representation and computing of visual information begin. Relativistic effects are therefore likely to play a significant role in the retina and retino-cortical axis. However, existing filters used in computational models of visual perception are not relativistically-invariant. In this paper, we introduce a relativistically-invariant 3D spatiotemporal Gabor-like filter, for representing the receptive fields of simple neuronal cells. We will call it the Gabor-Einstein filter. Computational simulations are presented demonstrating its behavioral adherence to pertinent physiological constraints.

Title: Functional role of acetylcholine in the primary visual cortex of rat

Authors: *S. SOMA[1,2], S. SHIMEGI[1,2], N. SUEMATSU[1], R. MIZUYAMA[3], H. SATO[1,2]; [1]Grad. Sch. of Frontier Biosci., [2]Grad. Sch. of Med., [3]Departments of Biol. Sci., Osaka Univ., Osaka, Japan

Abstract: Acetylcholine (ACh) is known to modulate neuronal activity in the rodent primary visual cortex (V1). We recently examined effects of a microionophoretically administered ACh in V1 of anesthetized rats, finding that ACh facilitated or suppressed visual responses to varying stimulus contrasts by multiplying the control responses, i.e. response gain control. This result raises important questions: 1) why opposing effects are concomitantly observed in a cortical area, 2) how interlaminar circuitry is modulated by ACh, and 3) whether ACh improves the detectability of visual contrast. To examine these points, we combined extracellular multi-unit

recordings and topical administration of ACh, and measured V1 neuronal responses to drifting sinusoidal grating stimuli in anesthetized rats. We confirmed that ACh changes the response gain upward or downward in facilitated or suppressed cells, respectively. These ACh effects showed a laminar bias, where the response suppression and facilitation prevailed in layers 2/3 and layer 5, respectively. Next, we examined ACh effects on the signal-to-noise (S/N) ratio and the grating-phase information calculated as F1/F0 ratio. In facilitated cells, ACh improved the S/N ratio, while in suppressed cells it enhanced the F1/F0 ratio without any concurrent reduction in the S/N ratio. These effects on S/N and F1/F0 ratios were observed in regular-spiking cells, but not in fast-spiking cells. Our findings suggest that ACh promotes the signaling of grating-phase information from supragranular cells to higher-order areas by the suppressive modulation, and enhances feedback signals with a high S/N ratio from infragranular cells to subcortical areas by the facilitatory modulation. To examine whether such fine regulation of visual information processing by ACh contributes to the improvement of visual performance in behaving animals, we trained rats to detect visual stimulus in a two-alternative forced-choice task combined with a staircase method and found that donepezil, a cholinesterase inhibitor, improved the contrast sensitivity depending on the stimulus conditions.

Title: Dual labeling of figural elements in primary visual cortex

Authors: M. CHEN[1], C. GILBERT[2], *W. LI[1];
[1]State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China;
[2]The Rockefeller Univ., New York, NY

Abstract: According to the "labeled line" theory in sensory processing, different neurons in the primary visual cortex (V1) register different local stimulus features; on the other hand, V1 neuronal responses can be affected by global stimulus context. Contextual influences in V1 have been interpreted to play diverse roles in mediating various center-surround interactions, but it is unclear whether the V1 signals conveying figural information defined by different stimulus contexts share similar properties. By examining the response properties of V1 neurons in monkeys detecting different forms of targets within complex backgrounds, we found that V1 plays a double role in stimulus labeling: registering the local stimulus attributes and marking the local elements within the global context as belonging either to the figure or to the background. The latter global labeling, which is superimposed on but can be dissociated from the local labeling, is independent of neuronal feature selectivities and of the global figural attributes when the saliency of the figure is fixed. For instance, when the figure to be detected was a global contour made of collinear lines embedded in randomly oriented lines, we could dissociate a general additive response component that was dependent on the global saliency of the contour but was independent of neuronal orientation selectivity and of the global contour orientation. Moreover, this additive effect was indistinguishable when the neuron's receptive field was centered on any local element lying on the contour path, even if the element in the receptive field was in marked feature contrast with the other stimulus elements. However, the response component associated with the global labeling gradually faded when the luminance contrast between the background and the figure was increased, indicating dependence of the global labeling process on the complex background. The other forms of stimuli with global figure-ground configurations showed similar results, suggesting a general mechanism for figure-ground processing in V1.

Title: Infrequent simple cells in the tree shrew primary visual cortex

Authors: *J. VEIT, A. BHATTACHARYYA, R. KRETZ, G. RAINER;
Univ. of Fribourg, Fribourg, Switzerland

Abstract: There is a notable difference in the occurrence of primary visual cortex (V1) „simple“ and „complex“ cells between mammalian species, for example between cat and monkey. Here we are interested in examining occurrence of these two response types in the tree shrew, a close relative of primates. Two criteria are commonly used to separate the two cell classes: spatial separation of antagonistic receptive subfields responding to luminance in- and decreases (subfield overlap) and the temporal modulation by a drifting grating stimulus (F1/F0 ratio). Here we quantified both subfield overlap as well as F1/F0 ratio in 120 single neurons recorded from V1 of 16 anesthetized tree shrews. The proportion of “simple” cells found with the two different methods differed dramatically: Using the F1/F0 criterion approximately 42% of neurons were classified as “simple”, whereas using subfield overlap only 7% fell into this category. We argue that this discrepancy is in part explainable by the robust black dominance of a large majority of tree shrew V1 neurons which inflates F1/F0 modulation measures. In a subset of 72 neurons we repeated the measurements after stimulation of the basal forebrain (BF stim), the main source of cholinergic projections to cortex. BF stim led to robust increases in firing rates and significantly reduced F1/F0 ratios ($p<0.01$), such that 19 cells that were classified as “simple” before were now behaving like “complex” cells. Interestingly, the overlap indices were not systematically affected by basal forebrain stimulation ($p>0.1$). Taken together we show that in tree shrew V1, “simple” cells occur rather infrequently and structural receptive field measures like the subfield overlap appear to be more robust to changes in firing rate than the F1/F0 ratio. Our findings suggest that tree shrew V1 does not rely heavily on “simple” cell signals, and these may thus not represent an obligatory step in the transformation of visual information.

Title: Spatial tuning for color and luminance in awake area V1

Authors: *M. JANSEN[1], X. LI[1], R. LASHGARI[1], J. KREMKOW[1], Y. BERESHPOLOVA[3], H. SWADLOW[3], Q. ZAIDI[2], J.-M. ALONSO[1,3];
[1]Biol. Sci., [2]Grad. Ctr. for Vision Res., SUNY Col. of Optometry, New York, NY; [3]Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Neurons in primary visual cortex are tuned to different spatial properties of the stimulus such as orientation and spatial frequency. These tuning properties have been extensively studied with achromatic stimuli but systematic comparisons with chromatic stimuli are rare (Johnson et al., 2001, 2008), in part because such comparisons require long recordings from single neurons, which are technically difficult. Here, we took advantage of ultra-thin chronic multielectrode arrays (Swadlow et al., 2005) that allowed us to record single neurons in awake primates for an average time of over 3 hrs. We modulated colors in the cone-based DKL space to generate chromatic red-green (RG) and blue-yellow (BY) gratings. A V1 neuron was classified as 'color neuron' if it responded stronger to chromatic gratings than achromatic gratings with 15% luminance contrast (this contrast value is equal to the maximum cone-contrast in RG gratings and larger than the maximum luminance-contrast artifact caused by the macular pigment in BY gratings). Only 11/42 (26%) were classified as color neurons; the rest were classified as 'luminance neurons'. Compared with luminance neurons, color neurons were less orientation selective (0.22 vs. 0.58, $p<0.05$, t-tests for this and following comparisons) and less sensitive to luminance contrast, both when measured at the contrast that generated the maximum response (90% for color and 61% for luminance, $p<0.05$) and at the half-maximum response (33% for color and 11% for luminance, $p<0.001$). Color and luminance neurons were not different in many other spatial properties including circular variance (0.77 vs. 0.69, $p=0.25$), direction selectivity (0.40 vs. 0.52, $p=0.24$), spatial frequency peak (0.75 vs. 0.82, $p=0.79$ cpd), spatial frequency cut off (0.67 vs. 0.77 cpd, $p=0.57$), low/high spatial frequency ratio (4.00 vs. 2.94, $p=0.63$), grating size that generated maximum response (2.8 vs. 2.3 degrees, $p=0.55$) and half-maximum response (1.3 vs. 1.0 degrees, $p=0.19$), size suppression (0.25 vs. 0.44, $p=0.17$) and phase selectivity (3.68 vs. 2.06, $p=0.17$). Some color neurons responded stronger to intermediate color axes than the sum of the responses to RG and BY axes. Two neurons responded to smaller stimulus sizes for RG than luminance gratings and two other neurons had different spatial frequency tuning for chromatic and achromatic stimuli: one was lowpass for BY and bandpass for luminance; another was lowpass for RG and bandpass for luminance. We conclude that cells representing color and luminance in area V1 have similarly diverse spatial properties but differ in population size, orientation tuning and sensitivity to luminance contrast.

Title: Convergence of thalamic inputs with multiple receptive fields having different patterns of synchronous spikes optimizes the output reliability and precision of spiny stellate cells in visual cortex

Authors: *C. F. SABOTTKE[1], H.-P. WANG[2], D. J. SPENCER[2], T. J. SEJNOWSKI[2];
[1]Louisiana State Univ., Baton Rouge, LA; [2]Computat. Neurobio. Lab., Salk Inst., La Jolla, CA

Abstract: Synchronous inputs from the lateral geniculate nucleus (LGN) in the thalamus allow visual information from the retina to reliably drive a spiny stellate cell (SSC) in the primary visual cortex (V1) receiving 300-400 thalamic inputs, which is only 5% of all their synaptic inputs. Additionally, LGN and retinal ganglion cells with similar receptive fields produce highly correlated spike trains with millisecond precision, and spike-triggered covariance and related analysis techniques have revealed that V1 neurons have multiple receptive field subunits. We investigated how SSC spike train reliability and precision varied with different patterns of input connections from LGN cells having both similar and different receptive fields. We studied the responses of a multi-compartment model of the SSC, with probabilistic release and short-term synaptic plasticity, to in vivo recordings from adult cat LGN responding to a sinusoidal grating and other visual stimuli. New methods were used to calculate reliability and precision to account for both similar spike patterns and shared periods of silence. We found that there is an optimal range of synchrony that balances high levels of reliability and precision against cellular resource costs. Depending on the connectivity of presynaptic LGN cells to the SSC synapses, different synaptic release patterns emerged that in turn affected the reliability and precision of the SSC spike trains. We found that 40-60 synchronous thalamic synapses maximize spiking reliability and precision, with a broad optimum at around 5-10 synapses per LGN axon, in agreement with anatomical measurements. These findings shed light on how the patterns of connectivity between LGN and V1 affect the reliability and precision of spike trains in the primary visual cortex. We also demonstrate how different combinations of LGN inputs, through synchronous firing, contribute to the receptive field properties of spiny stellate cells.

Abstract: In primate V1 and V2 most neurons with small spatio-temporal receptive fields respond selectively to oriented luminance contours, while only a subgroup of neurons signals non-luminance defined contours (second-order). These properties raise the question whether population responses of V1 and V2 mainly reflect the global representation of second-order contours or the processing of the local physical inducers that define second-order contours? Here we compared the population responses of macaque V1 and V2 to three types of second-order contour stimuli generated either by motion (kinetic contours), modulation of contrast, or phase reversal. We found that, both with intrinsic optical imaging and spatio-temporal energy model simulation, the local visual cues within these second-order contour stimuli drove the population responses within the orientation columns of both macaque V1 and V2. These results suggest that the primate early visual system initially makes use of local luminance and motion cues for processing the orientation of second-order contours, prior to form-cue invariant shape processing in higher-tier visual cortices. Our results of population responses to second-order contour stimuli defined by first-order inducers also suggest that the orientation maps within primate V1 and V2 can be described as a spatial-temporal energy map.

Title: Stimulus-dependent gamma-frequency shifting in the macaque v1

Authors: *K. LAKSHMINARASIMHAN[1,2], N. K. LOGOTHETIS[2,3], G. A. KELIRIS[2,4]; [1]Dept. of Neurosci., Baylor Col. of Med., Houston, TX; [2]Max-Planck Inst. for Biol. Cybernetics, Tuebingen, Germany; [3]Imaging Sci. and Biomed. Engin., Univ. of Manchester, Manchester, United Kingdom; [4]Bernstein Ctr. for Computat. Neurosci., Tuebingen, Germany

Abstract: The phase of spikes in the gamma cycle has previously been shown to be modulated by stimulus orientation in macaque V1 (Vinck et al. 2010, Womelsdorf et al. 2012). These studies suggested that such stimulus-dependent phase shifts selectively facilitate the impact of neurons that fire earlier in the gamma cycle, on their targets. However, such phase coding schemes implicitly depend on the generation of a consistent gamma oscillation frequency across stimulus conditions. To test this, we examined whether the stimulus orientation and the eye of presentation affected the peak gamma frequency in V1. Two macaque monkeys were trained to passively fixate on a central spot, while one of two orthogonally oriented gratings was presented monocularly through a mirror stereoscope for a period of one second. In different trials either the eye of presentation or the orientation, were changed. Local field potential (LFP) signals recorded from 168 sites across multiple sessions were found to exhibit significant coherence with concurrently recorded single-unit spikes in the gamma frequency range. The power spectral density of each of those LFPs was fit as the sum of a power function and a gaussian function, and the center of the gaussian was taken as the peak gamma frequency. We found that, across sites the peak frequency varied between 30 Hz and 45 Hz in both monkeys. Moreover, within each site there was a significant shift in the peak frequency both with orientation (median shift ~1.99Hz) as well as the eye of presentation (median shift ~0.89Hz). There was no systematic relationship between the direction of shift and stimulus preference. Given that the orientation-dependent phase shifts reported earlier were of a very small magnitude (only a few degrees), it follows that such frequency changes could be detrimental for phase-shift coding schemes that rely on entrainment of multiple cortical areas to a single ‘clock-like’ signal. Alternatively, neural

mechanisms implementing phase computations could be relatively invariant to frequency changes by using more intricate signal properties like instantaneous phase.

Title: Motion integration along a trajectory by neuronal population in alert monkey V1

Authors: *G. BENVENUTI, G. S. MASSON, F. CHAVANE;
INT, CNRS, Marseille, France

Abstract: We have recently shown that a bar approaching the RF of a V1 neuron along a trajectory can generate an “anticipatory” response that builds up gradually with time before the bar actually enters into the classical RF of the cell and modulates the response within the RF (Benvenuti et al. 2011, SfN). This study was conducted in alert monkeys over a population of 83 V1 neurons (SUA), recorded in different sessions, in response to a bar moving along straight trajectories of different length before entering the RF center. We proposed that this "anticipation" results from the integration of convergent propagations of activity dynamically recruited along the neuronal population that is getting gradually activated by the retinal input.
Using a similar experimental paradigm, we further studied this trajectory-dependent response at the level of V1 population of alert fixating monkey chronically implanted with multi-unit UTAH array (96 electrodes on a squared matrix of 4mm). It gave us the opportunity to record simultaneously single-unit, multi-unit and LFP from a population of neurons with partially superimposed RFs and different tunings properties over multiple recording sessions. The spatial profile and tuning properties of the recorded neurons’ RFs was first carefully characterized using sparse noise stimuli and local gratings. We then presented a bar moving towards and across the RFs with different trajectory lengths (1.5 ,3 ,6°). Over many sessions, we have investigated the dependence of the trajectory-dependent response to several stimulus parameters such as: bar directions (0, 90 ,135 ,180 ,225 ,270°), bar orientations (30, 60, 90, 120 and 150° relative to motion direction), speeds (2 ,6.6 ,12 ,16 ,19°/s) and bar lengths (1, 2, 4 , 8°). Depending on the stimulation configuration, RFs could be crossed one after the other by the bar, or at the same time, or none when we used a local mask over the population RF. Our results suggest that this

trajectory-dependent response is a contextual priming signal that influences the detection and the identification of various properties of the moving stimulus.

Title: Three distinct types of simple cells in visual cortex: Spatiotemporal receptive field properties derived from natural images

Authors: *V. TALEBI, C. L. BAKER;
McGill Vision Res. Unit, McGill Univ., Montreal, QC, Canada

Abstract: The retina and lateral geniculate nucleus (LGN) have many categorically distinct types of neurons, but in the visual cortex, simple and complex cells are the only well-defined classes. However our recent work using natural image stimuli to estimate a linear-nonlinear (LN) model has revealed three distinct classes of early cortical simple cells, based on their spatial receptive field (RF) structure and power law output nonlinearity. Here we quantitatively examine the spatiotemporal response properties of these three categories, to gain insight into their functional roles. Extracellular recordings were made from simple-type cells in area 18 (A18) of anesthetized, paralyzed cats in response to natural images. We utilized a primary dataset to estimate the 3D spatiotemporal RF, and independent hold-back datasets for regularization and predictive evaluation. A gradient descent, iterative regression algorithm with regularization was employed to estimate a linear model of the RF, and a subsequent zero-memory nonlinearity (half-wave rectifier and power law) was fit to the data. Estimated RF models were analyzed to characterize their spatial tuning, temporal dynamics, spatiotemporal behaviour, and spiking properties. The "non-oriented" RFs lacked orientation and direction selectivity, and had higher spatial frequencies and shorter temporal durations, suggesting that they might be more directly driven by LGN afferents. The other two categories of RFs were selective for orientation and often, direction of motion. The "expansive-oriented" cells differed from the "compressive-oriented" cells not only in shape of the output nonlinearity, but also in their responsivity and

degree of correspondence to an LN model, suggesting that they differed fundamentally in the degree to which a nonlinear gain control mechanism was engaged. The three classes also differed in the extent to which they spanned complementary ranges of temporal latencies and durations. Results so far suggest that each of the classes might be further subdivided on the basis of optimal spatial frequency. Other RF properties such as spatial frequency bandwidth, optimal orientation, aspect ratio, and RF ON/OFF dominance did not bear any relationship to the three categories. This work challenges the prevailing idea that due to the rich connectivity within cortical circuitry, each neuron will show some physiological attributes of many others, thus blending them together into a multi-dimensional continuum of RF properties. Rather, response properties in cortex are categorically distinct, implying that cortical neurons may have specialized functional roles.

Title: Role of sleep spindle in early visual areas and perceptual learning

Authors: *J. BANG, T. WATANABE, Y. SASAKI;
Brown Univ., Providence, RI

Abstract: Sleep is known to consolidate memory. However, the underlying neural mechanism has yet to be completely understood. Here, to better understand the mechanism for the

facilitatory effect of sleep on visual perceptual learning, we measured fine-scaled spatio-temporal neural activity during sleep after training of texture discrimination task (TDT) using a multimodal neuroimaging technique that combines MEG and MRI. A leading hypothesis suggests that the sleep spindle activity during the non-rapid eye movement sleep (NREM) is involved in the facilitatory effect. Since the TDT is associated with changes in the region of the early visual areas that retinotopically corresponds to the trained visual field quadrant, we tested whether the strength of sleep spindles in early visual areas is correlated with the facilitatory effect during sleep on TDT.
Young and healthy participants underwent an MRI session after 3 nightly MEG sessions including 1 adaptation, pre-, and post-training sleep. Before the post-training sleep, TDT was conducted twice; the initial test and intensive training in one visual field quadrant. After the post-training sleep, we conducted a re-test of TDT. Wavelet-transformed MEG during sleep was combined with high-resolution MRI to constrain the current locations to the cortical mantle individually. We measured the strength of the sigma activity that represents sleep spindles in the 2 cortical parts in early visual areas which retinotopically corresponds to the trained and untrained visual field quadrants, based on the retinotopic mapping. The results showed that sigma activity yielded greater power increase in the trained region of early visual areas than in the untrained region of early visual areas after training. In addition, the power change of sigma activity was significantly correlated with the learning amount in TDT. This suggests the feasibility of the hypothesis that the sleep spindle activity is involved in the consolidation of TDT during sleep.

Title: Development of GABAergic neuron response properties in visual cortex in-vivo

Authors: *S. J. KUHLMAN, R. ZHANG;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Cortical GABAergic inhibition is a key mediator of visual development, and accumulating evidence identifies aberrant GABAergic function in neurodevelopmental disease.

However, the mechanisms by which inhibition regulates experience-dependent development of vision are not well-defined, nor is it understood how disturbance of cellular signaling pathways within inhibitory interneurons impacts GABAergic circuit assembly in terms of recruitment of inhibition in-vivo. Using in-vivo targeted electrophysiological recording of an identified inhibitory interneuron cell type, the parvalbumin (PV+) fast-spiking GABAergic interneuron, we demonstrated that visual experience uniquely broadens orientation tuning of layer 2/3 PV+ interneurons (Kuhlman et al., Nat Neurosci 2011). Our results support a model in which PV+ broadening is mediated by the development of excitatory synapses onto PV+ interneurons.
We are currently testing the hypothesis that increased local recurrent feedback from excitatory neurons within layer2/3 is a critical step in the maturation of PV+ response properties, and are defining the role of tyrosine kinase signaling and AMPA receptor trafficking in this process. Response properties to visual stimulation are assayed using patch-clamp electrophysiology and gCamp6 calcium imaging in vivo.
Identification of the molecular pathways that mediate PV+ maturation and integration into the circuit will facilitate the generation mouse models in which maturation of PV+ neurons is either accelerated or stunted; the impact of aberrant recruitment of inhibition on sensory learning and new skill acquisition will be studied in go/no-go discrimination tasks.

Title: Combined repetitive Donepezil administration and visual exposure increases visual acuity in rats

Authors: *M. CHAMOUN, J. IL KANG, F. HUPPÉ-GOURGUES, E. VAUCHER;
Optometrie, Univ. De Montreal, Montreal, QC, Canada

Abstract: Memory and learning are associated with cortical release of acetylcholine(ACh). Rat's visual acuity and cortical activity for a specific pattern can be improved when repeated visual exposure of a specific stimulus is paired with electrical stimulation of basal forebrain cholinergic neurons. The clinical approach to stimulate the cholinergic transmission in human consists in increasing extracellular ACh level by acetylcholinesterase inhibitor (AChEI), the degradation

enzyme for ACh. Donepezil is a non-competitive and reversible AChEI which has been shown to cause significant increase of ACh concentration in humans as well as in rats. In addition, Donepezil induces beneficial effects on learning performance in rats.
In the present study we evaluated whether repeated visual exposure of a specific stimulus would also change the visual acuity of the rats for the trained stimulus when the exposure is paired with Donepezil administration. Visual evoked potentials (VEPs) to a sinusoidal phase converting grating pattern, shown in a pseudo-random manner for 30° and 120° orientations and different spatial frequencies (0.08 to 1 CPD), were recorded in rat's primary visual cortex (V1) before and after the two weeks visual exposure. The two weeks visual exposure consisted in 10 min daily exposure to a 0.12 cycle per degree (CPD) 30° sinusoidal pattern, in rats injected with Donepezil or saline 20 min prior to visual exposure. An index of variation (Ivep = post-exposure VEP amplitude - pre-exposure VEP amplitude) was then calculated to determine the variation of the cortical response.
Our results show that VEPs index of variation for the 30° orientation was significantly increased in Donepezil injected rats at high spatial frequencies (0.9 CPD: 0.5±0.18, Mann-Whitney p=0.027 and 1.0 CPD: 0.45± 0.2 Mann-Whitney p=0.050) but not in control animals (0.9 CPD: -0.15±0.14, 1.0 CPD: -0.20±0.13). The VEP amplitude for the 30° orientation showed an increasing tendency at the training frequency 0.12 CPD, (0.64 ± 0.39, Mann-Whitney p=0.64) but not in the control group (-0.04 ± 1.3). No significant difference was observed in the post- vs pre- VEPs amplitude to any spatial frequency for the 120° orientation.
Our results showed increased visual acuity in rats trained with Donepezil. This agrees with the previous study in which the cholinergic system stimulation was provided by electrical stimulation of the basal forebrain. Overall, we demonstrated the possibility to increase visual performance and cortical response by combination of cholinergic stimulation and visual exposure in rats.

Title: Environmental experience and visual system development and plasticity: Epigenetic effects

Authors: *L. BARONCELLI[1], I. MANNO[2], M. SCALI[1], G. SANSEVERO[1], L. MAFFEI[1,2], A. SALE[1];
[1]Neurosci. Institute, CNR, Pisa, Italy; [2]Scuola Normale Superiore, Pisa, Italy

Abstract: Despite more than 50 years of research on the effects of environmental enrichment (EE) on the brain, very few studies have investigated the influence of enhanced sensory-motor experience on the development and plasticity of sensory cortices. Recently, a new approach in which the traditionally separated fields of EE and manipulation of visual experience have been combined together has shown that early EE robustly accelerates the development of the visual system, and that exposure to EE in adulthood enhances visual cortex plasticity well after the end of the critical period. While some critical factors underlying these effects have already emerged, it remains unknown whether changes at the level of chromatin structure and function are also involved as possible mechanisms underlying the effects of EE. Here, we report that histone acetylation is enhanced both in the visual cortex of preweaning pups raised in enriched conditions, in parallel with an accelerated time course of the critical period for ocular dominance plasticity, and in the visual cortex of adult rats in which ocular dominance plasticity is reinstated by exposure to EE. These findings suggest an involvement of the epigenetic machinery as a possible mediator of the impact of EE on visual system development and plasticity.

Title: Correlating neuronal activity after adaptation-induced-plasticity in V1

Authors: *L. BACHATENE, V. BHARMAURIA, S. CATTAN, J. JEYABALARATNAM, S. MOLOTCHNIKOFF;
Dept. of Biol. Sci., Univ. De Montréal, Montréal, QC, Canada

Abstract: The primary visual cortex has the ability to adapt to modified environment features in order to acquire an unfamiliar property of the visual scene. In adult mammals, experience dependant plasticity within the orientation columns of primary visual cortex shifts the tuning curves of neurons which allows the adjustment of their selectivity. Perceptual adaptation to a non preferred oriented stimulus leads to such shifts. These plastic mechanisms may involve alterations in the synaptic weights between cells for the presented oriented stimuli potentiating change in orientation preference at the neuronal level. Thus the question arises: how these connectivity weights are modulated between pairs of neurons which share the same preference properties pre and post visual adaptation, i.e. how the connection probabilities vary after orientation-induced-plasticity?
In the present experiments, we used cross correlation between the trains of action potential of neuronal pairs in order to disclose the modifications of the probabilities of connections between cells before and after visual adaptation. We used electrophysiological recordings in primary visual cortex of anaesthetized adult cats that were visually stimulated by presenting sine-wave drifting oriented gratings. A non preferred orientation was presented for a prolonged duration (12 min) to promote visual adaptation. Cell pairs were selected based on the similarity of their original optimal orientation (±22 deg.) and the shift post adaptation. Shifted and subtracted crosscorrelograms were constructed between the trains of spikes of the cell pairs, and the two highest adjacent bins within ±5ms time window of the crosscorrelogram were compared pre and post adaptation to compare the probability of connection of neurons and its modulation. Results indicate a decorrelation of connection probabilities for the original optimal orientation as well as for the new acquired preferred orientation after adaptation which suggests a recalibration of connectivity strength when the modifications of orientation selectivity are occurring.

Title: Orientation-domains exhibit more plasticity than pinwheel-centers in V1

Authors: *S. CATTAN[1], V. BHARMAURIA[1], L. BACHATENE[1], J. JEYABALARATNAM[1], J. RIBOT[2], C. MILLERET[2], S. MOLOTCHNIKOFF[1];
[1]Sci. Biologiques, Univ. De Montréal, Montréal, QC, Canada; [2]Lab. de Physiologie de la Perception et de l'Action, Collège de France, Paris, France

Abstract: Object-orientations in the visual field are columned into specific orientation-domains in the primary visual cortex (V1), where neurons in one cortical column respond preferentially to a determined orientation. It has previously been shown that adapting V1 neurons for variable durations of time (Ghisovan et al., PLoS ONE 2008; Bao and Engel, Proc Natl Acad Sci U S A 2012; Bachatene et al., Eur J Neurosci 20013; Jeyabalaratnam et al., PLos ONE in press) induces shifts in neurons' original preferred orientation. Previous studies (Dragoi et al., Neuron 2001; Schummers et al., Prog Brain Res 2005) reported that neurons located at pinwheel-centers are more susceptible to adaptation, and display larger shifts than cells located within orientation-domains. We re-examined these results by comparing neuronal activity on optical-imaging-maps (i.e. mean activity of 0.38 mm² cortical areas corresponding to one pixel) before and after adaptation in anesthetized cats at three locations: in pinwheel-centers, at the junction of two orientation-domains and inside orientation-domains (see figure). Results indicate that shifts in pinwheel-centers are smaller than those in borders between two orientation-domains. In orientation-domains the shifts are largest.
We hypothesize that since neurons in pinwheel-centers have direct relationships with neurons tuned to different orientations, their orientation-selectivity post-adaptation can be attributed to either: 1). neuronal orientation-selectivity in pinwheels is less likely to be changed by neighboring neurons as the synaptic-links between them are weaker, consequently, the amplitude of shifts is smaller, or 2). since many orientations are interspersed in pinwheel, they are likely to get input from many orientations, thus resulting in higher variance of shift-amplitudes. Since our results show smaller shifts in pinwheel-centers, we conclude that our first hypothesis is more likely suggestible for conservation of orientation-maps at these areas of singularity.

Title: *In vivo* imaging of coordinated excitatory and inhibitory synaptic dynamics on pyramidal cell dendrites

Authors: *K. L. VILLA, K. P. BERRY, J. SUBRAMANIAN, J. CHA, P. T. C. SO, E. NEDIVI;
MIT, Cambridge, MA

Abstract: Inhibitory circuit development is important for defining critical period windows during development, and inhibitory cells continue to exert effects on experience-dependent cortical plasticity into adulthood. A common theme of neuronal plasticity is the capacity for dynamic adaptations to ever changing environments. One way this can be accomplished is through the structural remodelling of synapses and dendrites. Recent in vivo imaging studies demonstrate that long-term plasticity of inhibitory circuits can be manifested through structural rearrangements. Alterations in sensory experience drive structural remodelling of inhibitory interneurons in a cell type and circuit specific manner. Recently, we found that inhibitory synapse formation and elimination occurs with a great deal of spatial and temporal precision and that these events are often paired with excitatory synapse alterations within 10um on the same dendrite. To probe the nature of this ‘coordination’ between inhibitory and excitatory synapse dynamics, we triple-labelled L2/3 pyramidal neurons in the mouse visual cortex using YFP as a cell fill, PSD95-mcherry as a post synaptic excitatory synapse marker, and Teal-Gephyrin as a

post synaptic inhibitory synapse marker via in utero electroporation. These mice were implanted with cranial windows as adults and labelled neurons in the binocular visual cortex were imaged in vivo at short intervals using spectrally resolved two-photon microscopy. Surprisingly, we observed increased dynamics when imaging at these shorter intervals as compared to previous 4 day imaging intervals. Here we explore the kinetics, distribution, and probabilities of these dynamic events.

Title: Cortical enhancement induced by pairing cholinergic system and repetitive exposure to visual stimulus is mediated by GABAergic modulation

Authors: *J. KANG, F. HUPPE-GOURGUES, E. VAUCHER;
Sch. Optometry, Montreal Univ., Montreal, QC, Canada

Abstract: Daily pairing cholinergic system activation and visual stimulation with a specific pattern during 2 weeks induced an improvement of the visual acuity for this specific pattern as well as an increase of the cortical response of the primary visual cortex (V1). This process involves both glutamatergic and GABAergic local V1 neurons. In the present study, we investigated the involvement of the GABAergic system in these mechanisms that mediate the visual enhancement. The visual acuity and cortical response were measured by recording the visual evoked potentials (VEP) in V1 before and after the visual training combined with cholinergic system stimulation and local administration of GABAA receptors agonists or antagonists.
We recorded 40 field potentials on an isoflurane anesthetized rat. Visual stimulation consisted of sinusoidal grating pattern phase converting and shown in a pseudo-random manner for each orientation (30° and 120°) and spatial frequency (0.08 to 1 CPD). Pre- and post-training cortical responses (signal/baseline) were measured and compared in the V1. An index of variation (IVEP = post-exposure VEP amplitude - pre-exposure VEP amplitude) was then calculated to determine the variation of the cortical response. The visual training was performed on restrained awaken

rats during 10min/day for 7 days. Visual system activation (phase converting sinusoidal gratings at 0.12 CPD; 30°orientation) was displayed on 3 computer monitors. During visual stimulation, cholinergic system was electrically stimulated through an electrode previously implanted in the basal forebrain (BF). GABAergic agonist, muscimol (200µM) or GABAergic antagonist picrotoxin (100µM) was also infused during visual training through a pre-implanted push-pull cannula (i.c.) in the V1.
VS/BF stimulated group showed a specific increase of cortical response for the trained stimulus (1.81 ± 0.57, one-way ANOVA, post-hoc LSD, p=0.023) compared to control group (0.11 ± 0.44). No other spatial frequency than 0.12 CPD were significantly changed during 1 week of visual training. Muscimol injected group also showed no significant increase of VEP for 0.12CPD (0.15 ± 0.45) after training but picrotoxin injection during exposure induced an amplification of VEP increase (2.8 ± 1.1, p=0.003).
Our study demonstrates that the repeated visual exposure paired with cholinergic stimulation induces increase of cortical response. Also this increase can be abolished by GABA activation but GABAA receptor inhibition can enhance the cholinergic stimulation effect. Overall, these results indicate that the GABAergic system contributes to cholinergic-dependent plasticity.

Title: Molecular specificity for synapse and spine stabilization in layer II/III pyramidal neurons in visual cortex

Authors: *J. SUBRAMANIAN[1], J. CHA[2], P. SO[3], E. NEDIVI[4];
[2]Dept. of Mechanical Engin., [3]Dept. of Mechanical Engineering. Dept. of Biol. Engin., [4]Picower Inst. for Learning and Memory, Dept. of Biology, Deparment of Brain and Cognitive S, [1]MIT, Cambridge, MA

Abstract: The temporal sequence and mechanisms underlying formation and stability of dendritic spines in relation to their synaptic inputs are poorly understood. To simultaneously track formation and elimination of dendritic spines as well as excitatory and inhibitory inputs onto these spines, we developed a multi-color, two photon microscopy system for in vivo

imaging of entire layer 2/3 pyramidal neuron arbor in adult mouse visual cortex. We find that synapse formation and elimination are protracted processes that occur over a period of days. PSD95, a post-synaptic density protein is recruited to pre-existing dendritic spines and that the presence of PSD95 correlates with spine stability. We further show that CPG15, a molecule known to promote synapse maturation and stabilization mediates PSD95 recruitment to dendritic spine excitatory synapses, but is not required for inhibitory synapse formation. In the absence of CPG15, the density of mature dendritic spines was significantly lower. Fewer new spines were able to recruit PSD95, and the loss of spines lacking PSD95 was markedly increased. In contrast, the stability and the density of inhibitory synapses or dendritic spines innervated by them remained unaltered. Thus, dually (excitatory + inhibitory) innervated spines were comparable in their dynamics between WT and CPG15 knockout animals. Our data demonstrates distinct requirements for stabilization of excitatory and inhibitory synapses in vivo. Our data further supports a role for CPG15 in synapse maturation through stabilization of nascent spines and or synapses, and shows that synapse formation is a driving force in dendritic spine stabilization, irrespective of the synapse type.

Title: Population receptive field analysis of auditory frequency tuning in early blind individuals

Authors: *E. HUBER, J. M. THOMAS, I. FINE;
Univ. of Washington, Seattle, WA

Abstract: Introduction: Early onset blindness has been linked to enhanced auditory abilities and altered BOLD responses in both auditory and occipital cortex. In auditory cortex, changes in both the amplitude and extent of responses have been noted (Elbert et al., 2002; Stevens and Weaver, 2009). In occipital cortex, early blind subjects show cross-modal responses to a wide range of auditory stimuli across multiple visual areas (e.g., Poirier et al., 2006; Roder et al., 2002; Voss et al., 2008). Here, we measured tonotopic organization in early blind and sighted subjects to assess group differences in tonotopy and characterize the tuning properties of cross-modal responses to pure tones in early blind subjects. Methods: We carried out tonotopic

mapping in auditory and occipital cortex in early blind and age-matched sighted controls using functional magnetic resonance imaging. Our stimuli were pure tones ranging from 88 to 8000 Hz, presented in randomized sequences during six separate runs in a single scanning session. Data were analyzed using an adaptation of the population receptive field technique developed by Dumoulin and Wandell (2008). Our model treats the aggregate receptive field underlying each voxel's response as a one-dimensional Gaussian function of frequency. This technique provides an estimated sensitivity function for each voxel with a given center, or preferred frequency, and standard deviation which describes the population tuning bandwidth. Results: We obtained consistent and reliable tonotopic maps within auditory cortex for both subject groups. It remains to be determined with additional subjects whether tuning bandwidth and/or the size of PAC might differ across blind and sighted subjects. We also observed cross-modal responses to pure tones in early blind, but not sighted, subjects. Frequency selective population receptive field estimates in occipital cortex of blind subjects were as robust as estimates in auditory cortex. The majority of these occipital voxels were narrowly tuned to frequencies within a 1000-1500 Hz range. Conclusions: Population receptive field estimates suggest that the cortical mapping of frequencies in auditory cortex follows a similar organization in sighted and blind individuals. In addition, the distribution of preferred frequencies in occipital cortex of blind subjects suggests a greater representation in the range of 1000-1500 Hz, which may provide a basis for superior performance of various auditory tasks.

Title: The involvement of early visual cortex in tactile discrimination of Braille and visual discriminations of letters in a patient with low vision

Authors: *A. D. GOUWS[1], E. H. SILSON[1], K. L. HAAK[1], J. RODGERS[1], M. CROUCHER[1], M. HYMERS[1], H. A. BASELER[1,2], G. E. LEGGE[3], A. B. MORLAND[1,2];

Abstract: Patient S has low vision and can read Braille. Previous research on S has shown greater activity to Braille than visual stimuli at the occipital pole and lateral occipital areas, a pattern not found in normally sighted individuals (Cheung et al, Current Biology, 2009, 19, 596-601). The occipital pole normally forms part of early visual areas including V1. This study aimed to examine the causal role played by the occipital pole in S when discriminating letters, in both the tactile (Braille) and visual domains. We used fMRI to identify regions of the brain that had greater responses to Braille than to visual stimuli and vice versa. As previously, the results highlighted Braille selective responses at the occipital pole. As expected, controls only exhibited visually selective responses at the occipital pole. Both controls and S exhibited Braille selective responses in somatosensory cortex (S1). We used the outcome of the fMRI experiment to generate targets for TMS. Specifically, we defined (1) an occipital pole target (OP) as the most medial aspect of Braille selective cortex, (2) a target located in Braille selective cortex of S1 (S1). Targets were selected in the hemisphere contralateral to the Braille reading finger. In psychophysical experiments we then presented four Braille letters (A, L, Q, X) on a computer controlled Braille character array. All pins in the array were displaced for 200ms and the letter was defined by additional pin displacements. We established pin displacement thresholds for Braille letter discrimination (60 % correct) in a four alternative forced choice task. In similar forced choice experiments we established the size and contrast of the same letters presented visually. TMS pulses were delivered during stimulus presentation to OP and S1 while S performed tactile and visual letter discriminations of stimuli presented at his thresholds. In S, visual discrimination was strongly affected following stimulation of OP, but not S1. In contrast, stimulation of S1, but not OP, resulted in poor Braille discrimination. This double dissociation was entirely consistent with control data. It appears therefore that while fMRI shows that OP is Braille selective, it does not appear to play a causal role in S's ability to perform tactile tasks. It is possible that foveal representations in early visual areas at the occipital pole OP receive top-down input from extrastriate visual areas that are causally involved in Braille tasks. Further TMS experiments that probe the causal role of more lateral, extrastriate regions of Braille selective cortex in S are therefore warranted.

Title: The effects of retinal degeneration on crossmodal sensory takeover of the visual cortex

Authors: *M. K. JARVINEN, R. MORROW, B. SILVEIRA, J. MCEWEN;
Emmanuel Col., Boston, MA

Abstract: One fundamental principle of neocortex organization is the localization of functions to specific neural structures. The visual cortex is an excellent example of this principle. In rodents, the onset of the critical period that leads to mature visual function is well underway by postnatal day (PND) 28 and declines after PND 35. However, much less is known about the timeline and mechanisms involved in the structural reorganization of the visual cortex, particularly after naturally-occurring visual deafferentation. We previously identified when vision loss occurred in a mouse model of retinal degeneration (rd). By PND 49, the loss of vision corresponded with altered gene expression and cell population densities in the visual cortex. The main objective of this current study was to evaluate whether structural reorganization was evident in the visual cortex of rd mice and, if so, to identify the timeline and extent by which it occurred. For our pilot study, we sampled rd mice at PND 49 and randomly assigned them to two different groups. Group 1 (N=6) received auditory/tactile (80dB white noise + focused air flow from small fan) and Group 2 (N=6) received no crossmodal stimulation. After 90 minutes of sensory exposure, all animals were sacrificed, the visual cortices were harvested, and brain sections were processed using c-fos immunohistochemistry. Neurons that were above background threshold were quantified using image analysis software. We found a 15% increase in the number of c-fos labeled neurons in the visual cortex in Group 1 rd mice compared to Group 2 controls. We are currently validating these findings by using sensory stimulation kits from SR-Lab behavioral testing apparati to provide focal and systematic stimulation of the various sensory pathways. Our current data suggest that retinal degeneration modifies sensory wiring in the visual system at a time during development that may result in significant crossmodal sensory takeover. These active neurons may be functionally relevant and provide a mechanism for enhanced sensory detection.

Title: Neural activity in a midbrain cholinergic nucleus, the Ipc, during attention-demanding tasks in chickens

Authors: *J. SCHWARZ, D. SRIDHARAN, E. I. KNUDSEN;
Stanford Univ., California, NY

Abstract: The rapid and reliable selection of relevant stimuli (targets) for gaze and attention is essential for survival in complex environments. This process is governed by interactions within and between networks in the forebrain and the midbrain. Among vertebrates, the midbrain network is most differentiated in birds: the optic tectum is functionally segregated into 15 distinct layers, and the interconnected isthmic nuclei in the tegmentum are clustered into distinct nuclei. This midbrain network is thought to be involved in selecting stimuli for attention as well as targets for gaze shift. The *isthmi pars parvocellularis* (Ipc, homologous to the mammalian parabigeminal nuclues) is a cholinergic tegmental nucleus that connects reciprocally and homotopically with the optic tectum. The precise role of the Ipc in the process of selection remains unknown. We have developed a system for recording neural activity in the Ipc of domestic chickens (*Gallus gallus domesticus*) performing tasks of spatially cued localization and orientation discrimination. We observed that the Ipc stimulus-driven activity was modulated powerfully by a spatial top-down cue. In addition, it conveys gamma-modulated activity that reliably predicts the target of impending shifts of gaze. These results suggest that the Ipc participates in the selection of targets for gaze and attention, and support the hypothesis that this cholinergic nucleus is a critical node in controlling the locus of spatial attention.

Title: Beta/gamma cross-frequency interaction as a mechanism of top-down attentional bias

Authors: *C. G. RICHTER[1,2], W. THOMPSON[3,2], C. BOSMAN[4,5], P. FRIES[2,5];
[1]Lab. de Neurosciences Cognitives, L'Ecole Normale Superieure, Paris, France; [2]Ernst Struengmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt am

Main, Germany; [3]Karolinska Inst., Stockholm, Sweden; [4]Univ. of Amsterdam, Amsterdam, Netherlands; [5]Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands

Abstract: The neural mechanisms of top-down control, which are required for the implementation of processes such as selective attention, have remained poorly understood within the neurosciences for decades. Though fronto-parietal structures are believed to govern the control of spatial attention via top-down modulation of sensory areas, little is known about the mechanisms underlying the generation of this bias, or how it is conveyed to, or interacts with, sensory cortex. It has been demonstrated that neuronal gamma band synchronization is significantly increased in cortex activated by the presence of a visual stimulus, and is enhanced among neurons activated by an attended stimulus. This increased synchronization has been shown to occur both within and between cortical areas. Gamma frequency activity thus appears to be an attentionally modulated correlate of stimulus drive, and is a likely target of top-down modulation. Beta frequency processes appear to play a converse role as they have been increasingly linked to endogenous cognitive mechanisms, such as selective attention - suggesting that beta frequency oscillations may mediate top-down control. Based on these considerations, we hypothesized that top-down beta frequency influences emanating from the fronto-parietal system modulate stimulus driven bottom-up gamma band synchronization between visual areas via a cross-frequency interaction.
We recorded local field potentials with a 252 channel electrocorticographic grid in two rhesus macaques performing a cued covert spatial attention task. We demonstrate that top-down beta frequency interactions, indexed by Granger causality (GC), between posterior parietal area 7a and area V1, are enhanced with spatial attention to the corresponding visual hemifield, thus providing a suitable neural substrate for top-down bias. Crucially, we found a positive trial-by-trial correlation between top-down beta GC, between posterior parietal area 7a and area V1, and bottom-up gamma GC, between areas V1 and V4. This suggests that top-down bias modulates stimulus processing via a cross-frequency linkage between top-down beta frequency oscillations, and bottom-up stimulus driven gamma oscillations. It is possible that the coupling of beta and gamma rhythms within a unit of cortex, such as a macrocolumn, comprise a general computational circuit for top-down modulation whereby gamma frequency ascending stimulus drive may be modulated by descending beta frequency gain control.

Title: The influence of irrelevant distracters on the detection sensitivity of area MT to small changes in motion direction

Authors: *P. S. KHAYAT, J. MARTINEZ-TRUJILLO;
McGill Univ., Montreal, QC, Canada

Abstract: Most neurons in macaque area MT can reliably encode the direction and speed of a moving stimulus through fluctuations in their firing rates. Additionally the neuron's sensitivity to motion attributes correlates with the animal's performance during motion detection and discrimination tasks. These effects have been typically observed when an single moving stimulus was presented inside an MT neuron receptive field (RF), and distracter stimuli were either absent, or located outside the RF. How the ability of MT neurons to detect changes in motion attributes of a target inside their RFs varies in the presence of distracters located nearby remains poorly investigated. Moreover, whether and how the attributes of distracters (i.e., contrast and motion direction) modulate the neurons detection performance is unknown. Here, we investigated whether and how the contrast of a task irrelevant distracter inside MT neurons RF influences the detection of a motion direction change in a target. Monkeys were trained to detect a brief motion direction change in a target RDP, in the presence of another distracter RDP, both located inside the RF. The target RDP moved in the neuron's null direction, while the distracter moved in the preferred direction but had across trials different contrast levels. We examined the firing rates and the neural detection sensitivity (aROC) to the direction change of 73 cells, as a function of the distracter contrast. Although the target direction change was always the same, regardless of the distracter contrast, we found that neural activity reliably signaled the target event only when the distracter's contrast was low (aROC > 0.58). The strength of this effect was correlated with the animal's detection performance. Interestingly, across neurons the degree of distracter interference, measured by the neural detection sensitivity and the animal's behavioral performance, appeared to depend on the strength of response normalization. These results show that distracter attributes modulate the ability of MT neurons to detect changes in the direction of moving stimuli and suggest that response normalization may be one mechanism by which this effect can be explained.

Title: Spatial attention enhances the saliency of changes in motion direction at the expense of an accurate representation in area MT

Authors: *V. MEHRPOUR[1], J. MARTINEZ-TRUJILLO[2], S. TREUE[1,3];
[1]Cognitive Neurosci. Lab., German Primate Ctr. (DPZ), Göttingen, Germany; [2]Dept. of Physiol., McGill Univ., Montreal, QC, Canada; [3]Bernstein Ctr. for Computat. Neurosci. (BCCN), Göttingen, Germany

Abstract: The medial temporal area in the visual cortex (MT) plays a central role in the processing of visual motion information in primates. The activity of MT neurons has been shown to precisely encode the direction of visual motion and to be directly linked to accurate motion perception.
The response of MT neurons is enhanced by the allocation of spatial attention to their receptive field (RF). This attentional modulation has been typically investigated with a paradigm where the animal is trained to detect a direction or speed change in one of several moving visual stimuli located inside and outside the neurons' RF. Single neuron responses are then compared between different attentional conditions in the steady state period before the motion change. Much less is known about the neural responses around the transient change and their attentional modulation.
Visual responses of 52 MT neurons were recorded from two hemispheres of two awake, behaving rhesus monkeys performing a motion direction change detection task: while the animal kept its gaze on a central fixation point, a static random dot pattern (RDP) was briefly shown either inside or outside the receptive field, cueing the animal as to the target's location in the upcoming trial. Subsequently, two moving RDPs were simultaneously presented inside and outside the RF. At a random time the target or distracter direction changed by 25° for 200ms. The animal's task was to indicate a target change by releasing a lever and ignoring changes of the distracter.
Using 12 equally spaced directions we estimated the MT population response before and during the direction change. As expected, the profile accurately represented the stimulus direction before the change, with an enhanced response in those trials where the stimulus inside the RF was the target. However, after a change of the stimulus in the RF, the response profile indicated a direction change larger than the physical change. For distractor stimuli this error was approx. 8° and 13° for target stimuli.
Our data demonstrate that the neural encoding of transient motion direction changes does not match the physical direction change. Rather, the population of MT neurons exaggerates the magnitude of a direction change, making it more salient. Furthermore, the magnitude of the

encoded direction change is almost twice as high for attended vs. unattended stimuli. This finding suggests that the role of attention is not only to increase the strength and accuracy of an attended stimulus' representation but also to enhance stimulus changes, in particular if they are behaviorally relevant (such as a direction change in our experiment).

Title: Attentional modulation of LGN-V1 connectivity in the macaque monkey

Authors: *V. L. MOCK[1], A. M. BASTOS[2,3], J. R. HEMBROOK-SHORT[1], J. M. HASSE[1], F. BRIGGS[1];

Abstract: Increasing evidence suggests that attention modulates the activity of specific neuronal populations within a brain area and influences how information is communicated from one neuronal population to another. Parallel lines of research suggest that different neuronal populations, separated into laminar compartments, synchronize their activity at specific frequencies measured in the local field potential (LFP). We are examining how attention alters specific frequency modulations in LFPs recorded across the layers of primary visual cortex (V1) and/or frequency coupling between the visual thalamus (lateral geniculate nucleus or LGN) and V1. We record LFPs through electrodes placed within retinotopically-aligned regions of the LGN and V1 in awake-behaving monkeys performing a contrast change detection task that requires covert shifts in visual spatial attention. We assess the laminar location of V1 recording sites based on frequency analysis of recorded LFPs and current-source density analysis of linear contacts spanning the V1 cortical depth. Our preliminary results suggest that LGN/V1 recordings demonstrate three basic frequency profiles in response to visual stimulation: 1) enhanced gamma-frequency responses at V1 sites, attributed to superficial layers; 2) enhanced beta-frequency responses at LGN sites with enhanced low-frequency activity at V1 sites, attributed to

granular layers; and 3) enhanced alpha-frequency responses at V1 sites, attributed to deep layers. Interestingly, we observe attentional enhancement of coherence between LGN and V1 sites at the frequencies that show enhanced power according to laminar location. Furthermore, analysis of directed interactions using Granger causality reveals attentional modulation of directional connectivity between LGN and V1 in the feedforward direction for beta-frequencies. Together, these results support the notion that attention selectively modulates the activity of specific neuronal populations within a cortical area and that this specificity influences how information is communicated in the early visual pathways.

Title: Attentional modulation of distinct neuronal populations in primate V1

Authors: *J. R. HEMBROOK-SHORT, V. L. MOCK, J. M. HASSE, F. BRIGGS; Physiol. and Neurobio., Geisel Sch. of Med. at Dartmouth, Lebanon, NH

Abstract: Increasing evidence suggests that attention differentially modulates the activity of specific neuronal populations within a certain brain area. However, exactly how attention differentially alters neuronal activity in specific populations or laminar compartments is not known. In order to address whether and how attention differentially modulates the activity of specific neuronal populations, we examine attentional modulation of identified neuronal cell types at known laminar locations within primary visual cortex (V1) of awake behaving monkeys. A 24-contact linear multi-electrode array is used to record single-unit, multi-unit, and local field potentials (LFPs) within the parafoveal region of V1 in monkeys performing a contrast change detection task that requires covert shifts in visual spatial attention. The laminar location of V1 recording sites is assessed based on spectral analyses of recorded LFPs and current source density analyses of linear contacts spanning the V1 cortical depth. Also, downstream distance (in time and synaptic delay) of V1 recorded units is determined relative to visual thalamic activity

recorded through separate electrodes chronically implanted within the visual thalamus. The visual physiology of recorded single-units is determined based on their responses to drifting sinusoidal gratings that vary in contrast, orientation, size and spatial and temporal frequency. Finally, attentional modulation of neuronal activity is assessed by comparing responses on trials in which animals attend toward versus away from visual stimuli that overlap recorded receptive fields. Our preliminary data suggest that attentional modulation of neuronal firing rate varies according to laminar location and neuronal cell type. These results will greatly increase our understanding of how attentional signals are communicated among neuronal populations.

Title: Increased attentional suppression of cortical LFP with practice time

Authors: *X. LI[1], R. LASHGARI[1], M. JANSEN[1], Y. BERESHPOLOVA[2], H. A. SWADLOW[2,1], J.-M. ALONSO[1,2];
[1]Dept. of Biol. Sci., SUNY Col. of Optometry, New York, NY; [2]Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Spatial attention is known to modulate the activity of neurons in primary visual cortex, however, it remains unclear how these modulations are affected by extended periods of practice. To measure the time course of attentional modulations, we chronically implanted an array of ultra-thin sharp electrodes to record local field potentials (LFPs) in area V1 (Swadlow et al., 2005). Two monkeys were trained to perform two attentional tasks: orientation discrimination and color detection. In both tasks, the monkeys covertly attended a drifting grating that was cued at the beginning of the trial and that could be either inside or outside the LFP receptive field. In both tasks, the LFP was reliably modulated by attention around the time preceding the orientation/color change (average: 8.5/7.3%, p=0.005/0.009) but not at the time following the onset of the cued grating (average: 2.0/1.0%, p=0.380/0.658). Spatial attention

suppressed low LFP frequencies (0.5 - 13 Hz) and enhanced high gamma frequencies (70 - 160 Hz) in both tasks and both monkeys. The low-frequency suppression averaged -9% to -16% in the orientation task (delta: -16.4%; alpha: -10.5%; theta: -9.3%, $p<0.001$, Wilcoxon tests) and -8% to -10% in the color task (delta: -8.2%; alpha: -9.9%; theta: -10.8%; $p<0.001$, Wilcoxon tests). The high-gamma frequency enhancement was more modest and averaged +3.9% in the orientation task ($p<0.001$, Wilcoxon test) and +2% in the color task ($p=0.04$, Wilcoxon test). Interestingly, the magnitude of the attentional modulation was significantly correlated with practice time in both monkeys, but only for the orientation task. In the orientation task, practice time (monkey R: 20 months, monkey S: 6 months) was negatively correlated with the magnitude of the attentional modulations at low LFP frequencies and positively correlated at high LFP frequencies. The negative correlations (increased low-frequency-suppression with time) ranged from -0.7 to -0.8 in monkey S (delta: $r=-0.69$, $p=0.026$; alpha: $r=-0.85$, $p=0.002$; theta: $r=-0.76$, $p=0.009$) and -0.6 to -0.8 in monkey R (delta: $r=-0.63$, $p=0.050$; alpha: $r=-0.80$, $p=0.005$; theta: $r=-0.75$, $p=0.012$). The positive correlations (increased high-frequency-enhancement with time) were +0.71 ($p=0.021$) for monkey S and +0.76 ($p=0.010$) for monkey R. In the color task, attentional modulations did not change with practice time (monkey R: 12 months, monkey S: 6 months) with exception of a reduction in alpha suppression for monkey S ($r=+0.63$, $p=0.050$). These results demonstrate that the cortical effect of spatial attention changes over time, as it would be expected if focused attention plays an important role in perceptual learning.

Title: Predictive power of area V4 local field potentials in determining the state of attention

Authors: *J. MAYO[1], O. GOZEL[2], J. H. R. MAUNSELL[1];
[1]Dept. of Neurobio., Harvard Med. Sch., Boston, MA; [2]École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Abstract: Everyday behaviors require flexible mechanisms for processing visual information. The allocation of attention to specific regions of visual space is one such way in which the brain prioritizes information related to salient stimuli. Most work on the neuronal correlates of visual attention has focused on sustained attention to specific sites in the visual field. However, our focus of attention can change from one location to another frequently and rapidly. Methodological constraints largely prevented the investigation of these changes in attention at behaviorally relevant timescales. Thus, much less is known about how and when changes in attentional state occur at the level of single neurons.
Recent work in our laboratory measured the simultaneous spiking activity of small populations of neurons in visual area V4 to produce trial-by-trial measures of visual attention (Cohen and Maunsell, 2010). Here, we extend this work by examining the predictive power of local field potentials (LFPs) in a similar task. Two monkeys were each implanted with bilateral, 48-electrode arrays in V4 and trained in an orientation change-detection task. Two stimuli were presented simultaneously on a video display, with each stimulus located in the overlapping receptive fields of each electrode array. Stimuli were odd-symmetric Gabors at 100% contrast, sinusoidally counterphased at 10 Hz. Monkeys were trained to fixate in the center of the display and saccade to a stimulus only when it changed orientation. Attention to a stimulus was cued by instruction trials containing a salient cue stimulus at the beginning of each block of trials. Stimulus changes in a block occurred at the cued location ("valid") on 80% of the trials and at the other location ("invalid") for 20% of the trials. Cued locations alternated between blocks. We tested a range of task difficulties (i.e., orientation changes) and measured behavioral performance, spiking activity, and LFPs in over 75 recording sessions.
We found that LFPs sampled for 250 ms before the stimulus change--a putative measure of the animal's attentional state--could be used to predict with relatively high accuracy whether the animals were going to detect or miss the impending stimulus change in that trial. LFPs in the gamma range (30-80 Hz) had predictive power comparable to that of spiking activity. These results suggest that the combination of spiking activity and LFPs can be a powerful predictor of the behavioral outcome of the trials, useful for temporally precise studies of changes in the state of attention.

Title: Acetylcholine iontophoresed into the lateral intraparietal area enhances neuronal firing and improves the monkey's behavior on a difficult visual search task

Authors: *X. WANG[1], M. ZHANG[2], M. E. GOLDBERG[1,3];
[1]Dept of Neurosci., Columbia Univ. Med. Ctr., NEW YORK, NY; [2]Inst. of Neuroscience, Chinese Acad. of Sci., Shanghai, China; [3]New York State Psychiatric Inst., New York, NY

Abstract: Acetylcholine (Ach) is a major neuromodulator in the parietal cortex of the monkey, but little is known about its function. We previously showed that when monkeys perform interleaved difficult and easy visual search tasks, the baseline activity in LIP, measured while the monkeys fixate waiting for the search array to appear, predicts the monkey's success or failure on the difficult task, correlates directly with the intensity of the visual response to the array, the monkey's performance on the current trial, and the monkey's manual reaction time in task, and inversely with the monkey's history of success. The baseline effect is not spatially tuned, and is unrelatged to the monkey's locus of attention (Wang et al., SfN 2012). To study the cellular mechanisms, we applied ACh (0.1M), or the nicotinic receptor antagonist mecamylamine (0.1M), or the muscarinic receptor antagonist scopolamine (0.1M) iontophoretically in the LIP via a 7-barreled pipettte with tungsten wire in the central barrel with which we could measure the activity of single neurons while the monkey performed the search task. We found that Ach increases both the baseline activity and visual responses for both successful and unsuccessful trials. ACh also improves performance on the search task when the search target is in the receptive field of the neuron under study. Both mecamylamine and scopolamine suppress the baseline effects and visual responses of LIP neurons. We suggest that cholinergic neuromodulation of parietal activity is important in regulating the efficiency of behavior in the monkey, and that both nicotininc and muscarinic receptors may be involved.

Title: Decoupled neural and behavioral correlates of attention in a dual orientation discrimination task

Authors: *J. K. BARUNI[1], B. LAU[2,1], C. D. SALZMAN[1,3];
[1]Columbia Univ., New York, NY; [2]Ctr. de Recherche de l'Institut du Cerveau et de la Moelle épinière, Paris, France; [3]New York State Psychiatric Inst., New York, NY

Abstract: A large body of evidence links the behavioral hallmarks of attention (increased performance and decreased reaction time) with neuronal response gain in sensory areas like V4. The import of other cognitive factors, like reward and motivation, on response gain have been difficult to disentangle from those of spatial attention. Here, in an effort to understand the range of cognitive influences on visual perception, we systematically vary from trial-to-trial the reward available in each of 2 locations, decoupling effects of total expected reward and expected reward in a given location from those of spatial asymmetries in reward.
We recorded single unit activity in V4 while monkeys performed a "reward-cued' orientation discrimination task in which each trial has two phases. First, two motivational cues appear indicating the reward value (large or small) associated with correct performance in each hemifield. Second, two oriented stimulus patches appear in opposite hemifields. The monkey must discriminate the orientation of one of the stimulus patches, which is randomly selected by the experimenter and only identified to the monkey after the stimulus patches have been extinguished. Therefore, preceding motivational cues determine the behavioral relevance of each stimulus patch. Motivational cues define four reward scenarios: large reward in receptive field, small opposite (LS); small reward in receptive field, large opposite (SL); both targets largely rewarded (LL); and both lowly rewarded (SS).
We find that when one location is associated with a high reward, and the other with low reward (ie LS or SL), performance is increased and reaction time is decreased at the high reward location. In keeping with previous findings on spatial attention, these behavioral hallmarks of attention are associated with increased firing rates in V4 neurons. At low reward locations, average performance is markedly higher on SS trials than SL trials. Surprisingly, this behavioral difference occurs without commensurate increases in neuronal response gain. Conversely, comparing LL to SS trials (where the absolute values of both targets change, but relative values

of targets do not), we find substantial neuronal response gain in the LL condition that is not accompanied by commensurate behavioral benefits. Taken together, these data suggest that response gain may primarily affect attentional behavior by promoting efficient target selection.

Title: Manipulating attention strategy alters patterns of neural gain in human cortex

Authors: *S. ITTHIPURIPAT[1], J. O. GARCIA[2], N. RUNGRATSAMEETAWEEMANA[3,4], T. C. SPRAGUE[1], J. T. SERENCES[1,2];

Abstract: Over the last several decades, spatial attention has been shown to influence the activity of neurons in visual cortex in a number of different ways. In turn, these conflicting observations have inspired competing models to account for the influence of attention on perception and behavior. One recent model, the normalization model of attention (NMA), attempts to reconcile previous findings by showing how different modulatory patterns can arise due to differences in the spatial extent of attention. Here, we directly tested this model using electroencephalography (EEG) to assess steady-state visual evoked potentials (SSVEPs) in human subjects. While fixing the physical properties of the stimulus display, we show that highly focused spatial attention primarily enhances neural responses to high-contrast stimuli (response gain), whereas distributed attention primarily enhances responses to medium-contrast stimuli in a manner similar to increasing the physical salience of the stimulus (contrast gain). Moreover, we found that the scope of attention modulated responses evoked by both attended and ignored stimuli. Together, these data suggest that different patterns of neural modulation do not reflect fundamentally different neural mechanisms, but instead reflect changes in spatial extent of

attention as implemented by different attentional strategies.

Title: Near real-time spatial reconstructions of visual stimuli with EEG: Exploring the dynamics of spatial attention

Authors: *J. O. GARCIA[1], K. E. KAYE[1], T. C. SPRAGUE[2], J. T. SERENCES[2];
[1]Psychology, [2]Neurosciences, UC San Diego, La Jolla, CA

Abstract: Recently, patterns of fMRI responses across areas of visual cortex have been used to label, or to decode, the precise orientations (Kamitani & Tong, 2005), objects (Haxby et al., 2001), and even natural image (Kay et al., 2008) that a subject is viewing. Since then, encoding analyses have been developed, where, instead of using neural activity to predict information about a particular stimulus, a model of neural encoding is used to reconstruct a representation of a stimulus based solely on patterns of brain activity (Naselaris et al., 2011; Serences & Saproo, 2012; Tong and Pratte, 2012). We have recently demonstrated that encoding models can also be used to extract high temporal resolution information about stimulus orientation based on the spatiotemporal pattern of EEG responses across the scalp (Garcia et al., 2013). Here, we extend this technique to map the near real-time deployment of spatial attention to different positions within the visual field. We use high density EEG to measure steady state visual evoked potentials (SSVEPs) to small contrast-reversing (20Hz) discs in 36 locations arrayed across the visual field. Subjects were instructed to discriminate targets that appeared within the small discs or to report fixation brightness changes. We show (1) multivariate encoding algorithms can exploit the scalp distribution of SSVEP power to reconstruct an accurate representation of the visual stimulus, (2) these representations are influenced by intrinsic oscillatory activity, and (3) are modulated by attention.

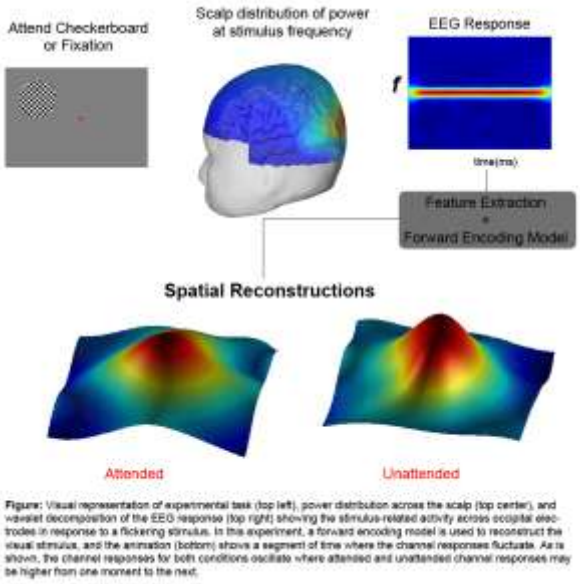

Figure: Visual representation of experimental task (top left), power distribution across the scalp (top center), and wavelet decomposition of the EEG response (top right) showing the stimulus-related activity across occipital electrodes in response to a flickering stimulus. In this experiment, a forward encoding model is used to reconstruct the visual stimulus, and the animation (bottom) shows a segment of time where the channel responses fluctuate. As is shown, the channel responses for both conditions oscillate where attended and unattended channel responses may be higher from one moment to the next.

Title: The spreading of attentional selection within an object's visual boundaries is a periodic process

Authors: *I. C. FIEBELKORN, Y. B. SAALMANN, S. KASTNER;
Princeton Univ., Princeton, NJ

Abstract: Much of the recent work investigating attentional selection has focused on its temporal dynamics, with several studies linking the behavioral consequences of attention to underlying oscillatory phenomena (e.g., phase reset). In the present study, we probed human behavior to investigate the temporal dynamics of visual-target detection under two conditions of attentional selection: spatial and object-based selection. Previous research has shown that preferential processing spreads from a cued location to uncued locations, if those locations are part of the same object (i.e., encompassed by the same visual boundaries). What remains unclear, however, is the extent to which attentional selection at the uncued, same-object location (i.e., object-based selection) shares common underlying neural processes with attentional selection at the cued location (i.e., spatial selection). Does attentional selection at these two locations reflect (1) a single set of neural processes that is dynamically guided by both location and object properties, or rather, (2) separable neural processes? Here, we varied the cue-target interval (300-1100 ms) and examined how detection of a near-threshold visual target evolves under conditions of spatial and object-based selection. We used an uncued location on a second object to track detection in the absence of spatial and object-based selection. Our data reveal an inverse relationship between spatial and object-based selection, which is attributable to antiphase coherence (at ~4 Hz) between visual-target detection at the uncued same- and different-object locations. That is, periodic enhancement of visual-target detection under conditions of object-based selection is accompanied by a periodic decrement of visual-target detection at the different-object (baseline) location. A comparison between visual-target detection under conditions of spatial and object-based selection, on the other hand, revealed periodicity in the theta range (at ~8 Hz) with significant cross-condition coherence and a near-zero phase shift. Such periodicity in the theta range was not present at the different-object (baseline) location. These results thus suggest the following: (1) the spreading of attentional selection within an object's visual boundaries is periodic rather than sustained, alternating between periods when the same-object location is preferentially processed and periods when the same- and different-object locations are equivalent, and (2) visual-target detection under conditions of spatial and object-based selection has a similar spectral architecture, supporting the case for common underlying neural processes.

Title: Entrainment of neuronal oscillations as a flexible mechanism controlling visuospatial attention

Authors: *M. J. GRAY, H.-P. FREY, J. J. FOXE;
Albert Einstein Col. of Med., Bronx, NY

Abstract: A long line of research has demonstrated that oscillatory coupling between groups of neurons can act as an efficient means for encoding and selecting information. Building on this concept, a recent influential hypothesis has proposed that the entrainment of low-frequency neuronal oscillations to a stimulus serves as a fundamental mechanism for perceptual selection within a complex and dynamic environment (Lakatos, 2009). EEG and ECoG experiments in humans have since demonstrated low-frequency entrainment to rhythmically-presented auditory and visual stimuli, and that modulation of the phase of the entrained oscillations can operate to select between these modalities. However, such experiments have used only one stimulus stream and one entrainment frequency, and thus it remains to be seen to what extent this mechanism can be used to select between multiple stimuli within the same modality. To answer this question, we devised a simple selective attention task in which subjects were required to covertly sustain their attention to one of two simultaneously presented checkerboards, each rhythmically alternating at a distinct frequency (1.3 Hz and 1.5 Hz). Using high-density EEG and leveraging long recording epochs to obtain a very high frequency resolution, we show that endogenous oscillatory entrainment can operate to select between multiple temporally and spatially distinct visual stimuli. Analysis of inter-trial phase coherence (ITPC) revealed selective and highly significant entrainment at the frequency of the attended stimulus. Significant ITPC was also seen at numerous harmonics of the fundamental stimulus frequency, extending up to around 8 Hz, suggesting that attentional selection and monitoring recruits oscillations well outside of the delta range, extending the original proposal. Furthermore, the topographical distribution of this broad range of specific entrainment frequencies was largely bilateral and extending into parietal areas, supporting the notion that synchronous oscillations provide an efficient means for transmitting relevant stimulus information from early sensory cortex for higher-order processing. Our findings provide evidence that the entrainment of a distributed, multi-frequency network of neuronal oscillations acts as a flexible means for the selection of temporal regularities unique to an attended stimulus within a given sensory modality.

Title: Characteristics of trial-to-trial spike count variability in MT neurons are consistent with bottom-up components of decision related response modulation

Authors: *H. KUMANO, T. UKA;
Dept. of Neurophysiol., Juntendo University, Grad. Sch. of Med., Tokyo, Japan

Abstract: Decision related response modulation (choice probability: CP) is observed in many sensory cortex and is believed to represent the association between perceptual choice and neuronal activity. Possible sources for the association include bottom-up and top-down components. A bottom-up explanation states that fluctuations in common noise among sensory neurons influence perceptual decision, whereas a top-down explanation states that signals of central origin such as feature attention influence the activities of sensory neurons. It has, however, been difficult to distinguish between these possibilities.
Here we report a new method for distinguishing between a bottom-up and top-down account of CP. We first predicted the amount of trial-to-trial spike count variability based on bottom-up and top-down models. In the bottom-up model, simulated sensory neurons fired with a spike count variability that was equal to the mean. Decisions were made via a circuit consisting of multiple independently firing neurons. On each simulated trial, responses of a simulated sensory neurons and the decision outcome was determined, and CP was calculated across trials. In this case, the overall variability in response to a visual stimulus did not change depending on CP, but variability measured separately for each behavioral choice decreased with higher CP. In the top-down model, a decision dependent signal was added to the neuron's response. In this case, variability measured separately for each behavioral choice did not depend on CP, but the overall variability increased with higher CP.
To determine which model better described the data, we analyzed CP measured in area MT during a task switching paradigm, where two tasks (direction discrimination and depth discrimination) were randomly interleaved (Sasaki and Uka, 2009, Neuron). For this dataset, CPs of MT neurons can be different depending on task, particularly for incongruent neurons whose preferred direction and preferred depth were related to opposite choices in the two tasks. Measurement of CP in two tasks thus allowed us to analyze the relative change in neuronal variability independent of the large fluctuations across individual neurons. The overall variability in response to visual stimulus did not change depending on CP. Conversely, variability measured separately for each behavioral choice decreased with higher CP, in line with the prediction of the bottom-up model. Overall, our results are consistent with the bottom-up account of CP.

Title: Ventral intraparietal (VIP) inactivation does not affect mulitsensory heading perception

Authors: *E. M. KLIER[1], S. LIU[2], Y. GU[3], G. C. DEANGELIS[4], D. E. ANGELAKI[2];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Neurosci., Baylor Col. Med., Houston, TX;
[3]Inst. of Neurosci., Chinese Acad. of Sci., Shanghai, China; [4]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: While deficits in sensory discrimination after reversible chemical inactivation are well documented for early sensory (e.g., middle temporal area) and late motor (e.g., frontal eye fields) cortical areas, its affects on intermediary sensorimotor areas are not well characterized. The ventral intraparietal area (VIP), like the medial superior temporal area (MST), shows strong multisensory convergence, including optic flow and vestibular signals, and strong correlations between neural activity and perceptual choice (i.e., choice probabilities) during heading discrimination tasks. To test for causal deficits in heading perception, muscimol (a GABA agonist) was injected bilaterally into area VIP of two macaque monkeys. Cues for the direction of motion were given by either visual motion via optic flow, vestibular motion via a motion platform, or combined visual and vestibular stimuli via synchronized optic flow and platform motion. This experiment was conducted under nearly identical conditions as a similar inactivation study in MSTd (Gu et al., J Neurosci, 2012). Across both animals, VIP heading thresholds did not increase significantly after inactivation (visual = 2.50 ±1.56; vestibular = 2.03 ±0.81; combined = 1.50 ±0.66) from their baseline levels (visual = 2.76 ±1.70; vestibular = 1.75 ±0.67; combined = 1.59 ±0.66) (t-tests, visual p = 0.55; vestibular p = 0.10; combined p = 0.88). In contrast, MSTd inactivation showed significant increases in heading thresholds across all stimulus conditions (Gu et al., J Neurosci., 2012). Notably, there is a clear dissociation between effects of inactivation in VIP and MSTd and choice probability measurements. Whereas inactivation disrupted heading perception in MSTd but not VIP, choice probabilities were much stronger in VIP than MSTd during the same task (Chen et al., J Neurosci, 2013). This indicates

that choice probabilities may not always be predictive of a causal contribution of neurons to perception. Taken together, these results suggest that sensorimotor parietal areas may not directly affect perception after chemical inactivation. This may be due to the fact that their functions are distributed across several cortical areas, or that their responses correlate with the outcome of a decision process without directly contributing to that process.

Title: Reward asymmetry modulates perceptual decision-related activity in the monkey prefrontal cortex

Authors: *L. DING;
Dept of Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Perceptual decisions about the presence or identity of external sensory inputs can be influenced by non-sensory, internal factors such as reward expectation. Prefrontal cortical neurons encode decision-related signals for both perceptual and value-based decision making, making them likely candidates to mediate modulation of perceptual decisions by reward expectation. A recent, preliminary study demonstrated reward-modulated activity in the prefrontal cortex in monkeys performing an asymmetric-reward visual motion speed-discrimination task. However, it remains unclear how such reward modulation relates computationally to the reward-biased behavioral reports.
Behavioral performance on a random-dot, visual motion direction-discrimination ("dots") task is well described by accumulate-to-bound computational frameworks. Previously we and others have shown that, on the dots task, frontal eye field (FEF) activity represents key features of the accumulate-to-bound process, and asymmetric choice-reward associations can induce a

behavioral reward bias that can be approximated by an adjustment in the starting value of the motion-accumulation process. In this study, I examined how asymmetric choice-reward associations modulate single-neuron activity in the FEF and how such modulation relates computationally to reward biases measured behaviorally.
Single FEF neurons were recorded in a monkey performing an asymmetric-reward reaction-time dots task. In alternated blocks, the choice associated with a FEF neuron's response field (RF) was paired with a larger or smaller reward than the other choice. A combination of statistical tests and validation by visual inspection was used to identify neurons with choice-selective activity and examine how motion strength and reward expectation influence such neurons. I focused on a preliminary sample of 23 cells with choice-selective activity before saccade onset, i.e., those likely contributing to impending choices, and observed three types of reward modulation: 1) before motion stimulus onset, 5 cells had increased baseline activity when the larger reward was paired with RF choices; 2) during motion viewing before RF choices, 2 cells had build-up activity that was modulated by both motion strength and expected reward size; and 3) just before RF-choice saccades, 11 cells had activity levels that were modulated by a combination of expected reward size and motion strength, instead of fixed final levels common to all conditions. These results suggest that reward asymmetry largely influences the starting value and bound height of the accumulate-to-bound-like process in the prefrontal cortex.

Title: The representation of object similarity but not choice certainty in LIP

Authors: *W. S. ONG[1], J. W. BISLEY[2];
[1]Dept. of Neurobio., Duke Univ., Durham, NC; [2]UCLA, Los Angeles, CA

Abstract: We are able to search for and locate specific objects in our environment by looking for its features and mentally comparing it to the object we are looking for. As such, while we are searching for that specific object, our attention may be drawn more to an object that is similar to

the target compared to an object that is different from the target. To do this, we would need to integrate both the features and location of objects in our visual space and compare them with the target object. We propose that the lateral intraparietal area (LIP) is key to this process as it receives direct input from the ventral, and dorsal visual processing streams as well as being part of the parietal-frontal network. Here, we investigate whether the activity across LIP combines bottom-up percepts with top-down instructions to create a map based on the similarity of the objects.

Two animals were trained to perform a 2-alternative forced choice, match-to-sample task. Each day, 5 line objects which varied parametrically from each other were randomly chosen from a set of 243. In this task, the sample object is presented at the fixation point at the center of the screen. The 2 choice objects are presented on either side of the fixation point, one of them in the receptive field of the neuron being recorded from. The choice objects can be presented up to 600 ms before or 200 ms after the presentation of the sample object. After the fixation point is extinguished, the animal makes a saccade to the object in the periphery that matches the sample object for a juice reward.

We recorded the responses from 204 LIP neurons in 2 animals. Using the performance of the animals across the session as a proxy for similarity, we show that the neural response to the non-target object in the receptive field of the neuron varies as a function of perceived similarity as early as 250 ms from the onset of the sample object. This average correlation increases in strength up to the time of the saccade onset. The monkey maintains fixation during this time as dictated by the task, and on average, the saccade occurs 850 ms after the sample onset. This correlation is not tied to the certainty or reward probability of the stimulus in the receptive field, as we do not find any significant correlation between the animal's performance and the neural response to the target object in the receptive field.

We suggest that the activity of LIP neurons represents the perceived similarity of the objects the animal is comparing with the sample object, and that the activity in LIP does not represent certainty or purely all-or-nothing motor movements.

Title: Dynamics of sensory information accumulation in LIP during task switching

Authors: *Y. SUDA, H. KUMANO, T. UKA;
Dept. of Neurophysiol., Juntendo Univ. Grad. Sch. of Med., Tokyo, Japan

Abstract: Switching behavior based on multiple rules is a fundamental ability for humans to behave properly according to context. Although the neural activity involved in the accumulation process for perceptual decision making has been well studied in the lateral intraparietal area (LIP) of the macaque, little is known about how the accumulation process changes when monkeys are required to read out distinct information from identical stimuli depending on task. To elucidate this question, we examined neural activity in LIP while monkeys performed a reaction time task version of a task switching paradigm. A Japanese macaque was trained to switch between direction and depth discrimination tasks. On a given trial, the color of the fixation point indicated whether the monkey had to discriminate motion direction (UP or Down) or stereoscopic depth (FAR or NEAR). The monkey was allowed to make a saccadic eye movement as soon as a decision was made. Difficulty of the tasks was varied by changing the percentage of coherently moving and binocularly correlated dots in the visual stimulus. While the monkey performed task switching, we recorded extracellular activity from isolated neurons in LIP. Using a memory-guided saccade task, we focused on neurons that showed delay activity. Switching performance was evaluated by calculating a switch ratio (SR). Mean SR for the direction discrimination task was 0.81 and that for depth discrimination task was 0.76, suggesting that the monkey successfully switched between the two tasks. Reaction time showed an inverted U shape as a function of the strength of the relevant stimulus feature, but was shifted horizontally depending on the strength of the irrelevant stimulus feature. Individual LIP neurons showed build-up activity depending on both motion coherence and binocular correlation, whereas their activities were similar around saccade time irrespective of these two stimulus features. Finally, the slope of the build-up activity changed depending on task so that build-up was prominent only for the stimulus dimension relevant to the task. Our results suggest that LIP neurons integrate relevant information depending on context to decide flexibly where to move the eye.

Title: Target facilitation and distractor suppression in the activity of macaque lateral intraparietal neurons during visual search

Authors: *S. NISHIDA, T. TANAKA, T. OGAWA;
Dept. of Integrative Brain Science, Grad. Sch. of Med., Kyoto Univ., Kyoto, Japan

Abstract: During visual search, neurons in the lateral intraparietal area (LIP) discriminate the target from distractors by exhibiting stronger activation when the target appears within the receptive field than when it appears outside the receptive field. It is generally thought that such target-discriminative activity is comprised of target-related facilitation and distractor-related suppression. However, little is known about how the facilitative and suppressive modulations emerge in target-discriminative activity of LIP neurons. To address this issue, we recorded activity from LIP of monkeys performing a visual search task that consisted of target-present and target-absent trials. Monkeys had to make a saccade to a target in the target-present trials, whereas they had to maintain fixation in the target-absent trials, in which only distractors were presented. By introducing the activity from the latter trials as neutral activity, we were able to separate the target-discriminative activity into target-related elevation and distractor-related reduction components. We found that most LIP neurons discriminated the target by the combination of target-related elevating and distractor-related reducing modulations or only elevating modulations in their activity, whereas very few neurons discriminated the target only by distractor-related reducing modulations. We also found that on average, target-related elevation was stronger and occurred earlier compared with distractor-related reduction. Further, as expected in previous model studies, the observed response properties were consistent with the simulation results derived from a network model with lateral inhibitory interactions. These findings provide insight into how neuronal modulation shapes target-discriminative activity during visual search.

Title: Spatial specificity of direction selectivity in the dorsolateral prefrontal cortex during memory-guided direction comparison task

Authors: *P. REN, A. SIMON, P. SPINELLI, T. PASTERNAK, Professor;
Univ. of Rochester, Rochester, NY

Abstract: As we interact with our environment, the features of objects in the visual scene are not consistently present on the retina and sensory cues used to guide visual behavior are not always available. Thus, active observers are faced with a ubiquitous task of comparing sensory stimuli across time and space. When monkeys compare directions of visual motion of two stimuli presented at the fovea, S1 and S2, separated by a delay, neurons in the dorsolateral prefrontal cortex (DLPFC) show direction selective (DS) responses suggestive of their origins in area MT. In addition, responses during S2, the comparison stage of the task, are often modulated by the direction presented during S1. However, DLPFC neurons respond to motion not only at the fovea but also across the entire visual field, receiving direct bottom-up inputs from neurons in the ipsilateral MT representing contralateral stimuli and indirectly from the opposite MT representing ipsilateral stimuli. We examined whether DLPFC retains the spatial specificity in DS characteristic of its retinotopic inputs by presenting stimuli in the contralateral and ipsilateral hemifields during the direction comparison task. We found that responses to visual motion of many DLPFC neurons changed with **Location:** they were more likely to be DS and this selectivity emerged earlier when stimuli appeared in the contralateral field. Preferred directions of neurons with DS for contralateral and ipsilateral stimuli were strongly correlated, suggesting alignment of direction information arriving in DLPF from MT neurons residing in the opposite hemispheres. Finally, response modulation during S2 also depended on stimulus location, weakening when the preceding S1 appeared in the opposite hemifield, suggesting participation of retinotopically organized cortical regions in the comparison process. Our results show that representation of visual motion in DLPFC is likely to be governed by its direct and indirect connectivity with area MT. The strong correlation between direction preferences in the two hemifields points to a mechanism that may facilitate integration of motion information across the visual field.

Title: Two-photon imaging of population activity in mouse visual cortex during a 2AFC task

Authors: *C. P. BURGESS[1,2], A. RANSON[1], K. D. HARRIS[3], J. F. LINDEN[2], M. CARANDINI[1];
[1]UCL Inst. of Ophthalmology, London, United Kingdom; [2]UCL Ear Inst., London, United Kingdom; [3]UCL Inst. of Neurol., London, United Kingdom

Abstract: Our understanding of the relationship between sensory encoding and perception has been greatly advanced by neuronal recordings in animals performing perceptual decision-making tasks. However, these measurements have been typically obtained as single-unit recordings in monkeys, and are thus limited in the number of cells that have been simultaneously recorded, and by an inability to track the same units over long periods. Sensory perception, on the other hand, results from the activity of large neuronal ensembles, whose activity may vary over days reflecting the learning of the task and other associations.

To study how neuronal populations encode sensory input, and how their activity relates to perceptual decisions, we developed a visual psychophysical task in head-fixed mice, and we paired it with two-photon imaging in primary visual cortex. The task is based on two-alternative forced choice (2AFC) design, which is superior to existing go/no-go designs because it is immune to variations in criterion and motivation. In the task, mice report the location of a grating stimulus by turning a wheel and receive water reward for correct responses.

Mice typically learned the task to proficiency in 2-3 weeks, and performed equally well in test chambers and under a two-photon microscope. They typically achieved upwards of 95% accuracy for the easiest stimuli, producing high-quality psychometric curves over a range of stimulus conditions. Typical contrast thresholds (to 75 % accuracy) were ~8% (for gratings of 0.1cyc/deg).

Two-photon calcium imaging allowed the simultaneous recording from large populations of cells during task performance and recording from the same cells over successive recording days. We used a viral vector (AAV2/1) to target expression of GCaMP6 to visual cortex, and found that of ~100 cells in a typical imaging frame, over 20% were significantly visually responsive ($\Delta F/Fs$ often exceeding 20%). In some experiments, a sizeable portion of the activity showed choice

probabilities beyond that expected by chance, and psychometric curves plotted contingent on neural activity revealed choice-related shifts.
We conclude that this combination of techniques provides a powerful tool to probe the activity of neuronal populations during perceptual judgements, and for unravelling the relationship between perception and decision making.

Title: Calcium dynamics in layer 1 of mouse visual cortex during sensory behavior

Authors: *A. RANSON[1], C. P. BURGESS[1], M. CARANDINI[1], K. D. HARRIS[2];
[1]UCL Inst. of Ophthalmology, Univ. Col. London, London, United Kingdom; [2]UCL Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: The apical tuft dendrites of many cortical pyramidal neurons arborize in layer 1 (L1), where they receive top-down synaptic input from higher-order cortical and thalamic regions. Bottom-up inputs from sensory thalamus, instead, terminate on more proximal dendrites. Coincident activation of the distal and proximal inputs may enable neurons to integrate sensory input with attentional, predictive, or motor signals.
We measured activity in L1 of primary visual cortex using 2-photon imaging of calcium signals in head-fixed mice performing a visually-guided task. Animals had to report whether a grating of variable contrast appeared on the left or right of a computer screen by rotating a wheel. Animals were water restricted, gained a water reward for correct responses, and achieved near perfect performance when contrast was highest. To measure calcium fluctuations we used the genetically encoded calcium indicator GCaMP6, delivered via an AAV vector. This indicator reports not only suprathreshold calcium signals associated with spikes but also subthreshold

calcium signals associated with synaptic inputs.
Calcium transients in L1 reflected an integration of visual input with behavioral variables. Large and reliable calcium transients were evoked by visual stimuli presented contralaterally to the imaged hemisphere. These transients increased progressively with stimulus contrast and followed faithfully the stimulus onset. However, they were not purely sensory-driven: they were larger when the animal produced a behavioral response. In fact, calcium transients could be seen even in the absence of effective visual stimulation, when stimuli were presented ipsilaterally. These transients were smaller than those evoked by visual stimuli, and their timing matched the onset of the animal's movements better than the onset of the visual stimulus.
These results suggest that L1 of primary visual cortex integrates visual signals with non-visual signals, which we hypothesize to be carried by top-down inputs.

Title: Naturally occurring and experimentally induced choice history biases in human observers

Authors: *A. ABRAHAMYAN, J. L. GARDNER;
Gardner Res. Unit, RIKEN Brain Sci. Inst., Wako-shi, Japan

Abstract: Perceptual decisions are not always guided by sensory evidence alone, but can be biased by the results of previous choices. For example, a previous successful choice may naturally prime making the same response, while an error in the past may inhibit making the same choice. We asked if humans have natural tendencies to exhibit these types of choice history biases and if naturally occurring biases could be modified by experimentally induced manipulations of trial order.
We examined naturally occurring choice history biases while humans performed a choice task in which they reported whether a visual stimulus was presented to the left or right side of fixation. Detection difficulty varied with contrast intensity (0.8%, 1%, 1.5%, 2%, 3% Michelson contrast). Stimuli were gabor patches (1 c/deg, 6 deg width) presented 12 deg to the left or right of fixation for 500 ms at a viewing distance of 50.5 cm. Subjects reported the location of the patch by

pressing a key. Auditory feedback of success or failure was provided. By applying a probabilistic choice model, we found that 6 of 9 subjects showed a natural tendency to switch between choosing left or right side when they failed on the previous trial. Successful responses on the previous trial had little or no effect on subjects' decisions.
We also examined whether choice history biases could be experimentally induced by manipulating choice history statistics. In particular, we changed the probability of alternating stimulus presentation side after a failure to 80% in one blocked condition. In another blocked condition, we repeated stimulus on the same side after a success 80% of the time. The model revealed that subjects were induced to have a choice history bias: they were more likely to stay on the same side after a success for the latter condition. There was a weaker enhanced tendency to switch after a failure for the former condition. Variance inflation factor (VIF) calculations suggested no colinearity artifacts.
We conclude that even experienced subjects have natural choice history biases in the form of switching after an error and that these biases can be modified by changing choice history statistics. If choice history biases can be manipulated by trial history statistics, it is puzzling why natural choice biases remain even for experimental designs in which such biases only serve to hurt performance. Model simulations showed that subjects' choice biases had only minor detrimental effects on psychophysical sensitivity. This suggest that when detrimental effects of natural choice history biases are modest, choice biases that may be optimal in a wider behavioral context may be retained even if they are suboptimal in the current context.

Title: Sympathetic and parasympathetic markers of visual awareness: A window into the mind-body interaction

Authors: *B. R. SHETH[1], Z. LI[2];
[1]Dept Elec, Comp Eng, [2]Dept Elec. Comp. Eng, Univ. Houston, HOUSTON, TX

Abstract: It has long been known that the brain does not exist in isolation but exists in a body and embodied cognition implies that the brain is constrained by the body. In exploring it, the mind-body dichotomy is an important beachhead. The only way to scientifically study the mind-

body interaction is to study the interaction between the brain (mind) and the autonomic nervous system (ANS), which controls the organs of the body. Here, we focus on the influence of consciousness, or visual awareness using three paradigms - visual detection (VD), visual localization (VL), and binocular rivalry (BR) - on the ANS using heart rate (HR), heart rate variability (HRV), pupil diameter, and pre-ejection period (PEP) as measures of the activations of the parasympathetic (para) and sympathetic (sym) components of the ANS.
There were three visual paradigms; each explores visual awareness from a different angle. In BR, observers (Os) viewed two stimuli (face, house) presented to different eyes and judged when each image was consciously perceived. In VD, Os viewed a near-threshold target stimulus on 50% of trials, and judged whether they detected one or not. In VL, a target of variable intensity (near-/above-threshold) was presented on left/right side of fixation on 50% trials each, and the O had to locate it. Confidence ratings were acquired. We expect changes in the para (high frequency spectral power of HRV, pupil diameter) and sym (PEP) systems due to the orienting response (OR), which is a reflexive, immediate response to environmental change, and an additional modulation dependent on the conscious perception of target.
Thus far, we have analyzed data from five Os. We investigated the effects of external (stimulus properties), and internal (correctness, confidence) factors. In VD, HR decreased in anticipation of a target but the change from baseline decreased if detection was correct (hits, correct rejects). HRV increased due to an OR, indicating para activation, and again, change from baseline was smallest on hits. PEP increased as well, indicating sym deactivation, but no modulation by awareness was seen In VL, confidence modulated the ANS: HR changes from baseline were delayed and HRV changes from baseline were delayed and larger when the O was not confident. None of the factors modulated PEP. In summary thus far, the para, but not the sym, system, appears to be particularly sensitive to internal factors, i.e. confidence and correctness of visual perception. Being confident and correct in one's perceptual judgment reduces para fluctuations from baseline. Conscious perception dynamically modulates the body's systems, not just the brain. Consciousness carries consequences to body and brain.

Title: Pupil dilation reflects specific perceptual alternations in a bistable visual illusion

Authors: *N. A. KLOOSTERMAN[1,2], T. MEINDERTSMA[2], A. M. VAN LOON[1,2], T. H. DONNER[1,2];
[1]Dept. of Psychology, Univ. of Amsterdam, Amsterdam, Netherlands; [2]Cognitive Sci. Ctr. Amsterdam, Amsterdam, Netherlands

Abstract: Purpose: Pupil dynamics at constant illumination have been proposed as an index of phasic neuromodulation during perceptual decision-making. Specifically, pupil dilation has been observed during behavioral reports of perceptual transitions in bistable perceptual phenomena. It is unknown to which extent these pupil modulations reflect the contents of perceptual transitions and/or the motor act used to report these transitions. Asymmetric bistable visual illusions like **"**motion-induced blindness" (MIB) provide an opportunity to address these questions. In MIB, a salient and physically constant visual target surrounded by a rotating mask spontaneously disappears from visual awareness, only to reappear after a few seconds. Here, we linked pupil dynamics to the contents of these MIB transitions under various manipulations of behavioral report.
Methods: Pupil diameter was measured at constant luminance in 19 subjects. The static MIB target was a full-contrast Gabor patch (diameter: 2°) located in one of the four visual field quadrants (eccentricity: 5°). It was surrounded by a rotating mask (17°x17° grid of black crosses, speed: 120° or 160°/s), and superimposed on a gray background. In different conditions, subjects viewed either the continuous MIB stimulus or the intermittent physical removal of the target ("Replay"). Further, in different conditions, subjects were asked to report target disappearance by: 1) button press, 2) button release (each complementary for reappearance); 3) switching from one to the other button press; or 4) counting and reporting the total number after each run (Replay only). The overall pupil modulation around report was quantified by linear projection of single-trial time courses onto the mean time course.
Results: The pupil constricted during an interval of ~1 s before report and dilated during ~ 1 s after report. The overall pupil modulation amplitude was larger around disappearance than reappearance reports. This difference was driven by the constriction phase, and it was larger during MIB than Replay, and independent of motor regimen. This difference was also evident in the counting condition, in the absence of any overt behavioral report.
Conclusions: The neuromodulatory systems controlling pupil diameter have access to detailed information about bistable perceptual transition processes: Pupil modulation (in particular the constriction phase) reflects the contents of perceptual transitions, irrespective of the occurrence and type of motor action used for behavioral report. The pre-report constriction and post-report dilation may be driven by central cholinergic and noradrenergic mechanisms, respectively.

Title: Pupil dilation reflects the dynamics and content of a perceptual decision

Authors: *T. H. DONNER, J. W. DE GEE, T. KNAPEN;
Psychology, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Background: Pupil dilation at constant illumination has been proposed as an index of phasic neuromodulation during decision-making. However, the exact nature of the link between pupil dynamics and decision-making is unknown. Simple perceptual decision tasks require the accumulation of noisy "sensory evidence" towards a categorical choice. They provide a well-controlled approach for linking pupil dynamics to the specific elements of a decision.
Purpose: We aimed to determine whether pupil dilation during perceptual decision-making reflects (i) the accumulation of sensory evidence during decision formation, or the final commitment to a choice; (ii) the content or the accuracy of the choice; and (iii) the decision-maker's intrinsic bias.
Methods: Pupil diameter was measured in 27 subjects performing a yes-no visual contrast detection task at constant luminance. On half the trials, only dynamic noise was presented (contrast: 5%). On the other half of trials, a low-contrast target pattern (contrast adjusted to the individual 75% correct threshold; range: 0.41% - 0.50%) was added to the noise. On each trial, subjects had to accumulate the "noisy evidence" and then choose between two button presses to report "yes, target seen" or "no, target not seen" (free response paradigm). Trials were sorted into hits and misses (target present trials), and false alarms and correct rejects (target absent trials). We used a general linear model (based on a canonical pupil impulse response function) to decompose decision-related pupil time courses into four components: transient on decision onset, sustained up- or down-ramp during decision formation, and transient on final choice. We quantified the overall decision-related pupil modulation by linear projection of single-trial pupil time courses onto the mean pupil response across all trials, aligned to the time of choice.
Results: All subjects exhibited prolonged decision times (range of median RT: 1002 - 2440 ms). The pupil exhibited significant positive transient components at decision onset and final choice, and a sustained up- (but not down-) ramp during decision formation. The overall modulation amplitude reflected the content, but not the accuracy, of the final choice: hits = false alarms > misses = correct rejects. The effect was stronger in the more conservative decision-makers (median split of subjects based on decision criterion).
Conclusions: We infer that the neuromodulatory systems controlling pupil diameter have access to rich information about ongoing decision processes: Pupil dilation reflects the dynamics and contents of decisions, and it is boosted when the decision-maker overrules her intrinsic bias.

Title: Certainly you're wrong: A dissociation between neural correlates of stimulus discrimination and confidence in perceptual decisions

Authors: G. BUZZELL[1], J. R. FEDOTA[1], D. M. ROBERTS[1], E. SHAW[1], *C. G. MCDONALD[2];
[1]George Mason Univ., Fairfax, VA; [2]Psychol, George Mason Univ., FairFax, VA

Abstract: The occipital-temporal N1 component of the event-related potential (ERP) has been shown to index a visual discrimination process. Given that this component is enhanced when stimulus discrimination is difficult (despite controlling for low-level stimulus features), its modulation is thought to reflect a top-down control process. Moreover, error trials are associated with a reduced N1 component, suggesting that lapses in top-down control lead to a failure of this early discrimination process and incorrect stimulus categorization. However, this assumption has not been explicitly tested. In addition, while there is support for the notion that the P3b indexes the sensory evidence available for perceptual decisions, the relationship between early sensory processes and evidence-based categorization processes remains unclear. The present study employed a difficult perceptual discrimination task designed to clarify the relationship between these processes. In addition, participants were required to provide a subjective rating of stimulus certainty after each trial, allowing for the evaluation of perceptual decision confidence. As expected, the N1 component was diminished on error trials as compared to correct trials, even when only error trials in which participants were uncertain of stimulus identity were analyzed. However, the N1 did not differ as a function of stimulus certainty on correct trials. In contrast, an exploratory analysis revealed that an early (210-230 ms) frontal positivity was sensitive to stimulus certainty, this component being diminished when stimulus identity was uncertain on both correct and error trials. Therefore, the present results suggest the occipital-temporal N1 indexes the accuracy of stimulus discrimination (but not certainty), whereas an early frontal positivity indexes stimulus certainty (but not accuracy). The amplitude of the P3b component predicted both accuracy and stimulus certainty. Collectively, the present findings suggest that

there are separable processes underlying stimulus discrimination and certainty of stimulus identity. We suggest that the interaction of these processes determines the outcome of perceptual decisions.

Title: Brain activity preceding internally generated switches in perception of a bistable structure-from-motion visual stimulus: A MEG study

Authors: *K. KRUG[1], S. BRAEUTIGAM[2], J. HEATH[1], A. J. PARKER[1], N. CICMIL[1];
[1]Dept Physiol, Anat & Gen, Oxford Univ., Oxford OX1 3PT, United Kingdom; [2]Dep Psychiatry, Oxford Univ., Oxford OX3 7JX, United Kingdom

Abstract: Perceptually bistable stimuli probe the neural mechanisms by which the brain resolves ambiguous sensory input (Kleinschmidt et al, 2012). During prolonged viewing, observers' perception 'switches' between possible interpretations although the stimulus does not change. Recent studies with apparent motion and Ruben's face-vase stimuli implicate both frontal and sensory networks in this process (Sterzer et al, 2009). However, the timing of different neuronal activity patterns preceding such perceptual switches has not been fully elucidated.
We measured brain activity with magnetoencephalography (MEG) in 9 volunteers as they judged the rotation direction of an ambiguous structure-from-motion cylinder. Recordings were taken in 5 blocks, each of 10 mins duration. In blocks A-D, a perceptual switch in rotation direction was externally induced by applying binocular disparity to separate the cylinder's front and back surfaces, at 12 to 82 second intervals for durations of 4 to 12 seconds. Disparities were matched to individuals' psychophysical thresholds for 95% correct responses. In block E, no disparity was applied so rotation direction was bistable. Block order was randomized across participants, who gave a left or right button press for clockwise or counter-clockwise rotation respectively.
MEG signals from 204 gradiometers were spatially aligned across participants, filtered at 1-30

Hz and epoched at -2000 ms to 0 ms pre-button press. Artefactual epochs were rejected. Statistical activity differences across sensors between internal and external switch conditions (paired Wilcoxon test of matched samples) were compared at group level as a function of time, following a $\chi 2$ distribution (Braeutigam et al, 2004).
We found significant differences in brain activity that preceded internally versus externally generated switches at around -1675 ms, -1490 ms, -1250 ms, -1170 ms, -1130 ms and -1015 ms ($\chi 2$ test, n=9, $p<0.001$). When internal switches were compared to baseline, significant activity occurred at -1665 ms, -1490 ms, -1290 ms, -1090 ms and -985 ms ($p<0.01$). Group results were confirmed by individual-subject statistics (Mann-Whitney-U test, $p<0.01$). Topologically, differences in right hemisphere frontal and parietal regions were seen early in the internal switch condition (-1665 ms).
In summary, activity unique to internally generated SFM perceptual switches is evident more than 1500 ms prior to the associated behavioral change. Activity patterns at this time implicate a contribution of fronto-parietal regions to internally generated switches whilst early activity in posterior regions appears to be more specific to externally induced switches.

Title: The role of synaptic depression in a biologically plausible model for percept choices at the onset of ambiguous visual stimuli

Authors: *R. VAN WEZEL[1], C. KLINK[2], W. WOLDMAN[3], M. TE WINKEL[1], S. VAN GILS[3], H. MEIJER[3];
[1]Biophysics, Radboud University, Donders Inst. For Brain, Cognition and Behaviour, Nijmegen, Netherlands; [2]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [3]Mira Inst. for Biomed. Technol. and Tech. Med., Enschede, Netherlands

Abstract: Visual percept choices for sequences of repeated ambiguous stimuli depend on the time interval between subsequent stimulus presentations. Short blank intervals cause the percept to alternate, while at longer intervals the percept stabilizes into a single perceptual interpretation (perceptual memory). Here we show a biologically plausible computational model that describes

the dynamics of these choice dynamics. The model consists of excitatory and inhibitory tuned neurons and it includes, cross-inhibitory interactions, spike adaptation (with a short time constant) and synaptic depression (with a long time constant). Simulations of the model are consistent with our previous human psychophysical and neurophysiological experimental data. The model predicts that adaptation and synaptic depression deterministically determine the transition from alternating to repeated percepts in sequences of ambiguous stimuli. Our model shows that no explicit (higher-order) memory or facilitatory component is necessary to explain these memory effects in visual perception.

Title: Head-restrained marmosets discriminate fine differences in orientation

Authors: *C. P. CHOW[1], J. H. REYNOLDS[2], C. T. MILLER[1], J. F. MITCHELL[2]; [1]Psychology, UCSD, La Jolla, CA; [2]Systems Neurobio., The Salk Inst., La Jolla, CA

Abstract: The small New World monkey, the common marmoset (Figure 1E), offers several advantages for studies of visual neurophysiology. They are lissencephalic, making them ideally suited for laminar recording and the recent development of transgenic lines (Sasaki et al, 2009) raises the possibility of cell-type-specific expression of proteins, such as opsins and genetically encoded calcium indicators. While the anatomy and physiology of the marmoset visual system has been studied extensively in anaesthetized animals (Rosa et al, 2009), it remains unclear if they can perform visual tasks with the head fixed. This will be crucial both for accurate eye tracking and standard neurophysiological methods. We tested if a marmoset could discriminate the location of an oriented Gabor that differed in orientation from distracters. Each trial was

initiated when the marmoset fixated a small flashing central point (Figure 1A). After holding fixation at the center for a variable period (Figure 1B), six equally spaced gratings (2 degrees in diameter, Gabor σ =0.5 degrees, spatial frequency varying from 1, 1.4, or 2 cycles/deg, random spatial phase) were presented at 5 degrees eccentricity (Figure 1C). Five of the six gratings were horizontally oriented while one was tilted (+/- 0, 2, 4, 8, 12, 16, 32, or 45 degrees). After 250 ms, the fixation point disappeared cueing the marmoset to make a saccade to the location of the tilted grating (Figure 1D). The marmoset was rewarded for holding fixation and then rewarded again for correctly indicating the target location, with reward increasing with task difficulty. The spatial frequency, tilt, and target location were chosen at random each trial. Performance was above chance at 4 degrees and >80% correct at 16 degrees (Figure 1F). Reaction times increased with difficulty (Figure 1G). These results establish the marmoset as a viable model for studies of visual perception.

Title: Developing awake behaving marmosets as a model for visual neuroscience

Authors: *J. F. MITCHELL[1], J. H. REYNOLDS[1], C. T. MILLER[2];
[1]Salk Inst., LA JOLLA, CA; [2]Psychology, UCSD, La Jolla, CA

Abstract: Our understanding of the neural mechanisms underlying perception and cognition has been limited by the lack of tools to modulate the activity of specific neural circuits in the awake

animal. Recent advances in optogenetics have begun to make this level of control possible in the mouse. However, mice are difficult to train, and their brain differs substantially from the primate brain. While the rhesus macaque has been the model system of choice for studying perception and cognition, smaller New World primates, such as the marmoset (Callithrix jacchus), offer many advantages including the potential to develop transgenic lines (Sasaki et al, 2009). The anatomical layout of visual areas and the properties of their visual neurons, recorded under anesthesia, are highly homologous to that of the macaque (Rosa et al, 2009). Detailed maps are available for their visual and oculomotor control areas, providing a sound basis for continued study in the awake animal. However, a critical unknown is whether marmosets can perform behavioral tasks when the head is stabilized, which facilitates neuronal recording and is critical for accurate measurement and control of eye movements. We replicated techniques for training macaques in fixation and visual tasks, but on a smaller scale appropriate for their smaller size. Here we show that in free viewing marmosets actively explore natural scenes with saccadic eye movements and target regions of interest such as faces (Figure 1A and B). More importantly, we show that they can control their fixation for liquid reward (see demo at http://www.snl.salk.edu/~jude/marmofix.MOV). We are currently investigating the receptive field properties of their visual cortical neurons using 16 channel laminar probes. Laminar recordings are particularly well suited for the marmoset due to their lissencephalic (flat) cortex. This enables perpendicular placement of the probes through the cortex even in extra-striate areas that would fall in sulci of macaques, which facilitates the identification of layer in recordings using current source density (CSD) analysis.

Title: Humans exploit uncertainty and bimodality of priors in motion direction estimation

Authors: *S. LAQUITAINE, J. L. GARDNER;
Gardner Res. Unit, Riken Brain Sci. Inst., Wakoshi, Japan

Abstract: What aspects of prior information do humans exploit when estimating perceptual quantities like motion direction? Bayesian inference suggests biasing towards the mean of the prior set of directions when sensory evidence is made weak by decreasing the coherence of motion. But certainty of the prior (i.e. width) should also affect how much to weight the prior mean in perceptual estimates. Moreover, there may be more than one single likely direction and so shape of the prior distribution (unimodal or bimodal) should also affect estimates. We used a motion direction estimation task and found that humans were sensitive to both changes in the width and shape of the prior.

Sensitivity to prior width was tested by changing the distribution of directions that subjects were asked to estimate. Four subjects performed a task in which a patch of random dots (5 deg diameter, 16.7 dots/deg, circular aperture) moving at 2.8 deg/sec in 36 different directions (5-355 deg evenly spaced) with 3 motion coherences (6, 12 and 24%) were shown for 0.3 secs in randomized order. Subjects reported the direction of motion by adjusting the orientation of an arrow with an electronic paddle wheel. At trial end, the true motion directions were displayed to subjects though they were not explicitly given feedback about correctness. Displayed directions were drawn randomly from 1 of 4 discrete Gaussian prior distributions with different standard deviations (10, 20, 40 and 80 degs) but the same mean. We found that subjects were biased toward the most likely direction and that this effect was strongest when the prior width was smallest (i.e. most certain) ($F(3, 177) = 60.528$, $p<0.001$, ANCOVA). These data were well fit by a Bayesian model in which likelihood and prior distributions were gaussian with means set by experimental parameters and standard deviations were model parameters ($R2 = 0.98$), showing that subjects tracked the width of the prior.

Sensitivity to prior shape was tested by creating a bimodal distribution of prior directions. The experimental design was the same except displayed directions were sampled from one of four discrete bimodal prior distributions (means of the two modes: 145 and 305, 165 and 285, 185 and 265, 205 and 245 degs) all with the same overall mean. We found that although each of the priors had the same overall mean, subjects' estimates changed depending on which set of bimodal distributions were used showing that performance tracked changes in the shape of the prior.

Altogether our results show that humans exploit complex aspects of prior knowledge such as the width (uncertainty) and shape (bimodality) of priors to improve direction perception, consistent with Bayesian inference.

Title: Precise characterization of dorsal stream neural activity during decision making

Authors: *J. YATES, I. PARK, L. K. CORMACK, J. PILLOW, A. C. HUK;
Inst. for Neurosci., Univ. of Texas At Austin, Austin, TX

Abstract: The accumulation of noisy sensory evidence is a necessary step in decision making. Over three decades of research recording from neurons in the primate brain during a motion discrimination task have suggested a circuit model where neurons in parietal area LIP integrate motion information encoded by neurons in MT. We sought to test this model directly by recording from populations of cells in MT and LIP simultaneously while a monkey performed a novel reverse-correlation motion discrimination task where the direction of local motion energy is precisely and independently varied over time. The reverse correlation stimulus consists of a series of motion pulses presented for 1,116ms on each trial. The pulses consist of a field of small flickering gabor patches. Each pulse lasts 166ms, during which a number and direction are drawn at random and that number of gabors drift in the chosen direction. This variable presentation allows us to measure how temporal variations in motion strength correlate with both the monkey's perceptual decision and the spiking activity of single neurons. We recorded 17 sessions from LIP (44 cells, 2-8 cells per session). Using Bayesian logistic regression to classify the monkeys choices and a generalized linear model (based on Poisson regression) to fit single trial spike trains, we were able to recover and compare the temporal weighting function of both monkey and neuron(s) within individual experimental sessions. We found the temporal weighting of the motion stimulus in LIP is consistent with the monkey's psychophysical weighting, although the effect of a single motion pulse on the spiking activity in LIP was considerably more complex, implying an indirect relation between LIP and decisions. Furthermore, we often observed fine timescale cross-correlations between neurons with overlapping RFs that were time- and decision-dependent, suggesting shared input. Analysis of the pulse-triggered average for MT neurons confirms that they represent the motion stimulus with high fidelity, in a manner that is less related to the eventual decision than in LIP. These

results reveal the feasibility of testing hypothesis of sensorimotor transformations during motion decisions at the level of single trials, using neural activity that spans multiple brain areas.

Title: Tuning of MST neurons during active steering

Authors: *S. W. EGGER[1], K. H. BRITTEN[2];
[2]Neurobiology, Physiologoy and Behavior, [1]Univ. of California, Davis, Davis, CA

Abstract: Neurons in the medial superior temporal sulcus (area MST) are hypothesized to guide navigation to a goal. In passive sensory tasks neurons in MST prefer complex motion stimuli similar to that observed during self-movement, suggesting MST neurons process optic flow for the purpose of recovering the components of self-motion. However, no one has measured the responses of MST neurons during active navigation tasks, leaving open the question of MST's role in guiding locomotion. To test if their responses can support active navigation, we recorded from single MST neurons as a monkey used a joystick to steer to a distant target in a virtual world. In this task, performance depends on two cues: the target direction and the optic flow. Because the stimuli viewed during each trial was different, traditional tuning measurements could not be employed to assess MST responses. We therefore developed a novel method for determining the tuning function of the neurons from individual trials. Using a smoothing function to estimate the underlying activation function of individual MST neurons, we found the tuning of each neuron based on the activation function, conditioned on the past values of different steering stimuli. From this we measured the tuning surface over the optic flow and target location cues. As expected, many MST neurons exhibited tuning to the large motion field experienced during simulated rotations of the monkey. More surprisingly, MST neurons also exhibited tuning to the location of the small target onscreen. Recording the stimulus as viewed during active steering, we were able to replay the same steering stimulus to the monkey multiple

times. The responses of MST neurons fired in a similar pattern, both to repeats of the replay stimulus and during active steering. These results allowed us to validate our methodology for determining the underlying tuning from individual trials. Taken together, our observations support the role of MST in guiding navigation, but suggest the role of MST is more complex than previously thought.

Title: Network configuration for task preparation in prefrontal cortex

Authors: *R. P. HEITZ, J. D. SCHALL;
Vanderbilt Univ., NASHVILLE, TN

Abstract: Nonspecific preparation can occur when an underdetermined action will be produced following some cuing event, such as a warning signal. Typically, nonspecific preparation is studied through the use of a variable foreperiod, beginning with some warning signal and ending with an imperative stimulus that requires perceptual analysis and overt response. A history of research indicates that such warning signals increase performance, so long as foreperiods are not excessively long or short. Despite decades of research, the neural mechanisms subserving nonspecific preparation have been limited to components of the EEG (e.g., the readiness potential over motor cortex).
Here, we explored the single-unit neural correlates of nonspecific preparation in macaque monkeys performing a difficult T/L visual search experiment. Trials began with the appearance of a small fixation point which monkeys were to fixate and maintain gaze. This foreperiod

ranged from 750 to 3000 ms drawn from a uniform distribution. No stimuli other than the fixation point were present during the foreperiod. Following the foreperiod, a visual search array appeared containing 1 target and 7 distractors; monkeys made saccades to the target to earn juice reward. Additionally, we included a speed-accuracy tradeoff manipulation, signaled by the color of the fixation point, which indicated whether the impending stimulus required a very fast or very accurate response.

We recorded the activity of single neurons in the frontal eye field (FEF), a region of prefrontal cortex integral to perceptual analysis, decision formation, and eye movement execution. We found that over the course of the foreperiod, absolute spiking rates were invariant, suggesting that the overall neural output did not change. However, measures of across-trial neural variability (Fano factor) declined progressively. Moreover, the decline was exaggerated when monkeys were instructed to respond more quickly to the upcoming stimulus than when instructed to respond more accurately.

These results suggest that nonspecific preparation is accompanied by a decrease in neural variability. This is consistent with an evolution of network activity into an optimal subspace to increase readiness. Such a network configuration may be driven by neural discharge modulation in medial frontal areas and could stem from increasing entrainment of neural networks through coherence.

Title: Bilateral modulation of motor systems by the stimulated visual field in an inter-hemispheric transfer task

Authors: *A. A. OMARI[1], V. DIWADKAR[1], R. WHITE[1,2], G. RAMBALDELLI[2], M. BELLANI[2], S. SAVAZZI[2], C. MARZI[2], P. BRAMBILLA[2];

Abstract: Introduction: Inter-hemispheric transfer has been assessed using the Poffenberger paradigm (Marzi, 1999), a task that depends on uni-manual responses to probes presented to either visual cortex. In general, regardless of response hand, the “crossed” condition, that is the

condition when visual information is presented to a different hemisphere than the response hand, results in increased response latency and increased cortical and callosal activations (Tettamanti et al., 2002). To examine whether the stimulated visual cortex modulated ipsi- and contra-lateral motor cortex during the crossed condition, we used psycho-physiological interaction (PPI; Friston et al., 1997).

Methods: fMRI (3T, Siemens Magentom Allegra) was acquired in sixteen healthy right-handed subjects between the ages of twenty and fifty. During the task, a probe was briefly presented in one of two visual hemi-fields and subjects responded with the left or right hand. Only right-handed responses were analyzed. PPI maps were constructed convolving time series from the excited visual cortex (right) within the contrast of interest (Crossed > Uncrossed). The maps, encoding modulation by the visual cortex, were submitted to a second level analysis to identify clusters of significant modulation.

Results:

Figure 1 depicts a mosaic of axial views with clusters showing significant ($p<.05$) modulation by the stimulated visual cortex. Clusters were observed bilaterally in the anterior cerebellum, pre- and primary motor cortex, supplementary motor cortex and bilateral primary motor cortexes.

Discussion:

These results are the first to suggest engagement of bilateral brain networks by the stimulated visual hemisphere during an inter-hemispheric visuo-motor transfer paradigm. Cross-hemispheric information transfer during the Poffenberger task may result from parallel signaling by the stimulated visual hemisphere of bilateral cortical and sub-cortical motor networks.

Title: Influence of top-down control on selective attention and response selection during motor decision making

Authors: *P.-A. KLEIN, A. ZÉNON, A. MOURAUX, S. NOZARADAN, J. DUQUE;
Univ. Catholique De Louvain, Brussels, Belgium

Abstract: At every moment, the environment presents us with multiple stimuli that call for attention and action. We continuously have to attend to and act towards stimuli which are the most compatible with our goals, while refraining from selecting less relevant, yet possibly appealing, options. Decision making involves at least two major interrelated processes. The first one, called “selective attention”, biases competitive interactions between sensory stimuli by favoring processing of information that is relevant to specific goals while ignoring irrelevant stimuli in the environment. The second process, “response selection”, is associated with the accumulation of activity in competing response representations so as to ensure that only motor activity related to the most beneficial action reaches threshold and is selected. Here, we used electroencephalography (EEG) to characterize the interactions between selective attention and response selection. Participants performed a version of the Flanker task in which they were asked to indicate by a left or right button-press the orientation of a briefly presented left- or right-facing central arrow, flanked by a set of two distractor arrows on each side which either pointed in the same (congruent trials) or in the opposite -conflicting- direction (incongruent trials). The proportion of congruent and incongruent trials was manipulated to produce two different contexts in terms of conflict expectation (mostly congruent [MC]: 80% congruent trials; mostly incongruent [MI]: 80% incongruent trials). Subjects expected more conflict in the MI compared to the MC. Selective attention and response selection processes were assessed in 12 subjects by assessing steady-state visual evoked potentials (SSVEP, central and distractor arrows flickered at different frequencies) and current source density (CSD) amplitudes over the relevant and irrelevant motor representations. Response times and error rates were larger in incongruent compared to congruent trials. However, this difference was attenuated in MI compared to MC, probably because control mechanisms were recruited in MI to help sharpen selective attention and response selection. SSVEPs indicate a larger processing of the central arrow in MI than MC, with no change observed for the distractor arrows. This increased selective attention was associated with larger CSD amplitude over the relevant motor representation in MI, mainly in incongruent trials. The role of specific parieto-frontal areas in selective attention and response

selection is currently under investigation by means of a combined EEG and repetitive transcranial magnetic stimulation protocol.

Abstract: The optokinetic reflex (OKR) and the angular vestibulo-ocular reflex (aVOR) complement each other to keep the line of sight stable despite of self- or world-motion , a joint mechanism that is critical for effective vision. It is currently hypothesized that signals from both systems integrate in a network of neurons operating as a velocity storage mechanism (VSM). When exposed to a rotating visual surround, subjects display the OKR, slow following eye movements frequently interrupted by fast resetting eye movements. Subsequent to light-off during optokinetic stimulation, eye movements do not stop abruptly, but decay slowly, a phenomenon referred to as the optokinetic after response (OKAR). The OKAR is most likely generated by the VSM. In this study, we observed the OKAR in larval zebrafish before the developmental emergence of the angular VOR. Our results suggest that the neural structures underlying the VSM may be already functional prior to being primarily regulated by angular vestibular signals. The VSM may be critical to ocular motor control in early development as it increases the efficiency of the OKR.

Title: The visual discharge of mirror neurons in monkey PMv is modulated by the gaze direction of the observed agent

Authors: *G. COUDE[1], F. FESTANTE[1], A. CILIA[1], V. LOIACOMO[1], M. BIMBI[1], L. FOGASSI[2], P. FERRARI[3];
[1]Univ. Parma, Dept Neurosci., Parma, Italy; [2]Univ. Parma, Dept Psychology, Parma, Italy; [3]Univ. of Parma, Dept Biol., Parma, Italy

Abstract: Mirror neurons (MNs) in the inferior parietal lobule (IPL) and ventral premotor cortex (PMv) can code the intentions of other individuals using contextual cues. Gaze direction is an important social cue that can be used for understanding the meaning of actions made by other individuals. It is known that nonhuman primates are sensitive to others' head and gaze orientation. Here we addressed the issue of whether PMv MNs are influenced by the gaze direction of another individual. We recorded single-unit activity in macaque PMv while the monkey was observing a human subject performing a grasping action while orienting his/her gaze toward (congruent condition) or away (averted condition) from the target object. Grasping could be performed either in the left or the right hemispace relative to the recorded hemisphere. We recorded 82 PMv MNs and found that 30 (36%) of them were modulated by the gaze direction of the human agent. Out of them, 12 (40%) of the neurons had a stronger firing rate during the congruent condition than during the averted one, while 18 (60%) of them preferred the averted condition. These preliminary results indicate that the discharge of a population of MNs in PMv is modulated by gaze direction. Since MNs modulated by gaze were also found in IPL, it is likely that MNs in PMv receive information concerning gaze direction from parietal cortex and, together with this latter cortical sector, use this information for decoding the intention of other individuals. The representation of actions in PMv could therefore be influenced by contextual information not only extracted from physical cues, but also from cues of a biological or social nature.

Title: Cue-dependent action-observation elicited responses in the ventral premotor cortex (area F5) of the macaque monkey

Authors: *V. PAPADOURAKIS[1,2], V. RAOS[1,2];
[1]Dept of Basic Sci., Univ. of Crete Med. Sch., Iraklion, Greece; [2]FORTH/IACM, Iraklion, Greece

Abstract: Our aim was to re-investigate the visual and motor properties of F5 mirror neurons (MNs), using a controlled paradigm in order to correlate the neuronal discharge with temporal events of the observed movement.
Initially, the monkey was trained to reach for and grasp 3D objects with the appropriate grips. At the beginning of each trial, a LED above the selected object turned on and the monkey had to fixate it and press a key. Following a fixation period, a dimming of the LED signaled the onset of the reach-to-grasp movement. The monkey had to reach for, grasp, pull and hold the object while fixating it until the extinction of the LED cuing its release. Then, the monkey was trained to observe the experimenter employing two variations of the above task (randomly interleaved) while maintaining its gaze straight ahead (OBS). In the first, the cuing LED was visible to the monkey (CUEOBS) whereas, in the second, the LED was off and the experimenter was getting instructions on a screen out of the monkey's view (NOCUEOBS). Moreover, a LED fixation condition in which the experimenter was not performing any movement was used as a control. Both forelimbs of the monkeys were gently restricted during the OBS conditions. The experimenter was standing next to the animal on its right side, and both reaching and grasping components of his movement were visible to the monkey.
We recorded 147 neurons responding to action observation. Out of them, 110 were tested also at the execution task and displayed motor discharge. Hierarchical cluster analysis of the observation-driven net (-spontaneous) normalized response profile (% of the max) in the CUEOBS, NOCUEOBS and LED conditions revealed two main, almost equally populated,

classes of neurons. The response of the neurons belonging to the 1st class starts after the onset of the movement, reaches its maximum when the experimenter's hand contacts the object and returns to baseline either during or at the end of the object-holding period, displaying an almost identical profile in the two OBS conditions. These neurons are similar to the MNs described by Rizzolatti and coworkers. In contrast, the response profile of the neurons in the 2nd class exhibits temporal differences between the two OBS conditions. In the NOCUEOBS the discharge starts with the beginning of the movement whereas in the CUEOBS the firing starts several hundreds of ms before it. The response reaches its maximum at the midway of the movement (with the peak in CUEOBS preceding that in NOCUEOBS in many cases) and returns to baseline soon after the object is grasped.
These results provide new elements about the response-triggering features of MNs and pave the way to new considerations about their functions.

Title: Effect of aging on inhibitory mechanisms involved in movement preparation

Authors: *C. PETITJEAN;
Univ. Catholique Louvain (UCL), Brussels, Belgium

Abstract: Top-down control is critical to select goal-directed actions, particularly when several conflicting options compete for selection. This control is thought to involve a mechanism that suppresses activation of unwanted response representations. The aging population shows a reduced ability to make appropriate decisions, especially when they are faced with conflicting information. Here, we tested the hypothesis that this alteration is due to a deterioration of inhibitory control regarding unwanted response representations.
Twelve young and ten elderly participants performed an Eriksen Flanker task in which they were asked to indicate by a left or right button-press the orientation of a briefly presented central arrow, flanked by a set of two distractor arrows on each side. The central and distractor arrows either pointed in the same (congruent trial) or in the opposite - conflicting - direction (incongruent trial). The proportion of congruent and incongruent trials was manipulated to produce two different contexts in terms of conflict expectation (mostly congruent [MC] context:

80% congruent trials; and mostly incongruent [MI] context: 80% incongruent trials). Obviously, subjects expected more conflict in the MI compared to the MC context. Motor evoked potentials (MEPs) were recorded from the left first dorsal interosseous muscle (FDI), an index finger agonist in the task, following single pulse transcranial magnetic stimulation (TMS) over the right primary motor cortex (M1). MEPs were elicited at one of two possible timings during movement preparation and compared to MEPs elicited at baseline (fixation cross presentation). This procedure provided us with a measure of corticospinal excitability change associated with a selected (during preparation of a left response) or non-selected (right response) muscle in congruent or incongruent trials, in a MI or MC context.
The behavioural data indicate that elderly subjects were slower but made less errors than young subjects. Aside from this, all subjects were slower and performed more errors in incongruent compared to congruent trials. However, both groups displayed a better performance in incongruent trials of the MI than MC context suggesting the recruitment of additional top-down control resources when conflict was expected in advance. In young subjects, MEPs were particularly inhibited in the MI context, suggesting that suppression of motor activity is an important component of conflict resolution. In contrast, in elderly subjects, MEPs were found larger in the MI context. These results suggest a different pattern of MEP changes during movement preparation under conflict in young and elderly subjects.

Title: Neural correlates of action choice and RT in dorsal premotor cortex

Authors: *C. CHANDRASEKARAN[1], D. PEIXOTO[2,3,6], W. T. NEWSOME[2,7], K. V. SHENOY[1,2,4,5];
[1]Electrical Engin., [2]Neurobio., [3]Sch. of Med., [4]Program In Neurosci., [5]Bioengineering, Stanford Univ., Stanford, CA; [6]Champalimaud Neurosci. Programme, Lisbon, Portugal; [7]Stanford Univ. / HHMI, Stanford, CA

Abstract: How does the primate brain make decisions based on sensory input and decide which action to perform when? Lesion studies suggest that dorsal premotor cortex (PMd) is involved in mapping sensory cues to actions. One action selection framework proposed for ambiguous circumstances is that PMd simultaneously encodes potential reach directions (Cisek & Kalaska, 2005). As information allowing for reach selection appears, populations of neurons selective for a reach direction compete and eventually one population wins, enhancing its firing rate over the other population and resulting in a reach. This makes three predictions. First, in ambiguous reach contexts, neurons in PMd selective for different reaches should initially respond regardless of eventual choice. Second, over time one selective population should enhance its firing rate, winning the competition and resulting in a reach. Third, the arm movement reaction time (RT) should closely follow the time course of neural competition. We tested these predictions in PMd of a monkey performing a visual choice RT task.
A trained monkey used his right arm to report the dominant color in a central static checkerboard composed of isoluminant red and green squares. The percentage of red and green in the stimulus varied from trial to trial. The monkey's behavior followed behavior typical of visual RT tasks; increases in difficulty led to more discrimination errors and slower RTs. Most RTs varied between ~400 ms for the easiest discrimination to ~550 ms for the hardest discriminations (range: 300 to 1000 ms). While the monkey performed this task, we recorded the activity of single neurons (70) and multi-units (19) from the arm region of left PMd.
We observed a mixed population of neural responses in PMd. Broadly, one subset of the population was movement sensitive (53/89), changing its firing rates just before (~200 ms) the reach onset. However, other neurons (36/89), resembling "visuomovement" cells responded rapidly after checkerboard onset regardless of the eventual choice. All three predictions were supported by data from visuomovement cells. Immediately after stimulus onset, cells selective for rightward and leftward reaches exhibited comparable firing rates. Over time, however, the absolute difference in activity of these two populations increased; achieving on average a 25 spikes/s difference (~100 ms) prior to movement onset. Importantly, the evolution of this activity difference was faster for fast RTs and slower for slower RTs. These results extend the competition hypothesis and suggest that dynamics in PMd neurons may mediate the selection of the action to perform and when to perform it.

Title: Altered oscillations in EMG variability explain impaired ankle movement control in children during a high-gain visual feedback condition

Authors: *H. MOON, C. KIM, M. KWON, Y. CHEN, E. J. FOX, E. A. CHRISTOU;
Univ. of Florida, Gainesville, FL

Abstract:

It is well-established that high-gain visual feedback exacerbates motor control in older adults compared with young adults due to altered activation of the agonist muscle. Nonetheless, it is unknown whether high-gain visual feedback has similar effects on the motor control of children. The purpose of this study was to compare the effect of high-gain visual feedback on movement variability and muscle activation in children and young adults. Six young adults (19.8 ± 0.6 yrs) and 9 children (9.4 ± 1.6 yrs) participated in one session. Subjects attempted to accurately trace a sinusoidal target by performing ankle plantar/dorsiflexion movements. The targeted range of motion was 10^{o} and the frequency of the sinusoidal target was 0.4 Hz for 35 s. We examined movement control at a low-gain (0.66^{o}) and a high-gain (4.68^{o}) visual feedback condition. Surface EMG was recorded from the tibialis anterior muscle. Movement variability was quantified as the standard deviation of the position fluctuations after the task frequency was removed with a band-stop filter (2^{nd} order; 0.3-0.5 Hz). EMG variability was quantified as the EMG fluctuations of the rectified low-pass (2 Hz) filtered EMG after the task frequency was removed as described for movement variability. In addition, we quantified the power spectrum of the movement variability and EMG variability using the following frequency bands: 0-0.3, 0.3-0.6, 0.6-0.9, 0.9-1.2, and 1.2-1.5 Hz. Children exhibited greater movement variability compared with young adults for both visual feedback gains ($P<0.05$). This age-associated difference was exacerbated during the high-gain visual feedback condition ($P<0.05$). Children exhibited greater power in their movement variability from 0-0.6 Hz and lower power from 0.6-1.5 Hz compared with young adults ($P<0.05$). The amplified ankle movement variability in children at the high-gain visual feedback condition was predicted by lower power within the 0.6-1.5 Hz of their movement variability ($R^2=0.57$, $P<0.01$). Similarly, the amplified ankle movement variability in children at the high-gain visual feedback condition was predicted by greater power within 0.3-

0.6 Hz and lower power within 0.6-0.9 Hz of their EMG variability (R^2=0.48, P<0.01). In conclusion, children exhibited impaired ankle movement control compared with young adults, especially during the high-gain visual feedback condition. This impairment was largely explained by altered oscillations of movement variability and EMG variability of the tibialis anterior muscle. The observed age differences may be due to the immaturity of the cortico-motor systems.

Title: Neurons in monkey dorsal premotor cortex are weakly sensitive to eye position when gaze fixation is untrained

Authors: *B. ALEMAYEHU, N. PAVLOVSKY, E. C. TYLER-KABARA, S. CHASE, A. BATISTA;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Arm movements require a sensory-motor transformation. Sensory-motor transformations are studied using reference frame techniques. Researchers disassociate eye and hand position to reveal the spatial processing scheme used by reach-related cortical neurons. This disassociation between hand and eye position is a learned behavior, requiring extensive training. Neurons in the dorsal aspect of premotor cortex (PMd) have been variously reported to encode reach goals using a reference frame defined by the position of the hand alone, or by the positions of the eyes and the hand. The literature provides no consensus on how much of an effect the direction of gaze has on reach coding in PMd. We studied the effect of gaze on PMd cells during a memory-guided reach task with gaze unconstrained. We analyzed whether gaze influenced reach planning responses by using linear regression and neural prosthetic decode algorithms. In animals not trained to fixate, the neural encoding of reach goals in PMd is only weakly influenced by the direction of gaze. This confirms the findings of Cisek and Kalaska (Modest Gaze-Related Discharge Modulation in Monkey Dorsal Premotor Cortex During a Reaching

Task Performed With Free Fixation, 2002) but stands in stark contrast to the findings of Pesaran et al (Dorsal Premotor Neurons Encode the Relative Position of the Hand, Eye, and Goal during Reach Planning, 2006) and Batista et al (Reference Frames for Reach Planning in Macaque Dorsal Premotor Cortex, 2007). Our observations suggest that PMd neurons exhibit sensitivity to whatever task parameters contribute to rewarded behaviors.

Title: Neural correlates of decision formation in PMd in a perceptual discrimination task

Authors: *D. PEIXOTO[1,2,3], R. KIANI[7], C. CHANDRASEKARAN[4], K. V. SHENOY[4,3,5,6], W. T. NEWSOME[3,8];

Abstract: Many prior studies of visually based decision-making have employed stimuli in which subjects decide the average direction of motion in stochastic random dot stimuli. Because subjects accumulate sensory evidence over time before committing to a decision, this framework provides an opportunity for electrophysiological analysis of evolving neural decision variables

that reflect integrated evidence. Most prior studies, however, have employed traditional single unit recording techniques, which limits their power to assess the dynamics of evidence accumulation and decision formation on single trials.
To address these issues, we recorded simultaneously from multiple units during the random dots motion discrimination task, using arm reach movements as the operant response. Neural activity was recorded from dorsal premotor (PMd) cortex, an area that is easily accessible to 'Utah' multielectrode arrays. Our goals were twofold: 1) to determine whether PMd activity reflects evidence accumulation toward decision about arm movement target selection, analogous to well-studied processes in pre-oculomotor structures, and 2) to leverage the statistical power conferred by simultaneous recordings to obtain insights into the decision formation process on single trials. We used logistic regression to predict the monkey's choices from neural population activity on individual trials using leave-one-out cross-validation. Logistic predictions were made in a 150 msec sliding window, allowing us to observe the evolution of decision-related activity in PMd. For strong motion coherences, average predictive activity, as measured by the fraction of correctly predicted trials, exceeded chance levels ~ 200 msec after onset of the visual stimulus, and reached 80% correct by 300 msec. As in LIP and other pre-oculomotor structures, predictive activity varied with stimulus coherence, rising faster and reaching higher levels for stronger coherences. Our data suggest that PMd activity reflects the accumulation of sensory evidence in the reach system, providing an opportunity to examine single trial neural dynamics underlying decision formation.

Title: Visual-motor processing in the central complex of walking *Drosophila*

Authors: *M. SIZEMORE, M. H. DICKINSON;
Biol., Univ. of Washington, SEATTLE, WA

Abstract: Successful navigation through a complex environment requires animals to extract useful sensory information and adjust their locomotor output accordingly, a process that involves

many stages. Whereas much work in systems neuroscience has focused on the initial and final steps of this process, relatively little is known about the critical bottleneck in which sensory signals are converted into a motor code. Investigating sensory-motor integration is particularly challenging, as it requires methods that permit recording and manipulating neurons and neural circuits while an animal is behaving. However, recent technical advances now make it possible to record from genetically-identified neurons in intact, behaving flies. We focus on the central complex (CX) as evidence from electrophysiology, anatomy, and behavior suggests that this region of the brain is a critical locus for visual-motor integration in flies and other insects.
As a first step towards exploring a visual-motor role for the CX during locomotion we have performed whole-cell current clamp electrophysiological recordings in flies walking on an air-supported spherical treadmill. We use machine vision to track the rotation of the sphere and provide visual stimuli using an arena of programmable LED panels. CX neurons are targeted by expressing GFP under control of the Gal4-UAS system. Cells are filled with biocytin during recording and visualized posthoc with confocal microscopy to determine cell morphology. We have recorded from fan-shaped body (FB) neurons and probed their responses to visual stimulation during walking and quiescence. While large field tangential neurons in the upper layer of the FB show spontaneous spiking activity that is unchanged whether the fly is walking or at rest, a class of tangential neurons in the lower layer of the FB increase their firing rate during bouts of walking. This increase can also be seen in the underlying membrane potential of neurons that are not spontaneously active, suggesting an increase in synaptic drive during locomotion. Drawing from available driver lines, we have also begun measuring the responses of classes of small field neurons in the fan-shaped body and other regions of the CX. By combining recording of individual classes of neurons with histological analysis of neuropil morphology we can begin to investigate sensory-motor processing in the CX.

Title: Neuromuscular recruitment during oculomotor decision-making in human

Authors: *L. N. KATZ, J. L. YATES, L. K. CORMACK, A. C. HUK;
Inst. for Neurosci., The Univ. of Texas At Austin, Austin, TX

Abstract: We sought to develop an experimental paradigm for use in humans that would provide a proxy for electrophysiological studies of oculomotor decision-making done in nonhuman primates. Neurons in the superior colliculus (SC) carry signals related to visual, cognitive, and motor components of eye-movements during decision-making. Unlike projections from SC to the oculomotor muscles, tectoreticulospinal projections from SC to the neck muscle system are not gated by omnipause neurons. This feature makes the neck a potentially fruitful site for probing oculomotor decision-making.

We recorded intramuscular electromyographic (EMG) activity bilaterally in a neck muscle involved in gaze shifts (splenius capitis, SPL) of 5 human subjects as they performed several variants of a well studied moving-dot direction-discrimination task, making either eye-only (head-fixed) or eye-and-head (head-free) gaze shifts to response targets. Gaze position was recorded using an Eyelink 1000 (500Hz, monocular, head free gaze tracking). EMG activity was recorded by inserting bipolar fine wire electrodes staggered 7-10mm apart along the axis of the muscle. We quantified responses by counting suprathreshold events or by rectifying and integrating the EMG signal.

Subjects performed both variable-duration (experimenter-controlled) and response-time (subject-controlled) versions of the moving-dot task. On each trial, subjects discriminated the direction of motion and conveyed their decision with a gaze shift to one of two targets (>30 degrees horizontal eccentricity). A burst of EMG activity was observed >100ms prior to saccade onset. In all head-free experiments, SPL was recruited during eye-and-head gaze shifts. In 19/28 experiments, SPL was recruited in a lateralized manner by eye-only gaze shifts made to targets at >15 degrees of eccentricity, in the absence of an overt head turn. In one-third of experiments (4/12), SPL activity during the response was modulated by stimulus coherence (task difficulty), with EMG amplitude inversely proportional to stimulus coherence. A similar effect on the latency of this response was observed in the response-time task (4/10 recording sites).

In conclusion, SPL EMG during oculomotor responses can be modulated by the strength of preceding sensory evidence. The richer and more prevalent effects seen in response-time conditions suggest that "leak" of SC activity may be more direct when decision formation and motor planning are coincident. Success in observing these cognitive signals in individual experiments is likely determined by differential innervation across electrode insertion sites and variable motor unit pooling.

Title: MEG during planning of visually-guided pointing movements

Authors: H. ALIKHANIAN[1], *G. BLOHM[1], W. C. GAETZ[2], H. C. GOLTZ[2], J. F. X. DESOUZA[3], D. O. CHEYNE[2], J. CRAWFORD[3];

Abstract: Planning visually guided reaches or pointing movements requires a complex sensory to motor transformation. Despite much recent progress, it still remains unclear where, how and when this transformation is carried out in the human brain. We use high spatio-temporal resolution magnetoencephalography (MEG) in an attempt to uncover (1) which brain areas are involved in transforming visual signals into appropriate motor commands for the arm, and (2) how does this transformation occur on a millisecond time scale.
Ten human subjects sat upright in the MEG apparatus and were asked to perform delayed (1500ms delay) visually-guided pro/anti-pointing movements towards (pro) or away from (anti) visual targets on a fronto-parallel screen. Pro- and anti-trials required opposite motor output following identical visual stimulation, which allowed distinction between the visual goal and motor plan. Subjects performed this task with either the left or right arm. To distinguish between intrinsic (muscle-based) and extrinsic (spatial) motor coding, we used three different forearm/wrist postures to perform the pointing with the right arm. A beamformer-based spatial filtering algorithm (event-related Synthetic Aperture Magnetometry) was employed to reconstruct brain activity from the MEG recordings. Brain areas were identified using a novel clustering method (Alikhanian, et al., 2013).
Preliminary analyses comparing differences in alpha and beta band synchronization for left versus right pro versus anti trials, show signatures of early coding of the visual goal (visual frame of reference) in V1-3, SPL, STS and IPL during the first 500ms after cue onset. At the same time, IPL, SPL and S1 also showed evidence for coding the motor plan, even at this early time after stimulus presentation. During the 500ms prior to movement onset, the early visual goal was coded largely present in V1-3, but there was also some evidence of visual information in

STS, FEF, PMd and ACC. However, there was now also a predominant motor code in IPL, S1, M1 PMv and even visual areas V2-3. We will also show effector and posture effects.
These findings suggest that the visual-to motor transformation occurs in a gradual fashion across the cortex and in time. In addition, visual/motor information seems to be coded in a frame of reference intermediate between the visual goal and the motor plan; indeed many brain areas show modulations both in a visual and motor reference frame. These findings are consistent with known monkey electrophysiology.

Title: Preparatory components and competitive advantages of Giant Fiber mediated escape takeoffs

Authors: *C. R. VON REYN, P. M. BREADS, G. M. CARD;
Janelia Farm Res. Campus, HHMI, Ashburn, VA

Abstract: Although escape behaviors are commonly associated with hard-wired, reflex-like motor programs, freely behaving animals perform complex and variable escapes when evading a predator. For example, as a simulated predator approaches, the fruit fly *Drosophila melanogaster* prepares for a jumping takeoff though a sequence of sub-behaviors, including freezing, postural adjustments, wing raising, leg extension, and wing depression. Using this sequence, the fly can alter both the trajectory and kinematics of its takeoff jump. However, the neural correlates orchestrating this behavior have yet to be identified. By recording whole-cell from tethered, behaving flies, we have demonstrated that two large descending neurons, the Giant Fibers (GFs), spike in response to looming stimuli mimicking approaching predators. Spiking in the GFs leads to a jump behavior, a rapid extension of the fly's middle legs. Here, we investigate how the GFs are incorporated into the sequence of sub-behaviors leading to an escape jump and what advantage is gained by enlisting the GFs in the behavior. Using whole-cell recordings and selective genetic silencing of GFs in freely behaving flies, we find that the GFs are involved in a subset of escape takeoffs. GF-mediated takeoffs require little preparation time, and often bypass

the full wing raising sequence. In addition, the interval between the start of jumping leg extension and the start of the first wing downstroke is consistently short, similar to what would be predicted by the motor outputs of the GF pathway. Although takeoffs can be evoked either with or without activation of the GFs across looming speeds, only GF-mediated takeoffs occur before predicted capture at high looming speeds. This suggests that the role of the GFs is to mediate takeoffs in response to the most rapid threats, demonstrating that *Drosophila* must coordinate multiple neural elements in order to select an appropriate motor program for predator evasion.

Title: Eye dominance influences triggering action and interhemispheric transfer time: A Behavioural and Electrophysiological study

Authors: *R. CHAUMILLON, J. BLOUIN, A. GUILLAUME;
Lab. De Neurosciences Cognitives, Marseille, France

Abstract: Our dominant eye (DE) is the one we unconsciously choose when performing a monocular task. Several studies revealed that the stimulation of this DE activates a larger cerebral network and with shorter
latency than the stimulation of the non DE (e.g *Shima et al. 2010*; Neuroreport 21(12), 817-21). Despite these results, the functions and behavioral consequences of this lateralization remain poorly understood. Here, through a Poffenberger paradigm we performed behavioural and electrophysiological measures to decipher the temporal impact of eye dominance on visuomotor transformation and on interhemispheric transfer time (IHTT) respectively. Firstly, by selecting participants according to their DE and handedness, and varying the side of the stimulated visual hemifield in a simple reaction time task, we examine the influence of the eye dominance in a sensori-motor task. We showed that the temporal impact of eye dominance strongly depended on whether the participants were right- or left-handed. In right-handers, reaction times (RT) were shorter for targets presented in the hemifield contralateral to the DE whereas in left-handers, RT of left hand was shorter only in participants with right DE, without hemifield difference.

Additionally, from the first use of the Poffenberger paradigm (1912), the idea is that, by comparing for a given responding hand reaction times for each visual hemifield, an estimation of the IHTT could be obtained. The present study demonstrates that this paradigm cannot lead to the correct estimation of the IHTT. In addition, it gives an explanation to the often reported IHTT negative values that otherwise appear illogical. Secondly, still in a Poffenberger paradigm, we used EEG recordings to more precisely evaluate the IHTT (eg *Rugg et al. 1984*; Neuropsychologia 22(2),215-25). Preliminary results in right-handers show a faster IHTT in subjects with right DE compared to those with left DE. In addition only right-handers with right DE show an asymmetry with a faster IHTT from right to left than from left to right. In sum, all these data converge to demonstrate a substantial impact of eye dominance on neural mechanisms involved in converting visual inputs into motor commands. These new findings highlights the need to consider the eye dominance that appears to be a hidden factor, in studies investigating the neural processes underlying visually-guided actions.

Title: Mirror neurons responding to inaction in the monkey ventral premotor cortex

Authors: *L. BONINI[1], M. MARANESI[1], A. LIVI[2], L. FOGASSI[2], G. RIZZOLATTI[1]; [1]Italian Inst. of Technol. - Brain Ctr. For Social and Motor Cognition, Parma, Italy; [2]Dept. of Neurosci., Univ. of Parma, Parma, Italy

Abstract: Mirror neurons (MNs) are a class of cells originally discovered in the ventral premotor area F5 of the macaque that discharge both during the execution and the observation of goal-directed motor acts. Human studies showed that areas belonging to the MNs system become active not only when subjects perform or observe a certain motor act, but also when they imagine an action performed by themselves or by another agent. However, no single neuron data are available on the possible involvement of MNs in motor imagery processes. Two monkeys were trained to execute a visuomotor task and to observe an experimenter performing the same task (observation task). Both tasks included two main conditions: one required the monkey to grasp a target object (action), the other to stay still for the entire duration of the trial(inaction). At the

beginning of the visuomotor task, the monkey had to maintain fixation in complete darkness. A cue sound instructed it either to grasp (high tone - action) or simply to fix (low tone - inaction) the subsequently presented target. After 800 ms a light switched on revealing one among three different graspable objects (target presentation). At the end of the sound (go/no-go signal), the monkey had to reach, grasp and pull the object (0.8 s) in case of action condition, or simply to fix it (1.2 s) during inaction condition. In the observation task the monkey had simply to fixate a spot of light in its extrapersonal space, while the experimenter performed the same conditions of the visuomotor task.We recorded 847 grasping neurons from area F5. Of them, 210 discharged also during action observation, but not during target presentation (MNs). Interestingly, part of these MNs became active during the observation task before the high tone ceased (go signal - action condition), anticipating the upcoming experimenter's action, while others discharged during the observation task even when the low tone ceased (no-go signal - inaction condition) and the experimenter remained still. Surprisingly, the activation profile of this latter class of MNs during action observation perfectly matched their activation profile during inaction condition. Importantly, this activation appeared specifically during the observation task, although cue signals and reward contingency were the same in the correspondent condition of the visuomotor task. These findings demonstrate that, in specific circumstances, MNs can activate even in the absence of visual information on other's action, suggesting that they could play a role in the internal generation of motor representations underlying motor imagery processes.

Title: Identification and single-trial characterization of visuomotor networks using electrocorticographic (ecog) activity

Authors: *W. G. COON[1,2], A. GUNDUZ[3], P. BRUNNER[1,4,5], B. PESARAN[6], G. SCHALK[1,2,4];
[1]Neural Injury & Repair, Wadsworth Ctr., Albany, NY; [2]Biomed. Sci., State Univ. of New York, Albany, NY; [3]Biomed. Engin., Univ. of Florida, Gainesville, FL; [4]Neurol., Albany Med. Col., Albany, NY; [5]Computer Sci., Graz Univ. of Technol., Graz, Austria; [6]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Humans can rapidly respond to visual stimuli. Previous studies have established the anatomical pathways that connect visual and motor cortices in animals, and recent imaging studies have begun to identify analogous tracts in humans. However, the spatiotemporal dynamics of cortical processes that translate visual input into motor output, as well as their functional significance (in particular with regards to variability in reaction time) remain to be characterized in full detail. A better understanding of the characteristics of the processes involved in visuomotor function and the neural basis for reaction time variability would expand existing neuroscientific understanding and may lead to new approaches to improve human performance. However, previous methodological limitations did not allow for characterization of such visuomotor networks at high spatial and temporal resolution, and/or in single trials.
In our study, we overcome these limitations by recording electrical signals directly from the surface of the brain (electrocorticography (ECoG)), which combine high spatial and temporal resolution with a high signal-to-noise ratio. We recorded ECoG signals from six human subjects while they performed a visuomotor response task. In this task, subjects were asked to respond with a button press as soon as they detected a change in a visual stimulus. To begin to characterize large-scale cortical processes, we used spectral estimates of gamma power (70 170 Hz; thought to reflect local cortical activation) to identify the network of locations that was activated by that task. We then applied a sensitive detection procedure to each of these locations to establish the timing of the onset of significant gamma activity modulation in single trials. Ongoing work is beginning to describe the characteristics of those networks, as well as their relevance to single-trial variance in reaction time in single trials. Specifically, we study the temporal variance of the activity onset times as well as cortical activation indexed by gamma power of each location in the identified networks, and how those characteristics co-vary with reaction time.
In summary, our study is beginning to provide the first detailed characterization of the spatiotemporal dynamics and functional significance of the largescale cortical processes that translate visual input into motor output. This work is setting the stage for the development of functional models of large-scale cortical processes by leveraging the power of single-trial analyses of brain activity and behavior.

Title: Direct sensorimotor matching rather than motor prediction appears to subserve activity in primary motor cortex during action observation

Authors: *N. GUEUGNEAU[1], S. MC CABE[2], J. I. VILLALTA[2], V. DELLA-MAGGIORE[2]; [1]Univ. De Buenos Aires, Ciudad De Buenos Aires – Argentina, Argentina; [2]Physiol. and Biophysics, Univ. De Buenos Aires, Ciudad De Buenos Aires, Argentina

Abstract: Despite the large consensus concerning the fundamental implication of the human motor cortex in action observation, the mechanism mediating the modulation of activity in the primary motor cortex (M1) remains a topic of debate. Does action observation necessarily imply predictive mechanisms based on internal (forward) models (Wolpert et. al. 2003) or does it rely on a frame-to-frame matching of the observed action onto its motor representation (Rizzolatti et. al. 2001)? Here we used Transcranial Magnetic Stimulation to assess the time course of corticospinal excitability (CSE) during the observation of unpredictable grasping actions. Fourteen healthy subjects observed grasping movements which final goal was unknown before movement onset, while motor evoked potentials (MEPs) were recorded at specific time points from the first dorsal interosseous (FDI) and the aductor digiti minimi(ADM) of their right hand. In order to assess precisely the temporal coupling between activity in M1 and the observed kinematics, CSE was recorded at 5 key time points during the observation of 3 grasping actions which kinematic features were very similar during the first third of the movement but differed drastically during the last two thirds. One action was directed to a large object, another action was corrected online, i.e. its goal switched from the large object to the small object, and a third action opened and closed unexpectedly before grasping the large object. We predicted that a mechanism based on direct matching would yield a temporal pattern of CSE finely tuned to the movement kinematics for the three actions, with no lag beyond sensorimotor processing. On the other hand, a mechanism based on forward models would result in longer latencies due to the occurrence of changes in movement kinematics that could not be predicted based solely on the motor plan for the large or the small object. Our results showed that CSE closely matched the movement kinematics for the FDI ($F(8,12)= 2.55$; $p=0.014$), but not for the ADM ($F(8,12)= 0.81$; $p=0.59$).MEPs lagged the observed action by 40-80 ms. The fact that MEP latency is ~25

ms and that 80-100 ms are necessary for visual information to influence an ongoing movement (Desmurget et. al., 2000) point to direct matching as the mechanism subserving motor resonance.

Title: Network dynamics of spike-spike interactions within and between frontal and parietal cortex

Authors: *B. WELLNER[1], S. B. SUWAY[2], H. SCHERBERGER[1];
[1]Neurobio., German Primate Ctr., Goettingen, Germany; [2]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Recently, techniques to record many neurons in parallel have greatly improved. This development has shifted research from single electrode recordings toward the analyses of neuronal populations and their interactions that can be recorded from many electrodes in parallel. In particular, analysis methods of interactions of many single neurons and their network dynamics have not been well developed. So far, it is impossible to record from the whole brain network with cellular resolution. For a reasonably large dataset, we therefore focused on the parietal-frontal network for grasp movements of macaque monkey (area AIP and F5), which is well known for sensorimotor integration. Two monkeys performed a delayed grasping task consisting of a fixation period that is followed by a short cue, a memory period where the monkeys had to keep fixation, and a movement epoch where the monkeys had to grasp a handle with one of two grip types. In both animals 128 electrodes where implanted chronically in AIP and F5 (2 arrays with 32 electrodes per area). We recorded and analyzed single neuron activity during 10 recording sessions (monkey S: 6; monkey Z: 4) and isolated on average 77 single units per session (min 54; max 100) that were recorded in parallel. To reveal functional connectivity

between all single neurons we calculated crosscorrelograms (CCG) of all possible pairs and corrected for covariation in firing rates based on methods described in Smith and Kohn, 2008 and Ramalingam et al 2013. Our main interest was to characterize the network of all single neurons by applying complex network analysis described in Rubinov and Sporns, 2010. We were interested if our network was hierarchical and/or modular organized. As expected, different networks were active for the different grasp types. In both networks, motifs (groups of stronger interconnected neurons) were found that were comprised of a mixture of neurons from AIP and F5. We analyzed the degree of functional connections to see if there is a hierarchical organization. Results were power law-distributed indicating the presence of few highly connected neurons (hubs) in addition to a majority of only sparsely connected neurons. Hub neurons were mainly located in AIP and the power spectrum of their CCG with other neurons showed a strongly increased beta power. In contrast the CCG power spectrum of sparsely connected neurons exhibited no beta peak. These observations suggest that communication in parietal-frontal action networks has a small-world architecture with their hubs functionally connected predominantly in the beta frequency range.

Title: A coherent gate links memory and planning systems in macaque prefrontal cortex

Authors: *D. A. MARKOWITZ, B. PESARAN;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The lateral prefrontal cortex (LPFC) sits at the intersection of distributed brain systems that support working memory and behavioral planning. Patients with disorders of LPFC function, such as schizophrenia and ADHD, show deficits of memory-guided behavior, but often retain planning abilities in tasks where memory is not required. This suggests that an arrested flow of information from memory into the planning system in LPFC may contribute to behavioral dysfunction. To investigate this problem, we recorded from populations of neurons across multiple depths of LPFC in two Rhesus macaques as they performed memory- and visually-guided saccades. By comparing single unit activity during a delay period across these tasks, we find evidence for populations of neurons that encode Visual, Memory and Planning information, respectively. During correct trials, Memory unit spikes were significantly coherent with Planning unit fields in the 20-40 Hz band across these populations during memory delays ($p<0.05$, permutation test) but not during visual delays ($p\geq0.05$, permutation test), suggesting task-specific coupling between systems. By contrast, during memory saccade error trials, coherence between Memory and Planning systems was not significant ($p\geq0.05$, permutation test), and Planning but not Memory units exhibited significantly lower rates than observed during correct trials ($p<0.05$, permutation test). Viewed together, these task and performance dissociations indicate that coherent coupling could act as a gate that controls the flow of information between the Memory and Planning systems in LPFC.

Title: Distinct neuronal mechanisms for remembering multiple locations within vs. across visual hemifields

Authors: *A. MATSUSHIMA, M. TANAKA;
Dept Physiol, Hokkaido Univ. Sch. Med., Sapporo, Japan

Abstract: Humans can remember up to four visual items simultaneously (Luck and Vogel, 1997). Recent studies have demonstrated that this capacity limitation of working memory depends on spatial arrangement of items; performance is improved when visual stimuli are displayed across left and right visual hemifields, compared to when displayed within the same hemifield (Delvenne, 2005). Since most previous studies presented only a single visual cue to explore the neuronal correlates of spatial working memory, it remains elusive which mechanism attributes to the difference in memory capacity between the above two conditions.
We examined single neuron activities in the dorsolateral prefrontal cortex and adjacent frontal eye fields when monkeys remembered location(s) of one or two visual stimuli during the delay period. In the multiple-memory-guided saccade (MMS) task, two sample cues and three test stimuli were separately presented across a 2-s delay. One test stimulus was presented at the same location as one of the two samples (matched stimulus), while the others were presented elsewhere (non-matched stimulus). Monkeys were trained to maintain fixation on the central spot during the delay, then made a saccade to the matched stimulus upon the fixation point offset. Since the location of the matched stimulus was chosen randomly from the two sample locations, monkeys had to remember both locations. As a control, we also used the single-memory-guided saccade (SMS) task, in which one sample cue and three test stimuli were presented.
We compared the delay period activities between the tasks. When two samples were located across different visual hemifields ("Across" condition), neuronal activities were comparable to that in the SMS trials with a sample at the preferred location. On the other hand, when two samples were located within the same hemifield ("Within" condition), neuronal activity was the average of the responses in the SMS trials. To examine if these different neuronal representations might be reflected in behavior, we conducted an additional behavioral experiment with a test stimulus presented at the middle of the two samples. The rate of erroneous choice of the middle one was significantly higher in the Within than the Across condition, as predicted from the neuronal data.
These results suggest that the representations of items in different hemifileds could be maintained independently, while those of items within the same hemifield might interfere with each other, possibly through the lateral inhibition. These distinct neuronal representations might account for the different memory capacities between across- and within-hemifield conditions, reported in humans.

Title: Human intracranial recordings during spatial exploration of a virtual environment

Authors: J. SNIDER, *[1], O. J. AHMED, *[4], E. HALGREN[2,3], H. POIZNER[1,3], *S. S. CASH[5]; [1]Inst. for Neural Computation, [2]Dept. of Radiology, [3]Grad. Program in Neurosciences, UCSD, La Jolla, CA; [4]Dept. of Neurol., Massachusetts Gen. Hosp. & Harvard Med. Sch., Boston, MA; [5]Dept Neurol, Mass Genl Hosp, BOSTON, MA

Abstract: In humans, neuropsychological evidence supports a crucial role of the hippocampal formation and associated temporal lobe structures in forming and retrieving recent episodic memories, regardless of whether they invoke spatial processing. However, the role of the human hippocampus and temporal neocortex in spatial encoding remains unclear. We recorded local field potentials directly from dozens of cortical and subcortical regions in patients who were undergoing a diagnostic intra-cranial EEG (iEEG) procedure prior to surgical treatment for medication-resistant complex partial seizures. Two patients navigated a first person view about a virtual 'storage room' via a joystick. There were virtual objects placed on shelves in the room, some of which were covered by opaque bubbles. The subjects' task was to navigate to an indicated virtual bubble and pop it by aligning a virtual hand with the bubble and pressing a button. Popping the bubble revealed the object hidden underneath which then stayed visible for the rest of the block. Subjects then rated their interest in the object, high or low, before proceeding to the next bubble. During the task, subjects were either moving from bubble to bubble (walking) or standing still. Theta power (~6-8Hz) increased during walking phases in the hippocampus and perirhinal cortex. Beta power (~15-20Hz) over sensory motor cortex (one subject) increased while walking, potentially reflecting maintenance of the motor act of squeezing the joystick controller. Further, in a separate EEG experiment with a similar task, but active walking, we have seen spatial autocorrelations of subjects' EEG isolated to the low theta frequency (~2-8Hz) and localized over posterior parietal cortex (PPC). Intracranially, one subject with surface electrodes over PPC also showed increased activity in the ~3-8Hz range, but lacked the spatial autocorrelation of the PPC signal. Strikingly, intracranial recordings of theta from the anterior part of the left temporal lobe (present in both subjects) showed significant spatial autocorrelation with the subjects' simulated spatial location in the storage room. These findings suggest that, as in rodents, human anteroventral temporal lobe neuronal activity is related to allocentric space. This activity appears to extend to human cortical areas which do not have a clear homology in rodents.

Title: Cortical dynamics during the preparation of antisaccadic and prosaccadic eye movements in humans in a gap paradigm

Authors: *M. ESCUDERO, I. CORDONES, C. M. GÓMEZ;
Univ. of Seville, Seville, Spain

Abstract: To compare the cortical dynamics of different oculomotor tasks, EEG and eye movements were recorded in 21 volunteers. Using a comprehensive approach, subjects were asked to perform saccadic tasks, which included a saccadic eye movement to a peripheral target (prosaccadic), a movement to the opposite side (antisaccadic), or maintain the gaze fixed (no-go). In mixed trials, prosaccadic, antisaccadic and no-go tasks were indicated by a color square (S1) present for 1900-2500 ms (instructive period). S1 disappeared for 370 ms (gap) and a black dot at 8 deg at right or left indicated the beginning of the task. Reaction times, amplitude of eye movements and number of errors were greatest in antisaccadic tasks, suggesting a greater difficulty. The EEG showed a contingent negativity variation (CNV) that increased progressively along the instructive period and suddenly during the gap: higher in antisaccadic, followed by prosaccadic and no-go tasks. Principal component analysis (PCA) disentangled fronto-central and occipital CNV-related and fronto-central gap-related components. The instructive period was characterized by fronto-central and occipital beta desynchronization (ERD) higher in antisaccadic than in no-go and parieto-occipital alpha synchronization higher in no-go than in antisaccadic tasks. During the gap, parieto-occipital beta and alpha ERD were higher in antisaccadic compared to no-go. The gap was further characterized by a fronto-central increase of inter-trial coherence in theta: highest during antisaccadic, followed by prosaccadic and no-go tasks. This phase locking in theta was also accompanied by theta ERS, which was significantly higher in antisaccadic than in the other two tasks. In PCA of spectral power two main components had dynamics similar to those extracted from voltage data, suggesting cross-

frequency coupling. These results suggest that the more difficult saccadic tasks are associated with top-down control mediated by frontal cortex, while simpler tasks rely more on bottom-up control mediated by posterior cortices.

Title: Behavioral responses to pulses of light in the Longfin Inshore squid

Authors: *S. P. HADJISOLOMOU, A. CHAVARGA, I. ABRAMOV;
Psychology, Brooklyn College, CUNY, Brooklyn, NY

Abstract: The unshelled coleoid cephalopods (octopus, squid, and cuttlefish) are renowned for their rapid, adaptive camouflage which is under direct neural control. This anti-predatory mechanism is extremely efficient at deceiving the visual system of predators and also allows for communication within and between species. This behavior is driven by a sensorimotor system, which receives information from the eyes and selectively activates intradermal color-pigmented skin cells called chromatophore organs. The question of how cephalopods control their chromatophores has received considerable attention from the perspectives of color modulation and contrast in ethology. While the anatomical arrangement of the neuro-muscular components of chromatophores and the sensory contributions of the visual system has been studied, the computation underlying the information processing of the chromatophore control system that enables such behavior is still unknown. The impulse-response system identification technique was used to test the hypothesis that a sudden, intense visual stimulus (pulse of light) can trigger chromatophore responses in squid. A camera recording at 240 Hz was used to capture behavioral responses before and after the pulse of light, providing a description of the timing relationships in the dynamics of brain function that control the chromatophore system response to light input. There was a rapid chromatophore expansion (~46 milliseconds) following the pulse of light. This behavior was extremely reliable across trials with a 3-second inter-stimulus interval (ISI), without signs of habituation. This is the first systematic study using the impulse-response system

identification technique to describe temporal dynamics of the squid sensorimotor system underlying chromatophore control. A description of the response to the flash illustrates the linear aspects of information processing in the squid brain and peripheral nervous system that control chromatophore activation across the skin.

Title: Rhythmical bimanual force production: Homologous and non-homologous muscles

Authors: *D. M. KENNEDY[1], C. WANG[2], J. B. BOYLE[2], C. H. SHEA[2];
[1]Dept. of Hlth. & Kinesiology, Texas A&M Univ., College Station, TX; [2]Hlth. & Kinesiology, Texas A&M, College Station, TX

Abstract: A large number of experiments over the last 40 years have isolated a coalition of constraints, including cortical and subcortical neural crosstalk, that influence the coordination of the two hands functioning together. Recent findings, however, have demonstrated that these constraints are eliminated or at least minimized when integrated feedback (e.g., Lissajous feedback) is used. An experiments was designed to determine participants' ability to coordinate 1:2 rhythmical bimanual force when homologous (N=10) and non-homologous (N=10) were activated. Given that neural crosstalk is defined as a mirror image command sent to the homologous muscles of the contralateral limb, we hypothesized that neural crosstalk should be more easily detected and characterized when the task required the activation of homologous muscles compared to when the task required the activation of non-homologous muscles to produce the goal pattern of coordination. The task was to rhythmically produce a pattern of isometric forces on a left side force transducer with the left arm that was coordinated with the pattern of isometric forces produced on a right sided force transducer with the right arm. The Lissajous display involved a goal template and a cursor indicating the forces produced with both limbs. The cursor moved from left to right as force was produced with the right arm and from bottom to top as force was produced by the right arm. The template illustrated the specific pattern of force requirements needed to produce the goal coordination pattern. The results indicated very effective temporal performance of the bimanual coordination patterns when both homologous and non-homologous muscles were activated. Additionally, the results indicated a

consistent and identifiable distortion in the force traces for both groups. However, it appears that crosstalk manifest differently during bimanual coordination depending upon whether homologous or non-homologous muscles are activated.

Title: The allocation of attention during the acquisition of a novel visuo-motor transformation

Authors: *S. SUELZENBRUECK;
Leibniz Res. Ctr. For Working Envrn. and Human Factors, Dortmund, Germany

Abstract: Our attention is generally focused on functionally relevant regions of our body and our environment ("selection-for-action", Allport 1987). Since for most actions our hands are functionally relevant, it is not surprising that increased attention is found for the area surrounding them. Increased attention is even found if the hands are not relevant for the respective task (Reed et al., 2006). When the segmental chain is extended by a tool, the location of the functionally relevant end effector is shifted from the hand to the tip of the tool. Previous studies indicate that during tool use increased attention is found for the area around the hand position as well as for the area surrounding the distal tip of the tool (Collins, Schicke & Röder, 2008; Reed, Betz, Garza & Roberts, 2010). For novel types of tools, so-called "pointing tools" (Holmes & Spence, 2005), the connection between the hand and the end effector is either only virtual (e.g. for the computer mouse) or cannot be accessed by direct vision (e.g. for the tools used in minimally-invasive surgical procedures). This experiment serves to investigate whether the same pattern of increased attention for the area surrounding the hand as well as for the area around the tip of the tool is also found for pointing tools and whether the locus of attention changes in the course of the acquisition of the visuo-motor transformation of the tool. Therefore the allocation of attention of two groups of young participants (n = 38) was investigated. Both groups were moving the effort arm of a two-sided lever to control a cursor on a computer monitor to different target positions. However, the groups differed in the visuo-motor transformations they had to master. While for one group the cursor represented the movements of the effort arm of the lever (a simple horizontal-vertical transformation), the cursor represented movements of the load arm of the

lever (an inversion of lateral hand movements and associated cursor movements). The distribution of attention was tested with a simple detection task which was preceded by the end of the goal-directed movement of the cursor to one of the targets. The endpoint of movement therefore served as an implicit cue for the subsequent detection task. The pattern of results indicates that indeed the distribution of spatial attention is modulated by the use of a pointing tool introducing a novel visuo-motor transformation, and that spatial attention changes in the course of the acquisition of a novel tool transformation. While attention is focussed on the cursor representing the tip of the tool at the beginning of practice, it is shifted towards the location of the hand position in later practice trials.

Title: Substitutional Reality for research in animal cognition

Authors: *Y. NAGASAKA, S. WAKISAKA, T. NOTOYA, N. FUJII;
RIKEN, Brain Sci. Institute, Lab. For Adaptive Intelligence, Saitama, Japan

Abstract: Comparative cognitive studies exploring dynamic social behavior have been accumulated. In the laboratory experiments, multiple trials under identical conditions are required, however, it has been difficult to present the same dynamic social situation in live. For human cognitive study, we recently have developed a substitutional reality (SR) system, an immersive human interface in which a participant were either presented with a live or a pre-recorded environment and hardly recognized which environment s/he was experiencing (Suzuki et al. 2012). In the present study, we modified the SR system for macaques (mSR) and evaluated it for practical use in the field of comparative cognition.
The mSR system consisted of a head-mounted display (HMD) fitted with a video camera at the front center of the HMD (mSR-headset), and a control PC. It had two presentation modes, 1) live-scene mode: the monkey viewed a live scene streamed from the camera, and 2) recorded-scene mode: the monkey viewed scenes that were pre-recorded by the camera. Because the monkey's head was calmly restrained, the scene in the headset was very similar in the live-scene and recorded-scene modes. In order to evaluate the system, we conducted a food-grabbing task in

which a monkey had to get a food from a stick handled by an experimenter (Chao et al. 2010). If the monkeys would react to a virtual environment in the same manner as in a live environment, this could validate the system for animal research.
In the experiment, the monkey wore the headset and performed the task under the live-scene mode after confirming successful performance in the task without the mSR-headset. All three monkeys performed the task successfully after a very short training (< 5 min) to get used to visual-motor-tactile coupling in the mSR system. Furthermore, under the recorded-scene mode all monkeys chased and tried to get the food; the behaviors were observed in the live-scene mode and the task without the headset. These observations suggesting that the monkeys experienced the virtual world with a feeling of being at a live event. In summary, we confirmed that the SR system was applicable for non-human animals, here macaques. The present mSR system is one of the ideal platforms to investigate cognitive processes in social interaction between macaques because of its capability for multiple presentation of the identical social situation many times, which generally occurs only once in the natural environment. Therefore, it opens the windows to broaden researches in comparative cognitive science.

Title: Chromatic properties of the phototactic response in the larval zebrafish

Authors: *D. A. GUGGIANA-NILO, C. RIEGLER, F. ENGERT;
Harvard Univ., Cambridge, MA

Abstract: Color vision research has made immense advances in determining the pathways followed by color information from the retina into the thalamus and then into the visual cortex. Although very comprehensive, these studies all result in a patchy and incomplete topographical map of the area being studied. This is a severe drawback when studying vision since it is known that the visual system operates in a number of parallel processing channels with a considerable degree of topography.
The zebrafish larva (Danio rerio) offers a unique platform to topographically characterize the chromatic component of the retinofugal projection, since its transparency coupled with the

ability to make transgenics expressing genetically encoded calcium indicators permits non-invasive 2-photon calcium imaging of many neurons simultaneously. Additionally the larval zebrafish retinofugal projections are all accessible and contain similar response properties and clustering as the mammalian visual system.
In this study we chromatically characterize the phototactic response in the larval zebrafish. The phototactic response is a well established and robust behavior in this organism and hence represents an ideal starting point to dissect the existing chromatic circuitry and its topology. Since the zebrafish has a tetrachromatic retina with UV sensitivity in addition to red, green and blue, we measured its 4-color behavioral spectral sensitivity function based on a previously reported phototaxis paradigm. In brief, we used a closed-loop projection system to present different colors at each side of the fish and force a choice of turning direction during each frame. The system allowed us to change light intensity and hue dynamically over the course of the experiment.
Our data supports previous observations of equivalent processing of all the color channels available to the fish, since turning direction preference depended solely on perceived intensity and not in the chromatic composition of the stimulus. In particular, preference peaked at a defined light level above background and then decreased all the way into avoidance when the light levels presented were very high.
As our next step the behavioral studies will then be complemented with functional imaging studies using multi-photon microscopy in combination with fluorescent protein-based calcium indicators. This will allow us to characterize the retinofugal projection in a color-dependent manner while the same visual stimuli used in the behavioral experiments are presented.

Title: Sociality predicts performance in exploratory behavior and sensorimotor gating in African cichlid fish

Authors: *T. PREUSS, M. PERKOWSKI, Z. BARANOV, L. DORDULAW, H. NEUMEISTER;
Psychology, Hunter College, City Univ. of New York, NEW YORK, NY

Abstract: African cichlid fish (Astatotilapia burtoni) have a complex social hierarchy with males reversibly transitioning between dominant (DOM) and subordinate (SUB) phenotypes. DOMs exhibit frequent aggressive and territorial behaviors, threatening or attacking SUBs, which respond either proactively i.e., engage and flee, or reactively by avoiding interaction with DOMs altogether. Here we test the notion that males with a reactive copying style to threats will show anxiety-related behavior and adaptive changes in attentional information processing (i.e., sensorimotor gating, PPI). Focal observations of dominant and submissive behaviors over a two-month period in seven fish communities were used to distinguish three phenotypes, namely high, intermediate and low interactive males. Testing swimming activity (N= 31) in an open field paradigm revealed a significant ($p=0.05$) decrease of time spent in the center field (thigmotaxis) in low interactive (i.e., reactive) males compared to high and intermediate interactive (i.e., proactive) cohorts.
To test for PPI, subjects (N=33) were exposed to a startling auditory stimulus consisting of a sound pip (pulse), preceded by a non-startling sound pip (prepulse), and responses were scored based on the presence of a C-start startle response. Trials were conducted with two different prepulse/pulse interstimulus intervals (ISI 50 and 200 ms). Comparing subjects on the basis of social interactivity (low, medium, and high) revealed that low-interactive males exhibited a significantly ($p<0.05$) lower PPI rate than the two other groups for both ISIs.
Taken together, our results imply that the observed deficits in PPI in low interactive males are likely related to anxiety. More broadly, the identification of a PPI phenotype in cichlids may provide a novel opportunity to understand the neural basis of PPI since it uses natural psychosocial interactions instead of pharmacological means to modify PPI.

Title: Noise from stochastic reference frame transformations affects decision making

Authors: *T. MURDISON[1,2], H. LI[1,2], G. BLOHM[1,2];
[1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Canadian Action and Perception Network (CAPnet), Toronto, ON, Canada

Abstract: It is known that reference frame transformations (RFT) induce variability in behavior and perception in sensorimotor tasks (McGuire and Sabes 2009; Burns and Blohm 2010; Burns et al. 2011). Thus RFTs must be regarded as being stochastic in nature. It is unclear whether RFTs also affect decision making, presumably though adding noise/variability to sensory evidence undergoing RFTs. Here, we investigated this effect using a 2-AFC random dot motion direction discrimination reaction time task with the head either straight or rolled to the left or right shoulder. Theory says that when the head is rolled, sensory signals need to undergo an RFT to rotate sensory signals into a reference frame appropriate for perception or action and we hypothesize that this will induce noise and deteriorate decision making. Four human subjects were asked to detect the direction (left or right) of a randomly selected subset of coherently (2, 10 or 20% coherence) moving dots. Subjects responded either with a left/right saccade or a button press. We created different RFT requirements by either (1) rotating only the on-screen stimulus, (2) rotating only subject's head, (3) rotating both the head and stimulus together or (4) rotating neither the head nor the stimulus.
Compared to no rotations (4), we found that head roll prolonged response latencies regardless of whether the retinal or spatial stimuli were rotated. This was true for both saccades and button press responses, with average increases (± SE) from 6.1% ± 9.3% to 19.9% ± 6.7% (corresponding to overall averages of 18 ms ± 85 ms and 110 ms ± 41 ms) for correct trials at the 10% coherence level. We also observed prolonged latencies with head roll across the other two coherence levels, with average changes from -1.2% ± 7.9% to 16.8% ± 6.6% (corresponding to -39 ms ± 73 ms and 84 ms ± 38 ms). Additionally, a standard LATER model for reaction times revealed that head roll induced variability into the rate of rise of the decision signal for all four subjects' saccades (increases from 58% ± 16% to 68% ± 10%) and for three of four subjects' button presses (increases from 86% ± 5.9% to 92% ± 3.2%) for correct trials at the 10% coherence level. These findings were representative of the other coherence levels.
Because using a button press response requires an explicit transformation of evidence into finger coordinates while saccadic responses technically do not require a RFT, our findings suggest that the sensory evidence used to make the decision is transformed into a common, non-retinal reference frame regardless of the response modality. These data show for the first time that reference frame transformations impact decision making.

Title: Influence of visual feedback on a goal-directed motor sequence: A virtual-reality study of prey capture in larval zebrafish

Authors: C. A. TRIVEDI[1], *J. H. BOLLMANN[2];
[1]Max Planck for Med. Res., Heidelberg, Germany; [2]Max-Planck for Med. Res., Heidelberg, Germany

Abstract: During goal-directed behaviors, the nervous system extracts relevant cues from the dynamic inflow of sensory information as a basis for selecting appropriate motor output. The motor output may be continuous or discrete in time depending on stimulus properties and the architecture of the nervous system. Prey capture in larval zebrafish is a visually driven goal-directed behavioral sequence in which target-directed swim bouts are separated by short periods of rest. These rest periods or inter-bout intervals (IBIs) range from a few tens of milliseconds to several hundreds of milliseconds and decrease monotonically with each subsequent swim bout as the larva approaches the prey. This burst and pause pattern, characteristic of intermittent locomotion, may enable the larva to sample visual input during the IBI and determine the subsequent motor pattern. Thus, testing the influence of individual stimulus properties on the IBI between chained swim bouts is of critical significance to begin to understand the neural mechanisms driving this goal-directed behavior.
In order to accomplish this, we reconstructed realistic stimulus sequences in a virtual reality assay based on a quantitative analysis of a wide range of stimulus conditions during naturally occurring prey capture. Minimally restrained larvae recapitulated target-directed swim sequences in a closed-loop projection system closely resembling natural prey capture behavior in terms of motor output parameters and monotonically decreasing IBIs. We then systematically varied the size, velocity, location and timing of the stimulus to test the input boundary conditions under which prey capture sequences could occur. Notably, the time course of these complex motor sequences was critically dependent on spatial and temporal properties of visual feedback. Having

characterized the influence of visual feedback on motor sequence generation, our virtual reality setup can be combined with functional techniques to enable the investigation of neural circuits involved in prey capture in larval zebrafish.

Title: A shared representation of the space near oneself and another person in the human premotor cortex

Authors: *C. BROZZOLI, G. GENTILE, L. BERGOUIGNAN, H. H. EHRSSON; Karolinska Institutet, Stockholm, Sweden

Abstract: Interactions between people require shared high-level cognitive representations [1], but do people also share their representation of space? The human ventral premotor (PMv) and parietal cortices contain mirror neurons [2-4]. Here, we identified neuronal populations in the human PMv encoding the space near both one's own hand and another person's hand. We measured BOLD-adaptation [2] in 26 individuals to test whether neuronal populations showing selectivity to an object near one's own hand [5] also encode an object near another person's hand (Figure 1).

We compared BOLD-adaptation to a real 3D object appearing near another person's hand or a prosthetic hand following identical visual stimulation near the participant's own hand. By swapping the relative locations of the prosthetic and other person's hand (Figure 1c), we controlled for the unspecific effects of seeing a hand and the object moving in particular spatial positions in non-hand-centered coordinates.

The left PMv (inferior part of the precentral sulcus with the cluster encompassing the precentral gyrus; T=3.95, pFWE-corrected=0.015; Figure 1e) showed stronger BOLD-adaptation to the object presented near the real rather than the artificial hand following stimulation near the participant's own hand. Thus, the left PMv contains neuronal populations that encode the space both around the participant's and another person's hand.

In a second fMRI experiment (n=20), we tested for bidirectional adaptation [2]. The results showed that the left PMv adapts to the object near the participant's hand and the other person's hand independently of the order of presentation (T=3.77, pFWE-corrected=0.016; Figure 1f).

This finding indicates that the same neuronal populations in PMv encode peri-hand space both for self and other.

We identified a subpopulation of neurons in the left PMv with mirror properties. The shared premotor representation of peripersonal space could support social interactions by coding sensory events [6], action programs and cognitive processes [3-4, 7] in a common spatial reference frame for self and other.

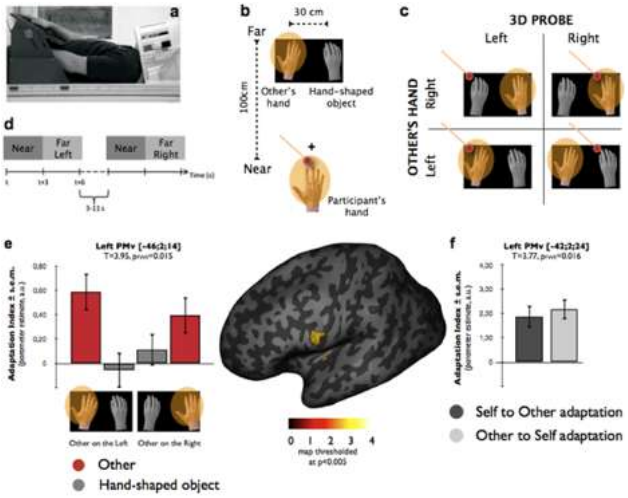

Figure 1. (a) Participant's tilted head and hand. (b) Spatial arrangement of the participant's, the other person's and the artificial hands around the fixation point (black cross). (c) Full-factorial design: independent manipulation of the positions of the prosthetic and the other's hand and the location of the 3D object. (d) Temporal schema of the events. (e) Experiment 1. A shared neuronal representation of the peri-hand space for self and other in the left PMv. The plots display the adaptation index. (f) Experiment 2. Significant bidirectional adaptation in the left PMv regardless of the order of stimulation.

Title: Motor cortex resting state functional connectivity in a large sample of healthy aging participants

Authors: *R. D. SEIDLER[1], B. ERDENIZ[2], V. KOPPELMANS[2], S. HIRSIGER[3], S. MERILLAT[3], L. JÄNCKE[3,4];
[2]Kinesiology, [1]Univ. Michigan, ANN ARBOR, MI; [3]Univ. of Zurich, Intl. Normal Aging and Plasticity Imaging Ctr. (INAPIC), Zurich, Switzerland; [4]Univ. of Zurich, Dept. of Psychology, Zurich, Switzerland

Abstract: Several studies have documented that aging is associated with impaired motor performance across a range of tasks, including decreased grip force strength, slowing of movement, and / or difficulties with balance and gait. Both primary neural representations of movement and potential compensatory cognitive mechanisms appear to be disrupted in older age (Seidler et al., 2010). Several studies have investigated age differences in the motor cortex during tasks that involve various motor paradigms, and one has investigated age effects on motor network connectivity (Langan et al. 2010), albeit with a relatively small sample size, and reported increased correlations between the two motor cortices for older adults. In the present study we investigated the effects of aging on functional connectivity of the motor network during the resting state in 212 healthy, right-handed subjects between the ages of 65 and 83. All participants had a normal mini-mental state exam (MMSE) (>26) and had no history of brain, heart, or metabolic diseases. The functional connectivity of the motor network in the resting state was measured by a seed-based correlation analysis. Based on a prior meta-analysis (Witt et al., 2008), a 4mm spherical region of interest (ROI) was defined in the left, dominant motor cortex. Participants' age and right hand motor tapping rates that were collected outside the scanner were used as covariates in a functional connectivity analysis. For this analysis we used the REST (Song et al., 2011) resting state functional imaging data processing software. Our results revealed that during the resting state, the left motor cortex showed correlations that varied with age and motor performance, primarily with the bilateral sensory-motor parts of the insular cortex and left middle frontal gyrus in the prefrontal cortex. Connectivity between the left motor cortex and these regions where higher in subjects that showed higher tapping rates outside the scanner. In addition, age was positively correlated with the strength of connectivity between left motor cortex and bilateral putamen. Collectively, the results of the current study showed that participants age is correlated with increased functional connectivity between the motor cortex and other cortical and limbic regions connectivity.

Title: A motor control-learning model enabling stiffness adjustment according to uncertainty of object's weight during load-on task

Authors: *H. KAMBARA[1], H. OGAWA[1], D. SHIN[1], Y. KOIKE[1,2];
[1]Tokyo Inst. Technol., Yokohama, Japan; [2]Crest, Japan Sci. and Technol., Tokyo, Japan

Abstract: When we try to receive an object, our brain predicts weight of the object from its physical appearance. Motor command signals, according to the predicted weight, is then sent to muscles in advance of the object's placement on the hand. Prediction of external world dynamics and anticipatory control based on the prediction are the keys to generate stable movements actuated by the muscles of which force cannot be changed instantaneously. Previously, we had proposed a motor control-learning model for load-on task in which an object is placed on the hand (Kim et al., 2009). We had confirmed that the model can reproduce subject's motion if the correct dynamics, the weight of the object in this case, is given to the model as a context cue. In our real world, however, it is difficult to predict exact dynamics of the world. In case the dynamics cannot be predicted accurately, we often stiffen our body and prepare for unpredictable external force. When we ride a bike on a dirt road, for example, we often stiffen our arm to stable the handle against unexpected force disturbance exerted by stones on the road. In this study, we investigated whether our motor control-learning model can learn to adjust the stiffness of the arm according to the uncertainty of the prediction of object's weight.
We run computational simulations of load-on task in which actual object's weight is determined randomly with Gaussian distribution in each load-on trial but the predicted weight was kept constant in all trials at the mean of the distribution. As the results, we confirmed that stiffness level of the arm became higher as the variance of Gaussian distribution became larger. This result shows the ability of our model to adjust the stiffness level according to probabilistic features of the external world.

Title: Sensory anticipation triggers activity in motor cortex

Authors: *D. REZNIK, R. MUKAMEL;
Tel-Aviv Univ., Tel-Aviv, Israel

Abstract: When we learn to execute a complex motor sequence (such as piano playing), we first break it into small fragments and then unify them to one seamless flow of actions. It has been suggested that mirror neurons might play a role in this dynamic coupling. Here we used whole-brain fMRI on 14 healthy right handed subjects to examine the role of the mirror system during anticipation of the sensory consequences of well learned motor sequences. The day prior to scanning, subjects were trained to perform 4 musical sequences on a digital piano keyboard - 2 unimanual sequences (one with the right hand and one with the left hand); and 2 bimanual sequences (one starting with the right hand and continuing with the left hand or vice versa). During the fMRI scan, subjects passively watched the same video recordings (including auditory feedback) that were used in the training session. We presented the subjects with full videos of the unimanual musical sequences and only the first half of the bimanual musical sequences (i.e., subjects saw the sequence played by one hand - thus creating expectation for the second half to be played with the other hand). We found that during the rest period following passive observation of the cropped bimanual videos, fMRI activity in primary motor cortex and in supplementary motor area was enhanced compared with the signal following viewing of the full unimanual videos. Interestingly, we found no lateralized response of this expectation signal in motor cortex - left and right motor cortices were activated to similar extent while expecting the sensory consequences produced by either hand. Our results support the involvement of the mirror neuron system during action preparation and expectation of musical sequences which is not specific to hand identity.

Title: Brain network properties of procedural consolidation

Authors: *S. SAMI[1], E. M. ROBERTSON[2], C. MIALL[1];
[1]Univ. of Birmingham, Birmingham, United Kingdom; [2]Berenson-Allen Ctr. for Non-Invasive Brain Stimulation, Harvard Med. Sch., Boston, MA

Abstract: Consolidation of procedural memories is a time dependent process by which fragile short-term memories of skill are transformed into long-term stable ones. Current neuroimaging approaches highlight a shift in activity for some cortical areas with the passage of time following learning. However, many of the same cortical structures that are active in short-term memory are also active in long term consolidation. Questions regarding changes in the cortical networks that lead to increased functional stability remain unanswered. Here we address this question by investigating the global brain network properties before and after consolidation of two forms of learning in the serial reaction time task (SRTT), by sampling changes in neural connectivity via resting-state scans once before and at three time points after task acquisition. We show that learning under implicit and explicit conditions leads to similar graph network changes after a 6 hour period of wakeful consolidation. There was an initial decrease in betweenness centrality immediately after learning followed by a significant increase at 6 hours. These reciprocal changes are also evident for local efficiency measures i.e. an early increase in network efficiency is later reversed. This suggests that consolidation may therefore be characterized by a more redundant memory storage.

Title: Sensorimotor adaptation is altered by mood priming

Authors: *O. L. BOCK[1], A. JESSE[2];
[1]German Sport Univ., Koln, Germany; [2]German Sport Univ., Köln, Germany

Abstract: Cognitive functions are influenced by mood: happy persons show a preference for globalized and fast processing, while sad persons prefer localized and accurate processing. Here we investigated how mood might influence the functions involved in sensorimotor adaptation. Subjects pointed at circular targets arranged around a central starting point while vision of their hand was distorted by a 60 deg rotation. A cartoon face was briefly shown at target onset: a standard "smiley" in group S, a "frowny" in group F, and a neutral facial expression in group N. We found that the initial pointing error increased abruptly at the onset of the visual distortion and then gradually decayed towards a plateau. This decay was most pronounced in group F, less in group N, and even less in group S. Aftereffects upon removal of the distortion did not differ between groups. Since aftereffects are thought to reflect genuine sensorimotor recalibration while improvements during adaptation may also be due to workaround strategies, we conclude that recalibration is resistant to mood changes while strategies are not: smileys discouraged strategies, while frownys encouraged them. A preference for localized and accurate processing might be beneficial for strategic thinking.

Title: Distributed action representations revealed with multi-voxel pattern analysis

Authors: *F. FILIMON[1], C. A. RIETH[2], M. I. SERENO[4], G. W. COTTRELL[3];
[1]Max Planck Inst. For Human Develop., Berlin, Germany; [2]Dept. of Psychology, [3]Dept. of Computer Sci. and Engin., UCSD, La Jolla, CA; [4]Dept. of Psychological Sci., Birkbeck Univ. of London, London, United Kingdom

Abstract: The roles of different brain areas in action representation and action understanding remain poorly understood. Based on neurophysiological evidence of mirror neurons in macaque ventral premotor area F5, the majority of human neuroimaging studies have emphasized the importance of Broca's area in action observation and execution, in addition to inferior parietal cortex and the STS. However, recent neuroimaging studies in both humans and macaques have revealed a much larger network of areas to be involved, outside of brain regions considered traditional mirror neuron areas.
We used multi-voxel pattern analysis (MVPA) to map the fine-grained representation of action execution, observation, and imagery in humans. Contrary to the presumed importance of traditional mirror neuron areas, we show that action representations:
1) are distributed across both dorsal (superior) and ventral (inferior) premotor and parietal areas;
2) can be discriminated in areas that are jointly activated by observation, execution, and imagery of reaching movements; and
3) can be accurately classified from either posterior parietal or frontal (premotor and inferior frontal) regions equally well.
These results challenge the presumed importance of traditional mirror neuron areas such as Broca's area in observation of action and action representation more generally. Moreover, unlike traditional univariate fMRI analyses, MVPA was able to discriminate between imagined and observed movements from previously indistinguishable BOLD activations in commonly activated regions, suggesting a finer-grained distributed pattern of activation within such areas.

Title: Updating target locations during continuous body motion

Authors: J. J. TRAMPER, *W. MEDENDORP;
Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Spatial updating is the process by which we keep track of objects in the space around us, even as we move our eyes, head or body. Many previous studies tested spatial updating *after*

an intervening movement, i.e., updating was probed in standstill. This work has shown that subjects make systematic errors in the updating process. Yet, many daily life situations require a continuous updating of the environment when we move. Therefore, in the present study, we examined the quality of spatial updating *during* ongoing motion. We subjected human participants to passive whole-body sinusoidal motion (A = 30 cm, f = 0.8 Hz), testing their updating behavior at different phases of the motion using a 2AFC psychophysical approach. After each reversal, when the chair reached a position of +15 cm or -15 cm, we briefly flashed an earth-stationary target light either in front or behind a fixation light. Then, after a displacement of 30 cm, we briefly flashed a probe light and subjects had to indicate whether they perceived the probe to left or to the right of the memorized target. Our null-hypothesis was that spatial updating during different phases of oscillatory self-motion is not different from each other, resulting in similar patterns of updating errors. Preliminary results show that during motion, subjects systematically erroneously update the location of remembered visual targets. We found that the updating errors were gaze-dependent, and that the direction and magnitude of the errors were similar to the results found for updating probed at the reversal points, i.e. in standstill. These results suggest that the integration of extraocular and vestibular signals to update a visual target is not affected by phase of the oscillatory movement.

Title: Continuous theta-burst stimulation of the right superior temporal gyrus impairs self-motion perception

Authors: *A. A. TARNUTZER, A. G. LASKER, D. S. ZEE;
Neurol., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Sensory input from the semicircular canals (SCC) and the otolith organs is centrally combined with signals from other sensory modalities to continuously update the internal estimate of self-motion. Constant-velocity vertical on-axis rotation leads to a decay of the nystagmus response from the horizontal SCC (angular vestibulo-ocular reflex) as well as of perceived angular velocity (PAV), and when the rotation stops a similar oppositely directed post-rotatory response occurs. Case reports and electrical stimulation studies suggest an involvement of the temporo-peri-Sylvian vestibular cortex in generating the PAV. Here we transiently inhibited parts of the temporo-peri-Sylvian vestibular cortex by use of continuous theta-burst stimulation (cTBS) and predicted an accelerated decay of PAV. Constant-velocity (100°/s) vertical-axis rotations were applied over 75 seconds before (1 block) and after (3 blocks) cTBS over the right superior temporal gyrus in six subjects. Breaks between the rotations (75sec) were initiated by abrupt stops. By use of a rotating potentiometer subjects indicated the PAV during and after the chair rotations. Simultaneously eye positions were recorded using a scleral search coil. Post-rotary PAV showed a trend towards shortened decay time-constants compared to the control trials ($p=0.086$) in the first 25 minutes after cTBS, while per-rotary PAV was not significantly changed. However, only early after cTBS the post-rotary PAV decay time-constant was significantly (9.4 ± 5.7 vs. 13.6 ± 5.9sec; $p=0.049$) reduced. Per-rotary and post-rotary angular vestibulo-ocular reflex decay time-constant were not significantly changed after cTBS ($p>0.05$). The findings from this pilot study support the hypothesis that the right temporo-peri-Sylvian vestibular cortex is involved in generating the percept of self-motion and can be modulated by means of cTBS.

Title: Characterization of central vestibular neuron responses during electrical stimulation delivered by a vestibular prosthesis

Authors: *D. E. MITCHELL[1], C. C. DELLA SANTINA[2], K. E. CULLEN[1];
[1]Dept. of Physiol., McGill Univ., Montreal, QC, Canada; [2]Dept. of Otolaryngology - Head & Neck Surgery, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Lesions that cause loss of vestibular function are relatively common in humans and hinder the ability to maintain stable gaze and balance. Ongoing research is focused on developing a chronically implanted vestibular prosthesis as a treatment option for patients suffering from vestibular loss. This device consists of a gyroscope, which senses the movement of the head, and electrode arrays implanted in each semicircular canal, which stimulate the vestibular nerve to send head motion information to the brainstem. Behavioural studies have shown that vestibular prosthetic stimulation produces reflexive eye and head movements, although these responses remain smaller than what would be expected from normal vestibular function. For example, the gain and time constant values of vestibulo-ocular reflex eye movements evoked by prosthesis stimulation are often lower than those observed in response to natural stimulation. To improve stimulation protocols and behavioural performance, it is necessary to determine how the brain responds to this type of stimulation.
Thus, to better understand the effect of prosthetic stimulation protocols on vestibular processing, we recorded the responses of neurons at the first stage of central processing (the vestibular nucleus) in alert rhesus monkeys while simultaneously delivering prosthetic stimulation. Neurons were identified based on their responses to eye position and during whole-body rotation. For neurons receiving direct input from the vestibular nerve, we determined the stimulation current amplitude for each unit by gradually increasing the current amplitude of biphasic pulses (200μs/phase) delivered at 100pps until spikes were reliably evoked at monosynaptic latencies (0.7-1.3ms). We ensured that the current amplitude used did not elicit any signs of facial nerve activation. Next, we applied pulse trains of 50pps-300pps to determine how neurons responded to sustained stimulation. We found that each neuron's spiking activity was highly time locked to pulses delivered through the prosthesis indicating that the vestibular afferent population was synchronously activated by prosthetic stimulation, which in turn drove synchronous central responses. We hypothesize that this synchronicity is in part the cause for the low behavioral performance obtained using the vestibular prosthesis thus far, and predict that desynchronizing afferent inputs will enhance the response of central vestibular neurons to prosthetic stimulation thereby improving behavioural performance. This work was supported by CIHR and NIDCD grant R01-DC002390.

Title: Human postural responses to stimulation of individual semicircular canal ampullae changes with head orientation

Authors: C. PHILLIPS, C. DEFRANCISCI, L. LING, K. NIE, A. NOWACK, *J. O. PHILLIPS, J. T. RUBINSTEIN;
Oto-HNS, Univ. of Washington, SEATTLE, WA

Abstract: Purpose: Vestibular sensory information is represented in a head centered coordinate frame. Changes in head position must be accounted for to produce appropriate postural responses to vestibular end organ inputs. We have developed a vestibular prosthesis for human use that targets individual ampullar nerves of the vestibular labyrinth. This allows us to evaluate individual semicircular canal contributions to the control of balance and posture in human subjects and their interaction with head position.
Methods: 4 patients with intractable unilateral Meniere's disease in the right ear were implanted with a vestibular prosthetic, employing three arrays of stimulating electrode sites inserted in the perilymphatic space adjacent to the ampulla of each semicircular canal. We tested the effects of electrical stimulation of individual canals on posture, as measured by computerized dynamic posturography. 2s duration 300 pulses/s trains of biphasic pulses of constant current were delivered during quiet stance in several postural contexts: stable support surface with eyes open and with eyes closed, with the subject's head oriented in one of seven positions: facing straight ahead, and turned horizontally 45º or 90º towards or away from the implanted ear, or pitched forward or back.
Results: Stimulation trains produced brief postural perturbations followed by a return to upright stance, the amplitude of which increased with stimulation current. With eyes open and eyes closed facing straight ahead, stimulation of the posterior canal produced an initial forward sway, while stimulation of the anterior canal produced an initial backward sway. Changes in head orientation during stimulation changed the amplitude and direction of the response. For example, during posterior canal stimulation, anterioposterior sway amplitude was greatly decreased with the head oriented away from the implanted ear and increased with the head oriented towards the implanted ear. In one subject, lateral canal stimulation produced a forward postural response

with the head oriented towards the implanted ear and a backward response with the head oriented away from the implanted ear.
Conclusion: Electrical stimulation of individual canals in human subjects produces consistent postural responses. The direction and amplitude of the postural response to stimulation in a specific canal changes with head orientation. These changes are consistent with canal-based models previously used to describe postural responses to transmastoid surface galvanic stimulation.

Title: Statistics of natural vestibular stimuli in monkey: Implications for coding

Authors: *A. D. SCHNEIDER, J. CARRIOT, M. J. CHACRON, K. E. CULLEN;
McGill Univ., Montreal, QC, Canada

Abstract: Understanding how neurons process sensory information requires not only a characterization of the neuronal responses, but also the natural stimuli encountered in an organisms sensory environment. This is in part because sensory coding is adapted to the statistics of natural inputs.

The vestibular system is comprised of 3 semicircular canals that sense angular velocity and 2 otolith organs that sense linear acceleration, in order to maintain stable gaze and posture. Canal afferents have been generally characterized by stimuli with standard deviations (std) around 40 deg/sec, and otolith afferents with linear accelerations of std around 0.2G (Fernandez and Goldberg 1971,1976). These neurons fire spontaneously around 100 Hz and are known to encode such stimuli through modulations in firing rate around the spontaneous value that are linearly related to the input, with precise spike timing not carrying behaviorally relevant information.

To characterize natural vestibular stimuli and their processing by the brain, we measured the head movements of Macaque monkeys, using a micro-electromechanical systems (MEMS) module sensitive to linear acceleration along and angular velocity about three axes (fore/aft, lateral, and vertical). Monkeys were free to move in a large play cage with a multi-level platform, while being monitored to identify behaviors associated with low (i.e. sitting and looking around), medium (i.e. foraging for food), and high (i.e. climbing and jumping across platform levels) levels of activity.

For the signals resulting from the three groups, we compared the probability distributions of the head angular velocity and linear acceleration signals to Gaussians with equal mean and variance, and found that the former have significantly longer tails as quantified by the fourth order moment kurtosis, as seen for natural auditory and visual stimuli (Ruderman 1994). We found that head angular velocity and linear acceleration signals could reach values up to 500-1500 deg/sec and 2-6G, respectively. Based on current otolith and canal afferent models, we predict that natural stimuli will elicit nonlinear responses in the form of cut-off (i.e. no firing) and saturation (i.e. firing at the maximum rate) in single afferents. We also predict that such nonlinear responses will synchronize the afferent population, in which case precise spike timing would carry essential stimulus information. These results challenge the traditional wisdom that early vestibular pathways are inherently linear, thus motivating a comprehensive rethinking of sensory coding in the vestibular system.

Title: Impacts of neuronal sensitivity and variability on the encoding of linear self-motion

Authors: *M. JAMALI, J. CARRIOT, K. E. CULLEN;
Physiol., McGill Univ., Montreal, QC, Canada

Abstract: Understanding the neural code is a fundamental challenge in neuroscience. Of particular interest is the role of discharge variability in sensory encoding. Accordingly, we took advantage of the otolith system which is well-defined anatomically and physiologically and benefits from easily characterized sensory stimuli (i.e., head acceleration). Moreover, otolith afferents have a broad diversity in their spontaneous discharge regularity. Despite the heterogeneity in their background discharge, otolith afferents are known for their faithful encoding of linear head acceleration through firing rate modulation. Here, we employed information theoretic and gain measures to probe the impacts of background discharge regularity on the encoding of linear acceleration by primary otolith afferents.
Extracellular recordings were made from utricular afferent fibers in head-fixed alert macaques while seated in a primate chair and translated by a servomotor. Neuronal responses were recorded during i) sinusoidal as well as ii) random noise stimulation with a Gaussian distribution of head acceleration along each afferent's preferred direction within the behaviorally relevant frequency range (0 - 15 Hz) with a peak acceleration of 0.2 g (g = 9.8 m/s2). We found that while the sensitivity of both regular and irregular afferents increased monotonically as a function of sinusoidal stimulus frequency, sensitivities reached much higher values for irregular units. In response to noise stimulation, irregular units also conveyed ~2 times more information at higher frequencies (e.g., >6Hz), while in contrast regular afferents only transmitted slightly greater information at low acceleration frequencies (≤2Hz). Interestingly, the lower and upper bounds on the mutual information density had similar shapes as a function of frequency for either class of otolith afferents, indicating that a linear model of encoding was nearly optimal. Finally, we found the addition of spike timing jitter to afferents spike trains produced a significant reduction

in information transmitted by regular afferents whereas it had little effect on irregular units. Thus, compared to regular afferents and despite higher level of intrinsic noise in their spiking, irregular units on average convey more information about linear self-motion over a broad frequency range due to higher gains and require less precision in their spike timing to encode the stimuli. These results suggest that while highly sensitive irregular afferents are more advantageous for transient and dynamic stimuli, the regular units can provide accurate information when the stimulus is less dynamic (e.g. static tilt).

Title: Efferent control of spike rate variability in the peripheral vestibular system

Authors: *X. YU[1], J. D. DICKMAN[1], S. NEWLANDS[2], D. E. ANGELAKI[1];
[1]Dept. of Neuroscience, Baylor Col. of Med., Houston, TX; [2]Dept. of Otolaryngology, Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Several studies have tested multiple hypotheses regarding the function of the vestibular efferent system, but little is currently known about how the efferent innervation of the vestibular periphery might modulate primary afferent activity. Sadeghi et al. (2007) specifically investigated a possible contribution of the efferent system to long-term processes of vestibular compensation after unilateral labyrinthectomy. Recordings from vestibular afferents revealed no difference in mean response properties, as compared to those in labyrinth-intact animals. However, response variability and detection thresholds were not compared.
Here we have measured direction detection thresholds of semicircular canal afferents using 0.5 Hz sinusoidal motion stimuli and ROC analysis. Canal afferent detection thresholds were measured from responses to 0.5 -16 °/s sinusoids delivered along the cell's preferred axis. Direction detection thresholds for semicircular canal afferents averaged 2.17°/s ±1.32 (geometric means± geometric deviation, n=85) for regular afferents and 1.91°/s ±1.58 (n=32) for irregular afferents in intact monkeys. After compensation from unilateral labyrinthectomy, canal afferent detection thresholds (from the contralateral vestibular nerve) were increased to 2.80°/s ±1.49 (n=66,$p<0.001$ comparison between intact and labyrinthectomy monkeys) for regular afferents

and 2.63°/s ±2.06 (n=29, p=0.12) for irregular afferents. Horizontal, anterior and posterior semicircular canal afferents had similar thresholds when tested along their preferred axis. Neuronal thresholds can depend on two properties that determine how much the two ROC distributions overlap: the difference in their means (amplitude slope) and their width (variance). No significant difference was found in the slope of response amplitude as a function of stimulus velocity for intact vs. labyrinthectomized monkeys. However, response variance was significantly increased after labyrinthectomy, and this increase lead to the increase in detection thresholds. Further analyses revealed that the increased variance had the timeframe of minutes (rather than seconds). The origins of such long-term control of neuronal variability, likely mediated by the vestibular efferent system, remain unknown. Further studies should also address whether the increased variances after labyrinthectomy were shared among the neurons or independent.

Title: Vestibular behavioral thresholds for yaw rotation discrimination in rhesus macaques

Authors: *C. D. GARCIA, J. D. DICKMAN, D. E. ANGELAKI;
Baylor Col. of Medicine, Neurosci., Houston, TX

Abstract: The vestibular system provides for perception of movement, orientation in space, and motion related behaviors. In relation to self-motion perception, human yaw rotation velocity thresholds have been previously measured to be 0.7 deg s^{-1} at 0.5 Hz (Merfeld et al. 2008). However, the available data on neuronal direction detection thresholds for semicircular canal afferents in macaques have been quite disparate. For example, average neuronal direction detection thresholds for semicircular canal afferents were reported to be ~3.75 deg s^{-1} for regular afferents and ~8.25 deg s^{-1} for irregular afferents by Sadeghi et al. (2007). In contrast, Yu et al. found average direction detection thresholds for semicircular canal afferents to be much lower at 2.17 deg s^{-1} ± 1.32 (n=85) for regular afferents and 1.91 deg s^{-1} ± 1.49 (n=32) for irregular afferents (2013 SFN Abstract). Both studies used sinusoidal stimuli without simultaneously measuring behavioral thresholds. Furthermore, both studies compared neural thresholds in

macaques with human perceptual thresholds. Thus, it is possible that macaque and human perceptual thresholds are different. Here we set out to investigate how macaque perceptual yaw rotation velocity detection thresholds compare with human thresholds. We measured macaque thresholds using transient smooth trajectories that followed a 1s Gausian velocity profile (peak velocity: 1.3-30 deg s^{-1}). Two rhesus macaques were trained to perform a two-alternative-forced-choice task, in which they reported leftward or rightward rotation by making a saccade to one of two targets presented at motion end. Psychometric functions then determined direction detection thresholds over time. Mean yaw rotation detection thresholds were initially 8.59 deg s^{-1} for monkey H and 6.85 deg s^{-1} for monkey I. However, after continued training, perceptual thresholds in both monkeys decreased to 3.31 deg s^{-1} for monkey H and 1.48 deg s^{-1} for monkey I. In order to directly compare neuronal and perceptual detection thresholds for yaw rotation, we are currently measuring canal afferent thresholds simultaneously with perceptual detection thresholds in both animals.

Title: Reduced choice-related activity and noise correlations accompany deficits of perceptual and neural discrimination thresholds after unilateral vestibular lesion

Authors: *S. LIU[1], J. D. DICKMAN[1], S. D. NEWLANDS[2], G. C. DEANGELIS[3], D. E. ANGELAKI[1];
[1]Dept. of Neurosci., Baylor Col. of Med., Houston, TX; [2]Dept. of Otolaryngology, [3]Dept. of Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Signals from the bilateral vestibular labyrinths work in tandem to generate robust estimates of our motion and orientation in the world. The relative contributions of each labyrinth to behavior, as well as how the brain recovers after unilateral peripheral damage, have been characterized for motor reflexes, but never for perceptual functions. We measured perceptual

deficits in a heading discrimination task following surgical ablation of the neurosensory epithelium in one labyrinth. We found large increases in heading discrimination thresholds and large perceptual biases at one-week post-lesion. Repeated testing thereafter improved heading perception, but vestibular discrimination thresholds remained elevated three months post-lesion. Electrophysiological recordings of single-unit activity from the contralateral vestibular (VN) and cerebellar nuclei (CN) revealed neuronal discrimination thresholds that were elevated as compared to normal animals, and trial-by-trial correlations with perceptual decisions ('choice probabilities', CPs) that were reduced. The relationship between CP and neuronal threshold was not significantly altered, suggesting that smaller CPs in lesioned animals were mostly attributable to greater neuronal thresholds.

Simultaneous recordings from pairs of neurons reveals highly structured correlated noise among subcortical vestibular neurons (Liu et al. 2013). In intact animals, although average noise correlations were close to zero, pairs of VN/CN neurons frequently exhibited large positive or negative noise correlations, and these showed a dependence on tuning similarity that was stronger than that typically seen for cortical neurons. Noise correlations are thought to arise from shared connectivity and common input. One of the sources of common input in the vestibular brainstem is convergence between the ipsilateral and contralateral labyrinths and this convergence might contribute to the large noise correlations observed in VN and CN (Liu et al. 2013). If so, a unilateral vestibular lesion should reduce correlated noise, in addition to reducing CPs.

Simultaneous recordings from pairs of neurons in lesioned animals revealed that the magnitude of noise correlations was systematically reduced after the lesion, along with the slope of the relationship between noise correlation and tuning similarity. Thus, cross-labyrinthine interactions appear to play important roles in enhancing neuronal and perceptual sensitivity, strengthening interneuronal correlations, and facilitating correlations between neural activity and perceptual decisions.

Title: Neuronal ensemble coding in early vestibular pathways during self-motion

Authors: *A. DALE, J. CARRIOT, K. E. CULLEN;
Physiol., McGill Univ., Montreal, QC, Canada

Abstract: The secondary sensory neurons of the vestibular system receive inputs from vestibular afferents, and their outputs mediate postural reflexes as well as perception and computation of movement. Behavioral studies have revealed, however, that detection thresholds for perception are better than those of individual neurons (Seemungal et al. 2004, Grabherr et al. 2008). Recent work also demonstrated that pooling the activity of multiple neurons more closely matches the output of the vestibular nuclei (VN) with behavior (Massot et al. 2011). In order to accurately model the neuronal output, however, it is important to determine whether the responses of individual neurons are independent. Accordingly, we investigated noise correlations between the activity of 1) pairs of regular and irregular afferent inputs and 2) pairs of vestibular-only (VO) neurons in VN.
First we considered the baseline level of synchrony when no stimuli were present. We found that the magnitude of noise correlations for both afferent pairs and VO pairs was not significant. This revealed that in the absence of stimulation, neither afferent nor other putative common inputs synchronize the activity of neurons in VN. Next, we considered whether afferents or VN neurons displayed changes in synchrony during sensory stimulation. We found that during passive sinusoidal rotation, VO neurons fired more synchronous spikes than in the baseline condition, resulting in noise correlation magnitudes that were slightly elevated over baseline. In contrast, the magnitude of noise correlations between afferent pairs remained insignificant. While these results suggest that common afferent input influences synchrony between VN neurons more strongly during self-motion, they also reveal that the responses of individual VN neurons, like their afferent inputs, are largely independent.

Title: Alpha-band modulations predict the quality of visual stability during whole-body motion

Authors: *T. P. GUTTELING, L. P. J. SELEN, W. P. MEDENDORP;
Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Despite the constantly changing visual input to the retina due to eye, head and body movements, we are able to maintain a stable representation of the environment. Various monkey single-unit and human imaging studies have suggested that the brain anticipates the visual reafference due to saccadic eye movement by remapping the neural image. A similar mechanism is thought to underlie visual stability during whole-body movements. Using electro-encephalography (EEG), we examined oscillatory activity related to spatial remapping during passive self-motion. Subjects (n=16) were seated in a computer controlled, custom-built vestibular sled, designed to impose translational motion along the interaural axis with a bell-shaped velocity profile (40cm, 1s). During the motion, subjects had to keep track of a remembered target that was initially presented in one visual hemifield, but needed to be remapped into the contralateral hemifield to maintain spatial constancy. The quality of the updating was characterized using a 2AFC task, in which we presented a second visual target and the subject had to indicate whether it was left or right of the original one. High-density EEG was recorded using an 88-channel active electrode system. Results show that the remapping of a spatial target during passive self-motion is reflected in lateralized alpha band (8-12Hz) activity. Alpha band suppression, indicative of enhanced sensitivity, occurs initially in parietal-occipital areas contralateral to the initial target location. During the motion, the shift of the remembered target to the opposing visual field was accompanied by a shift of alpha suppression to the other hemisphere. Importantly, the strength of the alpha band modulations correlated significantly with the updating error across subjects, i.e. a higher behavioral updating gain is associated with higher alpha band modulation. We conclude that self-motion remapping is reflected by alpha band activity, consistent with previous observation with head-fixed saccades. The role of other frequency bands in this process still remains to be studied.

Title: Modeling the influence of visual and vestibular tilt cues on the subjective visual vertical of rhesus monkeys

Authors: *M. F. KHAZALI, N. DADDAOUA, P. W. DICKE, P. THIER;
Cognitive Neurol., Hertie Inst. For Clin. Brain Res., Tübingen, Germany

Abstract: Our perception of the world as upright is reliably stable despite frequent changes of the orientation of the head and the body. The subjective visual vertical (SVV) is a measure of the percept of visual upright. The SVV of human subjects roll tilted relative to gravity shows deviations from the ideal. Actually, even without body tilt, the SVV can deviate from the gravitational vertical if a visual background (e.g. a visual frame), serving as reference, is tilted. The induced shift becomes more pronounced when the frame tilt is combined with body tilt.
In an earlier study (Daddaoua N. et al. , J. Vis., 8. 2008) we had tested the SVV of rhesus monkeys tilted around the roll axis in total darkness and found similar deviations as in previous work with humans. The human SVV has been successfully modeled by assuming that the SVV is an average of two vectors, namely a tilt estimate provided by the otolith organ and an idiotropic vector, corresponding to a representation of the body axis, needed to ameliorate insufficiencies of the otolith output for small tilts (Mittelstädt ,Naturwiss. 70, 1983). When applied to our monkey data, this model turned out to yield a good description of the experimental results obtained for monkeys as well.
In a subsequent experiment (Khazali M. et al., SFN2012 265.10) we had introduced a 28°x 28° visual frame tilted between +/- 45° in discrete steps around the vertical axis while the body axis of the monkey was upright or roll tilted by -45 or +45°. We found that the SVV was shifted relative to the vertical in the direction of the frame when the monkey was in the upright position. The amplitude of the induced shift was further increased when the monkey was roll tilted by +/- 45°. When again resorting to the Mittelstädt model (MM) to explain the experimental findings, we obtained reasonable fits, the exception being that the MM was unable to account for the increased amplitude of the shift of the SVV, observed when tilting both the frame and the body. To overcome this limitation we added features from another modeling approach (a Bayesian model proposed by Vingerhoets et al. , e.g. J. Neurophysiol. 101, 2009), namely the assumption that the vestibular signal is contaminated by noise increasing with tilt and secondly, the assumption that the visual background should be upright, a prior with tilt independent noise. Our model, combining the assumption of an idiotropic vector characterizing the MM, with key features of previous Bayesian approaches gives a very satisfactory description of the experimental findings, including the systematic variations known as A-and E-effects as well as the increased deviation of the SVV, observed when tilting both the body and the frame.

Title: Head direction-like cells in the primate subiculum and entorhinal cortex

Authors: *B. KIM[1], J. D. DICKMAN[2], J. S. TAUBE[3], D. E. ANGELAKI[2];
[1]Baylor Col. of Med., Katy, TX; [2]Neurosci., Baylor Col. of Med., Houston, TX; [3]Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Navigation is an essential skill for many animals and recent findings on place, head direction (HD) and grid cells in rodents provide a promising gateway to understand the neuronal mechanism of navigation. However few studies of the navigation circuit in primates have been reported. Here, we recorded the responses of cells in the subiculum (Sb) and the entorhinal cortex (EC), in rhesus macaques during 360° rotational motion in a dimly lit circular enclosure. The moneys had implanted search coils for monitoring eye and head position. The animals were trained to separate their head direction and eye direction by fixating separate visual targets. The animals' head was free to move within ±30° in the horizontal plane. Animals were trained to point a head-mounted laser onto a head target (green dot) and to visually fixate an eye target (red dot) that could either be coincident or separated from the head target. To determine directional tuning for each cell, we fit each neuron's response curves with von Mises functions in a head direction model and an eye direction model then compared the goodness-to-fit of each. As head direction and eye direction could be associated, we calculated the partial correlation coefficients and z-transformed them for comparison. Recordings from one monkey have revealed Sb and EC neurons that encode the monkey’s head direction relative to a visual cue card, similar to findings in rodents.

Title: Head direction signal degradation impairs landmark navigation

Authors: S. L. KIRBY[1], R. E. HARVEY[1], E. A. GOEBEL[1], J. R. KOPPEN[2], D. G. WALLACE[2], *R. M. YODER[1];
[1]Dept. of Psychology, Indiana - Purdue U Fort Wayne, Fort Wayne, IN; [2]Dept. of Psychology, Northern Illinois Univ., Dekalb, IL

Abstract: Head direction cells provide a neural representation of perceived directional heading relative to the environment. Lesion studies suggest an important role for this signal in spatial learning and navigation, but brain lesions can damage additional brain structures/signals that may underlie the observed deficits. As a complementary model, we evaluated the spatial performance of otoconia-deficient *tilted* mice which have intact brains with degraded head direction cell signals. A caveat to this approach is that vestibular dysfunction can alter hippocampal function, and this change may impair spatial abilities. We therefore evaluated the integrity of hippocampal cholinergic afferents as a marker of hippocampal function. **Method:** Homozygous *tilted* mice and their heterozygous control littermates performed spatial tasks on two mazes: a 6-arm radial maze and a Barnes maze. Two tasks - an intramaze cue task and an extramaze cue task - were used on the radial arm maze, with the same two arms baited for four trials per day, across ten days. On the Barnes maze, mice performed four acquisition trials per day across four days with a constant goal location, followed by a single 5-min probe trial on the fifth day with no goal available. Optical density was measured in hippocampal sections stained for acetylcholinesterase. **Results:** *Radial arm maze* Control and *tilted* mice showed increased percentages of correct arm choices across days on both tasks. However, *tilted* mice were impaired on the extramaze cue task but not on the intramaze cue task, relative to control mice. *Barnes maze* Control and *tilted* mice showed decreased number of errors, distance, and latency across days. *Tilted* mice were initially impaired but performed similar to control mice by the last day of acquisition. Both groups spent similar amount of time in the target quadrant during the subsequent probe trial. *Optical density analysis* Markers of hippocampal cholinergic function were similar across control and *tilted* mice, suggesting the navigation deficits of *tilted* mice did not result from structural changes to hippocampus or to the cholinergic septohippocampal projections. **Importance:** These results support previous suggestions that the head direction signal is an important component of navigation relative to distal cues.

Title: Short-term changes of hippocampal synaptic transmission after bilateral vestibular sensory loss in the rats

Authors: *J. N. ERON, V. A. KORSHUNOV;
Inst. of Higher Nervous Activity and Neurophysiol. of RAS, Moscow, Russian Federation

Abstract: Previously it has been shown in the number of human and animal studies that the damage of the vestibular sensory system causes the spatial memory deficit, the disorders in spatial perception and navigation and the reduction of efficacy of synaptic transmission and atrophy in the CA1 region of the hippocampus. The changes found after the complete vestibular loss (<60 days) were long-term. However, how the spatial information is encoded or compensated in hippocampus at the early stage after the complete loss or temporary deprivation of vestibular sensory inputs is unknown. It has recently been shown that the density of NMDA receptors was increased and no hippocampal atrophy was observed after the vestibular loss (Besnard et al., 2012).
The objective of this study was to estimate the efficacy of CA1 synaptic transmission in the early stage post-bilateral vestibular deafferentation (BVD). The fEPSPs of CA1 hippocampus were evoked by Schaffer collateral pair stimulation (at stimulus current ≤450 μA with interpulses interval 35 ms) and were recorded bilaterally in awaked freely moving rats (male Wistar rats, age 3-6 months). The animals were tested before and again 1, 2, 4, 5, 6, 10, 12, 15 days after BVD (n=3) or sham vestibular loss (n=2). There were no significant changes in the amplitudes for both fEPSPs in rats after sham surgery for post-operated term. In contrast, there was observed the typical dynamic change of fEPSPs during two weeks post-BVD term. After the BVD, the amplitudes of responses gradually decreased and achieved the maximal changes by day 4 (25-50%); however, by day 5 there was significant increase of the amplitudes of pair fEPSPs compared to controls. In 6 days after BVD the responses decreased again. The secondary facilitation of fEPSPs occurred during 10-12 days after BVD and then gradually irreversibly diminished over 15 days. Our data also showed that the decreasing of fEPSPs was accompanied by the increasing of threshold for synaptic transmission. The second of pair fEPSP had higher initial decrease and smaller its recovery than first one indicating the substantial derangement in

presynaptic transmission regulation.
Thus, two peaks in recovery of synaptic transmission efficacy in CA1 hippocampus after BVD was found in this pilot study. However, the mechanisms involved in the recoveries are still unknown. The facilitation could occur due to the local compensatory mechanisms of neuronal plasticity in hippocampus and also due to the external excitatory vestibular-independent interactions involved in spatial perception.

Title: Identification of Kv1.2 antisense RNA, an endogenous long non-coding RNA, in the dorsal root ganglion

Authors: *Y. TAO, X. ZHAO, F. E. ATIANJOH, J. ZHAO, L. LIANG, W. WANG, X. GUAN; Anesthesiol. and Critical Care Med., Johns Hopkins Univ. Sch. Med., BALTIMORE, MD

Abstract: Peripheral nerve injury down-regulates expression of Kv1.2 mRNA and protein in the dorsal root ganglion (DRG), a phenomenon that may contribute to induction of neuropathic pain. However, the molecular mechanisms that underlie this down-regulation are still unknown. Recent studies suggest that the mechanism for gene regulation involves widespread non- coding RNAs (ncRNAs), including long ncRNAs (lncRNAs). Here, we report a new native lncRNA that is expressed in the DRGs of rat, mouse, monkey, and human. Because most of its sequence is complementary to Kv1.2 RNA, we named it Kv1.2 antisense (AS) RNA. Kv1.2 AS RNA is expressed weakly in normal DRG. Approximately 21.5% of DRG neurons are labeled. Most were medium-sized, although some were small and a few large. Approximately 60.6% of Kv1.2 AS RNA-labeled neurons were positive for NF-200, 18.1% for P2X3, 15.3% for IB4, and 28.7% for CGRP. Although the distribution pattern of Kv1.2 AS RNA partially overlaps of Kv1.2 protein in DRG, most Kv1.2 AS-labeled neurons express a low level of Kv1.2 protein. The

characteristic of Kv1.2 AS RNA subpopulation distribution in the DRG indicates that it may have an important function in neuropathic pain.

Title: Peripheral nerve injury up-regulates Kv1.2 antisense RNA expression in the injured dorsal root ganglion

Authors: *J. ZHAO, X. ZHAO, F. ATIANJOH, L. LIANG, W. WANG, X. GUAN, Y.-X. TAO;
Dept. of Anesthesiology/Critical Care Med., Johns Hopkins Univ., Baltimore, MD

Abstract: We recently identified an endogenous Kv1.2 antisense (AS) RNA in the dorsal root ganglion (DRG). We also found that this AS RNA specifically and selectively targeted Kv1.2 mRNA expression in vitro and in vivo DRG. It is known that peripheral nerve injury down-regulates expression of Kv1.2 mRNA and protein in the DRG. To investigate whether this down-regulation was due to Kv1.2 AS RNA, we examined expressional level of Kv1.2 AS RNA in the DRG after unilateral L5 spinal nerve ligation (SNL). The level of Kv1.2 AS RNA was time-dependently increased in the ipsilateral L5 DRG after SNL. Neither SNL nor sham surgery changed the expression of Kv1.2 AS RNA in the ipsilateral L4 DRG or L5 spinal cord. Furthermore, the staining density and number of Kv1.2 AS RNA-labeled neurons in the ipsilateral L5 DRG were higher than those in the contralateral L5 DRG on days 3, 7, and 14 post-SNL. These changes occurred predominantly in large DRG neurons. These observations were

confirmed in rats subjected to sciatic nerve axotomy. Our findings suggest that Kv1.2 AS RNA can be induced in the injured DRG after peripheral nerve injury. This induction may be responsible for DRG Kv1.2 down-regulation after nerve injury.

Title: Impaired neuropathic pain and preserved acute pain in rats over-expressing voltage-gated potassium channel subunit Kv1.2 in primary afferent neurons

Authors: *L. FAN, J. ZHAO, V. TIWARI, Y.-X. TAO;
Johns Hopkins Univ. Sch. of Medicine/Accm, Baltimore, MD

Abstract: Voltage-gated potassium (Kv) channels are critical in controlling neuronal excitability and involved in the induction of neuropathic pain. Therefore, Kv channels might be potential targets for prevention and/or treatment of this disorder. We reported here that majority of the dorsal root ganglion (DRG) neurons were positive for Kv channel alpha subunit Kv1.2. Most of them were large and medium, although they had a verity of sizes. Peripheral nerve injury caused by lumbar (L)5 spinal nerve ligation (SNL) produced a time-dependent reduction in the number of Kv1.2-positive neurons in the ipsilateral L5 DRG, but not in the contralateral L5 DRG. Such reduction was also observed in the ipsilateral L5 DRG on day 7 after sciatic nerve axotomy. Over-expressing full-length Kv1.2 RNA in the injured L5 DRG attenuated the development of SNL-induced pain hypersensitivity without affecting acute pain and locomotor function. This effect might be attributed to the rescue of SNL-induced downregulation of Kv1.2 protein and the blocking of SNL-induced upregulation of endogenous Kv1.2 antisense RNA in the injured DRG. Our findings suggest that Kv1.2 may be a novel potential target for preventing and/or treating neuropathic pain.

Title: Over-expression of dorsal root ganglion Kv1.2 AS RNA leads to neuropathic pain symptoms

Authors: *V. TIWARI[1], F. E. ATIANJOH[2], J. ZHAO[2], X. ZHAO[2], L. LIANG[2], Y.-X. TAO[2]; [1]The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Dept. of Anesthesiol. and Critical Care Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: We recently reported that peripheral nerve injury increased expression of an endogenous Kv1.2 antisense (AS) RNA in the injured dorsal root ganglion (DRG). To test whether this increase is involved in neuropathic pain development, we over-expressed Kv1.2 AS RNA in the DRG via injection of AAV5-Kv1.2 AS unilaterally into L4/5 DRGs. We found that expression of the Kv1.2 AS RNA was significantly increased in the $L_{4/5}$ DRGs at 4 weeks, reached a peak at 8 weeks, and remained high for at least 12 weeks after viral injection. In contrast, the expression of Kv1.2 mRNA and protein was significantly and temporally reduced in the ipsilateral $L_{4/5}$ DRGs. Behavioral observations showed that injection of AAV5-Kv1.2 AS, but not of AAV5-EGFP (as a control), produced mechanical and cold hypersensitivities as demonstrated by ipsilateral decreases in paw withdrawal threshold and paw withdrawal latency, respectively. These hypersensitivities developed by 4 to 6 weeks, reached a peak at 8 weeks, and were maintained for at least 12 weeks. Neither AAV5-Kv1.2 AS nor AAV5-EGFP affected locomotor functions. These findings suggest that Kv1.2 AS RNA-triggered DRG Kv1.2 downregulation induces mechanical and cold hypersensitivities, two major clinical symptoms of neuropathic pain.

Title: mTOR and its downstream pathway are activated in the dorsal root ganglion and spinal cord after peripheral inflammation, but not after nerve injury

Authors: *L. LIANG, B. TAO, L. FAN, M. YASTER, Y.-X. TAO;
Dept. of Anethesiology and Critical Care Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Protein translation controlled through activation of mammalian target of rapamycin (mTOR) participates in many physiological and pathological processes. However, whether such activation is required for chronic pain is still unknown. Here, we examined activation of the mTOR signaling pathway during complete Freund's adjuvant (CFA)-induced chronic inflammatory pain and L5 spinal nerve ligation (SNL)-induced neuropathic pain in rats. Western blot analysis showed significantly increased levels of phosphorylated mTOR (p-mTOR) and phosphorylated p70S6 kinase1 (p-S6K1, a downstream effector of mTOR) in the ipsilateral L4/5 spinal cord 2h,1 day,3days, and 7days after intraplantar CFA injection and in the ipsilateral L4/5 dorsal root ganglions (DRGs) 1 and 3 days after CFA injection. Immunohistochemistry also demonstrated increases in number of p-mTOR-labeled neurons in the ipsilateral L4/5 DRGs and in density of p-mTOR-labeled immunoreactivity in the ipsilateral L4/5 superficial dorsal horn 1 day after CFA injection. Moreover, intrathecal administration of rapamycin, a selective inhibitor of mTOR, significantly blocked CFA-induced mechanical allodynia and thermal hyperalgesia 1 day post-CFA injection. Interestingly, expression of neither p-mTOR nor p-S6K1 was markedly altered on days 3,7,or14 after L5 SNL in L5 spinal cord or DRG. These findings indicate that in DRG and spinal cord, mTOR and S6K1 are activated during chronic inflammatory pain, but not during neuropathic pain. Our results strongly suggest that mTOR and its downstream pathway contribute to the development of chronic inflammatory pain.

Title: The oxidized linoleic acid metabolite-cytochrome p450 system is active in biopsies from patients with inflammatory dental pain

Authors: *S. RUPAREL[1], K. HARGREAVES[1], M. ESKANDER[2], S. ROWAN[1], J. DE ALMEIDA[1], L. ROMAN[3], M. HENRY[1];
[1]Endodontics, [2]Pharmacol. and Endodontics, [3]Biochem., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstract: Numerous studies have implicated a role for TRPV1 in mediating inflammatory hyperalgesia. Inflammation may lead to increased endogenous TRPV1 agonist activities. For example, oxidized linoleic acid metabolites (OLAMs) and the activity of oxidative enzymes releasing them [e.g., cytochrome P450 (CYP)], are upregulated following complete Freund's adjuvant (CFA)- induced inflammation in the rat. However, it is not known if such agonists are elevated in human inflammatory pain conditions. Since TRPV1 is expressed in human dental pulp nociceptors, we hypothesized that OLAM-CYP machinery is active in this tissue type and is increased under inflamed and painful conditions such as irreversible pulpitis (IP). Our data showed that the metabolism of exogenous linoleic acid (LA) was increased in IP tissues compared to normal tissues and pretreatment with a broad spectrum CYP inhibitor, ketoconazole, significantly inhibited LA metabolism. In addition, application of extracts obtained from LA-treated IP tissues onto cultured TG neurons, evoked significant inward currents that were blocked by pretreatment with the TRPV1 antagonist, IRTX. Moreover extracts obtained from tissues with LA and ketoconazole pretreatment showed significantly blunted inward currents in TG neurons. These data suggest that LA metabolites produced in human inflamed tissues act as TRPV1 agonists capable of activating peripheral nociceptors and that production of these metabolites can be targeted by inhibition of CYP enzymes. In addition, immunohistochemical analysis of two CYP isoforms, CYP2J2 and CYP3A1, were shown to be predominately expressed in immune cells infiltrating the dental pulp during inflammation, further emphasizing the paracrine role of CYP enzymes in OLAM-mediated inflammatory pain.

Title: Oxidative enzyme gene expression after traumatic injury

Authors: *H. M. BRANDFELLNER[1], S. B. RUPAREL[2], J. A. GELFOND[3], K. M. HARGREAVES[2];
[1]Gen. Surgery, [2]Endodontics, [3]Epidemiology & Biostatistics, Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Adequate pain management in traumatically injured patients is difficult and often complicated by many adverse effects of the medications being prescribed. In response to injury and inflammation linoleic acid is metabolized to form oxidized-linoleic-acid-metabolites (OLAMs), which are direct agonists for the pain receptor, Transient Receptor Potential Vanilloid Subtype-1 (TRPV1). Thus, OLAM production after trauma likely contributes to pain. The list of possible enzyme candidates involved in metabolizing linoleic acid is large and before additional studies can begin to target those enzymes involved in OLAM formation, a narrower focus must be established. Here, we tested the hypothesis that traumatic injury triggers a sustained upregulation in the expression of mRNA transcripts encoding oxidative enzymes that may be involved in OLAM synthesis.
The Glue Grant Trauma-Related Database (TRDB) was used to identify changes in expression patterns of transcripts from peripheral circulating leukocytes (PCL) after traumatic injury. The Affymetrix HG-U133 Plus 2 human microarray was used to analyze a total of 105 genes, including 86 genes known to oxidize poly unsaturated fatty acids (the general class of lipids that

includes linoleic acid). 187 traumatically injured subjects had an associated 785 microarrays from PCL samples. The injured subjects were compared against 95 controls. Data was analyzed by log2 expression differences from control.
As compared to controls, traumatic injury in humans triggered significant upregulation of specific (Cytochrome P450 (CYP) and Lipoxygenase (LOX)) gene transcripts in peripheral circulating leukocytes samples. The most significant upregulated and down regulated genes with a $p<0.001$ were well conserved from Day 0 to 28 post injury. Analysis of the relationship between the genes and Injury Severity, Max Denver 2, and APACHE II scores demonstrated common overlap amongst the genes with $p<0.001$.
Traumatic injury triggers a massive, selective and sustained alteration in the expression pattern of enzymes capable of forming OLAMs in the blood. The CYP family appears to play a critical role in OLAM formation, thus identifying and targeting specific CYP enzymes responsible for OLAM synthesis after injury could provide potential strategies for development of novel analgesics.

Title: Role of endogenous trpv1 agonists in a post-burn pain model of partial-thickness injury

Authors: *D. GREEN, S. RUPAREL, L. ROMAN, M. A. HENRY, K. M. HARGREAVES; Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstract: Background: Burns are an especially damaging form of trauma that few other injuries are capable of rivaling in regards to pain intractable to many available analgesics. The primary complaint of burn victims is an intense, often devastating spontaneous pain, with persistence of both mechanical and thermal allodynia and hyperalgesia.TRPV1 receptors are a class of ligand gated ion channels expressed on many pain-sensing nociceptive afferent neurons and transduce various noxious physical and chemical stimuli, including noxious heat (>48°C). However, the role of the TRPV1 receptor in mediating post-burn pain is incompletely understood. We previously have reported the production of endogenous TRPV1 agonists, oxidized linoleic acid metabolites (OLAMs), in skin heated to noxious temperatures. We hypothesize that persistent post-burn pain is mediated by a continuous release of membrane lipids from the burn site that activate or sensitize TRPV1.
Methods: Animals were anesthetized with isoflurane and a surgical plane of anesthesia was confirmed with a negative response to tail pinch. Thermal injury was induced by exposing an area of plantar hindpaw skin to a 100°C thermal stimulus for 30 sec. To promote reproducible thermal injuries, the same 1cm X 2cm region of the hindpaw was exposed in each animal, a stable stimulus temperature was maintained by a heating block and consistent hindpaw contact with the heated surface was achieved by placing a 30 g weight onto the dorsal hindpaw. Silver sulfadiazine cream (1%) was applied daily on the injured area to prevent infection. The injury was well tolerated and normal feeding and drinking behavior was maintained. OLAM levels in skin were obtained isolated after homogenization (Qiagen tissue lyser) in HBBS followed by extraction with 1ml chloroform:methanol (4:1; X1.5hr), addition of saline, centrifugation (335g X 5min) and drying the organic layer under N2. The lipid extract was re-suspended in 1ml of acetonitrile and subjected to LS-Mass Spectrometry to determine OLAM levels.
Results: The rat hind paw model of burn injury produced thermal allodynia peaking at 7d post thermal injury (ANOVA: $F=7.30$ $p<0.001$) and mechanical allodynia peaking at 14d (ANOVA: $F=55.61$ $p<0.01$). We observed that there was a significant ($p<0.05$) two-fold increase in OLAM levels from thermally injured skin when compared to extracts from skin obtained from non-injured animals.
Conclusion: These data indicate OLAMs are released from burned skin during times of post-burn allodynia and support the central hypothesis that oxidized linoleic acid metabolites contribute to persistent post-burn pain.

Title: Nerve growth factor-induced persistent allodynia is mediated by increased TRPV1 activities in rats

Authors: *M. ESKANDER[1], S. RUPAREL[1], E. POR[2], A. AKOPIAN[1,2], K. HARGREAVES[1,2]; [1]Endodontics, [2]Pharmacol., UTHSCSA, San Antonio, TX

Abstract: The management of pain remains a major health care problem due to an incomplete understanding of pain mechanisms, especially those involved in the transition to persistent/chronic pain states. Nerve growth factor (NGF) is a sufficient stimulus in humans to trigger a persistent pain state, but the mechanisms mediating this transition are unknown. We have tested the central hypothesis that NGF regulates the transition from acute pain to chronic pain via increased TRPV1 activities.
Using blinded observers, rats were injected with NGF for 5d and then tested for thermal allodynia in the hind paw up to 15 days after the last injection. NGF triggered a persistent thermal allodynia that extended up to 11d. Further, the allodynia was significantly reversed by systemic administration of anisomycin, a protein synthesis inhibitor ($p<0.01$) and by capsazepine (CPZ, $p<0.001$). Thus, NGF induction of a prolonged thermal pain state requires protein synthesis and is TRPV1-dependent. NGF treated animals also showed increased nocifensive responses to intraplantar capsaicin ($p<0.001$), suggesting either increased TRPV1 expression or sensitization. Therefore, we utilized whole cell patch clamp approaches to conduct a capsaicin concentration response in lumbar DRG cell bodies acutely cultured from NGF and vehicle treated rats. We observed a significant increase in Emax values from the NGF treated group with no significant difference in EC50 values. Western blot analysis indicated increased TRPV1 expression in lumbar dorsal root ganglia (DRG) plasma membrane after NGF treatment ($p<0.01$). Both electrophysiology and Western blot analysis indicate increased TRPV1 expression on the plasma membrane. Taken together, the results demonstrate that NGF produces prolonged state of thermal allodynia after systemic administration to rats that requires de novo protein synthesis and is mediated by increased TRPV1 expression. Further understanding of how NGF treatment modifies the TRPV1 channel and pore may help develop better analgesics for the treatment of chronic inflammatory pain.

Title: Investigating histone deacetylase four in peripheral sensory neurons

Authors: *M. CROW, S. B. MCMAHON;
Neurorestoration Group, King's Col. London, London, United Kingdom

Abstract: Histone deacetylase inhibitors have been shown to be analgesic in a number of preclinical pain models, but the contribution of specific histone deacetylases (HDACs) to pain states remains unclear. HDAC4 has previously been linked to aberrant nociception, however the study of this gene with traditional knock out methods is limited by its developmental role in chondrocyte differentiation, which leads to early post-natal lethality. The aim of this project was to investigate the role of HDAC4 in sensory neuron function *in vivo* using the Cre-loxP system to conditionally delete HDAC4 from a subset of primary sensory neurons and characterise transcriptional and behavioural outcomes in naive animals and following nerve injury.
Conditional knock out (cKO) of HDAC4 from the Nav1.8-positive population of primarily small, nociceptive neurons did not cause overt morphological or sensory behavioral changes. QRT-PCR analysis of a number of pain-related mRNA targets in naive lumbar dorsal root ganglia (DRG) indicated that HDAC4 was dispensable for expression of these transcripts. HDAC4 expression was not required for mechanical hypersensitivity in the partial sciatic nerve ligation (PNL) model of neuropathic pain. However assessment of transcriptional changes 28 days after PNL revealed that HDAC4 cKO animals had significantly reduced levels of activating transcription factor 3 (Atf3) and neuropeptide Y (Npy) mRNA compared to littermate controls. Similarly, 24 hours after sciatic nerve transection, Atf3 mRNA levels were attenuated in HDAC4 cKO. As Atf3 is known to promote peripheral nerve regeneration, the sciatic crush model was used to test whether the reduction in Atf3 levels could negatively impact regeneration. HDAC4 cKO showed delayed sensory recovery but normal motor recovery, consistent with knock out in small fibres.
Loss of HDAC4 from primary sensory neurons results in aberrant transcriptional responses following axonal damage. Pilot data indicates that this may have consequences for peripheral

nerve regeneration, but not for nociceptive responses. HDAC inhibitors are broad-acting compounds; by understanding the role of individual histone deacetylases in sensory neuron function we will have the groundwork in place to develop and implement more targeted therapies for pain and nerve regeneration.

Title: Advancing the transcriptional profiling of dorsal root ganglia: A novel method to isolate pure neuronal subpopulations

Authors: *N. RICHARDS[1], M. THAKUR[1], S. MCMURRAY[2], S. B. MCMAHON[1];
[1]King's Col. London, London, United Kingdom; [2]Neusentis, Cambridge, United Kingdom

Abstract: Transcriptional profiling is a useful tool to help identify the molecular processes involved in normal physiological function, as well as in pathophysiological conditions. In recent years, ribonucleic acid (RNA) expression changes within the dorsal root ganglia (DRG) have been investigated extensively following peripheral nerve damage, with the aim of advancing our understanding of the mechanisms underlying neuropathic pain. However, the DRG is comprised of a heterogeneous population of cells, including sensory neuron cell bodies as well as many non-neuronal cells such as fibroblasts, glial cells and immune cells. To elucidate which transcripts are expressed in neurons alone, we have devised a novel technique to isolate sensory neurons whereby RNA can be successfully extracted and measured. This technique utilises fluorescence activated cell sorting (FACS) to obtain pure (>95%) neuronal populations from the rat DRG. Although the FACS process results in around a 75% loss of neurons, we have optimised labelling and RNA extraction to obtain high quality material (RNA integrity number >7) from cells fixed immediately following dissociation. We are now able to obtain enough RNA from these pure populations to measure transcripts of interest using microarray cards and next generation sequencing. This method is flexible and can be used to isolate various subpopulations of sensory neurons (e.g. A and C-fibre cell bodies, or peptidergic and non-peptidergic C-fibres). The application of this technique is likely to enhance our understanding of the specific contribution that sensory neurons make to chronic pain conditions.

Title: Transcriptional landscape of functionally distinct subsets of nociceptors

Authors: *A. REYNDERS[1], S. GAILLARD[1], S. NIEDELET[2], S. RIALLE[2], L. JOURNOT[2], A. MOQRICH[1];
[1]Ibdml-Umr6216 CNRS, Marseille Cedex9, France; [2]MGX (Montpellier Genomics), Montpellier, France

Abstract: Nociceptors belong to the neuro-sensory system and are the primary sensors of the pain pathways. Nociceptors have been shown to exhibit a tremendous molecular heterogeneity, which shapes their
physiological activity and their responsiveness to distinct pain qualities. Nevertheless, data regarding how gene expression is specifically regulated within molecularly-defined subsets of nociceptors, is notably missing. We have identified a novel protein, GINIP (Gα-Inhibitory INteracting Protein) expressed within a subset of non-peptidergic nociceptors and generated a knock-in mouse expressing the *m-cherry* at *Ginip* locus. By using this unique mouse model (*Ginip+/m-cherry*), in combination with an IB4 staining, we FACS-sorted three subsets of nociceptors for transcriptome-wide analysis: 1) $IB4^{+}GINIP^{+}$ -nonpeptidergic noxious mechanical transducers; 2) $IB4^{-}GINIP^{+}$ -non-peptidergic C-Low Threshold Mechano-Receptors 3) $IB4^{-}GINIP^{-}$nociceptors. The subsequent RNA-Seq deep sequencing experiment led to the generation of unique sets of data representative of pure transcriptome profiles of each subset. As a result of this pioneering approach, we established the combinatorial expression of the sets of genes that may dictate the functional specializations of considered nociceptors.

Title: Transcriptional and electrophysiological characterization of primary afferent human DRG neurons

Authors: A. GERLACH[1], J. THEILE[1], M. FULLER[1], K. YOGER[1], A. MOSS[2], B. SIDDERS[2], *M. L. CHAPMAN[1];
[1]Pfizer Neusentis, RTP, NC; [2]Pfizer Neusentis, Granta Park, Cambridge, United Kingdom

Abstract: The transmission of painful stimuli originates in a specialized subset of peripheral nociceptive neurons. Limiting the excitability of peripheral nociceptors is an attractive drug development strategy to intervene at the initiation of pain signaling and to minimize CNS-related dose limiting side effects. The cell bodies of most primary afferent nociceptive neurons are located in the dorsal root ganglia. Although the gene expression and electrophysiological profiles of nociceptors has been characterized to various extents in pre-clinical species, the relevance to human nociceptor function is not well demonstrated. We have used low-PMI human DRG tissue to examine the human DRG transcriptome and to examine the electrophysiological properties of viable cells.
Using RNA-seq on four unrelated human DRG we observe a correlation >0.9 between the transcriptome of the replicates compared to a correlation >0.95 between four inbred rats, suggesting that the variability between humans is not as great as often feared. Across 18,743 orthologous genes the overall correlation in gene expression levels is 0.6 between human and rat DRG, indicating a gross similarity between the species.The acutely isolated cells were found to have excitability properties similar to those reported in preclinical species. Application of 100 nM capsaicin resulted in a membrane depolarization (26 ± 5 mV, N=5/5 cells tested) and repetitive action potential firing, confirming the nociceptive phenotype of the cells. Resting membrane potentials were -66 mV to -27 mV in excitable cells (-45 ± 2 mV, N=40), with occasional spontaneous activity in the more depolarized cells. Voltage-gated sodium currents were too large to be accurately voltage-clamped in normal extracellular solution, requiring a reduction to 20 mM external Na^+. Under these conditions, TTX-resistant Na^+ current densities were 105 ± 26 pA/pF (N=13). Accurate quantification of fast TTX-sensitive currents was not feasible due to the size of the currents (>10 nA) and the size of the cells (76 ± 16 pF, N=6). In summary, low-PMI human peripheral nociceptive neurons are grossly similar to cells from preclinical species. Further biophysical and pharmacological characterization will be required to better determine the extent of cross-species similarity between human and rat nociceptive

neurons. A specific focus on the proteins differentially expressed in human and rat, the ion channels in particular, will likely uncover any subtle phenotypic differences not yet apparent.

Title: Identifying a population of peripheral neurons involved in mechanical hyperalgesia and allodynia in a mouse model of osteoarthritis

Authors: *L. D. TOWNSON[1], M. MINETT[2], J. WOOD[2], A. H. DICKENSON[1];
[1]NPP, [2]Wolfson Inst. for Biomed. Sci., UCL, London, United Kingdom

Abstract: AIMS: In order to elucidate new targets for analgesia in Osteoarthritis (OA), it is imperative that we understand the mechanisms underlying the chronic pain of this condition. Here we have tested the involvement of a specific population of peripheral neurons involved in the mechanical hyperalgesia and allodynia of OA using the Monosodium Iodoacetate (MIA) model of OA in genetically engineered mice.
METHODS: OA was induced using an injection of 0.2mg MIA in 5ul of 0.9% saline to the left knee of 6-8wk old anaesthetized mice in which all the post-mitotic sensory neurons containing sodium channel Nav1.8 had been eradicated through the expression of diphtheria toxin subunit A (DTA) (Science 321, 702-5). Behaviour was examined on days 0, 3, 10 and 14 to assess changes in the 50% paw withdrawal thresholds (PWT) and incapacitance scoring. This was followed by electrophysiological recordings from Lamina V WDR cells on days 14-16, where evoked responses to mechanical, thermal and electrical stimulation to the hind paw were recorded.
RESULTS: MIA produced a significant overall decrease in the 50% PWT of littermate controls, but not DTA mice, following induction of OA, demonstrating an essential role for Nav1.8-containing sensory neurons in mechanical hypersensitivity in OA. Channel transcripts enriched in Nav1.8+ neurons include TRPA1, the knockout of which has a Randall-Selitto loss of function phenotype in paw but not tail, and TRPC3 and TRPC6 that have been implicated in touch

transduction. Further analysis of channel knock-outs in the MIA model may help define molecular targets for OA treatment.
CONCLUSIONS: We demonstrate here that it is the population of Nav1.8 containing peripheral neurons that are responsible for the mechanical hyperalgesia and allodynia associated with OA. These neurons, previously established to have a substantial role in mechanosensation, cold and inflammatory hyperalgesia, could present a major target for future pharmacotherapy in OA.
We thank the Welcome Trust, MRC and Arthritis UK for generous support.

Title: Role of nonpeptidergic subset of primary afferent neurons in inflammatory hypernociception in mice

Authors: *L. G. PINTO, G. R. SOUZA, A. H. P. LOPES, J. TALBOT, F. Q. CUNHA, T. M. CUNHA, S. H. FERREIRA;
Pharmacol., Univ. of São Paulo, Ribeirao Preto, Brazil

Abstract: Sensory information is transmitted from the periphery to the spinal cord by distinct subsets of primary afferent neurons, including small diameter unmyelinated C-fibers, which plays an important role in detecting noxious stimuli. C-fiber nociceptors have been divided into two classes, the peptidergic and nonpeptidergic. While many of the differences between peptidergic and nonpeptidergic neurons are now appreciated, a possible functional difference between these two classes of C fibers in the genesis of acute nociception as well as inflammatory pain is still unclear. Thus, this study aims to clarify the role of nonpeptidergic C fibers in acute nociception induced by mechanical, thermal and chemical stimuli as well as in inflammatory hypernociception. In order to elucidate differences between these two classes of C fibers, a neurotoxin was used to selectively eliminate the nonpeptidergic C fibers: a saporin conjugated to isolectin B4 (IB4). Nociceptive threshold was evaluated through thermal (Hargreaves) and mechanical (filaments and electronic von Frey) tests in C57BL/6 mice. Nociception models were

induced by intraplantar (i.pl.) injection of capsaicin and formalin (acute nociception) or by i.pl. administration of prostaglandin E2 (PGE2), epinephrine, endothelin, NGF, GDNF and carrageenan (inflammatory hypernociception). P2X3 and TRPV1 expression were analyzed by Western blot of dorsal root ganglion (DRG). The expression of IB4-labeled in spinal cord was determined by immunofluorescense using confocal microcopy. Firstly, it was observed that the intrathecal administration of IB4-saporin did not change baseline thermal and mechanical nociceptive threshold of the mice paw when compared to saline and saporin-control groups. The intrathecal administration of IB4-saporin reduced mechanical inflammatory hypernociception induced by carrageenan, epinephrine, endothelin, PGE2 or GDNF, but not NGF, in mice. Similarly, the treatment with IB4-saporin inhibited the nociception caused by intraplantar injection of the capsaicin. By contrast, the acute nociception induced by formalin did not change by administration of IB4-saporin. In addition, the expression of TRPV1 and P2X3 in DRG were reduced after treatment with IB4-saporin. Consistent with these findings, we found that IB4-saporin injection decreased the expression of IB4-labeled in spinal cord. These results suggest that absence the nonpeptidergic C fibers does not affect basal nociceptive threshold. However, these fibers are essential for the development of nociception in the paw of mice induced by inflammatory stimuli like PGE2, epinephrine, endothelin, carrageenan and capsaicin.

Title: Genetic control of the segregation of sensory neurons innervating ectodermal versus mesodermal/endodermal tissues

Authors: *F.-C. YANG[1,2], T. TAN[1,2], T. HUANG[1,2], J. CHRISTIANSON[3,4], O. ABDEL SAMAD[1,2], Y. LIU[1,2], D. ROBERSON[2], B. M. DAVIS[3], Q. MA[1,2];

Abstract: Sensory neurons of the dorsal root ganglion (DRG) receive painful stimuli throughout the body. The peripheral targets of DRG neurons can be divided into two zones: (1) superficial ectodermal tissues and (2) deep mesodermal/endodermal tissues. Here we identify a large molecular program that is required to selectively sense deep tissue pain. Retrograde labeling and genetic marking reveal that these genes are associated predominantly or exclusively in sensory neurons innervating deep tissues. Developmentally, expression of these genes is excluded from sensory neurons innervating superficial ectodermal tissues through Runx1-mediated repression. Accordingly, we show that the impairment of these deep tissue neurons in a mutant mouse model leads to the loss of sensory innervation to the deep tissues and the virtual abolition of muscle pain and visceral pain. Thus this study illustrates a genetic program controlling the molecular segregation of sensory neurons innervating ectodermal versus medodermal/endodermal tissues, and provides new insight into the molecular and cellular basis of deep tissue pain.

Title: Contralateral tactile allodynia from ipsilateral ET-1 injection requires contralateral efferent nerve conduction

Authors: *G. R. STRICHARTZ[1], Y.-W. CHEN[2], J. C.-F. WANG[3], A. KHODOROVA[3]; [1]Dept Anesthesia Res. Labs, Pain Res. Center/ BWH, BOSTON, MA; [2]Physical Therapy, China Med. Univ., Taichung, Taiwan; [3]Pain Res. Ctr., Brigham & Women's Hosp., Boston, MA

Abstract: We previously reported that 1d after endothelin-1 (ET-1, 2nmol) is injected into one rat hindpaw, the contralateral hindpaw showed a heightened response to noxious mechanical and chemical (ET-1, formalin) stimuli. This sensitization was prevented by blocking afferent transmission with local anesthetic (0.25% bupivacaine) injected at the ipsilateral sciatic nerve before ET-1's injection into the ipsilateral paw. Current studies, presented at this SfN meeting,

report the essential role of spinal aPKC/PKMζ and PI3K in this same contralateral sensitization, confirming a role for central (spinal) sensitization in this process. In order to determine if an efferent outflow to the contralateral paw contributed to this contralateral tactile allodynia, we conducted the following experiments. After injection of ET-1 (2nmol), withdrawal thresholds of the ipsilateral (ILP) paw fell from 12g at baseline to 2g at 2.5h, 3g at 24h and 3g at 48h. The contralateral paw (CLP) threshold fell insignificantly at 2h after ET-1, but at 24h was significantly lower, at 4g. Direct injection of plain bupivacaine (0.25%, 0.04mL) into the plantar aspect of the ILP before ipsilateral ET-1 injection, causing analgesia to tactile stimulation for ~30 min, prevented the contralateral allodynia, without preventing ipsilateral sensitization, thus showing that local sensitization did not require the acute impulse activity necessary for CLP sensitization. This *Control* CLP sensitization was altered, however, when the *contralateral* sciatic nerve was blocked for many hours by a biodegradable microsphere formulation that slowly released bupivacaine (MS-BUP, 5mg). Injected 3h before the ipsilateral injection of ET-1, this dose of MS-BUP, which inhibited nocifensive responses to tactile stimulation in normal rats for 12h, prevented any significant drop in the CLP threshold from ipsilateral ET-1. Allodynia of the ILP was unaffected by this contralateral nerve block. These results show that efferent transmission through the contralateral innervation is necessary for sensitization of the CLP, and suggest that release of substances that cause paw sensitization in the CLP is essential for contralateral sensitization.

Title: Evidence for spinal atypical PKCs and PI3K involvement in peripheral ET-1's induction of central sensitization

Authors: *A. KHODOROVA[1], G. STRICHARTZ[2];
[1]Harvard Med. Sch. Brigham and Women's Hosp, BOSTON, MA; [2]Pain Res. Ctr., Brigham & Women's Hosp., Boston, MA

Abstract: Previously we have shown that the unilateral intraplantar (i.pl.) injection of ET-1 sensitized both the ipsilateral and contralateral paws to subsequent mechanical and chemical stimulation. For example, a second i.pl. dose of ET-1 (2 nmol), injected into the contralateral paw 24h after the first injection (also 2nmol), resulted in a greater acute nocifensive flinching response, as also occurred for the second phase of the response to contralaterally injected formalin after ipsilateral ET-1. Block of the ipsilateral sciatic nerve by local anesthetics during the initial ET-1 flinching period (~2h) prevented the later contralateral increase in acute nociception, confirming the importance of afferent transmission for contralateral hypersensitivity, and implicating central sensitization (CS) in these contralateral changes. However, the cellular mechanisms that maintain ET-1-dependent CS remain unclear. Because other peripheral substances that cause prolonged mechano-hypersensitivity, e.g. NGF, rely on spinal atypical PKCs (aPKCs), in the current experiments a myristolated pseudosubstrate inhibitor of aPKCs (PKC_{ζ}/PKM_{ζ}), mPSI, was injected intrathecally (i.t., 5g/10µl) 2 d before a first i.pl. ET-1 injection. Controls (i.t. vehicle) showed clear contralateral potentiation of the *acute nocifensive response* (TF = total number of hindpaw flinches/70min) to ET-1 (2nmol) (TF^{2nd}=225±38 compared to TF^{1st}=133±18 ; n=10, P<0.05).The inhibitor of aPKCs had no effect on the initial acute nocifensive response to ET-1 (TF^{1st}=129±31, n=10, p>0.5 compared to control, above), but fully prevented, even depressed, the contralateral sensitization (TF^{2nd}=87±18; n=10, P<0.05). In addition, i.t. wortmannin (5µg), a potent and selective inhibitor of PI3K, given 0.5 - 2h before the first ET-1 injection, did not affect the initial acute flinching, but fully prevented delayed sensitization. Peripheral mPSI (40-200µg/20µl), injected into the plantar paw a day before ET-1 (0.1 nmol), slightly attenuated the ipsilateral reduction of paw withdrawal threshold, by ~30% (dose 200µg; n=10), whereas local wortmannin (9µg total dose/per paw), was ineffective (n=4). The findings indicate that $aPKC_{\zeta}$/$PKCM_{\zeta}$ and PI3K at central loci are key mediators in the development of contralateral sensitization caused by subcutaneously delivered ET-1, while at the periphery $aPKC_{\zeta}$/$PKCM_{\zeta}$ makes a minor contribution, and PIK3K none, to the induction of acute mechano-hyperalgesia.

Title: The p75NTR signaling cascade mediates mechanical hyperalgesia induced by nerve growth factor injected into the rat hind paw

Authors: *G. D. NICOL[1], A. KHODOROVA[2], G. STRICHARTZ[2];
[1]Pharmacol. & Toxicology, Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Pain Res. Ctr., Harvard Med. Sch., Boston, MA

Abstract: Recent studies show that NGF augments excitability of isolated rat sensory neurons through activation of the p75 neurotrophin receptor (p75NTR) and its downstream sphingomyelin signaling cascade, wherein neutral sphingomyelinase(s) (nSMase), ceramide, and the atypical PKC (aPKC), PKMζ, are key mediators. Here we determine if these same effectors participate in mechanical hypersensitivity caused by NGF. Mechanical sensitivity was quantitated by the number of paw withdrawals in response to 10 stimuli by a 4g von Frey hair (VFH, testing "allodynia") and by 10 g & 15 g VFHs (testing "hyperalgesia"). NGF (500 ng/10 μL) injected into the male rat's plantar hindpaw induced long-lasting ipsilateral mechanical hypersensitivity. The paw withdrawal frequency (n/10) for the strong VFHs increased significantly at 0.5-1.5 h after NGF injection, and remained elevated at 21-24h compared to both baseline responses and those of the contralateral paw. Injection of N-acetyl sphingosine (C2-ceramide, 20 μg/10 μL), a cell-permeant ceramide analog, induced ipsilateral "allodynia" that persisted for 24h, and an acute "hyperalgesia" that resolved by 2h after injection. Three consecutive injections of this dose of C2-ceramide, spaced 1.5 h apart, resulted in a significant hyperalgesia at 2 h, but not at 4 h, after the 3rd injection. Acute intraplantar pre-treatment with the nSMase inhibitors, glutathione and GW4869, prevented the acute hyperalgesia from NGF at 1.5h, but not that at 21-24h. Hyperalgesia was prevented by intraplantar injection of the myristolated pseudosubstrate inhibitor of PKCζ/PKMζ (mPSI, 40 μg/20 μL) 1d before NGF. Paw injection of a non-hydrolyzable form of the p75-selective agonist Pro-NGF gave virtually identical effects as NGF. The mechano-sensitizing effects of both Pro-NGF and NGF were prevented by pre-injection of the paw with the p75NTR blocking anti-body (gift of L. Reichardt, UCSF). These findings indicate that p75NTR and its activation of the sphingomyelin signaling cascade are essential for mechanical hypersensitivity resulting from NGF.

Title: Role of PCAF in chronic postsurgical pain

Authors: *Z. MENG, X. LIU, Y. TIAN, T. GIN, M. T. V. CHAN;
A&IC, The Chinese Univ. of Hong Kong, Shatin, Hong Kong

Abstract: Objective:
There is emerging evidence to suggest that epigenetic modifier proteins (such as HDAC, P300) regulate pain perception. PCAF (P300/CBP Associated Protein), which is an epigenetic modifier, has been reported to interact with NF-κB and to stimulate COX-2 transcriptional activation. The aim of our study is to find out the direct impact of PCAF on pain modulation.
Method:
In our laboratory pain model, 0.1ml of CFA was injected in hindpaws of 8 SD rats. From Day 0 to Day 5, PCAF inhibitor anacardic acid (40 nmol/10ul) was injected intrathecally in 4 rats twice daily, while other 4 rats received saline. Behavioral tests, including Von Frey test and Hargreaves test, were performed 1h after anacardic acid injection.
The function of PCAF was also investigated in a clinical pain study of 1,152 post-surgical patients. Patients were genotyped for 49 SNPs in *PCAF* gene by GoldenGate genotyping assay. Haplotype combination was calculated by using Haploview 4.2. Patients were followed up at three months and one year after surgery and they were required to rate their pain score on a 0-10 scale.
Result:
In our rat CFA pain model, we found a trend that PCAF inhibitor anacardic acid can reduce both mechanical allodynia and thermal nociception. From Day 2 to Day 5, a higher mechanical threshold was observed in rats with anacardic acid treatment. Similarly, rats with anacardic acid showed longer nociceptive heat latency from Day 2 to Day 4. (Figure 1.)
In our pain database, patients with PCAF mutations reported altered chronic pain. Heterozygotes of rs6808352 experienced less pain at three months [0.59 (1.38) vs. 0.93 (1.84), P = 0.038]. Carriers of the minor allele at rs2948087 were more likely to have severe chronic pain (pain score > 5) at one year (OR = 11.62, 95% CI 2.99 -45.19, P < 0.001). Carriers with SNP at rs2948083 and a haplotype GAGG showed similar severe pain experience (P = 0.002 and < 0.001, respectively)
Conclusion:
Mutations in PCAF result in changed perception of post-surgical chronic pain in patients and inhibition of PCAF lead to reduction in inflammatory pain in rats.

Title: Further evidence that activation of AMPK inhibits acute and chronic post-surgical pain

Authors: *D. V. TILLU, M. N. ASIEDU, O. K. MELEMEDJIAN, T. M. HUGHES, G. DUSSOR, T. J. PRICE;
Med. Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Surgery is a major cause of persistent pain suggesting that treatments that directly target the molecular pathology promoting post-surgical pain, particularly those that contribute to the progression to chronic pain, are needed. We have previously demonstrated that dysregulated protein translation regulation pathways, in particular ERK/eIF4E and mTOR signaling pathways underlie persistent pain states and that AMPK activators can profoundly inhibit ERK and mTOR signaling in sensory neurons. We have also demonstrated that local injection of resveratrol, a potent AMPK activator, into the hindpaw following plantar incision dose-relatedly reverses incision-mediated mechanical hypersensitivity as well as hyperalgesic priming induced by incision. The aim of the present study was to pharmacologically establish AMPK activation as a bona-fide mechanism for the alleviation of post-surgical pain. To do this, we utilized multiple AMPK activators, including metformin, OSU-53 and A-769662, that possess different mechanisms of AMPK activation to demonstrate a shared endpoint - inhibition of incision-induced mechanical hypersensitivity and hyperalgesic priming. Metformin, which is clinically available and widely prescribed, stimulates upstream LKB1 activity to activate AMPK whereas OSU-53 and A-769662 are positive allosteric modulators that directly activate AMPK. Using the Brennan incision model in mice, we demonstrate that systemic metformin or local OSU-53 injection dose-dependently and efficaciously attenuates incision-induced mechanical hypersensitivity as well as the development of hyperalgesic priming precipitated by hindpaw injection of PGE2 following resolution of incision-induced mechanical hypersensitivity. Interestingly, systemic A-769662 was not effective in blocking incision-induced acute mechanical hypersensitivity; however it significantly blocked hyperalgesic priming. This effect

was paralleled by lower doses of metformin, which had no acute effect yet blocked hyperalgesic priming. Finally, co-treatment with systemic metformin and local resveratrol at individually sub-efficacious doses at the time of incision blocked acute hypersensitivity and hyperalgesic priming suggesting potential super-additive effects of combined AMPK activator use. None of these treatment approaches adversely affected wound healing. These results provide further evidence for activation of AMPK as a novel treatment avenue for acute and chronic pain states induced by surgery. These preclinical findings afford the opportunity for immediate clinical testing due to the clinical availability of metformin.

Title: Critical role of local translation and retrograde axonal transport of nascently synthesized CREB in IL-6-induced nociceptive sensitization

Authors: *O. K. MELEMEDJIAN[1], M. N. ASIEDU[2], J. K. MOY[2], T. J. PRICE[2];
[1]Dept Pharmacol, Univ. Arizona, TUCSON, AZ; [2]Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Transcriptional regulation of genes by cAMP response element binding protein (CREB) is essential for the maintenance of long-term memory. Moreover, retrograde axonal trafficking of CREB in response to nerve growth factor is critical for the survival of developing primary sensory neurons. We have previously demonstrated that injection of the pro-inflammatory cytokine, interleukin-6 (IL-6), induces prolonged nociceptive sensitization which is prevented by the protein synthesis inhibitors. Moreover, treatment of primary sensory neurons in culture with IL-6 results in increased CREB levels. We hypothesized that retrograde axonal trafficking of nascently synthesized CREB might link local, activity-dependent translation to long-lasting changes in nociceptive sensitivity. To test this, we first determined if IL-6 enhances the expression of CREB and if it subsequently undergoes retrograde axonal transport, IL-6 injection into the mouse hindpaw caused an increase in CREB protein within 30 min and an increase in the sciatic nerve only after 2 hrs, consistent with retrograde transport. Importantly, co-injection of IL-6 with the methionine analogue azido-homoalanine (AHA), to assess nascently

synthesized proteins, demonstrated an increase in CREB containing AHA in the sciatic nerve 2 hrs post injection, indicating retrograde transport of nascently synthesized CREB. Behaviorally, knockdown of intraplantar CREB mRNA with siRNA, blockade of retrograde transport by disruption of microtubules or inhibition of dynein or intrathecal injection of cAMP response element (CRE) consensus sequence DNA oligos that act as decoys for CREB prevented the development of IL-6-induced mechanical hypersensitivity. Consistent with previous studies in inflammatory models, intraplantar IL-6 enhanced the expression of BDNF in dorsal root ganglion (DRG). This effect was blocked by inhibition of retrograde axonal transport and by intrathecal CRE oligos. Hence, these findings elucidate a novel mechanism of axonal translation and retrograde trafficking linking locally-generated signals to long-term nociceptive sensitization.

Title: Highly potent agonists reveal Protease Activated Receptor Type 2 (PAR2) -dependent hyperalgesic priming relying on central trkB/aPKC maintenance mechanisms

Authors: *T. J. PRICE[1], D. V. TILLU[2], M. N. ASIEDU[2], S. BOITANO[3], J. VAGNER[4]; [1]Pharmacol., Univ. Arizona, TUCSON, AZ; [2]Pharmacol., [3]Physiol., [4]Bio5 Inst., Univ. of Arizona, Tucson, AZ

Abstract: Protease Activated Receptor Type 2 (PAR2) is a G-protein coupled receptor (GPCR) containing a tethered ligand in the N-terminal domain that is exposed upon protease digestion of the N-terminal domain. This peptide sequence, SLIGRL in rodents, has served as a basis for peptide ligand discovery at the native receptor capable of bypassing proteolytic cleavage of the N-terminal domain. We have developed a wide range of highly potent and efficacious agonists to probe PAR2 function in vitro and in vivo. PAR2 is thought to play an important role in inflammatory- and cancer-evoked pain based on studies using PAR2-/- mice. Recently hyperalgesic priming has emerged as important model system for probing plasticity in the nociceptive system. We have shown that the maintenance of hyperalgesic priming evoked by a

single injection of interleukin-6 relies on a dorsal horn signaling axis involving Brain Derived Neurotrophic Factor (BDNF) signaling via trkB to atypical PKC (aPKC). Here we have tested the hypothesis that specific activation of PAR2 should be capable of evoking hyperalgesic priming. We have further tested whether the maintenance of this priming involves a BDNF/trkB/aPKC signaling axis. We find that intraplantar injection of the potent and specific PAR2 agonist, 2-aminothiazol-4-yl-LIGRL-NH2 (2at-LIGRL), evokes a long-lasting acute allodynia (EC50 ~ 0.03 nmoles) that is followed by a profound hyperalgesic priming to subsequent prostaglandin E2 (PGE2) injection. The pro-allodynic effect of 2at-LIGRL is completely absent in PAR2-/- mice as is hyperalgesic priming. Hence, stimulation of PAR2 is sufficient to evoke hyperalgesic priming in mice. We then asked if the maintenance of this hyperalgesic priming can be reversed by inhibition of BDNF/trkB/aPKC signaling. Systemic dosing with the trkB antagonist ANA-12 (0.5 mg/kg) following the resolution of acute 2at-LIGRL-induced allodynia inhibited priming precipitated by PGE2 injection into the hindpaw. Likewise, injection of the aPKC inhibition, ZIP, into the lumbar spinal cord completely reversed the maintenance of priming over the same time course. Hence, PAR2 activation is sufficient to evoke hyperalgesic priming. Moreover, the maintenance of this primed state is dependent on a CNS BDNF/trkB/aPKC signaling axis suggesting a generalized role for this signaling pathway in maintenance of hyperalgesic priming.

Title: Nociceptive sensitization by activated Proreinase-activated receptor 2

Authors: *K. KIDO, E. MASAKI;
Tohoku Univ. Hospital, Dept. of Dent. Anesthesia, Sendai, Miyagi, Japan

Abstract: Background- Peripheral mast cells degranulate and its number are largely reduced following tissue injury. Furthermore, we previously indicated that the prevention of mast cell degranulation reduced guarding pain and mechanosensitivity in a postoperative pain model of mice. Proteinase-activated receptor 2 (PAR-2) is a G protein-coupled receptor that is expressed in the peripheral sensory neurons and may play an important role in inflammatory and injured

pain by binding with tryptase from mast cells.In this study, we investigated effects of PAR-2 agonist SLIGRL-NH2 on the plantar skin of the rat hindpaw.
Method- Using the rat glabrous in vitro skin-tibial nerve preparation, afferent nerve activities from single mechanosensitive nociceptors were recorded. Spontaneous activities, and responses to mechanical stimuli (5, 10, 20, 40, 80 and 120 mN) were recorded before and after SLIGRL-NH2 application or phosphate buffered saline (PBS) control. Responses to heat and cold stimuli (From 12°C to 47°C) were recorded once after exposure to either with SLIGRL-NH2 application or PBS control.
Results- 100μM SLIGRL-NH2 increased spontaneous activities in 8 of 18 C-fibers (44.4%) within 5 minutes. SLIGRL-NH2 application did not change the responses to mechanical stimuli in C- fibers. C-fibers were sensitized to heat and cold stimuli: 1) The percentage of fiber that responded to heat (70.8% vs. 53.3%) and cold (84.6% vs. 54.5%) was significantly increased respectively; 2) Cold thresholds were significantly decreased (21.0°C vs. 27.0°C); 3) Heat thresholds and total action potentials during the heat stimulus were not significantly differences from control.
Conclusion- PAR-2-mediated excitation and sensitization of peripheral primary nociceptors may contribute to PAR-2-mediated pain, such as postoperative pain.

Title: Opioid-induced hyperalgesia contains a peripheral component

Authors: *M. P. ROWAN[1], S. M. BIERBOWER[2], M. A. ESKANDER[3], E. D. POR[1], R. GOMEZ[1], N. A. JESKE[1];

Abstract: Chronic pain is a critical national health problem and the most common cause of long-term disability, affecting over a third of the population. Drugs acting at mu opioid receptors

(MOR) are essential in the treatment of moderate to severe chronic pain. However, prolonged use of opioids can lead to severe side effects including tolerance and dependence that are largely absent in animals lacking β-arrestin2. Chronic treatment with opioids can also lead to opioid-induced hyperalgesia (OIH), characterized by exaggerated pain sensitivity and diffusivity. OIH is difficult to treat, in large part because the cellular mechanisms underlying OIH are poorly understood. Recent evidence has shown a crucial role for the transient receptor potential vanilloid type 1 (TRPV1) channel in OIH. TRPV1 is a sensor of multiple forms of noxious stimuli, is co-expressed on primary sensory neurons with MOR, and displays enhanced responsiveness following chronic morphine treatment. We have recently shown that TRPV1 is desensitized by β-arrestin2, so we hypothesize that chronic opioid treatment leads to TRPV1 sensitization following β-arrestin2 recruitment to MOR in primary sensory neurons.
Primary sensory neurons from rat trigeminal ganglia (TG) were nucleofected with MOR-GFP and assessed for TRPV1 activation following capsaicin-mediated stimulation. Pretreatment with DAMGO or morphine, MOR agonists that recruit β-arrestin2 in TGs as verified by TIRF-FRET, significantly enhanced the TRPV1 response. Pretreatment with herkinorin, a MOR agonist that does not recruit β-arrestin2, had no effect on the TRPV1 response. Additionally, the DAMGO-mediated increase in TRPV1 response was absent following siRNA knockdown of β-arrestin2. Treatment of TG neurons with morphine or DAMGO, not herkinorin, reduced the interaction of TRPV1 and β-arrestin2. Rats and mice injected chronically with peripherally restricted doses of morphine and DAMGO, not herkinorin, developed OIH. TRPV1 knockout mice did not develop OIH. Together these data suggest that β-arrestin2 recruitment to MOR, away from TRPV1, may play a peripheral role in the development and/or maintenance of OIH.

Title: Virus-mediated knockdown of Nav1.3 in dorsal root ganglia of diabetic rats alleviates mechanical pain

Authors: *O. A. SAMAD, A. M. TAN, S. D. DIB-HAJJ, S. G. WAXMAN;
Yale Univ. and VA CT Healthcare Syst., West Haven, CT

Abstract: Pain affects a substantial number of people with diabetic neuropathy, making it a major public health problem. To date, available clinical treatments remain only partially effective against diabetic neuropathy, and are accompanied by important side effects. We have shown that voltage-gated sodium channel Nav1.3 is upregulated in Dorsal Root Ganglion (DRG) neurons of diabetic rats that develop pain. Moreover, this upregulation correlates over time with the decrease in mechanical thresholds of diabetic rats. Since Nav1.3 upregulation drives neuronal hyperexcitability, and its suppression in rats results in attenuation of neuropathic pain due to peripheral nerve injury, we predict that knockdown of Nav1.3 in painful diabetic neuropathy can attenuate pain. To test this hypothesis, we used a validated recombinant Adeno-Associated Virus AAV-shRNA-Nav1.3 viral vector (Samad et al., 2013) to knockdown Nav1.3 in DRG of diabetic rats. We asked the following specific question: Is knockdown of Nav1.3 within multiple DRG neurons in vivo via AAV-shRNA effective in attenuating pain due to diabetes?
To induce diabetic neuropathy in rats, we used the Streptozotocin (STZ)-induced diabetes model. We and others have shown that this established model of diabetes induce neuropathic pain symptoms in rats, and is therefore well-suited to test potential pain-reducing therapies. We used a clinically applicable intrathecal injection method of AAV-shRNA-Nav1.3 to knockdown Nav1.3 in multiple DRGs of diabetic rats and compared them to rats injected with control AAV-shRNA-NT (Non-Targeting shRNA control). The viral vectors were administered intrathecally on the fourth day after STZ-injection and the animals analyzed over a period of one month. Our preliminary results indicate that Nav1.3 knockdown in DRG attenuates mechanical allydonia in diabetic rats. Other ongoing outcome measures being assessed include: cFos expression analysis and excitability of wide dynamic range neurons in the dorsal horn, and assessment of efficacy and specificity of viral infection. Our study offers a promising approach to gene therapy for painful diabetic neuropathy.

Title: The functional implications of the differential distribution of na+/ca2+ exchanger isoforms in rat sensory neurons

Authors: *N. SCHEFF, E. YILMAZ, M. S. GOLD;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: We have shown previously that depolarization-evoked Ca2+ transients differ greatly among subpopulations of dorsal root ganglion neurons, in association with the differential contribution of Ca2+ regulatory mechanisms. One of these Ca2+ regulatory mechanisms, the Na+/Ca2+ exchanger (NCX), appears to play a selective role in the regulation of the duration of the high K+-evoked Ca2+ transient in IB4-binding and capsaicin sensitive small and medium diameter DRG neurons. The purpose of the present study was to 1) further define the subpopulation of neurons in which NCX functions, 2) identify the isoform(s) underlying NCX activity, and 3) begin to assess the function of this isoform in vivo. In retrogradely labeled neurons from the glabrous skin of adult male Sprague-Dawley rats, evidence of NCX activity, as assessed with non-specific block with replacement of Na+ with Li+ or choline, was restricted to a subpopulation of small diameter IB4+, largely capsaicin sensitive neurons. While single cell PCR analysis suggested that mRNA encoding all three NCX isoforms (NCX1-3) was detectable in this subpopulation of cutaneous neurons with NCX3 below the level of detection in ~40% of neurons assessed, Ca2+ imaging data with NCX1 and 3 selective blockers SN-6 and KB-R7943, respectively, suggested that NCX3 was responsible for >85% of NCX activity, and NCX2 was responsible for the remainder. Interestingly, western blot analysis suggested both the presence of sensory neuron-specific NCX3 splice variants and differential trafficking of NCX3 splice variants to central and peripheral terminals. We have evidence to suggest NCX is not only present in peripheral C-fiber axons but appears to primarily function in reverse mode, contributing to the maintenance of a hyperpolarized membrane potential, secondary to the influx of Ca2+. Finally, small interfering RNA (siRNA) was utilized to knock down each isoform in vivo. Knock-down of NCX3 resulted in a decrease in both mechanical and thermal nociceptive threshold, suggesting a role for NCX3 in the regulation of transmitter release from nociceptive afferents. Ongoing studies are being done to determine the functional consequences of the differential trafficking of NCX3 to the peripheral and central terminals.

Title: Neto protein assembly with kainate receptors in sensory neurons

Authors: *C. VERNON, B. A. COPITS, G. T. SWANSON;
Mol. Pharmacol. and Biol. Chem., Northwestern Univ., Chicago, IL

Abstract: Ionotropic glutamate receptors (iGluRs) are mediators of nociceptive signaling throughout the pain neuraxis. Two families of iGluRs, AMPA and NMDA receptors, contribute substantially to excitatory signaling and plasticity in pain pathways, but therapeutic targeting of these receptors for pain (or neurological disease) is known to have debilitating side effects that to date preclude their clinical use. A third family of iGluRs, the kainate receptors (KARs, formed from GluK1-GluK5 subunits), represent more promising therapeutic targets. KARs are expressed throughout the peripheral and central nervous system, including in those pathways comprising the pain neuraxis. Minimal side effects have been reported with effective doses of KAR antagonists in both healthy volunteers and migraine sufferers. These human studies support the findings of more than a decade of animal studies which show KARs, and in particular GluK1-containing receptors, to be involved in the mediation of allodynia and hyperalgesia following peripheral inflammation or nerve injury in rodents.

KARs are expressed in dorsal root ganglion (DRG) neurons, and in the spinal dorsal horn neurons that comprise the targets of DRG innervation. In DRG, KARs are expressed predominantly in IB4-positive C-fiber nociceptors and serve at least two functions: (i) peripheral chemosensing and (ii) presynaptic modulation of glutamate release from afferent terminals in the dorsal horn of the spinal cord. Recently, neuropilin and tolloid-like 1 (Neto1) and Neto2 were shown to profoundly modulate recombinant and endogenous KARs in receptor subunit- and Neto isoform-dependent fashions, and therefore could be important but poorly characterized constituents of KAR function in sensory pathways. We find that KAR kinetics are altered in Neto-null DRG neurons, suggesting functional assembly of Neto with native receptors in peripheral sensory neurons. Given this coassembly, we are examining the impact of Neto loss on KAR function in peripheral and central DRG projections. Despite the demonstrated importance of GluK1 in formalin-induced spontaneous pain and hypersensitivity, we find these pain modalities to be unaffected by genetic deletion of Neto proteins and are investigating the role of Neto in other pain behaviors.

Elucidation of how Neto proteins shape KAR function in sensory signaling pathways is key for

developing a clear mechanistic understanding of the relevance of KARs to sensory transmission and their potential utility as therapeutic targets.

Title: Ligand-induced membrane delivery of $P2X_3$ receptor in primary sensory neurons

Authors: *L. BAO[1], X.-Q. CHEN[1], J.-X. ZHU[1], Y. WANG[1], X. ZHANG[2];
[1]Inst. of Biochem. and Cell Biology, Chinese Acad. of Sci., Shanghai, China; [2]Inst. of Neurosci. and State Key Lab. of Neuroscience, Inst. for Biol. Sciences, Chinese Acad. of Sci., Shanghai, China

Abstract: ATP-gated channel $P2X_3$ receptor is mainly expressed in primary sensory neurons and responsible for pain processing. Increased membrane insertion and functional upregulation confers $P2X_3$ receptor sensitization under pathological conditions. Multiple signaling pathways are involved in the regulation of $P2X_3$ receptor function by various inflammation mediators under pathological conditions. Our previous study has reported that ATP potentiates endocytosis and retrograde transport of $P2X_3$ receptor in the axons of primary sensory neurons. Here, we also showed that ATP promoted membrane delivery of $P2X_3$ receptor in a time-dependent manner. $P2X_3$ receptor-mediated Ca^{2+} influx-activated Ca^{2+}/calmodulin-dependent protein kinase II (CaMKIIα) regulated the membrane insertion of $P2X_3$ receptor in a tertiary structure-dependent manner. The N terminal of $P2X_3$ receptor was responsible for binding with CaMKIIα, whereas Thr388 in the C terminal was phosphorylated by CaMKIIα. Thr388 phosphorylation increased the interaction between $P2X_3$ receptor and caveolin-1, leading to potentiated membrane insertion of $P2X_3$ receptor. Moreover, the regulated forward trafficking of $P2X_3$ receptor by ligand also drove membrane delivery of $P2X_2$ receptor which co-assembles with $P2X_3$ receptor. Together, we present a novel mechanism responsible for the ligand-induced membrane delivery of $P2X_3$ receptor.

Title: Neurotropin suppresses lidocaine-induced neurotoxicity in cultured dorsal root ganglion neurons

Authors: *R. ISONAKA[1], T. TAKENAMI[2], T. KATAKURA[1], T. KAWAKAMI[1];
[1]Physiol., [2]Anesthesiol., Kitasato Univ. Sch. of Med., Sagamihara, Japan

Abstract: Neurotropin is an analgesic agent, and the main ingredient of this drug is a non-protein extract from inflamed skin of rabbits inoculated with vaccinia virus. It is used for the treatment of various chronic pains, and some reports showed that neurotropin affect the axonal degeneration induced by the drug for colorectal cancer. Lidocaine is a major local anesthetics, it is used for the treatment of allodynia and chronic pains in the field of orthopedics, neurology and anesthesia. However, lidocaine is known to have neurotoxicity and inhibit axonal transport. We hypothesized that neurotropin relieves lidocaine-induced inhibition of axonal transport. To test our hypothesis, we investigated that the effect of a combination with lidocaine and neurotropin on axonal transport in cultured mouse dorsal root ganglion neurons. We used the video-enhanced microscopy, which allowed us to observe the real-time dynamics of axonal transport. Simultaneous addition of neurotropin significantly blocked the lidocaine-induced inhibition of axonal transport. These results suggested that neurotropin may lead to suppress lidocaine-induced neurotoxicity.

Title: NMDA receptors in primary afferents are potentiated by BDNF released by microglia during the induction of neuropathic pain

Authors: *J. G. MARVIZON[1], W. CHEN[1], H. S. ENNES[1], W. WALWYN[2], J. A. MCROBERTS[1];
[1]Dept. of Med., [2]Dept. of Psychiatry and Biobehavioral Sci., UCLA, LOS ANGELES, CA

Abstract: We previously found that BDNF induces the activating phosphorylation of the NR2B subunit of NMDA receptors in primary afferents, increasing NMDA-induced neurokinin 1 receptor (NK1R) internalization, a measure of substance P release. Since spinal cord microglia release BDNF during the onset of neuropathic pain, we hypothesized that these NMDA receptors become potentiated after nerve injury. To confirm this, we gave rats chronic constriction injury (CCI) of the sciatic nerve and intrathecal NMDA (10 nmol, with 10 nmol D-Ser) at various times thereafter. Measures of hind paw withdrawal to von Frey hairs confirmed that allodynia developed during the first two days after CCI. Ipsilaterally to CCI, there was a marked increase in NMDA-induced NK1R internalization that peaked 6 hr after CCI and lasted 3 days. Contralaterally, NK1R internalization increased in days 2 and 3 to values similar to the ipsilateral side. Intrathecal saline after CCI or intrathecal NMDA after sham surgery resulted in negligible NK1R internalization, showing that substance P release required both NMDA receptor activation and nerve injury. To investigate the signals involved in NMDA receptor potentiation, rats were given microglia inhibitors (200 nmol minocycline, 1 nmol fluorocitrate or 10 µg propentofylline), the BDNF scavenger trkB-Fc (10 µg), the trkB antagonist ANA-12 (100 nmol), the Src family kinase inhibitor PP2 (10 nmol) or saline. These compounds were injected intrathecally twice: immediately after CCI and 3 hr later; followed by intrathecal NMDA 6 hr after CCI. All of the compounds inhibited NMDA-induced NK1R internalization. We also determined whether activation of microglia with lipopolysaccharide (LPS) increases NMDA-induced NK1R internalization. We gave rats intrathecal LPS (2 µg) or saline twice, 24 hr apart; and NMDA or saline 6 hr after the second injection. LPS induced microglia activation, measured as staining for the microglia marker Iba-1 in the central dorsal horn. NK1R internalization was high when NMDA was given after LPS, but not when NMDA was given after saline, when LPS was followed by saline, or in the saline-saline controls. NMDA-induced NK1R internalization peaked 6 hr after LPS and disappeared by 24 hr. The increase in NMDA-induced NK1R internalization produced by LPS was decreased by trkB receptor antagonist ANA-12, the BDNF scavenger trkB-Fc or the Src family kinase inhibitor PP2. Therefore, NMDA receptors in primary afferent terminals are potentiated during the induction of neuropathic pain as the result

of BDNF release from microglia, activation of trkB receptors and phosphorylation of the NR2B subunit by a Src family kinase.

Title: BDNF increases NMDA receptor currents in primary afferent neurons by inducing phosphorylation of Tyr1472 of the NR2B subunit

Authors: *J. A. MCROBERTS[1], W. WALWYN[2], H. S. ENNES[1], W. CHEN[1], J. MARVIZON[1];
[1]Dept Med., [2]Dept Psychr & Biobehav Sci., UCLA, LOS ANGELES, CA

Abstract: NMDA receptors are present in the central and peripheral terminals of primary afferent neurons. Previously, we found that the ability of NMDA to induce substance P release from the central terminals of primary afferents was markedly increased by BDNF. Using dorsal root ganglion (DRG) neurons from adult rats cultured for 2-3 days, we investigated whether BDNF increased NMDA receptor currents, and induced the phosphorylation in Tyr1472 of the NR2B subunit, which is known to increase NMDA receptor activity. Prior to whole cell patch-clamp recording, DRG neurons were left untreated or were pre-treated with BDNF (30 ng/ml) for 1-2 hr. Once the cells had stabilized at a holding potential of -70 mV, NMDA (250 μM) and glycine (10 μM) were applied for 10 s by pressure ejection and the peak current measured. BDNF increased the NMDA/Gly induced inward current from -149 ± 45 pA to -459 ± 119 pA ($p = 0.0168$, t-test, Figure). There was also an increase in the number of cells that responded to NMDA/Gly above 50 pA: untreated, 50 %, n = 25; BDNF, 95 %, n = 19 ($p = 0.001$, Fisher's exact test). There was no difference in the size of the cells recorded as assessed from cell capacitance (untreated: 41 ± 4 pF, BDNF: 49 ± 5 pF). To determine if BDNF increases tyrosine phosphorylation of the NR2B subunit, cultured DRG neurons were left untreated or treated with 20 ng/ml BDNF for 1 hr, then harvested and protein extracts prepared for electrophoresis. Western blots were first probed with an antibody to phospho-Tyr1472-NR2B, then stripped and reprobed with antibodies to total NR2B and ß-actin. Although there was NR2B phosphorylation

in control cultures, BDNF caused a 2.1 ± 0.4-fold increase in phospho-NR2B ($p < 0.008$; t-test). Therefore, BDNF increases NMDA receptor currents in primary afferents by inducing the phosphorylation of Tyr1472 of the NR2B subunit. In related experiments that measured NMDA-induced substance P release, we found that this phosphorylation is mediated by activation of trkB receptors and a Src family kinase. The potentiation of NMDA receptors in primary afferents by BDNF may contribute to neuropathic/chronic pain.

Title: A role for spinal brain-derived neurotrophic factor in persistent pain in a rat model of mechanical facet joint injury

Authors: *J. KRAS, C. WEISSHAAR, J. QUINDLEN, B. WINKELSTEIN;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Neck and back pain represent the most frequent causes of job-related disability, with costs exceeding $50 billion annually. The facet joint is a common source of neck and low back pain and is susceptible to mechanical injury. Although animal studies support tensile loading of the cervical facet capsular ligament as a cause of persistent pain and report associated upregulation of pain-related molecules, such as substance P, and induction of neuronal

hyperexcitability, the mechanism(s) of pain from this joint injury are still undefined. Changes in brain-derived neurotrophic factor (BDNF) levels are implicated in a host of painful conditions, but the relationship between BDNF and injury-induced joint pain also remains unknown. In this study, we defined the BDNF response in both the dorsal root ganglia (DRG) and spinal cord following painful cervical facet joint loading; we also evaluated if there is a functional contribution of BDNF in the spinal cord to the maintenance of persistent pain that develops from joint injury. Separate groups of male Holtzman rats underwent a painful bilateral C6/C7 facet joint distraction injury or sham surgery. Bilateral forepaw mechanical hypersensitivity was assessed using von Frey filaments applied to the plantar surface of the forepaws. In separate rats after behavioral testing on day 1 or day 7, the C6/C7 spinal cord and DRG were harvested, and BDNF mRNA and protein levels were quantified using real-time RT-PCR and immunohistochemistry, respectively. Facet joint distraction induced significant ($p<0.001$) mechanical hypersensitivity at both time points. BDNF mRNA was unchanged in the DRG after painful injury compared to sham levels at both time points, but BDNF protein significantly increased ($p<0.016$) over sham in the DRG at day 7. Both BDNF mRNA ($p=0.031$) and protein ($p=0.047$) significantly increased in the spinal cord at day 7 after painful injury. In a separate study, sequestering endogenous BDNF via intrathecal administration of trkB-Fc on day 5 after injury returned the forepaw withdrawal threshold to baseline levels on days 6 and 7. Yet, administration of the matched vehicle IgG-Fc did not change the withdrawal threshold after injury. Additionally, the expression of pERK1/2 relative to total ERK1/2 in the spinal cord at day 7 was significantly reduced ($p<0.045$) in the trkB-Fc treated group compared to the vehicle group. In the context of increased spinal BDNF after painful mechanical facet joint injury, this reduction in ERK activation coupled with the reduction in pain that is achieved by spinal BDNF sequestration suggests ERK-mediated contributions of spinal BDNF in the maintenance of mechanical joint pain.

Title: Painful whole body vibration induces increased expression of nerve growth factor & brain-derived neurotrophic factor in cervical intervertebral discs in a rat model

Authors: M. E. ZEEMAN, S. KARTHA, H. A. BAIG, B. B. GUARINO, *B. A. WINKELSTEIN;
Bioengineering, Univ. Pennsylvania, PHILADELPHIA, PA

Abstract: Chronic neck pain is a common disorder with high costs, affecting many in the general population. Discogenic pain is a common source of pain and is hypothesized to originate when the typically aneural intervertebral disc (IVD) becomes innervated after injury or with degeneration. Spinal injury from whole body vibration (WBV) has been linked to low back and neck pain, with increased loading in the vertebral column and discs speculated as a potential pain source. Yet, the biochemical mechanisms leading to discogenic pain from its hyper-innervation and/or degeneration are unclear. Studies report upregulation of the neurotrophins, nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF), in lumbar degenerated IVDs. Because these growth factors mediate nerve growth they are believed to contribute to disc pain. Although there is increasing focus on defining the role of these factors in discogenic pain, work has largely focused on the lumbar discs, and no study has determined if similar mechanisms exist in the cervical spine. This study aimed to define if painful WBV induces changes in neurotrophins in the cervical IVDs. WBV was imposed along the spine's long-axis under inhalation anesthesia with the rat in the prone position. Vibration was applied for 30 minutes at 15Hz and 0.55g daily for 7 days followed by 7 days of rest. Sham rats underwent the same paradigm with anesthesia exposure only. Mechanical hyperalgesia was assessed prior to, during, and after the WBV exposure period. On day 14, cervical spines were harvested to evaluate NGF and BDNF mRNA and protein expression using RT-qPCR and western blot (n=8/group). Immunohistochemistry (n=4/group) was used to localize and quantify NGF and BDNF expression levels in different regions of the disc. WBV exposure induced behavioral hypersensitivity in the forepaw through day 14 that was not present in shams ($p<0.01$). In association with pain, WBV increased NGF and BDNF transcripts by 1.6-fold and 2.0-fold over sham, but not significantly. WBV did produce a significant ($p<0.006$) 5-fold increase in BDNF protein and a significant ($p<0.04$) 1.8-fold increase in the 75kDa NGF isoform. The 28kDa isoform of NGF increased 4.9-fold, but this was not significant. After WBV, both NGF and BDNF labeling significantly ($p<0.01$) increased in the inner annulus compared to the outer annulus of the disc. These findings suggest that painful WBV may induce similar patterns of upregulation of neurotrophins as in disc degeneration. Results also suggest that the same painful processes present in the lumbar spine may occur in the cervical spine and may explain one such potential mechanism responsible for the development of chronic neck pain.

Title: Methylation of BDNF genes in rat oro-facial neuropathic pain model~possible biomarker of neuropathic pain in the future~

Authors: *A. NAKAE, K. NAKAI, T. TANAKA, Y. ISHIDA, S. ISHINO, K. HOSOKAWA, T. MASHIMO, Y. FUJINO;

Abstract: Background and Goal of the study:
Pain is a subjective symptom and the mechanisms are unclear. Thus, chronic pain, especially neuropathic pain, is diagnosed by patient symptoms rather than an objective test. One of the most important requirements is an objective useful biomarker.
Brain-derived neurotrophic factor (BDNF) can potentiate pain transduction from primary sensory neurons to spinal dorsal horn in response to nerve injury and is well known that DNA methylation affects transcription of BDNF.
Towards that end, we examined the methylation profile of the BDNF in trigeminal ganglion after infra-orbital nerve (ION) injury as an orofacial neuropathic pain model to identify an appropriate epigenetic biomarker for the objective diagnosis of neuropathic pain.
Material and Methods:
We used ION loose ligation model using SD rats (N=8 each). 28 day after surgery when injured animal expressed pain behavior, the trigeminal ganglion samples were taken from each animal. All methylation analysis was performed using Solid4 system (Life Technologies, CA). Clustering analyses were performed using JMP 9.0.1 software, with the Ward's method. The difference in the methylation rates was compared by one-way ANOVA and statistical differences were resolved post-hoc using Tukey-Kramer multiple-comparison test ($p<.05$).
Results and Discussion:
28days after injury, pain threshold values from injured rats were statistically significantly lower than from sham and naïve rats.
The methylation rates are shown in table and analyses of the dendrogram from methylation profiles of exon I, II, VI, and VII each promoter region demonstrated that classification of nerve injured rats and naïve controls at the first branch completely matched the condition. Our results

indicate that classification based on the DNA methylation profiles of BDNF gene may be a valuable diagnostic biomarker for neuropathic pain.
Conclusion:
Based on analyses of the methylation profiles within the CpG island at the promoter of the BDNF gene in trigeminal ganglion, we could accurately classify animals into two groups (nerve-injured and naïve).

Title: The role of AT1 R in the development of pain hypersensitivity after peripheral nerve injury

Authors: N. KALYNOVSKA, M. DIALLO, *J. PALECEK;
Dept. of Functional Morphology, Inst. of Physiol., Prague, Czech Republic

Abstract: Neuropathic states are often characterized by chronic pain and increased sensitivity to innocuous and noxious mechanical and thermal stimuli, allodynia and hyperalgesia. Neuroinflammatory changes at the spinal cord level are considered to be one of the possible mechanisms leading to the neuropathic pain states after the peripheral nerve injury. Several

studies have documented that Angiotensin II, the main effector molecule of Renin-Angiotensin system (RAS), is involved in neurodegenerative processes due to its proinflammatory effects. In this study the role of Angiotensin II receptor type 1 (AT1 R) signaling in the development and maintenance of neuropathic pain was investigated using AT1 R antagonist losartan. Male adult Wistar rats were used with the L5 spinal nerve ligation (SNL) model of peripheral neuropathy. Electronic von Frey mechanical stimulation and heat plantar test were used to determine withdrawal threshold levels for mechanical and thermal stimulation. Behavioral tests were performed before SNL to register the control value and then 1, 3, 5, 7, 9, 12 and 14 days after the SNL operation. Neuropathic rats were treated either with systemic (100 mg/kg) or intrathecal (20µM/10µl) administration of losartan. SNL caused significant reduction of the threshold to the heat stimulus reflected by reduced paw withdrawal latency (PWL). Maximal decrease of PWL on the side ipsilateral to the SNL was detected on the 9th postoperative day (16.5±0,1s) when compared to the control value (22, 8±0,1s, ($P \leq 0,001$)) and to the contralateral side (20,3±0,2 s, ($P \leq 0,001$)). Reduced PWL persisted till the end of the experiment and indicated thermal hyperalgesia. Treatment with losartan significantly attenuated changes in PWL on the 9th postoperative day (20,3±0,2 s ($P \leq 0,001$)). However, losartan treatment did not affect mechanical allodynia, induced by the SNL. No significant difference between the systemic and intrathecal losartan administration was observed. These results suggest that blockade of the AT1 R attenuates thermal hyperalgesia in the neuropathic pain model, presumably at the spinal cord level. Further experiments are needed to confirm therapeutic effect of AT1 R antagonists and to investigate the role of AT1 R signaling in initiation and maintenance of pain hypersensitivity after nerve injury.

Title: Application of Angiotensin II-Receptor 1 antagonist (Losartan) attenuates spinal cord neuroinflammation in a model of neuropathic pain

Authors: *M. S. DIALLO, N. KALYNOVSKA, J. PALECEK;
Acad. of Sci. of Czech Republic, Praha, Czech Republic

Abstract: It is now well documented that the immune system and neuroinflammatory changes at the spinal cord level are widely involved in the initiation and maintenance of neuropathic pain present after nerve injury. Recently, it has been shown that the angiotensin II-receptor 1 (AT1R), receptor of the major Renin-Angiotensin System (RAS) effector, may play a role in neuroinflammatory processes in the CNS. In our study, the effect of losartan (AT1R antagonist) application was tested in a model of neuropathic pain in rats induced by spinal nerve ligation (SNL). Behavioral tests were used to confirm the presence of increased sensitivity to mechanical and thermal stimuli after the SNL. Western blot analysis was used to quantify and compare the expression levels of neuroinflammatory markers in the spinal cord L4-L6 lumbar segments, in the SNL rats on the operated (ipsilateral) and the controlateral sides at the 7th post-operative day. Our data showed that SNL evoked an upregulation of different proinflammatory factors and their receptors on the ipsilateral side when compared to the contralateral half of the spinal cord segment. Chemokine C-C motif ligand 2 (CCL2) and its receptor CCR2; and the cytokine tumor necrosis factor-α (TNF-α) and its receptor TNFR1 were increased to 144.8 ± 22.9 %, 156.7 ± 10.1, 128.3 ± 3.7 and 139.2 ± 8.3 %; respectively. SNL injury also induced, as expected, a microglial activation documented by strong increase of microglial marker OX42 levels in the ipsilateral spinal cord to 174.9 ± 31.4%. The levels of the AT1R protein expression were also increased on the ipsilateral side 158.1 ± 15.4 %. In another group of animals chronic treatment with losartan per os (100 mg/kg) was used during and after the SNL model induction. The expression level of the inflammatory factors in this group was not different when the ipsilateral and contralateral sides were compared: CCL2: 93.9 ± 4.4 %; CCR2: 102.2 ± 7.7 %; TNF-α: 83.8 ± 8.9 %; TNFR1: 88.2 ± 3.3 %; OX42: 108.3 ± 6.1 %; AT1R: 93.9 ± 10.5. Our results suggest that AT1R activation is involved in the cascade of neuroinflammatory changes present after the SNL ligation in the spinal cord. Further experiments are needed to evaluate the possible use of losartan, an AT1R antagonist, as a possible neuropathic pain treatment.

Topic: D.08. Pain

Title: Chronic neuropathic pain provokes adaptive changes in the response of endogenous pain inhibition in rats

Authors: *A. PARENT[1], P. TETREAULT[1], M. ROUX[1], K. BELLEVILLE[1], C. AURAY-BLAIS[2], P. GOFFAUX[3], P. SARRET[1];
[1]Dept. of physiology and biophysics, [2]Dept. of pediatrics, [3]Sch. of rehabilitation, Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: As chronic pain sets in, physiological responses to tonic experimental pain may be altered, providing important clues to the development of chronic pain and to its neurobiological underpinnings. The underlying mechanisms leading to the development of chronic pain may also differ depending on the type of chronic pain (e.g. inflammatory or neuropathic). In order to better understand the pathological changes associated with the development of chronic pain, the formalin test was performed in separate groups of male SD rats, 12, 28 and 90 days after induction of chronic neuropathic or inflammatory pain. Central (CSF) and peripheral (plasma) serotoninergic (5-HTergic) activity was also measured immediately after the formalin test.
The hind paw complete Freund's adjuvant (CFA) model and the chronic constriction injury (CCI) model were used to induce chronic inflammatory and neuropathic pain, respectively. At each endpoint (days 12, 28 or 90), responses to tonic experimental pain were evaluated by injecting 50 µl of formalin 5% in the plantar surface of the contralateral hind paw in control and CFA/CCI animals. CSF and plasma samples were collected immediately after the formalin test, and the 5-HTergic activity was assessed using mass spectrometry.
In both models, we first highlighted the development of chronic pain by assessing mechanical withdrawal thresholds over time. We next observed a trend towards decreased pain-like behaviors during the formalin test among the neuropathic pain group on **day 12**. On **day 28**, a significant 55% decrease in pain-like behaviors (all ps<0.01) was measured during the acute and inflammatory phases of the formalin test in CCI rats. Interestingly, this decrease in pain-like behaviors was completely reversed on **day 90** (all ps>0.05). In sharp contrast, CFA-treated rats showed no apparent changes in their response to formalin. Moreover, we demonstrated that the formalin test triggered changes in the activity of the 5-HTergic system that may explain temporal

variations in behavioral responses in the different pain paradigms.
Our data reinforce the idea that chronic pain develops through diverse pathological mechanisms, depending on the origin of pain (neuropathic vs inflammatory). The decrease in pain-associated behaviors in CCI rats (on day 28) during the formalin test suggests that active pain inhibitory mechanisms and/or central desensitization are present in the early days of chronic pain. These processes may be part of a transitory adaptive process occurring at an intermediate developmental stage of chronic neuropathic pain.

Abstract: Chronic pain is a major health problem, affecting over 100 million adults annually in the USA, with considerable economic costs in healthcare and loss of productivity. Notable progress has been made in elucidating neural mechanisms underlying pain sensing and processing, leading to important insights into the maladaptive changes that produce persistent or chronic pain. Moreover, susceptibility to such maladaptive changes depends in part on the individual's genetic makeup as well as the interaction between genes and environment. There are on-going efforts to identify molecules or genes that mark specific neuronal cell types and their respective roles in pain behavior to better understand at the molecular level the transition from

acute to chronic pain and to provide essential tools for tailoring effective pain treatments. Here, we propose the novel TMEM35 (TUF1) is one such candidate. Our group investigates a 167-aa polypeptide (TMEM35/TUF1) that is strongly expressed in developing and adult neural and endocrine networks that mediate pain (i.e., skin, dorsal root ganglia, spinal cord, brain stem, amygdala, hippocampus, cortex, and HPA axis). The involvement of TUF1 in pain was indicated by evidence of thermal hyperalgesia and mechanical allodynia in the tuf1 KO mice. In addition, there is a strong link between chronic pain and anxiety. The tuf1 KO mice exhibit increased anxiety-like behavior accompanied by higher basal level of plasma corticosterone and adrenal hyperplasia, providing additional rationale for assessing TUF1's role in pain pathways. Current experiments are investigating whether there are interactions between the stress and pain perception or whether these are independent effects of tuf1 gene deletion.

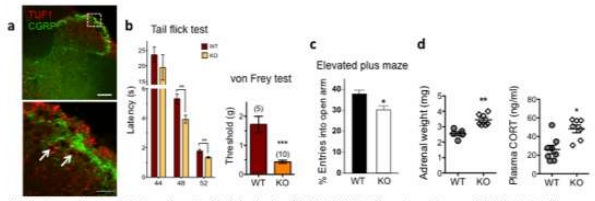

*Fig. 1: Increased pain sensitivity and anxiety-like behavior in tuf1 KO. **a)** CGRP+ fibers (green) innervate TUF1+ (red) cells (arrows in lower panel, scale bar = 20 μm) in adult rat dorsal cord lamina I. **b)** Tail-flick responses and paw-withdrawal tests (von Frey microfilaments) show lower pain thresholds in KO mice, WT=9, KO=10 at 48C, n=7/genotype at 52C. **c)** Anxiety-like behavior tested by elevated-plus maze shows KO made fewer entries into the open arms (WT=12, KO=6). **d)** Adrenal weight and basal plasma corticosterone (CORT) level were higher in KO mice. Unpaired t-test, *P<0.05, **P<0.01, ***P<0.001.*

Title: Increased responses to glutamate in dorsal root ganglion (DRG) neurons after peripheral nerve injury

Authors: *K. GONG[1], A. BHARGAVA[2], L.-H. KUNG[3], P. T. OHARA[3], L. JASMIN[3];
[1]Dept. of anatomy, [2]Dept. of Surgery, [3]Dept. of Anat., Univ. of California San Francisco, San Francisco, CA

Abstract:
Recent evidence supports the idea that glutamate in the periphery is involved in nociception. Using patch clamp we recorded neuronal
responses in dorsal root ganglia (*ex-vivo* DRG preparation). Following CCI, small DRG neurons (<30μm) exhibited an increased excitability associated with a decrease in the membrane threshold and Rhoebase.
Puff application of glutamate or of the selective ionotropic receptor agonists AMPA, KA, and the group I metabotropic receptor (mGluR) agonist DHPG, induced larger inward currents compared to naïve DRG. NMDA receptor mediated currents were unchanged. Additionally, we found that after CCI more neurons responded to glutamate, AMPA, DHPG as well as to NMDA, but not to KA. We also investigated the trafficking of glutamate receptors in the DRG. Following CCI there was a redistribution of NMDA receptors to the neuronal membrane while proportion of KA at the surface vs. in cytosol remained unchanged. We then examined the effect of group I mGluR activation on neuronal excitability and glutamate receptor responses. In naive rats, incubation of the whole ganglion in DHPG (50 μM) for 2 hours resulted in decreased membrane threshold and larger inward currents following KA application but smaller responses to AMPA and NMDA. In the CCI group, DHPG incubation increased neuronal rhoebase and decreased AMPA and NMDA induced currents. KA induced currents were unchanged. These results show that following nerve injury DRG neurons have increased excitability and larger inward currents to glutamate application. In addition, activation of Group I mGluR modulates the activity of ionotropic glutamate receptors differentially in naïve vs. nerve injured DRG neurons. We propose that peripheral glutamatergic transmission is involved in the initiation of neuropathic pain.

Title: Peripheral nerve injury reduces efficacy of gabapentin on neurotransmitter release in the prefrontal cortex and locus coeruleus

Authors: *T. SUTO, J. C. EISENACH, K. HAYASHIDA;
Anesthesiology, Pain Mechanism Lab., Wake Forest Univ. Shcool of Med., Winston-Salem, NC

Abstract: We have previously demonstrated that the antiepileptic drug gabapentin activates noradrenergic neurons in the locus coeruleus (LC) via glutamate-dependent mechanisms and that gabapentin induces a similar degree of spinal noradrenaline release in normal and L5-L6 spinal nerve ligated (SNL) rats. The current study examined whether SNL alters effects of gabapentin on noradrenaline release in the prefrontal cortex (PFC) and glutamate release in the LC following systemic or local gabapentin administration. We also examined attention-related behavior following systemic injection of gabapentin in normal and SNL rats.
Right L5-L6 SNL was performed in male Sprague-Dawley rats. Extracellular concentrations of noradrenaline in the PFC and glutamate in the LC ipsilateral to SNL were measured by microdialysis in behaving rats after SNL surgery, following either local perfusion into the PFC or intraperitoneal (i.p.) injection of gabapentin. Attention-related behavior was examined 1 hour after i.p. injection of gabapentin by measuring the time that animal showed physical contacts with the newly placed object in his cage.
In normal animals, PFC-perfused gabapentin concentration-dependently reduced the extracellular concentration of noradrenaline in the PFC, while systemically injected gabapentin dose-dependently increased extracellular concentration of noradrenaline in the PFC, associated with the increase in extracellular concentration of glutamate in the LC. In SNL animals, both local and systemic effects of gabapentin on noradrenaline release in the PFC and glutamate release in the LC were reduced compared to normal animals. SNL rats showed less attention-related behavior compared to normal animals and gabapentin did not affect attention-related behavior in either normal or SNL animals. These results indicate that peripheral nerve injury reduces efficacy of gabapentin on noradrenaline release in the PFC as well as glutamate release in the LC in behaving rats.

Title: Somatostatin and its 2A receptor in dorsal root ganglia and dorsal horn of mice and man: Expression, trafficking and possible role in pain

Authors: *T. SHI[1,2], M.-D. ZHANG[3], Q. XIANG[2], S. BARDE[3], K. FRIED[1], S. SCHULZ[4], T. HÖKFELT[3];
[1]Dept. of Dent. Medicine, Karolinska Institutet, Huddinge, Stockholm, Sweden; [2]Harbin Inst. of Technol., Harbin, China; [3]Dept. of Neuroscience, Karolinska Institutet, Stockholm, Sweden; [4]Friedrich Schiller Univ. Jena, Jena, Germany

Abstract: Anti-nociceptive effects of somatostatin (SST) and its receptor subtypes have been reported. We now demonstrate, using immunohistochemistry and *in situ* hybridization, presence of SST and SST receptor 2A (sst2A) protein and transcript in mouse and human dorsal root ganglia (DRGs) and spinal cord. sst2A immunoreactive (IR) neurons were found in mouse and human DRGs, the receptor protein always mainly cell membrane-associated and in mouse colocalized with CGRP (mostly) and/or NPYY1 receptor (sometimes) in small neurons. A high density of fibers was detected in lamina II in both mouse and human spinal dorsal horn. Dorsal root rhizotomy did not appear to abolish sst2A-immunoreactivity (LI) in the ipsilateral dorsal horn. Accumulation of sst2-LI was detected on the proximal and, more strongly, on the distal side of a sciatic nerve ligation. Systemic treatment of animals with the sst2 agonist octreotide (Oct) caused a dramatic internalization of sst2A in the DRG neurons, as also observed in dorsal horn and DRG neurons after intrathecal administration. Oct treatment attenuated the reduced pain threshold in a neuropathic pain model, in parallel suppressing the activation of p38 MAPK in the DRGs. These findings highlight a significant role of the SST system in pain signaling and suggest that sst2A may represent a novel target for pharmacological treatment of neuropathic pain.

Title: Pituitary adenylate-cyclase activating polypeptide (PACAP) is possibly regulated by RE1-silencing transcription factor (REST/NRSF) isoform in neuropathic pain

Authors: *Y. SHUDO, M. SHIMOJO, S. ITO;
Med. chemistry, Kansai Med. Univ., Hirakata/Osaka, Japan

Abstract: Neuropathic pain is one of the most common type of intractable pain which control is difficult, even if with morphine and detailed pathophysiological mechanism of neuropathic pain is still unknown. Our previous study reported that neuropeptide pituitary adenylate-cyclase activating polypeptide (PACAP) is required for the development of spinal sensitization and induction of neuropathic pain (Mabuchi *et al.*, J. Neurosci. 2004). PACAP is distributed widely in dorsal root ganglia (DRG) and increases after nerve injury. However detail mechanism remains unknown. It was reported that functional RE1-like element located in PACAP gene and the regulation of RE1 is controlled by the RE1-silencing transcription factor (REST/NRSF). Further studies reported that this RE1-like element contains many mismatches, resulting that *in silico* prediction identified the new RE1 site upstream of mouse PACAP gene. To analyze the regulation of PACAP gene by REST in neuropathic pain, we employed L5 sciatic nerve transection (L5-SNT) mouse model. The immunostaining and qRT-PCR analysis showed that PACAP dramatically increased in DRG in L5-SNT mice. REST4, a neuron-specific splicing isoform of REST also increased in DRG of L5-SNT mice, suggesting PACAP gene is regulated by REST4. To analyze the functional RE1 *in vitro*, we have cloned mouse PACAP promoter region with either wild or mutant RE1 into promoter-less luciferase vector. Reporter gene analysis performed with PC12 cells showed that wild-type RE1 suppressed promoter activity compared to mutant RE1. Over expression of REST4 in PC12 showed that PACAP expression increased. It was reported that novel protein nSR100 directly promotes alternative splicing of REST transcripts to produce REST4, thereby activating expression of REST targets in neural cells. In L5-SNT mice the expression of nSR100 increased higher corresponding to the expression of REST4. Taken together, these results suggested that the abnormal alternative splicing of REST producing REST4 by nSR100 might be involved in the regulatory mechanism of PACAP expression in neuropathic pain.

Title: Differential effects of natural rewards and pain on vesicular glutamate transporter (VGLUT) expression in the nucleus accumbens (NAc)

Authors: *M. LEE[1], D. TUKEY[1], D. XU[1], S. EBERLE[1], Y. GOFFER[2], E. ZIFF[1], J. WANG[1]; [1]NYU Sch. of Med., New York, NY; [2]Columbia Univ. Col. of Physicians and Surgeons, New York, NY

Abstract: Pain and natural rewards have both been shown to alter neuronal activities in the nucleus accumbens (NAc), a key component of the brain reward system, despite eliciting opposite behavioral consequences. Medium spiny neurons (MSNs) of NAc receive excitatory glutamatergic inputs and modulatory cholinergic and dopaminergic inputs from a variety of cortical and subcortical structures. In particular, glutamatergic projections from the prefrontal cortex, thalamus, amygdala, and hippocampus to the NAc provide distinct synaptic and ultimately, behavioral functions. The family of vesicular glutamate transporters (VGLUTs 1-3), which have distinct expression patterns throughout the brain, mediates the accumulation of glutamate into synaptic vesicles and plays a key role in glutamate transmission. In this study we use a spared nerve injury (SNI) model for chronic pain and a sucrose self-administration model for natural rewards in rats to examine the levels of VGLUTs (1-3) in the synaptoneurosomes of the NAc. We find that levels of VGLUT1 and VGLUT3 are decreased with chronic pain, and that VGLUT3 levels are increased with chronic administration of natural rewards. These results demonstrate that pain and natural rewards have distinct effects on VGLUT expression patterns in the NAc.

Abstract: Paclitaxel (Taxol®), a commonly used antineoplastic agent, causes peripheral neuropathy characterized by prominent impairment of touch sensations. Little is known about the mechanisms underlying paclitaxel-induced peripheral neuropathy. Although co-administration of neurotrophin such as nerve growth factor (NGF) has been reported to prevent peripheral neuropathy in preclinical studies, the therapeutic effect of such a treatment is not clear in clinical trials. The goal of this study is to determine the role of two neurotrophic factors, NGF and brain-derived neurotrophic factor (BDNF), in dorsal root ganglia (DRG) in the development of paclitaxel-induced peripheral neuropathy. Adult Sprague-Dawley rats (55-60 days) were treated with paclitaxel (2mg/kg, q2d x 4, i.p.) or vehicle and sacrificed 4 hours, 7 days, 16 days and 29 days after treatment. The L4 and L5 DRGs of both sides were collected for rtPCR and western blotting experiments. The mRNA level of NGF but not BDNF was increased at both 4 hours and 7 days following chemotherapy. Western blotting detected an increase of both NGF and its receptor TrkA 7 days following chemotherapy. The protein of BDNF was not detected in DRG while the expression of its receptor TrkB was not changed. Finally, intrathecal application of anti-NGF antibody before and during chemotherapy partially prevented paclitaxel-induced mechanical hypersensitivity but such a treatment did not reverse the established neuropathy induced by paclitaxel. The results suggest that the paclitaxel induces the activation of NGF-TrkA signaling in DRG which may contribute to the initiation but the not the maintenance of paclitaxel-induced peripheral neuropathy.

Title: Differential relationship between insular gray matter volume, pain sensitivity and cognitive performance in younger and older fibromyalgia patients

Authors: *M. CEKO[1,2], M. C. BUSHNELL[2], M.-A. FITZCHARLES[1], P. SCHWEINHARDT[1]; [1]McGill Univ., Montreal, QC, Canada; [2]NCCAM, NIH, Bethesda, MD

Abstract: We have previously reported insular gray matter (GM) increase in younger fibromyalgia (FM) patients (Ceko et al. 2012), which correlated with lower pain sensitivity, possibly indicating the recruitment of endogenous pain modulatory mechanisms. Here we investigate the effect of insular GM hypertrophy in these patients on the relationship between cognitive performance and pain sensitivity, and explore if age-related insular GM decline (Ceko et al. 2012) affects this relationship in older patients.

We measured cognitive performance and pain sensitivity in 14 younger FM patients compared to 15 controls (mean ages of 42.4 and 43.1, p=0.8), and 14 older patients compared to 13 controls (mean ages of 55.0 and 55.4, p=0.8), matched for handedness, education, physical activity, and socioeconomic status. All subjects underwent anatomical magnetic resonance imaging (MRI). Cognitive performance was assessed using the Auditory Consonant Trigram (ACT) memory task. Pain sensitivity was assessed in response to a standardized pressure stimulus applied on the thumbnail. Anatomical MRI data were preprocessed in SPM8. Group difference on the ACT were tested with an univariate ANOVA. Mean GM in areas of group differences was correlated pain sensitivity, as well as with the ACT score (difficult level), controlling for age.

Both groups of patients had cognitive impairment compared to matched controls. Cognitive performance was in younger patients inversely related to pain sensitivity. Younger patients with lowest pain sensitivity and best cognitive performance had most GM in the insula. In older patients, insular GM was no longer positively correlated with cognitive performance (or protective against pain sensitivity). Similarly, while negatively correlated in younger patients, cognitive performance and pain sensitivity were no longer negatively correlated in older patients. In younger patients, insular hypertrophy is related to decreased pain sensitivity and increased cognitive performance. As patients age insular GM declines and thus the positive effect on pain sensitivity and cognitive performance is lost.

Title: Integration of pain and reward in decision making: An fMRI study

Authors: *M. MARUYAMA[1], W. YOSHIDA[1], S. ISHII[1,2], B. SEYMOUR[3,4];
[1]Advanced Telecommunications Res. Inst. Intl., Kyoto, Japan; [2]Integrated Systems Biol. Laboratory, Dept. of Systems Science, Grad. Learning Laboratory, Dept. of Engin., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Current theories of the motivational basis of pain highlight it's inhibitory relationship with reward. In particular, the Motivation-Decision model (1,2), and the Opponent Reinforcement model (3,4) predict a simple additive process between the positive value of rewards and the negative value of pain, with the net value determining motivational responses and decisions. Although this model explains a wealth of behavioural and neural data (5,6), recent imaging findings have suggested that reward and pain might not only sum, but interact (7) - finding that fits awkwardly with standard models. The current study used fMRI in healthy subjects to investigate how the brain integrates values of monetary reward and painful shock as gain and cost, respectively, to explore the nature of this interaction. Each trial started with an offer that was a pair of visual cues indicating a subjective pain intensity and an amount of monetary reward. The subjects were instructed to press one of two buttons immediately after they made a decision to accept or reject the offer. In one condition, when the offer was accepted, they received both the painful shock and money with a fifty percent probability. In a second condition, they received *either* the painful shock or the money. Comparison of the two conditions allowed evaluation of the nature of the potential interaction between decision outcomes. The delivery of painful shock occurred at the end of trials, and the total accumulated reward money was remunerated after the experiment. Although the choice behaviour of subjects was similar

between each condition, the reaction time was longer both when the net subjective value offer was close to zero (i.e. more decision conflict), and in the condition when the outcomes where presented as either – or alternatives compared to when they occurred together. To probe this further, we modeled the data using a hierarchical drift diffusion model (8,9) to provide a specific, mechanistic account of value integration. fMRI data will be presented that support the corresponding neural basis of the integration and decision process.

Title: Long-lasting effect of transcranial direct current stimulation (tDCS) in healthy subjects: An evoked potential study

Authors: *M. HUNG[1], J.-C. HSIEH[1,2], D. M. NIDDAM[1,2];
[1]Inst. of Brain Sci., Natl. Yang-Ming Univ., Taipei, Taiwan; [2]Integrated Brain Res. Unit, Dept. of Med. Res. and Educ., Taipei, Taiwan

Abstract:
Background: Anodal tDCS over primary motor cortex (M1) can reduce acute pain. However, relatively little is known about how to best prolong the modulatory effect while minimizing the number of tDCS sessions. Here we seek to test a novel "boost" paradigm in which stimulation is performed daily for 5 days in the first week and on the fifth day of the 2nd and 3rd week. Hypothesis: Repetitive tDCS stimulation using a "boost" paradigm can (1) elevate the acute pain

threshold (PT) and this effect can be maintained for up to 9 weeks post tDCS, and (2) modulation of the PT is reflected in cerebral activity as measured with contact heat evoked potentials (CHEPs). **Methods:** 48 healthy subjects received either anodal or sham tDCS according to a novel "boost" paradigm. Before and after each stimulus session, sensory and pain thresholds to warm thermal stimuli were recorded. In addition, CHEPs were recorded before and after the 1st, 5th, 6th and 7th tDCS sessions. The stimulus temperature used to evoke CHEPs was rated as moderately painful prior to the first tDCS session and was kept constant at subsequent CHEP recordings. To monitor the durability of the 7 tDCS sessions, sensory and pain thresholds were also recorded in response to thermal stimulation on day 5 in week 4, 5, 6, and 12 without tDCS stimulation. **Results:** Anodal tDCS substantially increased the thermal PT. The elevated pain thresholds were sustained up to 12 weeks after the initial tDCS and 9 weeks after the last tDCS session. The peak-to-peak CHEP amplitude at the vertex decreased on the fifth day of tDCS and this reduction was sustained until the 3rd week (7th tDCS session). **Conclusions:** Repetitive anodal tDCS over M1 delivered in "boosts" can maintain an elevated heat PT for up to 9 weeks post tDCS. Elevation of the PT was mirrored by reduced CHEP amplitudes. Taken together, both subjective and objective measures support a prolonged sustained effect in response to our "boost" paradigm. The tDCS protocol presented here is less time consuming than daily stimulation for several weeks and offers a reduced burden to possible patients.

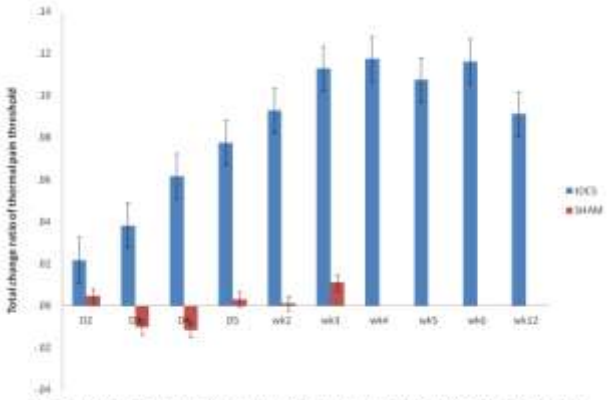

Fig. Significant differences between groups were found on day 3 (D3) to week 3(wk3)($p<0.001$). Significant within group differences were found in week 2 (wk2) to week 12 (wk12) ($p<0.01$). The standard error of the mean is indicated by bars.

Title: Neuronal activity in the precuneus and superior temporal gyrus during the initial experience of pain predicts exaggerated pain at recall

Authors: *L. LAGRANDEUR, J. PLOURDE-GAUTHIER, K. DAIGLE, G. LÉONARD, P. GOFFAUX;
Ctr. De Recherche Clinique (CRC), Ctr. Hospitalier Universitaire De Sherbrooke (CHUS), Fleurimont, QC, Canada

Abstract: Introduction:
Past pain is rarely recalled accurately, a phenomenon known as mnemonic pain bias. Although the existence of mnemonic pain bias is well documented in both clinical and experimental settings, the underlying neurophysiology is poorly understood. In the present experiment, we tested the possibility that mnemonic pain bias could be traced back to the functional brain activity evoked when pain is initially experienced (i.e., encoded).
Methods:
Thirteen healthy adults were exposed to painful transcutaneous sural nerve shocks. Shock-evoked cerebral activity was measured using somatosensory-evoked brain potentials (SEPs). SEPs were transformed from scalp recordings to intracranial current sources using standardized low-resolution electromagnetic tomography (sLORETA). Subjective pain intensity was assessed using a visual analog scale devoid of numerical anchors. Two months after having experienced sural nerve pain in the lab, participants were called back and asked to recall the intensity of the pain they had initially experienced. The difference between recalled pain and the pain initially felt was used as our metric of mnemonic pain bias. In our main analysis, correlations between pain-evoked brain activity and mnemonic pain bias were analysed using Pearson correlations corrected for multi-voxel comparisons (SnPM). This approach allowed us to identify the set of brain regions which predict individual differences in mnemonic pain bias.
Results:
Results revealed that mnemonic pain bias was negatively correlated with early, contralateral precuneus activity ($r=-0.89$, $p<.002$, activated 112-116ms after shock onset), and positively with late contralateral superior temporal gyrus activity ($r=0.90$, $p<0.007$, activated 428-432ms after shock onset). These structures were not part of the network of brain regions which predicted subjective pain intensity (which in our study included the supplementary motor area, the anterior cingulate cortex, and the insula).
Conclusions:
Exaggerated pain recall was associated with both decreased precuneus and increased superior temporal gyrus activity during then encoding process. This suggests that mnemonic pain bias involves brain regions important for both self-perception (precuneus) and memory formation (superior temporal gyrus).

Title: Disrupted brain circuitry for reward/punishment in fibromyalgia

Authors: *M. L. LOGGIA[1], C. BERNA[3], J. KIM[2], C. CAHALAN[4], R. L. GOLLUB[5], A. D. WASAN[4], R. E. HARRIS[7], R. R. EDWARDS[4], V. NAPADOW[6];

Sch., Boston, MA; [5]Psychiatry, [6]Radiology, Mass. Gen. Hosp. / Harvard Med. Sch., Boston, MA; [7]Univ. of Michigan, Ann Arbor, MI

Abstract: While patients suffering from fibromyalgia (FM) are known to exhibit hyperalgesia, the central mechanisms contributing to this altered pain processing are not fully understood. In this study we investigated potential dysregulation of the neural circuitry underlying cognitive and hedonic aspects of the subjective experience of pain such as anticipation of pain and anticipation of pain relief. We adopted a region-of-interest (ROI) approach focused on the nucleus accumbens (NAc) and the ventral tegmental area (VTA), two mesolimbic structures known to be involved in the processing of reward and punishment, and that were implicated in FM pathophysiology in PET studies.
BOLD FMRI (Siemens TIM Trio, 3T, TR/TE=2sec/30ms, voxel size=3.1x3.1x4mm) was

performed on 31 FM patients and 14 controls while they received cuff pressure pain stimuli on their leg, calibrated to elicit a pain rating of ~50/100. During the scan, subjects also received visual cues informing them of impending pain onset (pain anticipation) and pain offset (relief anticipation). Patients exhibited less robust activations during both anticipation of pain and anticipation of relief within regions commonly thought to be involved in sensory, affective, cognitive and pain-modulatory processes. In healthy controls, a direct search in the ventral tegmental area (VTA) revealed a pattern of activity compatible with the encoding of punishment: activation during pain anticipation and pain stimulation, but deactivation during relief anticipation. Furthermore, in these subjects, VTA responses to anticipation of pain and relief anticipation were negatively correlated ($r = -0.76$, $p = 0.002$). In FM patients, however, VTA activity during pain and anticipation (of both pain and relief) periods was dramatically reduced or abolished. Moreover, VTA responses to pain anticipation and relief anticipation were not significantly correlated in the FM patients ($r = -0.12$, $p = 0.52$). No group differences were observed for the NAc.
Our results suggest that FM patients exhibit disrupted brain responses to reward/punishment. The VTA is a source for reward-linked dopaminergic/GABAergic neurotransmission in the brain and our observations are compatible with reports of altered dopaminergic/GABAergic neurotransmission in FM. Disruption of these pathways may relate to the augmented central processing of pain and reduced efficacy of opioid treatments in FM patients.

Title: Further evidence for sensory hypersensitivity in fibromyalgia: Sensitivity to visual stimuli and response to pregabalin

Authors: E. ICHESCO[1], A. KAIRYS[1], E. CHANG[2], G. RAMIREZ[1], D. J. CLAUW[1], R. E. HARRIS[1], *S. E. HARTE[1];
[1]Dept Anesthesiol., [2]Mol. & Behavioral Neurosci. Inst., Univ. of Michigan, ANN ARBOR, MI

Abstract: INTRODUCTION: Fibromyalgia (FM) is a chronic disorder characterized by widespread pain and muscle tenderness. Additionally, FM patients report hypersensitivity to non-somatic sensory stimuli including auditory and olfactory stimulation, suggesting a global central nervous system state of sensory amplification. Here we examined the enhanced sensitivity to experimental visual stimuli in FM.
METHODS: Nine female FM patients underwent two presentations of a 3 minute visual stimulation task, consisting of an alternating series of flashing blue-yellow annulus checkerboard images displayed at varying intensities of illuminance (5 lux - 75 lux) and a static fixation cross (control image). Subjects rated each image and the entire task on a 21-box numerical descriptor scale of sensory unpleasantness. These results of quantitative sensory testing were compared with results in 11 age- and sex-matched healthy controls (HC). An independent samples t-test was performed using SPSS to compare overall unpleasantness ratings between the FM and HC groups. In a separate sample of 17 FM participants, a 3 minute fMRI scan was conducted with the presentation of the same flashing checkerboard visual stimulus. Data were preprocessed in SPM5 and single subject results were contrasted between the flashing checkerboard and static fixation blocks. A one-sample t-test was performed using age as a regressor, and results deemed significant at $p < 0.05$ corrected at the cluster level with an uncorrected voxel extent threshold of $p < 0.001$.
RESULTS: FM patients (mean = 9.9, SD = 6.2) rated the visual stimulus task to be significantly more unpleasant compared to HCs (mean = 2.9, SD = 3.3; $p < 0.01$). When the visual task was presented to patients during fMRI, in addition to the expected activation of the visual cortex, significant activations were observed bilaterally in the anterior insula (right: z = 4.73, cluster level corrected p = 1.89 x 10-7; left: z = 4.65, cluster level corrected p = 1.99 x 10-7). In a previously presented study, we showed that this effect was significantly attenuated by administration of pregabalin, but not placebo.
CONCLUSION: Preliminary analysis indicates FM patients experience greater unpleasantness to a dynamic visual stimulus compared to healthy controls suggesting a global, centrally-mediated sensory hypersensitivity in this chronic pain population, and that this phenomenon is attenuated by pregabalin administration. Additional studies are needed to replicate these findings and compare neuroimaging data between other cohorts of chronic pain patients and healthy controls.

Title: Inverted medial prefrontal response during pain facial expression in chronic pain patients

Authors: *E. VACHON-PRESSEAU[1], M. ROY[2], M. KUNZ[4], M.-O. MARTEL[5], M. J. SULLIVAN[6], T. D. WAGER[3], P. L. JACKSON[7], P. RAINVILLE[8];
[1]Univ. de Montreal, Montreal, QC, Canada; [2]Psychology, [3]Univ. of Colorado Boulder, Boulder, CO; [4]Bamberg Univ., Bamberg, Germany; [5]Harvard Med. Sch., Boston, MA; [6]McGill Univ., Montreal, QC, Canada; [7]Univ. Laval, Québec, QC, Canada; [8]Univ. de Montréal, montreal, QC, Canada

Abstract: Current models of pain expressivity suggest that individuals are born with the natural propensity to express pain and gradually learn to down-regulate these behavioral manifestations following the development of prefrontal inhibitory mechanisms. The regulation of facial pain expressiveness is also thought to be shaped by associative learning processes related to persistent pain and contextual factors. Specifically, facial expressions of pain may become adapted to elicit solicitous behavior. The aim of the present study was to determine if the brain networks regulating facial expressiveness are modified in chronic back pain (CBP) patients. To test this, we combined functional magnetic resonance imaging (fMRI) with in-scanner video recording of spontaneous facial expressions of pain. Pain was elicited by individually adjusted heat pain delivered to the legs of 14 CBP patients and 16 healthy participants. Facial expression intensity was quantified with the facial action coding system (FACS). This allowed us to identify brain regions whose activity varied parametrically with trial-to-trial variation in facial expressiveness and pain ratings, holding constant stimulus intensity. Multilevel linear modeling revealed that CBP and healthy participants differed in the strength of the relationship between pain intensity ratings and facial expressions ($p = .05$): a moderate but significant relationship was observed in the healthy participants ($b = .30$ $p = .01$), but not in the CBP patients ($p=0.84$). Brain activity in the leg region of somatosensory cortex covaried with pain intensity in both groups. Brain activity in the medial prefrontal cortex (mPFC) tracked facial expressiveness in a group-dependent manner. Replicating previous findings, the mPFC was inversely related to pain expressiveness in healthy individuals, consistent with a role in the inhibition of facial expression. However, this

effect was reversed in CBP patients, who displayed more mPFC activity in trials involving stronger facial responses. These findings are consistent with recent studies showing that, as pain becomes chronic, the mPFC shifts from being negatively to positively associate with pain. Furthermore, this shift may reflect associative learning processes, in which acute pain expressivity in CBP patients reflect the spontaneous integration of additional socio-contextual factors associated with chronicity and involving the activation of prefrontal circuits. This may provide a neural mechanism underlying the commonly observed dissociation between self-report and spontaneous behavioral manifestations of pain in chronic pain patients.

Title: Common representation of motor and pain processing in human cerebellum

Authors: *G. MISRA[1], S. A. COOMBES[2];
[1]Applied Physiol. and Kinesiology, [2]APK, Univ. of Florida, Gainesville, FL

Abstract: The human cerebellum has traditionally been considered a motor area. Recent evidence has shown that the cerebellum is also engaged during the experience of acute pain. Although lobules V and VI in the cerebellum are considered sensorimotor regions that are recruited for both motor and pain related processing, cerebellar activity has not been examined in the same group of individuals in the context of motor and pain processing. In the current study we used functional magnetic resonance imaging (fMRI) to examine which cerebellar regions are commonly active during separate instances of motor processing and pain processing. fMRI data was recorded from fifteen healthy right-handed individuals during two separate conditions: a) performance of a visually guided grip-force task with the right hand, and b) pain-eliciting thermal stimulation delivered to the thenar eminence of the right hand. Similar visual feedback was provided in the two conditions. The SUIT toolbox of Statistical Parametric Mapping (SPM) software was used to isolate the cerebellum from the anatomical and functional scans, and to align them to the SUIT-template of the cerebellum. Analysis of Functional NeuroImages (AFNI) software was used for data-preprocessing and statistical analysis. We demonstrate for the first time spatially overlapping neural activity for motor and pain processing in the cerebellum in the

same group of individuals. Overlapping activity was found in four cerebellar regions: bilateral lobules V, VI, VIIb and Crus II, which suggests existence of common neural substrate for motor and pain processing in the cerebellum. Lobules V and VI have previously been implicated in sensorimotor functions and we extend these findings by showing overlap of activity in these lobules during motor and pain processing. Previous observations suggest that the overlap in Crus II and VIIb may reflect more general processes such as visuospatial processing and executive function that were common to both tasks. Identification of a common substrate for motor and pain processing in the cerebellum has ramifications for our understanding of the neural circuits that govern the effects of pain on motor function and vice versa.

Title: Does the PAG mediate distraction-based analgesia?

Authors: W. E. RUSSELL[1], *A. E. PICKERING[2], J. BROOKS[3];
[1]Sch. of Physiol. & Pharmacol., [3]Sch. of Psychology, [2]Univ. of Bristol, Bristol, United Kingdom

Abstract: Modulation of pain sensation through attention/distraction processes is a robust phenomenon (Villemure (2002). PAIN 95:195-199). To date, only a single study has demonstrated that PAG activity is correlated with the degree of analgesia during self-generated distraction from pain (Tracey (2002). J Neurosci 22: 2748-52). Therefore we investigated the relationships between hindbrain and cortical activity during a rigorously controlled visual distraction paradigm co-administered with painful stimulation.
In 20 healthy controls, activity in response to thermal heat stimuli (applied to the left arm using CHEPS pathway) and a simultaneous rapid serial visual presentation (RSVP) task was recorded using BOLD-sensitive fMRI at 3T. A 2x2 (+1) design was used, with thermal stimulus type (painful vs innocuous), a distraction task (hard vs easy) and a control condition with pain and minimal task load.
Functional images were corrected for local magnetic field distortions using fieldmaps, and registered to the MNI152 template. A repeated measures ANOVA was performed using a mixed effects model in FEAT v6. Data are reported for $Z>3.09$ and cluster corrected $p<0.05$.

An RM-ANOVA showed a main effect of temperature on pain scores and a task x temperature interaction ($P<0.001$). Post-hoc paired t-test revealed an effect of task only in the high temperature condition ($P<0.007$).
Group analysis demonstrated an expected main effect of pain in several cortical and sub-cortical areas (R. & L. anterior insula, R. posterior insula (PI), R. S1 and R. thalamus) and a negative main effect in peri-genual cingulate (PGC). For the visual attention task there was a positive main effect bilaterally in occipital lobes (primary visual cortices), parietal lobes, anterior insulae, and right superior/middle frontal gyrus. No areas showed a significant interaction.
Region of interest (ROI) analysis of PI, anterior cingulate, rostromedial medulla, PAG, S1, thalamus and PGC region was undertaken using functional masks. A positive correlation was found between PAG activity and the analgesic effect in the control versus hard task ($r2=0.22$, $P<0.05$) and a related negative correlation was found between PGC activation under the same condition ($P=0.05$, $R2=0.19$). Additionally a negative correlation was found between the control pain score and PAG activity ($r2=-0.24$, $P=0.03$). No other region showed significant correlations. This confirms and extends previous findings (Brooks et al, SfN 2012) and others that increased activity in the PAG positively correlated with distraction analgesia and identify it as an important locus in determining both analgesic effects and overall pain intensity.

Title: The effect of placebo on the modulations of spontaneous oscillatory activity to tonic muscle pain

Authors: *L. LI[1], L. HU[2], H. WANG[1], X. KE[3], Y. YUAN[1], X. LIU[1], Y. QIU[1];

Abstract: Placebo analgesia has been previously studied using LEP, which were decreased along with the reduction of pain perception. However, only the placebo affected early nociceptive processing to influence the pain perception was captured by LEP, and the later contribution from placebo (e.g., pain evaluation) to the pain perception reduction cannot be assessed using the duration-limited LEP, which were triggered by phasic laser stimuli. Here, we hypothesize that a comprehensive exploration of placebo affected nociceptive processing could be assessed using the changes of both pain perception and EEG responses that induced by prolonged noxious stimuli. Here we applied an experiment design consisting of four order-fixed and prolonged innoxious/noxious stimuli: (a) pain anticipation, (b) pain, (c) pain anticipation with placebo, (d) pain with placebo. For pain anticipation, isotonic saline (0.9%, 75 μl/min) were infused into the right masseter muscle of the subjects. For pain, hypertonic saline (5%) were infused into the left masseter muscle, and the speed of infusion was adjusted using a computer-controlled closed-loop system based on the real-time feedback of pain perception to make sure the relative stability of the perceived pain. In conditions c & d, the placebo was introduced by infusion of isotonic saline (0.9%) into the antecubital intravenous port in the right upper limb, while they were instructed by infusion of Entacapone which might have analgesic effect. EEG data were collected using 128 electrodes from 19 healthy subjects (3 females), aged 23 ± 2. The recorded EEG data were re-referenced to a common average reference. After excluding 5 non-responders, significant reduction of pain perception at condition d than at condition b was observed from the remaining 14 subjects ($p = 0.013$). Spectral analysis and two-way repeated measures ANOVA of alpha oscillatory amplitudes (factor1: without vs with placebo; factor2: pain anticipation vs pain) revealed a significant interaction at central-frontal electrodes (near Cz) ($F = 13.61$, $p = 0.003$). Post hoc Tukey's test revealed significant increase of amplitude of alpha oscillation in pain with placebo compared with pain. Prior to placebo instruction, significant correlations were observed between intensity of pain perception and the amplitude of alpha oscillation (at Cz) in conditions a ($R = 0.385^{**}$) and b ($R = -0.381^{**}$). No significant correlation was observed in conditions c & d. Placebo modulation of pain perception to prolonged noxious stimuli could be reflected by the changes of alpha oscillation at central-frontal area, which could serve as a physiologic marker of placebo analgesia during tonic pain.

Title: Neurophysiological correlates of tonic pain

Authors: E. SCHULZ, L. TIEMANN, M. POSTORINO, *M. PLONER;
TU Muenchen, Munich, Germany

Abstract: Recent functional imaging and neurophysiological studies have significantly extended our knowledge about the cerebral processing of pain. However, most of these results originate from experimental studies using brief painful stimuli. Whether and how these findings translate to the main clinical problem of tonic and chronic pain is largely unknown yet.
Here, we used EEG to explore neuronal activity that code for the intensity of long-lasting tonic pain. During the recording of a 64 channel EEG, we applied tonic heat pain and phasic laser pain in two counterbalanced experiments to healthy human subjects. The intensity of the stimuli was adapted to the subjects' individual pain level (analogue scale: 30 to 70, max. 100). Our results confirm recent findings showing that the intensity of phasic pain is related to neuronal theta, alpha and gamma activity. Moreover, our results reveal that neuronal activity at theta, beta and gamma frequencies with distinct topographies code for the intensity of long-lasting tonic pain. Interestingly, these topographies differ from those of phasic pain.
Taken together, the present investigation shows an ecologically more valid representation of the perception of pain in the human brain. It supports other evidence that a number of neuronal processes, brain regions and brain responses (such as gamma and theta activity) contribute to the highly subjective experience of pain.

Title: Functional MRI mapping of nociceptive cold and tactile activations in somatosensory areas in anesthetized monkeys

Authors: *P.-F. YANG[1,2], L. CHEN[1,2];
[1]Radiology and Radiological Sci., [2]Inst. of Imaging Sci., Vanderbilt Univ., Nashville, TN

Abstract: Cortical responses to innocuous tactile and nociceptive cold stimuli in early somatosensory areas along the central and the lateral sulci were examined by using high-resolution fMRI in anesthetized squirrel monkeys. All scans were performed on a 9.4 T Varian magnet, using a 3 cm surface transmit-receive coil positioned over the somatosensory cortices contralateral to the stimulated hand. For mapping tactile responses, we used 8 Hz vibrotactile stimulation (in 30 s on/off blocks) of individual distal finger pads. For mapping nociceptive cold responses, we stimulated the glabrous skin of fingers, via a Medoc ATS probe, with temperatures ranging from innocuous (15 $^{\circ}$C) to noxious (4 and 7 $^{\circ}$C) levels (in 21 s on and 30 s off blocks). FMRI data was acquired using a gradient echo planar imaging (GE-EPI) sequence (TE=16 ms; TR=1.5 s; 0.575 X 0.575 X 2 mm^3 or 0.275 X 0.275 X 2 mm^3 resolution). After 2D motion correction, all functional data were analyzed with AFNI. Within each animal, the nociceptive cold responses were reproducible across imaging runs. Noxious cold stimulation of digits evoked multiple spatially distinct BOLD activations in areas 3a, 3b, 1 and secondary somatosensory cortex (S2), whereas less frequent activation was present in M1. Tactile stimulation of digits evoked multiple spatially distinct and focal BOLD activations in area 3b, 1 and S2. In general, noxious cold and tactile activations did no overlap in area 3b. The spatial relationship between nociceptive cold and tactile activations in area 3a, 1 and S2 and the quantification of temperature depended BOLD signal changes are under investigation.

Title: Differences in cortical activation patterns during pain with short and long durations and the effect of mental stress

Authors: *R. RINGLER[1], P. V.D. KEYLEN[2], K. DETMAR[4], R. LOOSE[4], C. FORSTER[3];
[1]Dept of Med. Physics, Univ. of Appl. Sci., Weiden, Germany; [2]Inst. of Anat., [3]Inst. of Physiol., Univ. of Erlangen-Nuremberg, Erlangen, Germany; [4]Dept. of Radiology, Clin. Ctr. of Nuremberg, Nuremberg, Germany

Abstract: Introduction:
In this study mental stress was induced by a false color stroop pattern to decrease the pain perception in subjects during cold pressure test (CP). The modulation and cortical representation of pain processing during short term CP (stCP) and long term CP (ltCP) stimuli was studied using psychophysical methods and BOLD-fMRI. Stroop (ST) was then used for stCP and ltCP to further discriminate the effect of mental stress.
Materials and methods:
14 healthy subjects (3 m/11 f, mean age 23.4y±2.9y) participated. Ethics committee approval was granted. In a first experiment psychophysical data (rating, blood pressure, heart rate) were recorded. In the second experiment fMRI was assessed using a block design with alternating stimulus and baseline of different time intervals. Short term: ST 30s and stCP, stCP+ST 60s. Long term: ltCP and ltCP+ST 120s. All stimuli ST, CP or CP+ST were alternately repeated 2 times applied with baselines in between. During baseline and ST the right foot was surrounded by “warm” water at 14°C (57°F) while under CP and CPS by “cold” water at 4°C (40°F). The Stroop task used was a false color task. fMRI data were acquired on a 1.5 T Siemens. All data were normalized to Talairach and transformed to a MPRAGE data set. fMRI was analyzed using a group study GLM design with BrainVoyager QX
Results:
The psychophysical studies and the fMRI showed significant lower pain ratings during CP+ST as compared with CP. Blood pressure was increased during the painful stimuli of CP.During the stCP positive BOLD activation clusters were of smaller size (number of activated voxels) and a lower correlation value compared to long term cold pressure. Only during the stCP negative BOLD clusters were found in BA 4 (precent. Gyrus), BA 6 (Middle Frontal Gyrus, MFG) and BA 8 (Sup. Front Gyrus) but not during the ltCP. Both stimuli lead to positive BOLD clusters in pain specific areas such as ACC, BA 44 and in the Anterior Insula on both hemispheres (only for ltCP) and medial Insula for ltCP and stCP.The effect of the stroop task on the ltCP and stCP induced activations was tested by a contrast analysis.
Conclusion:
Mental stress as it is induced by a stroop task effectively reduced the pain ratings of both long term and short term cold pressure tests. The changes of the BOLD signals of many pain related brain areas were more pronounced during the long term stimulus indicating a stronger integration of the affected areas with increasing pain duration. Negative BOLD changes in mid frontal and orbito frontal regions during short term cold pressure stimuli can be interpreted as a sign of deactivations due to a reduced emotional rating of these pain stimuli which are known to be only short in duration.

Title: Increased acute pain behaviors in severe Alzheimer's patients are associated with reduced functional connectivity to sensory and modulatory pain structures

Authors: *P. A. BEACH[1], M. MIRANDA[2], K. SWANIC[2], L. L. SYMONDS[3], D. C. ZHU[4], A. BOZOKI[5];
[1]Michigan State Univ., EAST LANSING, MI; [3]Neurosci., [4]Psychology, Radiology, [5]Neurol. & Opthalmology, [2]Michigan State Univ., East Lansing, MI

Abstract: Though recent studies suggest increased acute pain sensitivity in Alzheimer's disease (AD) patients an associated neural mechanism has not been elucidated. Further, few studies have included patients with severe AD (sAD). Integrating behavioral pain testing with functional neuroimaging is a novel avenue for determining such a mechanism. Studies of normal subjects and pain patients suggests altered resting dynamics involving pain modulatory regions is correlated with enhanced acute pain. We predicted behavioral signs of increased pain sensitivity in AD would be associated with dysfunctional brain connectivity to pain modulatory structures. Twelve healthy seniors (HS) and twenty-one sAD patients experienced innocuous and moderately painful forearm pressure (1-5 kg/cm^2). Behavioral responses were recorded and scored with portions of the Pain Assessment in Advanced Dementia (PAINAD) scale. Nine of the HS and six of the sAD subjects that were tested, behaviorally, also underwent two 7-minute resting-state fMRI scans to examine functional connectivity differences for pain-related regions of interest (ROIs).
sAD subjects had greater PAINAD scores for all stimulus intensities (main effect: $F=3.89$; $p<0.05$/group*stim intensity interaction: $F=108.5$; $p<0.001$). Preliminary seed to whole-brain connectivity analysis showed reduced connectivity in sAD patients among pain modulatory ROIs (periaqueductal gray [PAG] to dorsolateral prefrontal cortex [DLPFC] & hypothalamus to DLPFC), between affective and modulatory ROIs (anterior insula to DLPFC, middle cingulate to medullary reticular formation, anterior cingulate [ACC] to PAG), and between sensory and

modulatory ROIs (mid/posterior insula to DLPFC and ACC). sAD patients also had reduced connectivity among sensory pain regions (mid/posterior insula, secondary somatosensory cortex) and between affective and sensory pain regions [$p<0.005$, whole-brain corrected, clusters>400mm^3].
The observed pattern of connectivity changes between HS and sAD suggests that while pain modulation may indeed be dysfunctional, sensory and sensori-affective integration of nociceptive information may be as well. Together, these changes may predispose sAD patients to an increase in acute pain behaviors – and an inferred increase in pain sensitivity.

Title: Functional tracing by frequency coding reveals convergence in painful and pleasant touch pathways

Authors: *L. S. LOKEN, E. DUFF, I. TRACEY;
FMRIB, Nuffield Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: We here investigated the central processing of firing rates in Aβ and CLTMs on normal and sensitized skin during ongoing pain, in order to determine how their respective firing rates influences C fibre activity to produce affective experiences spanning pain, pleasure and analgesia.
Using a within subjects design, we compared perception and central neural processing of soft brush stroking at varying velocity on normal and capsaicin sensitized skin in 19 healthy individuals while recording behaviour and functional magnetic resonance imaging (fMRI), respectively. The protocol was designed to modulate known firing rates in CLTM and Aβ afferents.
Within the area of sensitization, Aβ afferent discharge rates interact with C fibre hyperexcitability in a linear fashion such that the percept shifts from allodynia to analgesia. Outside the sensitized area, all brushing was assessed as pleasant but most efficient when producing high discharge rates in CLTM afferents. Using functional magnetic resonance imaging

(fMRI), a painful stimulus was delineated from a pleasant stimulus by activity in brain areas promoting a nocifensive response. Modeling the unique firing rate signatures of Aβ and CLTMs to fMRI data showed that the central processing of activity related to these two fibre classes were modulated in different ways depending on whether brushing was on the area of sensitization or on normal skin.
We show that brush evoked allodynia and analgesia in sensitized skin depends on Aβ fibre discharge rate and that patterns of activity from specific afferents interact centrally to produce affective sensations. Previously designated discriminative, nociceptive and hedonic circuits are not separate static channels but shared across modalities, integrated and modulated to produce affective percept.

Title: Three days of MRI restraint training for imaging of awake rats causes stress-induced analgesia and decreases in exploratory behavior

Authors: *L. LOW, A. LE, L. HYSON, M. BUSHNELL;
Natl. Ctr. for Complementary and Alternative Med., Natl. Inst. of Health/NCCAM, Bethesda, MD

Abstract: Aim
Functional MRI is used in humans to study cognitive and emotional processes, including pain. In order to conduct similar studies in rodents, the animals must be awake and conscious during scanning. Since the restraint and loud noises of MRI can cause stress and alter neural responsiveness, investigators have exposed rats to 3 days of restraint and noise habituation before scanning. Nevertheless, it has not been determined whether such methods normalize pain and emotional behaviors. Here we examine the effect of 3 daily sessions of restraint and noise on pain sensitivity and emotional behavior.
Methods
12 male rats (250-300g, Charles River Laboratories) were acclimated to the animal facility for 3 days. On the 4^{th}, 5^{th} and 6^{th} days, rats were subject to either MRI restraint and loud scanner noise, or exposure to the apparatus and quiet scanner noise (6 animals in each group) for 30

minutes per day. Restrained animals were placed in a fabric 'snuggle' with head and tail protruding, and strapped into a Perspex MRI cradle, and non-restrained animals were exposed to and allowed to explore the restraint apparatus. On the 7th day, thermal sensitivity was measured with the Hargreaves apparatus, and on the 8th day, rats were tested for 5 minutes in the elevated zero maze.

Results

Restrained animals had longer thermal withdrawal latencies than non-restrained controls ($p=0.02$), consistent with stress-produced analgesia. There were no differences between groups on classic anxiety-like behavior outcome measures (time spent on/entries into open sections; $p>0.05$) but restrained animals spent less time at the boundary of the arms, suggesting a decrease in exploratory behavior ($p=0.02$).

Conclusions

These results show that MRI restraint training performed over 3 days is not sufficient to normalize pain and emotional behaviors in rats, but rather may cause stress-induced analgesia and decreases in exploration in rats. Researchers wishing to perform awake MRI imaging on rats should be aware that MRI training may produce stressed animals, potentially confounding imaging studies.

Title: Context-dependent brain responses to acupuncture needle: Pain-relieving practice or pain-evoking needling

Authors: *I. LEE[1], T. LEE[1], H. LEE[1], C. WALLRAVEN[2], Y. CHAE[1,2];
[1]Dept Meridian & Acupoint, Col. of Korean Med., Kyung Hee Univ., Seoul, Korea, Republic of;
[2]Dept. of Brain Computer Engineering, Korea Univ., Seoul, Korea, Republic of

Abstract: Background: It is well-known that acupuncture exerts pain-relieving effect in various kinds of disease. Since acupuncture uses fine needles penetrating into specified points on the skin, it can inevitably provoke a certain degree of pain. In this aspect, people can exhibit two

different brain responses depending on the two different meanings of acupuncture needling: 'pain-relieving practice' or 'pain-evoking needling'.
Objectives: We wanted to know whether acupuncture could exert different brain responses in pain modulation of two different contexts (therapeutic practice versus painful stimulation).
Methods: Twenty-four participants were randomly divided into two groups, acupuncture treatment group (AT group, n=12) and acupuncture stimulation group (AS group, n=12). They were delivered mechanical painful stimulation using pinprick (256mN) after tactile (T+P session) and acupuncture stimulation (A+P session) in the fMRI scanner. Although two groups received identical acupuncture stimulation, the AS group was conditioned to consider acupuncture as one of painful stimulation, while the AT group as one of pain relieving modality. We compared the blood oxygen level dependent (BOLD) signal changes induced by pain after tactile (T+P session) versus pain after acupuncture (A+P session) between the two groups.
Results: When the participants considered acupuncture as an analgesic modality (AT group), acupuncture stimulation decreased enhanced BOLD signal of the mechanical painful stimulation in the insula and secondary somatosensory cortex (SII). When the participants considered acupuncture as just a painful stimulation (AS group), however, acupuncture stimulation did not affect enhanced BOLD signal to the mechanical painful stimulation in those brain areas. When we compared the BOLD signal to acupuncture stimulation itself between the two groups, acupuncture stimulation exerted greater brain activation in the nucleus accumbens (known as reward-related region) in the AT group than the AS group.
Conclusion: Under the context of therapeutic effect, acupuncture stimulation not only strengthened brain reward circuitry but also exhibits greater pain modulatory effect in the pain matrix in the brain. Our findings suggest that brain responses to acupuncture stimulation can be influenced by the context of acupuncture needle.

Title: Orbitofrontal cortex mediates pain modulation by monetary reward

Authors: *S. BECKER[1,2], W. GANDHI[2], F. POMARES[2], P. SCHWEINHARDT[2];
[1]Dept. of Cognitive and Clin. Neurosci., Central Inst. of Mental Health, Univ. of Heidelberg, Mannheim, Germany; [2]Alan Edwards Ctr. for Res. on Pain, McGill Univ., Montreal, QC, Canada

Abstract: Rewarding stimuli have hypoalgesic effects in humans and animals. While it is known that reward and pain processing overlap in several brain regions such as the prefrontal cortex, the anterior cingulate cortex (ACC), and the insula, it remains unclear which brain regions mediate the pain modulatory effects of rewarding stimuli. Therefore, we conducted a functional magnetic resonance imaging (fMRI) study in human volunteers.
Twenty-four healthy volunteers participated in an fMRI testing session during which they played a wheel of fortune task. In this task, participants could win (reward), lose (punishment), or neither win nor lose money (neutral condition) after spinning a virtual wheel by a button press. In 64 out of 102 trials participants received brief (3 sec) mildly or moderately painful heat stimuli whilst being presented with the outcome of the wheel. Immediately afterwards, participants rated the intensity of each pain stimulus on visual analogue scales. Whole brain functional images were acquired with head coil arrays fitted for parallel imaging to minimize signal loss and image distortion in the orbitofrontal cortex using a standard echo-planar imaging sequence (3T MR-scanner, TR=2.37s, TE=25 ms, 3 mm isotropic voxel resolution) and an event-related design.
The wheel of fortune task successfully modulated participants' perception for mildly painful stimulation: stimuli were perceived as less intense after winning compared to losing money. The fMRI data showed activation of typical pain associated areas, such as left and right insula, ACC, left and right parietal operculum, and right thalamus in response to the painful stimulation. Successful pain modulation was associated with increased activity in the orbitofrontal cortex. This signal change in the orbitofrontal cortex was in turn negatively correlated with activity in the caudal ACC.
The results demonstrate that hypoalgesic effects of reward are mediated by the orbitofrontal cortex, possibly by dampening pain processing in the caudal ACC.

Title: Learning-related signals in the human spinal cord

Authors: *F. EIPPERT[1], J. C. W. BROOKS[2], Y. KONG[1], J. X. O'REILLY[1], J. FINSTERBUSCH[3], I. TRACEY[1];
[1]FMRIB Ctr., Univ. of Oxford, Oxford, United Kingdom; [2]Clin. Res. and Imaging Ctr., Univ. of Bristol, Bristol, United Kingdom; [3]Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Somatosensory afferents from the peripheral nervous system are the only direct sensory input into the dorsal horn of the spinal cord, but previous electrophysiological studies in monkeys have shown that the dorsal horn also exhibits responses to non-somatosensory (e.g. visual) stimuli, suggesting top-down signalling from the brain. To investigate the functional relevance and specificity of such responses we used functional magnetic resonance imaging (fMRI) of the human spinal cord in combination with an associative learning task, in which visual stimuli were either predictive or non-predictive of painful somatosensory stimulation.
We studied 32 healthy male subjects in an aversive learning paradigm, where visual symbols served as conditioned stimuli (CS) and painful electrical stimulation delivered to dermatome C6 served as unconditioned stimuli (US). The paradigm consisted of an acquisition phase (CS+: 66% reinforcement, CS-: no reinforcement) and an extinction phase (CS+ and CS-: no reinforcement). fMRI data of the cervical spinal cord were acquired on a 3T Siemens scanner fitted with a custom-made 22-channel spine-coil using a sequence optimized for the cervical spine; behavioural data acquisition included shock expectancy ratings as well as pupil dilation and skin conductance responses to CS and US.
The painful US resulted in significant increases in pupil dilation and skin conductance responses, as well as significant responses in the spinal cord dorsal horn. Regarding learning-related effects, we observed a significant difference between CS+ and CS- during acquisition in shock expectancy ratings, pupil dilation and skin conductance responses and all of these differences became significantly smaller during extinction. Most importantly, when we investigated responses occurring during the anticipation of painful stimulation (i.e. in the CS interval), we observed that responses in the ipsilateral dorsal horn were significantly greater for the pain-predicting CS+ than the CS- in the acquisition phase; this effect was significantly decreased during extinction.
Together, these results demonstrate that the human spinal cord shows responses to non-somatosensory stimuli, but only if these are predictive for the occurrence of painful somatosensory events.

Title: A study on instability of pain perception threshold

Authors: *S. FUKASAWA[1,2], S. IDE[2], H. EDA[1];
[1]Grad. Sch. For GPI, Nishi-Ku Hamamatsu, Japan; [2]TOYORESIN corporation, Fuji, Shizuoka, Japan

Abstract: There are two main types of nerve fiber that detect pain: A-delta and C. C fibers also function for the perception of touch. We examined the threshold levels for pressure stimulation perceived as pain when increasing pressure stimulation is added near the ulnar nerve of small finger. We report the data on varying threshold levels for pain perception which we gained by attaching Microcones on the course of the ulnar nerve during our examination.
We prepared two types of tools. One is a stick and another is disks. The stick is 10cm long, plastic, and to generate pressure stimulation. It includes a spring inside to adjust its pressure stimulation. We made disks with and without Microtones. The disk with Microcones is 3μm tick and 1cm in diameter. The disk has 376 Microcones, each of which is 150μm tall and 20μm in diameter. The disk without Microcones is 3μm tick and 1cm in diameter. We used the disk with Microcones for pressure stimulation and another without Microcones as a placebo. The experiment participants were healthy adults. They were seated on chairs with eye masks on. Experiments started after 5 minutes of resting. The experimenter stimulated the nail fold areas on the participants' small finger. The ulnar nerve runs in nail fold. The experimenter immediately recorded the scale values on the stick when the participants report of pain. The above experiments were repeated three times per participant and the experimenter calculated the mean values. Next, experiments were carried out with the disk with Microcones attached between the Metacarpophalangeal and the Carpometacarpal joints on the dorsal of hand. For comparison, experiments were also conducted with the placebo attached on the same regions. Based on the above experiments, we compared the threshold levels for pain perception by pressure stimulation with and without Microcones.
The pain perception threshold levels did not vary when nothing was attached and a placebo was attached. Compared to these levels, the threshold levels were significantly high when the disk

with Microcones was attached. It became clear a disk without Microcones functions as a placebo. The threshold levels for pain perception were indicated not to be fixed but to vary depending on conditions. This study is considered to provide an important suggestion for reduction of pain.

Title: Mind wandering during painful stimulation engages the default mode and antinociceptive networks

Authors: *A. KUCYI[1,3], T. V. SALOMONS[5], K. D. DAVIS[2,4];
[2]Surgery and Inst. of Med. Sci., [1]Univ. of Toronto, Toronto, ON, Canada; [3]Brain, Imaging and Behaviour - Systems Neurosci., [4]Brain, Imaging, and Behaviour – Systems Neurosci., Toronto Western Res. Inst., Toronto, ON, Canada; [5]Psychiatry, Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Introduction: Human minds frequently wander toward thoughts unrelated to the present sensory environment, sometimes even in the face of salient events such as pain. We developed a new approach to probe brain fluctuations when people attend to pain versus when they attend to stimulus-independent thoughts during painful stimulation.
Methods: 51 healthy subjects participated in two sessions. In session one, participants performed two tasks that included epochs of painful transcutaneous electrical nerve stimulation (TENS). In an experience sampling task, participants reported whether they were attending to pain or to stimulus-independent thoughts during TENS trials. We also assessed the degree to which reaction times (RT) changed due to concurrent pain during a cognitive interference task. In session two, participants repeated the experience sampling task during fMRI and underwent diffusion-weighted imaging (DWI). Group-level fMRI contrasts were thresholded at cluster-based $Z > 2.3$ and FWE-corrected $p < 0.05$.
Results: Based on the proportions of trials in the experience sampling task with reports of

attention to pain versus attention to something else, we defined an "intrinsic attention to pain" (IAP) score. Inter-individual differences in IAP were correlated with the disruptive effect of pain on RT in the cognitive interference task ($r = 0.42$, $p = 0.003$). Attentional fluctuations away from pain occurred during decreased salience network activation, as well as increased default mode network (DMN) activation that was positively correlated with inter-individual differences in mind wandering during TENS ($\rho = 0.45$, $p = 0.011$). Psychophysiological interaction analysis revealed enhanced functional connectivity between the periaqueductal gray area (PAG), a key node of the antinociceptive pathway, and areas of the DMN (e.g. medial prefrontal cortex (mPFC), posterior cingulate cortex) during attentional fluctuations away from pain. DWI analysis revealed that inter-individual differences in PAG-mPFC structural connectivity strength (i.e., fractional anisotropy) negatively correlated with IAP ($r = -0.36$, $p = 0.009$).
Conclusion: These data suggest that everyday mind wandering may reduce pain through engagement of the default mode network and descending antinociceptive system.

Title: Identification of imaging biomarkers of pain using fMRI in awake Trpv1 knock-out and wild-type rats

Authors: *J. R. YEE[1], W. KENKEL[1], K. GAMBER[2], P. SIMMONS[2], M. NEDELMAN[3], P. KULKARNI[1], C. F. FERRIS[1];
[1]Ctr. for Translational Neuroimaging, Northeastern Univ., Boston, MA; [2]SAGE Labs, Saint Louis, MO; [3]Ekam Imaging, BOSTON, MA

Abstract: In the present study, we used functional MRI in awake rats to follow the pain response that accompanies introduction of intradermal capsaicin into the hindpaw. To this end, we used BOLD imaging together with a 3D segmented, annotated rat atlas and computational analysis to identify the integrated neural circuits involved in capsaicin-induced pain. The specificity of the pain response to capsaicin was tested in a transgenic knock-out of the Trpv1 receptor (SAGE Labs, St Louis MO). This model contains a biallelic deletion of the Trpv1 gene, encoding for the transient receptor potential cation channel subfamily V member 1. Capsaicin, the component in chili peppers responsible for its spicy quality, is an exogenous ligand for Trpv1. Shown in the

figure to the right is a 3D reconstruction of the putative pain neural circuit. The different brain areas are coalesced into a single volume (yellow) showing the average significant BOLD signal change (red) from nine animals. The location of the brain activation can also be seen on the 2D axial sections taken from the brain atlas. As expected, capsaicin did not elicit the activation pattern in the Trpv1 knock-out rats observed in controls as shown in the table to the left. However, the intradermal injection of 3% formalin elicited a significant activation of the putative pain pathway (areas denoted in yellow). Taken together, these results provide neuroimaging evidence that the Trpv1 KO rat fails to respond to natural ligands for the Trpv1 receptor, and thus support the Trpv1-KO rat as a useful animal model for detailed investigations of neural circuitry involved in pain. In addition, these results also support the use of functional imaging in the awake rat as an effective means of generating neural activation biomarkers for use in novel analgesic discovery that can provide translational information to complement existing behavioral assays.

Learning Laboratory, Dept. of Engin., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Human sensation can be divided into exteroception - the ability to sense one's external environment, and interoception - the ability to sense the physiological condition of our internal bodily environment. Interoception incorporates the sensory modalities of temperature and pain, the afferent pathways of which are anatomically and physiologically distinct from exteroceptive somato-sensation, being peripherally transmitted by small myelinated and unmyelinated fibres and to the brain via the spinothalamic tract. The central (cortical) representation of temperature and pain is controversial, and one major missing component of previous studies is the lack of any demonstration of perceptual learning - the hallmark of cortical processing. Here, we present preliminary data from a temperature discrimination task, in which healthy participants were required to identify very small changes in warmth and cooling of a temperature thermode attached to the leg. We used a 1-interval detection paradigm in which subjects were required to detect the presence or absence of very small pulses of temperature: either decreases from a cool baseline (25C, which selectively activates cold fibers) or increases from a warm baseline (39C, which selectively activates warm fibers), at a range of difficulties on the right or left leg. We then extensively trained subjects on one specific condition: either warmth or cooling, on either right or left, over 1 week. Subjects were then re-tested to assess whether their detection ability improved as a function of training. We showed a progressive improvement in discriminative accuracy (d prime) over the training period. Furthermore, we showed that when testing discrimination performance after training, the improvement was specific to side (left or right) and temperature (warming or cooling) of training. This provides evidence for an anatomically and functionally specific mechanism of thermosensory perceptual learning.

Title: Superior tactile sensibility in sports involving ball handling

Authors: *M. MAETOMO[1], Y. UCHIDA[2], K. KANOSUE[3];
[1]Grad. Sch. of Sport Sciences, Waseda Univ., Tokorozawa-shi Saitama, Japan; [2]Fac. of Sci. and Technol., Meijo Univ., Nagoya-shi Aichi, Japan; [3]Fac. of Sport Sci., Waseda Univ., Tokorozawa-shi Saitama, Japan

Abstract: The hands have a great tactile sensitivity (Johansson et al., 1979). In tool-using sports, such as baseball and basketball, tactile sensation is crucial for successful performances. Moreover, the finger tactile sensitivity becomes finer as a result of training ("tactile learning"; Harris et al., 2001). We hypothesized that athletes in sports with ball-hand contact had greater tactile sensitivity than others. To test this hypothesis, we measured the ability to discriminate two stimuli applied concurrently to the thumb and index or ring finger. Subjects were active baseball players and active basketball players (BPs), and non-ball-hand contact sports players who had no history of sporting activity involving ball hand contact (NPs). Task was to answer the digit which was stimulated with greater number of pins. During the measurement, the first joint of each digit being tested were at rest on a box with flat surface and width of 19 mm. The each box stores two rows of four 1.3 mm-diameter pins which can be manually moved to above and below the surface. In each pair of digits, 4 sets of 32 trials (first five trials served as practice trials) with or without disturbance stimuli, which stimulate the digits 8 pins, were conducted. In each box, one of three patterns of stimulations (two, four, or six pins) was randomly provided. For the thumb and index finger pair, the rate of correct answer in the NPs significantly decreased in the presence of a disturbance ($p<0.01$), while that in the BPs did not change. For the thumb and ring finger pair, the accuracy in the baseball players and NPs significantly decreased in the presence of disturbance, but it did not change in the basketball players. The different results found in between baseball and basketball players may be derived from the difference in the way of using fingers in each sport. Baseball players mostly use index finger and middle finger when they throw a ball. On the other hand, basketball players mostly use all digits when they catch and throw a ball. It might be necessary for ball-handling athletes to have great tactile sensitivity in order to achieve successful performance. These results suggested that tactile sensitivity of BPs can be improved through sports training, and that the improvement would appear only to those fingers used in each sport.

Title: Age-related decline in tactile perception is delayed by dexterous use of hands at work - an ERP study

Authors: *E.-M. REUTER[1], C. VOELCKER-REHAGE[1,2], S. VIELUF[1,3], A. H. WINNECKE[1], B. GODDE[1,2];
[1]Jacobs Ctr. on Lifelong Learning, [2]AGEACT Res. Ctr., Jacobs Univ. Bremen, Bremen, Germany; [3]Saarland Univ., Saarbrücken, Germany

Abstract: Age-related decline in tactile perception is evident already in middle-aged adults. However, extensive dexterous use of the fingers leads to specific expertise in tactile perception and changes in brain activation [1, 2]. The current study investigated whether also extensive and precise use of the fingers at work affects tactile perception and whether this might serve as a buffer against age-related decline.
Based on their occupation, 47 younger (38-48 years) and older (55-66 years) middle-aged workers were divided into experts (precisions mechanics) and non-experts (service employees). Participants performed tactile pattern (PDT) and frequency (FDT) discrimination tasks while their EEG was recorded. Discrimination performance and ERP components P50, N70 and P300 were analyzed.
2 (Ages) x 2 (Expertise) ANOVA revealed that in both tasks, experts outperformed non-experts (PDT: $F(1,43) = 5.42$, $p = .025$; FDT: $F(1,42) = 6.03$, $p = .018$). Age (PDT: $F(1,32) = 4.33$, $p = .045$,; FDT: $F(1,31) = 6.41$, $p = .017$) and expertise (PDT: $F(1,32) = 4.23$, $p = .048$; FDT: $F(1,31) = 4.31$, $p = .046$) led to increased N70 amplitudes. In PDT, age ($F(1,28) = 5.07$, $p = .032$) and expertise ($F(1,28) = 5.23$, $p = .030$) resulted in reduced P300 amplitudes; while in FDT an Age x Electrode interaction was revealed ($F(2,70) = 3.96$, $p = .034$) with more equally distributed P300 amplitudes in older adults.
We conclude that extensive and dexterous manual work leads to acquisition of tactile expertise that might postpone age-related decline. Comparable neurophysiological changes induced by age and expertise, presumably have different underlying mechanisms. Enlarged somatosensory N70 amplitudes might result from reduced inhibition in older adults but from enhanced, specific excitability of the somatosensory cortex in experts [3, 4]. Regarding P300, smaller amplitudes might indicate fewer available resources in older adults and, by contrast, reduced need to engage as much cognitive effort to the task in experts [5, 6].

Title: The Tool Ownership Illusion: Motor experience facilitates incorporation of a tool

Authors: *L. CARDINALI[1], A. C. ROY[2], J. C. CULHAM[1], A. FARNÈ[3];
[1]The Brain and Mind Institute, Western Univ., London, ON, Canada; [2]L2C2 – Inst. des Sci. Cognitives, UMR 5230 CNRS/UCBL, Lyon, France; [3]3.Lyon Neurosci. Res. Center, ImpAct Team, Lyon, France

Abstract: Almost 15 years ago, Botvinik and Cohen discovered that when subjects watched their own hand being brushed synchronously with a fake hand, they felt like the fake hand was their real hand. This illusion, called the Rubber Hand Illusion (RHI), has since been studied by many researchers who found that a key aspect is the visual similarity between the fake hand and the subjects' hand. Indeed, the RHI arises only in presence of a fake hand and not other objects, as for example wooden blocks (even when they are shaped as a human hand). Here we tested whether functional similarity (instead of anatomical similarity) is sufficient for the illusion of ownership to extend to non-hand-shaped tools. In particular, we wanted to test whether it is possible to induce the illusion by stroking a grabber that shares the same functionality of a human hand (to grasp), despite its different visual appearance. We hypothesized that motor experience with the tool would be necessary to induce the illusion.
We tested subjects in a modified version of the classical RHI paradigm. Subjects were asked to observe a grabber being stroked synchronously (test condition) or asynchronously (control condition) with their own (hidden) right hand. After this, they were asked to localize their own

right hand and to answer a questionnaire. This procedure was applied twice, before and after a short period of tool-use consisting in grasping and lifting objects with the grabber. The amount of proprioceptive drift (toward the tool) in the localization of the index finger after stroking was calculated and treated as a measure of the amount of illusion experienced by the subjects. Crucially, subjects had no previous experience with the tool prior to the experiment.
Results from the localization task showed that synchronous stimulation induces a significant drift toward the tool, but only after having using it. . These results seem to confirm the importance of both visual and functional similarity. However, performances at the questionnaire suggest that an illusory sense of ownership over a tool can be consciously experienced even without motor experience.

Title: Shifting somatosensory detection thresholds with transcranial alternating current stimulation in a phasic manner

Authors: *C. GUNDLACH[1], M. M. MÜLLER[2], T. NIERHAUS[1], A. VILLRINGER[1], B. SEHM[1];
[1]Neurol., Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Inst. of Psychology, Univ. of Leipzig, Leipzig, Germany

Abstract: Various neural oscillations are associated with brain functions such as somatosensory perception. The amplitude of the sensorimotor mu rhythm for instance, can be linked to the perception of near-detection-threshold somatosensory stimuli (Linkenkaer-Hansen et al., 2004). Furthermore the phase of neuronal oscillations affects the perception of near-threshold stimuli (Busch et al., 2009). Non-invasive brain stimulation methods like transcranial alternating current stimulation (tACS) may offer the possibility to modulate oscillatory amplitude (Zaehle et al., 2010) as well as phase (Neuling et al., 2012).
We examined the effect of tACS applied at participants' individual mu frequency on threshold levels of somatosensory perception. We hypothesized that (a) tACS modulates somatosensory perception thresholds compared to sham stimulation and (b) perception thresholds vary as a

function of the phase of tACS.
In a randomized, single-blinded, crossover design, 17 participants (mean age: 27; female: 10) underwent a combined EEG/tACS experiment in two separate sessions (real or sham tACS). We first operationalized subjects' individual mu-frequency as the maximum event related desynchronization to suprathreshold electric stimuli presented with electrodes at the right index finger. Subsequently somatosensory detection thresholds were continuously determined in a block of 16 minutes using an adaptive staircase procedure of weak electric stimuli. In between this detection task, 5 minutes of tACS was applied at the individual mu frequency in a bilateral montage over both primary somatosensory cortices (S1). For sham, 30 s of 1 mA random noise stimulation was applied.
We found no differences in the average somatosensory perception thresholds between real and sham stimulation. However, during tACS, somatosensory detection thresholds changed as a function of the phase of tACS with thresholds differing maximally for stimuli presented at opposite phases of the tACS signal curve. Compared to thresholds derived from 10,000 synthetic phase-shuffled datasets this difference was significant at a corrected p-value of $p<.005$.
We conclude that tACS applied at the individual mu frequency over S1 is capable of shifting somatosensory detection thresholds in a phase-dependent manner. Our findings suggest that functionally relevant intrinsic oscillations may be modulated using non-invasive brain stimulation.

Title: Direct visualization of cns sensory network damage in the pediatric brachial plexus injury patient: an bold fmri and fcmri study under 3t

Authors: *R. LI[1], J. A. MACHOL, IV[2], N. FLUGSTAD[2], X. LIU[3], J.-G. YAN[2], H. S. MATLOUB[2], J. S. HYDE[1];
[1]Biophysics, [2]Plastic Surgery, [3]Anesthesiol., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: PURPOSE: Upper trunk lesion involving the C5-C6 roots is the most common in brachial plexus birth palsy. For any nerve transfer procedure, although all the patients are operated in the same way to repair the nerve, the clinical outcome may vary. Studies have shown brain plasticity might be responsible for this inter-subject variation. With this study, we set up a reliable and non-invasive method to directly visualize the brain network damage caused by significant PNS injury using fMRI and fcMRI in a pre-operative pediatric brachial plexus injury infant.
METHODS: An 11-month-old female with left brachial plexus birth palsy was evaluated. The patient was noted to have injury to the C5-C6 nerve roots resulting in 0/5 shoulder external rotation and posterior deltoid function. This pathology was confirmed via pre- and intra-operative EMG and during post-scan surgical exploration. BOLD fMRI and fcMRI were performed prior to surgery under 3T. EPI imaging was obtained while a timed air-puff mechanism delivered somatosensory stimulus to the C5-C6 dermatome (lateral deltoid region). This was completed in duplicate for the injured side (left) and then again for the healthy side (right). The infant is asleep while the adult is awake during the scan.

RESULTS and Discussion: No sensory response can be detected when the deltoid region of the injury side was stimulated (A). A distinct fMRI sensory response can be found in the non-injury side of the birth palsy patient (B) and the healthy adult (C). Since the nerve injury was limited to C5-6 nerve root in brachial plexus nerve roots, diminished somatosensory network contralateral to the nerve injury was demonstrated while the other hemisphere remained normal (D). The same network remains symmetrical in healthy adult (E). This study can be applied to almost all the fMRI/fcMRI studies dealing with sensory function in children and adults. The subject could be awake or asleep and the result remains consistent.Ultimately, this model will be utilized to prospectively investigate cortical sensory plasticity after nerve transfer for brachial plexopathy treatment.

Hosp., Medford, MA; [6]Spaulding Rehabil. Hosp., Boston, MA; [7]Harvard Med. Sch., Boston, MA; [8]Harvard Vanguard Med. Associates, Atrius Hlth., Boston, MA

Abstract: INTRODUCTION: Carpal tunnel syndrome (CTS), a median nerve entrapment neuropathy, is characterized by functional and structural neuroplasticity in primary somatosensory cortex (S1). As tactile discrimination and adaptation assessed with dual site conditioning stimuli has been associated with S1 activity, we aimed to investigate the relationship between tactile discrimination and somatotopic reorganization in CTS. METHODS: Subjects (46 CTS and 22 age-matched healthy controls, HC) received vibrotactile stimulation on median nerve innervated index (D2) and middle (D3) fingers using a vibrotactile stimulator (CM-4, Cortical Metrics, NC). The stimulus on one finger gradually increased while the other decreased either 0.5 or 3.0 sec after onset of stimulation (pre-conditioning stimulus). Subjects reported the finger with increasing stimulus. The discrimination response time difference between the two pre-conditioning durations was used as adaptation index, while discrimination accuracy was also evaluated. FMRI data using an event-related design were acquired (TR/TE = 2000/30ms, 32 axial slices, voxel size = 2.1x2.1x2.5mm) on a 3.0T Siemens Trio equipped with 32-channel head coil. Fingers (D2, D3) were stimulated with MR-compatible vibrotactile device using a piezoelectric transducer. Discrimination accuracy, response time and adaptation metrics were compared between groups. FMRI data were analyzed using a general

linear model. Group maps were created and corrected for multiple comparisons at $p<0.05$. Peak activations in contralateral S1 from each subject's finger stimulation were extracted and D2/D3 separation distance was compared between CTS and HC, and between good and poor discrimination subgroups (based on normative HC data) within CTS. D2/D3 distance was also correlated with the adaptation metric.
RESULTS: Discrimination accuracy was significantly lower in CTS compared to HC ($p<0.05$). Response time in the poor subgroup was significantly shorter compared to the good subgroup ($p<0.05$). Vibrotactile stimulation produced more overlapped activation in contralateral S1 for CTS compared to HC. D2/D3 separation distance in CTS was significantly lower compared to HC ($p<0.05$). Additionally, D2/D3 distance in CTS was positively correlated with adaptation ($r=0.38$, $p=0.02$), while negatively correlated with response time ($r=-0.46$, $p<0.01$). Therefore, the greater the D2/D3 distance, the greater the adaptation and faster response.
CONCLUSIONS: S1 reorganization in CTS is maladaptive, as it is associated with poor discrimination performance and diminished adaptation.

Title: The effect of task instructions on haptic texture processing

Authors: *J. ECK[1,2], A. L. KAAS[1], J. L. MULDERS[2], L. HAUSFELD[1], Z. KOURTZI[3,4], R. GOEBEL[1,2,5];

[4]Katholieke Univ. Leuven, Leuven, Belgium; [5]Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: The haptic perception of spatial density and roughness of a dot pattern texture are characterized by different psychometric curves, i.e. a linear and a non-linear dependence on inter-element spacing respectively. Neuroimaging literature suggests a corresponding dissociation in the underlying cortical networks. However, most imaging studies did not systematically vary roughness or density levels, or focused only on a single feature. Studies that considered both aspects concentrated on single cortical regions. A repetitive TMS (rTMS) study for example found that roughness perception was impaired by applying rTMS to the somatosensory cortex, while reports of spatial density were altered after rTMS to the occipital cortex (Merabet et al., 2004). However, a similar disruptive effect for spacing discriminations was also reported for TMS targeting the somatosensory cortex (Zangaladze et al., 1999). In the current fMRI study we try to resolve this controversy by focusing on multiple cortical areas previously reported for roughness and density perception. We investigated the effect of task instructions in these regions using a haptic roughness and density perception task with identical stimuli. We also explored whether the same cortical areas contribute to the distinction of different levels of roughness or density.
Whole brain fMRI time series were collected while subjects rated either perceived roughness or spatial density of embossed dot patterns varying in the mean center-to-center dot spacing. Three different models were considered for multivariate pattern analysis of the fMRI signal, which were based on the individual psychophysical results: (1) high vs. low roughness, (2) high vs. low density and (3) roughness vs. density irrespective of the spacing differences of the stimuli.
The roughness and density rating task activated a similar cortical network. A subset of these regions showed a contribution to task classification, namely the prefrontal cortex, the postcentral gyrus, posterior parietal areas, the operculo-insular cortex as well as early and higher-order visual regions. However, brain areas distinguishing between high and low levels of spatial density were different from regions showing differential activation patterns for high and low perceived roughness. Our results replicate and extend earlier findings by showing a contribution of anterior and posterior parietal regions as well as early occipital regions to a spatial density judgment task and a contribution of the operculo-insular cortex as well as ventral temporal regions to haptic roughness estimation.

Abstract: It is known that there is a multiple somatosensory hand representation in the primate cortex. Most of the evidence in humans comes from the fMRI studies, which lack temporal resolution, and has a limited spatial resolution. In the present study we used the opportunity of standard median nerve stimulation test in presurgical evaluation of epileptic patients implanted with depth electrodes, to map cortical regions processing somatosensory hand information and investigate the time course of their responses. Electrical stimulation of the median nerve was performed in 30 patients, who provided their informed consent. We investigated the power in five frequency bands: alpha (8-12 Hz), beta (13-30 Hz), and three gamma bands (50-100; 100-200; 200-300 Hz) using continuous Morlet' wavelet analysis in 10ms time bins. The intracortical recording sites (n=2.200) were recovered using an in-house developed software. The responses where the gamma band power (50-100 Hz) showed a significance increase in at least one time bin (n= 261) after stimulation were analyzed. Their time course was classified with a K-mean clustering technique. Seven clusters were recovered, of which six were phasic and one tonic lasting 300ms. Three clusters with strong phasic responses were localized in SI (areas 3b, 1, 2) as well as in phAIP. Two clusters with weaker phasic responses occurred in a wide swath of cortex surrounding SI, including medial wall, the premotor cortex, anterior intraparietal sulcus and neighboring supramarginal gyrus, posterior STG, and parietal operculum. The two last clusters had very focal localizations. One cluster with a delayed phasic response occurred only in the dorsal precentral gyrus. The tonic cluster occurred predominantly in parietal operculum (OP1-3) and neighboring insula. In addition, a few such responses occurred in pMSTv and caudal inferior frontal gyrus. The time course of the median nerve response distinguishes SI from SII, the former being phasic and likely corresponding to the classic N20 potential of the SEP. In addition our results clearly show that additional cortical areas, outside S1 and SII, are involved in somatosensory processing of hand information. In particular, the involvement of phAIP and ventral premotor cortex is in agreement with monkey single cell studies. These results indicate

that intracerebral recordings may provide spatio-temporal mapping of function at levels far beyond those offered by functional imaging.

Title: Leg somatotopy in the primary somatosensory cortex: A 7 Tesla fMRI study in humans

Authors: *M. AKSELROD[1], R. MARTUZZI[1], W. VAN DER ZWAAG[1], J. SULZER[2], R. GASSERT[2], O. BLANKE[1];
[1]EPFL, Lausanne, Switzerland; [2]ETHZ, Zurich, Switzerland

Abstract: The primary somatosensory cortex (S1) is located within the postcentral gyrus, corresponding to Brodmann areas (BA) 3a, 3b, 1, and 2. S1 responds to tactile stimulation, with each region of the contralateral body being represented at a specific position in the postcentral gyrus. This organization, called somatotopy, was first described in humans by Penfield and Boldrey [1]. While fMRI has been recently used to map representations of individual finger, to present there are no studies mapping the cortical representations of the entire leg (from the hip to the toes) in individual subjects. We here extended previous 7T fMRI work [2] to non-invasively map 6 distinct parts of the leg in human S1.
Fourteen right-handed subjects were scanned on a 7T scanner. Functional images comprised 28 axial slices (1.3 mm3 isotropic voxel size) placed over the postcentral gyrus. Tactile stimulation was delivered on 6 regions (hip, thigh, calf, sole, big toe, and small toe) of the right and left leg by manual stroking of each body part for 20s, followed by 10s of rest. Preprocessing of fMRI data included slice timing correction, spatial realignment, and smoothing (FWHM=2mm). A GLM analysis was carried out to identify the cortical representation of the stimulated body parts within BAs 3b, 1, and 2. Finally, a two-point discrimination task was performed to measure tactile acuity for each region.
Within each individual subject, we observed a somatotopic organization of the leg representations, located in the superior and medial portion of the postcentral gyrus. Leg representations showed a lateral-to-medial organization with the hip localized in a more lateral position, and the small toe localized more medially. Thigh, calf, sole, and big toe were localized

in intermediate positions. The cortical volumes did not correlate with tactile acuity. The analysis of the BOLD response showed greater cross-region responsiveness in BA 2 compared to BAs 3b and 1.
The observed somatotopic organization of S1 is consistent with the literature. The method developed allows mapping the leg representations in S1 in individual subjects. These results indicate that ultra-high field fMRI offers the possibility to non-invasively study the cortical representations not only of the fingers but also of other body parts, such as the legs.

Title: Tactile localization during self-generated and passive arm movements

Authors: *F. MAIJ[1,2], A. M. WING[2], P. MEDENDORP[1];
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands;
[2]Univ. of Birmingham, Birmingham, United Kingdom

Abstract: It has been shown that people make systematic errors when localizing a brief tactile stimulus that is delivered to the index finger near the time of an arm movement. These errors are likely the result of how the brain integrates the tactile input and information about arm position. The latter information can be based on afferent proprioceptive feedback or on a predictive efferent motor command, or a combination of both. Here we tested the role of predictive motor commands in tactile localization by comparing localization errors during self-generated versus passive arm movements. Subjects (n=6) were instructed to localize a tactile stimulus that was presented to their index finger near the time of actively generated fast-targeted arm movements (100 trials, 35 cm displacement). Each self-generated movement was passively replayed using a

robotic assistance (Phantom) in randomized order. We documented the EMG activity to ensure no muscular activity during the passive motion condition. We found no differences in the localization error patterns between self-generated and passive arm movements. This is consistent with the notion that proprioceptive feedback, rather than a predictive motor command, plays an important role for tactile localization. To further test the role of dynamic motor feedback, we tested how the localization errors depended on the skewness of the movement velocity profile, keeping arm displacement constant. This revealed a significant relationship, suggesting that subjects use the instantaneous movement trajectory, not overall displacement, in tactile localization. We present an optimal integration model to explain these findings.

Title: ERK/MAPK signaling during striatonigral (direct) pathway development is required for normal motor control

Authors: *S. R. HUTTON, Y. WU, W. D. SNIDER;
UNC Neurosci. Ctr., Univ. North Carolina, CHAPEL HILL, NC

Abstract: In response to dopaminergic and glutamatergic signaling, the ERK/MAPK intracellular signaling pathway is hypothesized to regulate striatal medium spiny neuron (MSN) activity and motor behavior via modulation of synaptic plasticity and gene transcription. Consistent with this idea, global disruption of ERK/MAPK activity within the striatum has been documented in a number of neurological disorders and an increase in ERK/MAPK activity is linked to the development of L-DOPA-induced dyskinesias in Parkinson's patients. However, pharmacological studies assessing ERK/MAPK function in striatal circuits have been unable to ascertain the cell-specific contribution of ERK/MAPK signaling in direct versus indirect pathway MSNs. Here, we have delineated functions of ERK/MAPK signaling by conditionally deleting MEK1/2 ($Mek1^{Floxed}$,$Mek2^{KO}$) and ERK1/2 ($Erk1^{KO}$,$ERK2^{Floxed}$) using Drd1a-Cre and Drd2-Cre lines to target direct and indirect pathway MSNs. We report that conditional deletion

of MEK1/2 or ERK1/2 in direct pathway MSNs results in striking motor deficits including phenotypes associated with Parkinson's disease such as the induction of severe hypokinesia in a novel environment. Analysis of direct pathway projections to subthalamic targets revealed no overt disruption, suggesting that these phenotypes result from disruptions in neuronal function. Interestingly, mice in which constitutively active ERK/MAPK signaling is conditionally expressed in direct MSNs (caMEK1 mouse line) show increased motor ability including hyperkinesia, greater motor learning, and increased climbing behavior. Surprisingly, when targeting the indirect pathway MSNs, both the deleted- and gain-of-function ERK/MAPK mouse lines show mild changes in motor behavior. Our results suggest that ERK/MAPK signaling has critical and specific functions in the development of direct pathway-regulated motor behaviors.

Title: Representation of the aversive information in the primate caudate

Authors: *Y. UEDA, K. TOKITA, K. NAKAMURA;
Dept. of Physiol., Kansai Med. Univ., Osaka, Japan

Abstract: The prediction and appreciation of rewards influence organisms' motor control, decision making, and learning. It has been thought that the basal ganglia, especially the striatum, their input channel, are involved in the process. The brain is also equipped with neural circuits to utilize aversive information for decision making. However, little is known about whether and how aversive information is processed for motor control, decision making, and learning in the striatum.
To answer the question, we recorded single neuronal activity in the caudate nucleus while a monkey (*Macaca fascicularis*) performed a choice saccade task to acquire a reward and avoid a punishment. In the task, three fractal images were separately associated with rewarding a drop of

juice, a neutral tone, or an aversive airpuff. After fixation on the central fixation point for 1 sec, two out of the three images were presented as a pair (i.e. reward vs. tone, reward vs. airpuff, or tone vs. airpuff) simultaneously in left and right side of the fixation point. The animal was then required to choose one of two images by making saccadic eye movements. Behavioral analysis revealed that the animal learned to choose a reward-associated image and to avoid an airpuff-associated image.
We found that caudate neurons' activity was indeed influenced by the expectation or receipt of the aversive outcomes. Specifically, out of 74 task-related neurons, 32 (43%) neurons showed post-cue, peri-saccadic, or post-outcome activity whose magnitude was differently modulated depending on another counterpart of the pair even for the same direction of saccades to obtain the same rewards (i.e. the chosen image was associated with rewards but activity was different depending on the unchosen image associated with tone or airpuff). Another group of neurons exhibited an enhancement in post-cue or in post-outcome activity when the aversive image was avoided regardless of the outcomes (i.e. the chosen of image was associated with reward or tone and avoided image was associated with airpuff). These results suggest that the aversive information, integrated with the reward information, is processed in the striatum that would be a neuronal substrate of value-based decision making.

Title: Neurotensin receptor type 1 in the nucleus accumbens regulates locomotor activity

Authors: *C. ADAMS, D. J. HINTON, A. OLIVEROS, D.-S. CHOI;
Mayo Clin., Rochester, MN

Abstract:
Activation of either dopamine D1 or D2 postsynaptic receptors in the nucleus accumbens (NAc) generally evokes locomotor activity. Interestingly, neurotensin receptor type 1 (NTS1) is highly expressed in the striatum and on midbrain dopaminergic neurons, which overlaps with the

expression of D1 and D2 receptors. Not surprisingly, neurotensin is known to modulate dopaminergic neurotransmission in the NAc. Systemically administered neurotensin receptor agonists and overexpression of NTS1 in the NAc has been demonstrated to inhibit psychostimulant-mediated hyperlocomotion. However, it remains unknown whether striatal NTS1 signaling suppresses D1 and D2 receptor-mediated hyperlocomotion. Therefore, our goal was to determine the effects NTS1 activation in the NAc on basal activity and dopamine receptor-mediated hyperlocomotion. PD149163, a selective NTS1 agonist that readily crosses the blood brain barrier, was used to examine the locomotor effects of NTS1 stimulation. Systemically administered PD149163 dose-dependently reduced locomotor activity of C57BL/6J mice in an open-field experiment. Moreover, mice did not develop tolerance when they were given 3 repeated injections. Microinjection of PD149163 into the NAc reduced basal locomotor activity whereas locomotor activity was not altered when PD149163 was microinjected to the medial prefrontal cortex. Our data indicate that NTS1 activation in the NAc reduces locomotor activity and this may be through modulation of dopaminergic signaling in the NAc.

Title: Discerning linear and nonlinear dynamics in the corticostriatal motor system with Kernel Granger causality

Authors: *A. MURPHY-NAKHNIKIAN[1], G. V. REBEC[2], L. L. DWIEL[2], L. M. GRASSE[2], Z. P. TRITSCH[2], J. M. BEGGS[2];
[1]Program Neurosci., Indiana Univ., BLOOMINGTON, IN; [2]Program in Neurosci., Indiana Univ., Bloomington, IN

Abstract: Our group demonstrated that corticostriatal influence is bidirectional, with dorsal striatum (dStr) exerting reciprocal control of primary motor cortex (M1) during spontaneous motor output (Nakhnikian et al., 2013, J. Neurophy, In Revisions). Interestingly, we found that dStr influence over M1 vanishes almost entirely during anesthesia and sleep, and increases with motor output. Here, we applied Granger causality (GC), a temporal-precedence causality metric based on the general linear model. A major limitation of conventional GC is that it is insensitive to nonlinear interactions. To overcome this problem, Marinazzo et al (2008, PRL, 100;14) propose a method for mapping nonlinear features of a data set to a linear space using the theory of Reproducing Kernel Hilbert Spaces. In the present study, we used kernel GC to analyze local field potentials (LFPs) isolated in M1 and dStr of rats: 1) under anesthesia, 2) sleeping, and 3) engaging in a variety of spontaneous behaviors. We used the inhomogeneous polynomial kernel, a kernel that has well-known properties (Shawne-Taylor and Cristianini, 2004, Cambridge University Press), and is appropriate for GC analysis (Ancora and Stramaglia, 2006, Phys Rev. E 70). When the kernel order is one, corresponding to the linear case, we find the same causality patterns revealed by conventional GC analysis, lending credence to Marinazzo et al.'s method. As the kernel order increases, we find increasing GC during some spontaneous behaviors, but not during anesthesia and sleep. Furthermore, we find that while M1->dStr drive exceeds dStr->M1 drive in the linear case, in some cases dStr->M1 drive exceeds M1->dStr drive at higher model orders. This is a particularly interesting finding given the anatomy of the basal ganglia. Striatal information must traverse a polysynaptic loop to influence cortical targets, and nonlinear interactions between the time-series could reflect increased complexity in the temporal precedence patterns. Drive in the M1->dStr, though lower than dStr->M1 drive at higher model orders, is nevertheless higher than the M1->dStr connection observed in the linear case. Our findings thus suggest that information flow in both the corticostriatal and striatocortical directions exhibits nonlinear patterns that must be considered when analyzing this system.

Title: Naturalistic burst stimulation drives opposing patterns of heterosynaptic plasticity at two inputs to a songbird motor cortex analogue

Authors: *W. H. MEHAFFEY[1], A. J. DOUPE[2];
[1]UCSF, Ctr. for Integrative Neurosci., San Francisco, CA; [2]Psychiatry, UCSF, San Francisco, CA

Abstract: The avian song system has been a powerful model system to study the neural basis of learned complex motor skills, and in particular, learned vocalizations. The zebra finch (Taeniopygia guttata) sings a precise song consisting of a number of distinct elements ('syllables'), organized sequentially into repeating motifs. A well-defined set of specialized brain nuclei underlie this vocal-motor behavior, including motor cortical analogues (HVC, and RA, the Robust Nucleus of the Archistriatum), and a 'cortico'-basal ganglia loop (the Anterior Forebrain Pathway, the AFP) homologous to cortico-basal ganglia loops of mammals. Specifically, HVC inputs to RA are required to produce learned components of song, while AFP inputs are required for song variability and plasticity. HVC and LMAN inputs converge onto single RA neurons, suggesting that RA is an important site for plasticity that could shape song. Despite a wealth of knowledge about the roles of specific nuclei in song production and plasticity, a mechanistic understanding of how song changes are reflected in synaptic and neuronal dynamics remains unclear.

We show here, in 60-120 d old (adolescent-adult) zebra finches, that we can induce synaptic plasticity at the inputs to RA from its two major input pathways, LMAN and HVC. Naturalistic stimulation protocols based on patterns of high frequency spikes observed in in vivo extracellular recordings proved important in inducing changes in the synaptic strength of both input pathways. These changes in synaptic strength depended on firing in both pathways, and in particular required bursting of the LMAN inputs like that seen in LMAN when birds sing alone ('undirected' song). Strikingly, activity in LMAN and HVC inputs caused opposing shifts in the strengths of the two input pathways, such that when one was potentiated, the other was depressed. Moreover, when the relative timing between HVC and LMAN stimulation times was shifted, both the magnitude and the valence of the changes in synaptic strength changed, although the shifts in strength remained opposite for the two inputs.

Together, these data suggest that synaptic plasticity in avian motor cortical circuitry requires patterns of stimulation known to be present during song production. The opposing changes in synaptic strength in the two input pathways could underlie the dynamic shift from LMAN-driven variability to HVC-driven song stabilization that is thought to occur during song sensorimotor learning. Furthermore, the dependence of these changes on the relative timing of input stimulation raises the possibility that this timing carries information important to the learning process.

Title: Intrinsic feedback pathways shape the basal ganglia output and modulate voluntary movement

Authors: *J. BROWN, J. T. DUDMAN;
Janelia Farm Res. Campus, HHMI, Ashburn, VA

Abstract: Dysfunction of the basal ganglia (BG) produces severe deficits in the timing, initiation, and vigor of voluntary movements. These diverse impairments suggest a control system gone awry. In engineered systems feedback is critical for stable control. By contrast, functional models of the BG focus on intrinsic feed-forward circuitry. The substantia nigra pars reticulata (SNr) is the main output nucleus of the dorsal BG in rodents. SNr neurons project to premotor areas outside of the BG, but also elaborate axonal collaterals within the SN. These intranigral collaterals are the sole source of direct feedback on the afferent output of the BG. We have explored the role of local inhibitory feedback within the SNr in awake, behaving mice. Using a transgenic mouse line and targeted virus injection we expressed channelrhodopsin-2 specifically in SNr projection neurons. SNr unit activity was recorded using extracellular recording arrays while a small population of SNr projection neurons were optically stimulated. Robust light evoked activity could be recorded from units close to the light source, while robust inhibition was observed from units surrounding the excited neurons. The transient feedback inhibition was eliminated following blockade of local inhibition. Kinematic analysis of movement revealed diverse roles of intranigral feedback inhibition. These results suggest that feedback inhibition mediated by axonal collaterals of SNr projection neurons are critical determinants of both the output of the BG and voluntary movement. Thus, despite its absence from canonical models, our results suggest intrinsic feedback inhibition could be an essential feature of BG function.

Title: Functional dissection of the cortical control of direct versus indirect pathways in the striatum

Authors: *J. R. KLUG[1], F. OSAKADA[2], E. M. CALLAWAY[2], X. JIN[1];
[1]Mol. Neurobio. Lab., [2]Systems Neurobio. Lab., Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: The dorsal region of the striatum and their cortical inputs are involved in action learning and selection. These abilities are compromised in human patients with neurological disorders affecting the striatum and its afferents, like Parkinson's and Huntington's disease. Medium spiny neurons (MSNs), the principal GABAergic projection neurons of the striatum, receive dense glutamatergic inputs from various cortical regions as well as thalamic nuclei. There are two intermixed subpopulations of MSNs: dopamine receptor 1 - containing (D1-MSNs, direct pathway) and dopamine receptor 2 - containing (D2-MSNs indirect pathway). While the two major neural pathways constitute the core components of the classic model of basal ganglia, very little is known about the connectivity and specificity of their cortical inputs. For example, the functionality and plasticity of excitatory synapses onto D1- vs. D2-MSNs from different cortical subregions remains unknown. In order to address these fundamental questions, we have used AAV-Cre-dependent helper viruses along with a modified rabies virus system (SAD delta G Rabies) to selectively visualize and manipulate cortical neurons projecting to D1- or D2-MSNs, respectively. Helper viruses are injected into subregions of dorsal striatum of D1-Cre or A2a-Cre mice, followed by an injection of modified rabies virus in the same location to allow retrograde monosynaptic tracing and expression of Channelrhodopsin-2 (ChR2-mCherry) or Archaerhodopsin (Arch-GFP) in presynaptic cortical neurons. The region and layer distributions of labeled cortical neurons are found to be consistent with reported anatomy. The functional expression of ChR2 or Arch was verified by electrophysiological recording both in brain slice and in vivo. An optical system designed for delivering fine-scale spatiotemporal light patterns was used to functionally map corticostriatal synapses. Optic fiber based optogenetic stimulation was employed to examine the contribution of ChR2-expressed corticostriatal neurons in different cortical subregions to operant learning. This system provided a unique opportunity to dissect different excitatory inputs to D1- vs. D2-MSNs and importantly, the contribution of region- and pathway-specific corticostriatal subcircuits to behavior.

Title: Modulation of the excitability of hindlimb motoneurons by the basal ganglia efferents to the brainstem in relation to the control of postural muscle tone and locomotion in the decerebrate cat

Authors: *K. TAKAKUSAKI[1], T. NOZU[2], T. OKUMURA[3];
[1]Reserach Ctr. for Brain Function and Med. Engin., [2]Dept. of Regional Med. and Educ., [3]Dept. of Gen. Med., Asahikawa Med. Univ., Asahikawa/Hokkaido, Japan

Abstract: Locomotion requires appropriate level of postural muscle tone. Gait disturbance is one of the cardinal symptoms in patients with Parkinson's disease (PD). Efferents from the basal ganglia project to the brainstem in addition to the cerebral cortex via the thalamocortical loops. Basic neuronal systems responsible for controlling postural muscle tone and locomotion are located in the brainstem and spinal
cord. Because the output from the basal ganglia is considered to be increased in PD, the present study was designed to understand how the basal ganglia efferents to the brainstem contribute to the control of postural muscle tone and locomotion. For this purpose, changes in postural muscle tone and intracellular activities of hindlimb motoneurons were examined in acutely decerebrated cat preparations (n=14) where basal ganglia structures were mostly removed except for the substantia nigra. Repetitive electrical stimulation (50 Hz, 20-40μA) applied to the midbrain locomotor region (MLR) generated rhythmic membrane oscillations in motoneurons, so-called fictive locomotion. The same type of stimulation applied to the ventrolateral part of the pedunculopontine tegmental nucleus (PPN) resulted in muscular atonia that was associated with membrane hyperpolarization of motoneurons. On the other hand, stimulation of the locus coeruleus (LC) increased the level of muscle tone and depolarized membrane potentials of extensor and flexor motoneurons. Although conditioning stimulation (100Hz, 40-60 μA) applied to the substantia nigra pars reticulata (SNr), a basal ganglia output nucleus, did not alter the excitability of motoneurons, it attenuated the rhythmic membrane oscillations and generated

tonic firing of both extensor and flexor motoneurons. Particularly, amplitude of hyperpolarizing phases of membrane oscillations was reduced. In addition, conditioning SNr stimulation greatly reduced the PPN-induced membrane hyperpolarization of extensor and flexor motoneurons. However the SNr stimulation did not reduced the LC-induced membrane depolarization, it rather facilitated the depolarization. Microinjections of bicuculline, a $GABA_A$-receptor antagonist, into the PPN/MLR areas blocked the effects by stimulating the MLR/PPN. These results suggest that an increase in the GABAergic basal ganglia output from the SNr to the MLR/PPN area terminate locomotion by decreasing the activity of central pattern generators and by increasing muscle tone of both extensor and flexor muscles. Excessive GABAergic basal ganglia efferents from the SNr to the MLR/PPN area are possibly involved in the gait failure and muscle tone rigidity (hypertonus) in PD.

Title: Study of the physiology of the thalamostriatal system using optogenetics in nonhuman primates

Authors: *A. GALVAN, X. HU, Y. SMITH, T. WICHMANN;
Yerkes Res. Ctr. and Dept. Neurol., Emory Univ., ATLANTA, GA

Abstract: The caudal intralaminar nuclei, namely the centromedian/parafascicular complex (CM/PF), provide massive thalamic inputs to the striatum. In primates, the CM innervates mostly the sensorimotor region of the striatum (post-commissural putamen), while the PF sends afferents to the associative striatal territory (caudate nucleus). Both striatal projection neurons and interneurons receive synaptic inputs from the CM/PF. To understand how CM/PF influences striatal activity, we have begun to study the electrophysiological responses of striatal cells to light stimulation of channelrhodopsin (ChR2)-bearing CM/PF terminals in the monkey.
One monkey received recording chambers for access to CM/PF and the caudate/putamen. We injected 37 µl of AAV5-hSyn-ChR2-EYFP in 7 injection tracks to cover the extent of the CM/PF complex. After 9 weeks, the light stimulation experiments started. Optrodes (standard tungsten electrodes glued to 0.2 mm OD optical fibers) were introduced into the putamen or the caudate nucleus to light-activate ChR2s-positive terminals transfected via anterograde transport from the CM or PF injections, while we simultaneously recorded the extracellular activity of striatal neurons in response to light pulses (473 nm, 60-200 mW/mm2; trains of 10 pulses, 10 ms width, 20 Hz or 3 pulses, 10-30 ms width, 5 Hz).
We recorded 84 cells in the caudate nucleus, and 145 in the putamen. About 10% of caudate and 20% of putamen neurons responded significantly to the light stimulation, either during the train or within 0.5 ms after the end of the train. The responses were brief (<10 ms duration), not timed to the occurrence of individual light pulses, and appeared with a relatively long latency after the trains (>30 ms in many cases). While most responding neurons showed an increase in firing, 3 putamen cells decreased their activity following light stimulation. Both projection neurons and interneurons were among the responders. The long latencies to responses, and the recorded inhibitory effects of light stimulation upon striatal neurons, suggest that the physiological effects of CM/PF-striatal terminals stimulation are mediated in part through activation of the intrastriatal circuitry. Postmortem histological analysis will be performed to analyze the pattern of distribution and density of expression of ChR2s in CM/PF-striatal terminals across the caudate nucleus and putamen.

Title: Type III-Nrg1/ErbB4 signaling within the nucleus accumbens

Authors: *I. OBIORAH[1,2], L. W. ROLE[2,3], D. A. TALMAGE[1,2,3];
[1]Dept. of Pharmacol., [2]Centers for Nervous Syst. Disorders, [3]Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Nrg1-ErbB4 signaling has been implicated in the maintenance of synaptic plasticity, dendritic spine density, neuronal migration and survival, and GABAergic, dopaminergic, cholinergic and glutamatergic transmission. Type III-Nrg1 heterozygous mice show: (a) altered functional connectivity between the ventral hippocampus and the nucleus accumbens, and (b) deficits in behaviors in which the hippocampus-accumbens circuit plays a role. Based on these findings, we hypothesized that Nrg1-ErbB4 signaling plays an important role in synaptic transmission within accumbens circuits. Type III Nrg1 is expressed in neurons that project to the nucleus accumbens, whereas ErbB4 is expressed in the accumbens. In the early post-natal period, a subset of striatal medium spiny neurons, parvalbumin-positive neurons and cholinergic interneurons express ErbB4. Striatal ErbB4 expression decreases as animals mature and in adults becomes restricted to parvalbumin-positive interneurons. In order to begin to understand the role of Nrg1-ErbB4 signaling in excitatory transmission in the nucleus accumbens, we quantified the levels of AMPA receptor subunits in the accumbens of Type III Nrg1 heterozygous and ErbB4 knockout mice. Our major findings are: (a) GluA1 alternative splicing changes as animals mature. At birth 95-100% of GluA1 transcripts contain the flip exon, at P21 70% of GluA1 transcripts contain the flip exon and in adults 50% do. (b) Type III Nrg1 heterozygotes have alterations in the developmental profile of GluA1 splice variants; the transition from all flip to a mix of flip and flop containing transcripts seen in wild type animals is accelerated in the Nrg1 heterozygotes. The splicing of GluA1 transcripts in ErbB4 knockout mice is similar to WT profile. Thus, although ErbB4 expression in striatal MSNs and GluA1 splicing change in parallel during maturation, the regulation of GluA1 splicing by Type III Nrg1 appears to be ErbB4 independent. On going studies are to investigate the signaling mechanisms by which Type III-Nrg1 mediates splicing of GluA1 transcripts.

Title: Functional connectivity between the cerebellum and basal ganglia in a songbird

Authors: L. PIDOUX, C. LEVENES, D. DUBAYLE, *A. LEBLOIS;
CNRS / Univ. Paris Descartes, Paris, France

Abstract: Human speech is a complex sensorimotor skill and vocal learning is one of the most striking cognitive abilities of the brain. As many other complex motor skills, vocal learning involves the basal ganglia (BG)-thalamo-cortical network and the cerebello-thalamo-cortical network in humans. While the BG and cerebellar sub-cortical loops have been shown to interact at least through two different pathways in mammals, the role of their interaction during sensorimotor learning, and in particular during vocal learning, remains undetermined. Songbirds are one of the few accessible animal models for vocal learning, as they have a specialized portion of their BG-thalamo-cortical circuitry dedicated to song learning. Additionally, a cerebellar projection to the thalamic region adjacent to the song-related thalamic nucleus receiving BG input (DLM) suggests that the BG and cerebellum may interact during song learning. However, very little is known about song-related circuits in the cerebellum, or about a putative cerebellar function in song learning. We are studying the interactions between BG and cerebellar sub-cortico-cortical loops involved in avian song learning.
First, we confirmed the anatomical connection from the deep cerebellar nuclei to a thalamic region adjacent to the song-related BG-target thalamic nucleus DLM, which in turn projects to the song-related basal ganglia nucleus Area X, as shown previously. More importantly, we show that this anatomical pathway is functional. Indeed, electrical stimulation in the deep cerebellar nuclei consistently evoked fast excitatory responses in pallidal neurons located in the song-related nucleus Area X, with relatively short latencies consistent with a disynaptic pathway between the two structures. Finally, we also explored putative anatomical pathways linking the song control areas in the forebrain to the cerebellum.
Overall, our results suggest that the cerebellum is involved in song learning through its interaction with the song-related BG-thalamo-cortical loop in songbirds, providing a unique model to study the interactions between cerebellum and basal ganglia during sensorimotor learning.

Title: Effects of caged-dopamine photolysis on spike-timing dependent long-term depression in mice striatal neurons

Authors: *M. OCHI-SHINDOU, T. SHINDOU, J. R. WICKENS;
Neurobio. Res. Unit, Okinawa Inst. of Sci. & Tech., Okinawa, Japan

Abstract: Recent evidence suggests that the temporal association of cortical and striatal neuron activity modifies corticostriatal synaptic efficacy. Dopamine (DA) has been suggested to play a crucial role in the corticostriatal synaptic plasticity. We have studied spike-timing dependent plasticity (STDP) and found that spike-timing dependent long-term depression (t-LTD) was induced by prepost protocols in D1R-expressing projection neurons in the striatum. Here we tested the hypothesis that DA plays a crucial role in corticostriatal t-LTD using the rapid application techniques by caged-dopamine photolysis. Whole cell recording in slice preparations obtained from adult BAC transgenic mice that selectively express GFP in D1R-expressing cells was performed in this study. Photolysis of CNB-caged DA by xenon flash induced DA release with a peak concentration of approximately 0.5 µM, estimated by fast-scan cyclic voltammetry methods. The photolysis of caged-DA elicited large hyperpolarisation in DA neurons in substantia nigra, which was selectively blocked by a D2R antagonist, confirming that uncaged-DA acts on DA receptors in our experimental conditions. Then the effects of photolysis of caged-DA on corticostriatal t-LTD were investigated. The photolysis was applied at 300 ms prior to, 0 msec, 300 msec, or 2 seconds after the pairing protocols. Of these timing conditions, the photolysis at 2 seconds after the pairing blocked the t-LTD, whereas there were no effects of other conditions on t-LTD. We suggest that the timing of DA release could be an important factor to modulate the corticostriatal synaptic plasticity.

Title: Long-term potentiation of external globus pallidus-subthalamic nucleus synapses following activation of motor cortical inputs

Authors: H.-Y. CHU, *M. D. BEVAN;
Dept Physiol., Northwestern Univ., CHICAGO, IL

Abstract: The frequency and pattern of activity in the subthalamic nucleus (STN) are intimately related to motor function and dysfunction and are influenced in large part by the STN's major glutamatergic afferent, which arises from the motor cortex and its major GABAergic afferent, which arises from the external globus pallidus (GPe). In order to understand how the balance of cortical excitation and pallidal inhibition is regulated in the STN, the impact of optogenetic activation of motor cortical inputs on GPe-STN inputs was studied in *ex vivo* brain slices using patch clamp recording. Repeated optogenetic activation (300 ms trains of 50 Hz stimulation repeated 30 X at 0.2 Hz) of motor cortical inputs led to heterosynaptic long-term potentiation (LTP) of GPe-STN inputs. IPSC1 potentiated by 41 ± 7%. LTP was associated with a reduction in the ratio of IPSC2:IPSC1 (from 0.84 ± 0.01 to 0.72 ± 0.02) and a reduction in the coefficient of variation of IPSC1 (0.12 ± 0.02 to 0.06 ± 0.01), consistent with an increase in the initial probability of GPe-STN transmission. LTP was mimicked by bath application of 50 μM NMDA (43 ± 7%) and prevented by blockade of NMDA receptors (NMDARs) with 50 μM D-APV or chelation of postsynaptic Ca^{2+} with 20 mM BAPTA applied via the patch pipette. LTP was also prevented by inhibition of nitric oxide synthase with 100 μM L-NAME or scavenging of nitric oxide (NO) with 30 μM PTIO or inhibition of guanylate cyclase (GC) with 10 μM ODQ or inhibition of PKG with 1 μM KT5823. LTP was not induced by application of NO donors 100 μM SNAP or 100 μM spermine NONOate, suggesting that NO/GC/cGMP/PKG signaling is necessary but not sufficient for LTP. Together these data suggest that motor cortical inputs activate postsynaptic NMDARs leading to the production of NO and activation of GC/cGMP/PKG signaling in GPe-STN axon terminals, which mediates an increase in the probability and strength of GPe-STN transmission. Following the chronic loss of dopamine GPe-STN synapses proliferate leading to a profound increase in the strength of GPe-STN transmission. We are therefore investigating whether cortical excitation can ultimately trigger synaptic remodeling of GPe-STN inputs.

Title: The relative role of thalamic and cortical afferents in driving cholinergic interneuron-evoked striatal dopamine release

Authors: *P. KOSILLO[1], S. THRELFELL[2], S. CRAGG[2];
[2]Dept. of Physiology, Anat. and Genet., [1]Univ. of Oxford, Oxford, United Kingdom

Abstract: Acetylcholine (ACh) and dopamine (DA) are two striatal neuromodulators, critical for the basal ganglia (BG) circuits. Both neurotransmitters are important for the balance between direct and indirect BG pathways, thereby regulating normal motor output. Further, ACh and DA extensively modulate striatal function, and hence are involved in the processes of action selection, learning, habit formation and addiction.

ACh and DA were traditionally conceptualized to co-exist antagonistically, as the two systems reciprocally inhibit each other's release. However, this hypothesis is oversimplified in the light of data showing dynamic gating of striatal DA release probability by ACh and optogenetic paradigms demonstrating an unprecedented level of ACh-DA co-operativity. The latter experiments established that synchronous activation of a small population of cholinergic interneurons (ChIs) both in vivo and in vitro is capable of directly driving DA release from striatal dopaminergic terminals via ACh acting at nicotinic ACh receptors. Crucially, this local striatal mechanism for ChI-evoked DA release bypasses parent cell body activation of DA neurons residing in subtantia nigra pars compacta and ventral tegmental area. The physiological context for this direct axon-axonic action of ACh on striatal DA terminals remains incompletely understood. This project aims to identify and characterize which striatal inputs are capable of driving ChI-evoked DA release.

Two major glutamatergic inputs known to make synaptic contacts with and regulate the firing rate of striatal ChIs originate from somatosensory cortex and caudal intralaminar thalamus. In this study we use fast-scan cyclic voltammetry to monitor real-time striatal DA release in combination with optogenetic activation of the cortical or thalamic striatal terminals, following transfection with ChannelRhodopsin2 of the two regions of interest in CamK2a-cre transgenic mice. Experiments performed in acute brain slices aim to investigate the relative roles of these projections in driving ChI-mediated DA release. Preliminary data suggests that somatosensory cortical afferents, as well as inputs from caudal intralaminar thalamus are capable of driving ChI-evoked DA release. However, the two pathways differ in the relative contribution from NMDA and AMPA ionotropic glutamate receptors and the dynamic timecourse of DA re-release. These

data highlights previously unappreciated role of thalamic and cortical afferents in control of local striatal circuits regulating DA release and adds a new level of complexity in understanding BG function.

Title: Heterosynaptic ltp of identified gabaergic inputs onto dopaminergic neurons

Authors: *D. SIMMONS, C. PALADINI;
Univ. of Texas At San Antonio, San Antonio, TX

Abstract: The net output of a dopaminergic neuron depends on the balance between excitatory and inhibitory inputs onto the cell, and tonic imbalances of these inputs persistently alter the release of dopamine. Inhibitory, GABAergic inputs onto a dopaminergic neuron in the ventral tegmental area exhibit long term potentiation (LTPGABA) following LTP-inducing activity of glutamatergic inputs onto the same cell. Therefore, a heterosynaptic balancing mechanism exists whereby high-frequency activity that increases glutamatergic synaptic weight also increases GABAergic synaptic weight. It is unknown, however, which GABAergic and glutamatergic inputs participate in LTPGABA. Rostromedial Tegmental nucleus (RMTg) and Nucleus Accumbens (NAc) are the largest GABAergic projections to ventral tegmental area dopaminergic neurons. The Pedunculopontine (PPN) and Subthalamic (STN) nuclei are glutamatergic inputs to dopaminergic neurons whose activity may induce LTPGABA. We infected each of these nuclei with the light-activated protein, channelrhodopsin, and found that LTPGABA enhanced both RMTg- and NAc-specific IPSCs. High-frequency stimulation of projections from PPN, but not STN, induced LTPGABA from IPSCs evoked by electrical stimulation. IPSCs from RMTg inputs, but not NAc inputs, exhibited LTPGABA following high-frequency stimulation of PPN projections. In conclusion, RMTg synapses use LTPGABA to counterbalance LTP at PPN synapses onto dopaminergic neurons. Future studies will determine which glutamatergic input is counterbalanced by LTPGABA at NAc synapses.

Title: Cholinergic modulation of corticostriatal synaptic response of direct and indirect projection neurons

Authors: *M. B. PEREZ-RAMIREZ, D. TAPIA, J. BARGAS, E. GALARRAGA; INSTITUTO DE FISIOLOGIA CELULAR, MEXICO D.F., Mexico

Abstract: Striatal projection neurons (SPNs) receive monosynaptic glutamatergic inputs from diverse cortical areas. Monosynaptic contacts between pyramidal neurons and striatal neurons of the direct and indirect pathways (dSPNs and iSPNs), as well as with striatal interneurons, have been described based on the small variation in latency of the synaptic events. High levels of acetylcholine (ACh) can be found in the neostriatum.
SPNs activity can be modulated by Ach trough M_1 muscarinic acetylcholine receptors (mACh-R M_1). It is well known that this receptor type modulates several currents, one of which is the potassium Kv7 current. Yet, the cholinergic modulation of the synaptic response in the dSPN and iSPNs is unknown. Based on the electrophysiological differences that distinguished these projection neurons, with whole cell recordings, we studied the cholinergic modulation by activating (with 1-10 μM muscarine) or inhibiting (with 5nM of the muscarinic toxin MT-7) the mACh-R M_1. We also blocked the Kv7 current (with 20μM XE991). Here is shown that cortical input is received by the cholinergic interneurons and by the dSPNs and iSPNs with different latencies: TAN 1.24 ± 0.11 ms; dSPN 2.37 ± 0.22 ms; iSPN 2.82 ± 0.22 ms.
We confirm in Wistar rats and transgenic BAC-D1 and BAC-D2 mice, that the synaptic corticostriatal responses are different in the SPNs: in dSPNs, the responses are more prolonged and evoke more action potentials, while in iSPNs the synaptic responses are briefer and exhibit

intrinsic autoregenerative responses (Flores-Barrera et al, 2010). When mACh-R M_1 was blocked with the M_1 muscarinic toxin MT-7, a decrease in the area under the synaptic response was observed: dSPN 18% and in iSPN 22%. On the other hand, when M_1 receptors were activated with muscarine, there was an increase in the area under the synaptic response in both dSPNs and iSPNs, 14% and 28% respectively. Similar results were obtained after XE991, a Kv7 channel blocker. It is concluded that cholinergic modulation through Kv7 channels, is important to reduce synaptic facilitation in SPNs and to decrease the generation of dendritic autoregenerative calcium potentials in iSPNs.

Title: Optogenetic inhibition of the primate nigro-collicular connection and its effects on saccadic eye movements

Authors: H. F. KIM[1], M. YASUDA[1], E. S. BOYDEN[2], *O. HIKOSAKA[1];
[1]Lab. Sensorimotor Res., Natl. Eye Inst., NIH, BETHESDA, MD; [2]MIT, Cambridge, MA

Abstract: As our first step toward the primate optogenetics, we chose to manipulate an output connection of the basal ganglia: the inhibitory connection from the substantia nigra pars reticulata (SNr) to the superior colliculs (SC). The nigro-collicular connection controls the initiation of saccadic eye movements. This was demonstrated by antidromic activation of SNr neurons by electrical stimulation of SC and reversible inactivation of SNr neurons by local injection of a GABA agonist (muscimol) (Hikosaka and Wurtz, 1983 & 1985).
We expressed Archaerhdopsin (ArchT), a light-driven proton pump, in the moneky's SNr to inhibit action potentials by optical stimulation (O-STIM). To this end, we injected AAV8 vector containing the ArchT-GFP gene selectively into the SC-projecting region of SNr in one monkey. Beginning 2 months after the virus injection, we performed three experiments using a custom-made optrode to deliver 532 nm laser.
1. Effects of O-STIM in SNr on the spike activity of SNr neurons.
All SNr neurons fire spontaneously with high frequencies. Most of the SNr neurons were suppressed during the O-STIM (duration: 500-1000 ms), followed by a rebound excitation. This

suggests that ArchT was expressed and functional in SNr neurons. Some SNr neurons, however, were activated during the O-STIM, presumably through collateral connections among SNr neurons.
2. Effects of O-STIM in SC on the spike activity of SC neurons.
A majority of pre-saccadic neurons in SC were activated during the O-STIM, followed by a rebound inhibition. This result indicates that ArchT expressed in SNr neurons was carried along their axons to their terminals in SC, on which the O-STIM acted to reduce the SNr-induced inhibition on SC neurons.
3. Effects of O-STIM in SC on saccadic eye movements.
The monkey performed a memory-guided saccade task with 8 directions. The O-STIM was delivered after a go-signal (i.e., fixation point offset) (duration: 500 ms) on randomly chosen trials. The end points of memory-guided saccades were shifted weakly but systematically by the O-STIM: away from the center for the directions close to the response fields of nearby SC neurons, and toward the center for the opposite directions.
Our data indicate that the optogenetic technique using ArchT has a potential to overcome the previous limits of the primate circuit study.

Title: Synaptic activation of dendritic plateaus in medium spiny neurons - role of GABAergic inputs

Authors: *K. DU[1], J. HELLGREN KOTALESKI[2];
[1]Dept. of Neurosci., Karolinska Inst., Stockholm, Sweden; [2]Sch. of Computer Sci. and Communication, KTH Royal Inst. of Technol., Stockholm, Sweden

Abstract: Striatum is the entrance to the basal ganglia, gating the information from cortex and thalamus. Medium spiny neurons (MSN) are principal neurons in striatum and play a key role in processing the cortical and thalamic inputs. In vivo experiments have shown that the membrane potential of MSNs fluctuates between a hyperpolarized “down" state and a depolarized “up" state, and the transition from down-state to up-state is likely driven by synchronized inputs from cortex (Stern et al., 1998). A recent in vitro experimental study (Plotkin et al., 2011) showed that synchronized activation of clustered spines in the distal dendrites of MSNs can give rise to long-lasting plateaus in the dendrites and soma simultaneously, indicating that synaptically driven dendritic plateaus might be essential for understanding how MSNs process synchronized inputs from cortex.

The striatal circuit is a predominantly inhibitory GABAergic network, which includes lateral “feedback" inhibition among MSNs and a powerful “feedforward" inhibition from fast-spiking interneurons (FS) to MSNs. To investigate how these GABAergic inputs affect dendritic plateaus in MSNs, we have built a biophysically detailed MSN model, which contained complex dendritic morphology and a large array of ion channels (Paille, et al., 2013) verified by experimental data. This MSN model can faithfully reproduce the phenomenon of dendritic plateaus as shown in Plotkin et al. (2011). The simulations showed that both feedforward and feedback inhibition have weak influence on dendritic plateau formation when the MSN model rests at -80 mV, as in the in vitro down state. Interestingly, when the MSN model fluctuates around -65 mV, as during in vivo-like conditions, the GABAergic inputs can greatly dampen the dendritic plateau, in particular when the reversal potential of GABA is set to -75 mV. Our simulations thus suggest that the GABAergic effects on dendritic plateau formation in MSNs are sensitive to experimental conditions, in particular the resting membrane potential and the reversal potential of GABA.

Title: Consequences caused in the neuronal activity of the putamen by an enhancer stimulus

Authors: *M. MONTES LOURIDO[1], A. F. VICENTE[2], M. A. BERMUDEZ[2], M. C. ROMERO[2], R. PEREZ[3], F. GONZALEZ[4];
[1]Fisiología, Univ. De Santiago De Compostela, Santiago De Compostela, Spain; [2]Dept. of Physiology. Univ. of Santiago de Compostela, Santiago de Compostela, Spain; [3]Dept. of Ophthalmology, Hosp. da Barbanza, Ribeira, Spain; [4]Dept. of Ophthalmology, Univ. Hosp., Santiago de Compostela, Spain

Abstract: The putamen is part of the basal ganglia and its function is mainly related to motor coordination. However the hypothesis of this work assumes that neural activity into the putamen nucleus is to be modulated by the different components of the task, the presence or absence of a stimulus enhancer, motor act, and the presence of the reward. In our study we used a visual stimulus (silhouette of a white square) as enhancer of another visual stimulus (abstract image). We used four abstract images: two images meant 'Yes' and were associated with obtaining reward and two images meant 'Non' and were associated with no reward. In the images 'Yes' the animal had to press a lever to obtain a reward, in the images 'No' the animal could not press the lever. In some trials, featuring the 'Enhancer' after the appearance of the images. The 'Enhancer' indicated the existence of double reward in Images 'Yes' and more waiting between trials if it presented before the images 'Non'. We recorded the activity of neurons in the putamen of a monkey (Maccaca mulatta) trained to perform this visuomotor task that requires the execution of a movement and retention of a move to the presentation of different images. We used an ANOVA statistical test to study neuronal activity during task execution. Of all the recorded neurons, 8% increased their activity after the presentation of the 'Enhancer' (ANOVA, $p < 0.05$), 61% increased their activity around the lever down (ANOVA, $p < 0.05$) and 31% increased their activity after the presentation of the reward (ANOVA, $p < 0.05$). These results indicate that the putamen is related to stimulus processing relevant to the task, with the motor action and reward processing.

Title: Regulation of NMDAR-dependent burst firing in midbrain dopaminergic neurons by glycine release from glia

Authors: *G. M. BEAUDOIN, III, C. A. PALADINI;
Neurosciences Inst., Univ. of Texas San Antonio, San Antonio, TX

Abstract: The firing activity of dopaminergic neurons reflects the integration of information from complex environmental stimuli via afferents. Activation of glutamatergic afferents of dopaminergic neurons induces burst firing, however the molecular mechanisms regulating induction of burst firing are unknown. While activation of NMDA-type receptors regulates burst firing, we now find that glycine release from glia controls induction of NMDAR-mediated currents required for burst induction. Using slice electrophysiology, treatment with glycine can increase NMDAR-mediated currents and induces bursts with more spikes. Rather than glycine coming from glycinergic afferents, we suggest glycine comes from glia as inhibition of the glial glycine transporter, GLYT1, decreased both NMDAR-mediated currents and burst induction. This effect is specific for glycine as inhibition of glutamate transporters increases NMDAR-mediated currents and induces stronger bursts. Mechanistically, we find glycine regulates both activation of extrasynaptic NMDARs and conductance of synaptic NMDARs. By inhibiting either synaptic or extra-synaptic NMDARs, our results show that burst induction requires both sources – synaptic and extra-synaptic – of NMDAR-mediated currents. Glycine regulation of synaptic NMDARs is due to a unique configuration of these receptors containing the NR3 subunit with the traditional NR1 and NR2B or D subunits. The NR3 subunit binds glycine, increasing the dependence of this triheteromeric NMDAR on glycine. Together, these mechanisms regulate the induction of NMDAR-mediated currents and burst firing in dopaminergic neurons, and suggest this mechanism as a coincidence detector. Supported by grants from NIH-NIDA and NIMH.

Title: Cerebellar modulation of corticostriatal plasticity

Authors: *C. H. CHEN, E. ARTEAGA-BRACHO, K. KHODAKHAH;
Albert Einstein Col. of Med., Bronx, NY

Abstract: The cerebellum and basal ganglia are structures critical for the control of movement. We have observed in awake, freely moving mice that optogenetic or electrical stimulations of the cerebellum can elicit short latency (8-12 ms) responses in ≈50% of cells in the dorsolateral striatum. These responses are abolished upon inactivation of thalamic intralaminar nuclei and remain with cortical inactivation, indicating that they are routed through the thalamus. This data corroborates published anatomical tracing data, and also provides functional evidence for a robust and short-latency pathway mediating subcortical motor communication between the cerebellum and basal ganglia. In addition to allowing rapid coordination of the two structures, we wondered whether this pathway provides the cerebellum with the ability to modulate synaptic plasticity and thus learning in the basal ganglia. A major site of plasticity in the basal ganglia is the corticostriatal synapse. It has been shown in vitro that high frequency stimulation (HFS) of the corticostriatal synapse results in its long term depression (LTD). However, if the striatal neuron is depolarized during HFS the sign of the plasticity is reversed and the corticostriatal synapse undergoes long term potentiation (LTP) rather than LTD. We postulated that the short latency cerebellar activation of striatal neurons can effectively depolarize the striatal neurons and thus modulate the direction of corticostriatal plasticity. To test this hypothesis we first confirmed that in awake-freely moving mice HFS of the motor cortex resulted in LTD of the corticostriatal synapse. We then paired the HFS of the cortex with simultaneous HFS of the cerebellum. We found that under these conditions the corticostriatal synapse showed LTP, rather than LTD, thus reversing direction. This data demonstrates that cerebellum can regulate the direction and perhaps extent of plasticity at corticostriatal synapses, thus enriching the nature of interactions between these two structures.

Title: Intrinsic and synaptic properties of subthalamic nucleus neurons in BACHD mice

Authors: *J. F. ATHERTON, E. L. MCIVER, M. D. BEVAN;
Physiol., Northwestern Univ., CHICAGO, IL

Abstract: The BACHD mouse model of Huntington's disease expresses full-length human mutant huntingtin and is associated with abnormal intrinsic and synaptic properties in cortical and striatal neurons together with neuronal degeneration and motor dysfunction. The subthalamic nucleus (STN) is a key element of cortico-basal ganglia thalamocortical circuitry but its properties have not been thoroughly characterized in the BACHD model. The aim of this project was therefore to determine whether the STN exhibits abnormalities that contribute to the BACHD phenotype. The intrinsic and synaptic properties of STN neurons in BACHD and wild type (WT) litter mate control mice were compared at pre-symptomatic (<2 months) and symptomatic (6 months) ages using patch clamp recording of *ex vivo* brain slices.
At 6 months (but not at <2 months) autonomous STN activity was reduced in its frequency and precision in BACHD (WT: freq = 8.4 ± 6.2 Hz, CV = 0.46 ± 0.32, n = 65; BACHD: freq = 5.2 ± 5.0, CV = 0.64 ± 0.46, n = 77) with 0% of WT and 16% of BACHD neurons inactive. Autonomous STN activity in BACHD was restored to WT levels by application of the K_{ATP} channel blocker gibenclamide (100 nM) (WT: freq = 14.6 ± 4.4 Hz, CV = 0.17 ± 0.09, n = 8; BACHD: 12.9 ± 3.9 Hz, CV = 0.17 ± 0.10, n = 9). Autonomous activity in WT neurons was persistently disrupted after preincubation in 12.5 μM NMDA for 60 mins (control: freq = 5.7 ± 3.3 Hz, CV = 0.38 ± 0.25, n = 24; NMDA: freq = 1.4 ± 2.8 Hz, CV = 1.08 ± 0.80, n = 14) or by acute application of the NO donor SNAP (100 μM) (control: freq = 5.6 ± 3.6 Hz, CV = 0.18 ± 0.10, n = 7; SNAP: freq = 3.0 ± 2.8 Hz, CV = 0.90 ± 0.88, n = 7) but was restored to control levels by K_{ATP} channel blockade. Together these data imply that NMDA-NOS-NO-GC-cGMP-PKG signaling-mediated upregulation of K_{ATP} channels may underlie disrupted autonomous STN activity in BACHD similar to that observed in Parkinson's disease models.
The frequency of mEPSCs in BACHD was greater at <2 months (WT: 0.17 ± 0.12 Hz, n = 13; BACHD = 0.82 ± 0.43, n = 11) but similar at 6 months (WT: 0.22 ± 0.21 Hz, n = 14; BACHD = 0.14 ± 0.16, n = 9). mEPSCs recorded at -70 mV were largely mediated by AMPA receptors (Rs) and exhibited similar amplitudes and kinetics in BACHD and WT at both time points. mEPSCs recorded at 40 mV were largely mediated by NMDARs and exhibited prolonged decay time constants in BACHD versus WT at <2 (WT: 44.1 ± 13.2 ms, n = 14; BACHD = 84.3 ± 40.6 ms,

n = 10) and 6 months (WT: 40.8 ± 20.8 ms, n = 7; BACHD = 82.0 ± 27.1 ms, n = 6). Together these data suggest that disruption of autonomous STN
activity may be related to abnormalities in STN NMDARs in the BACHD model.

Title: Identification and characterization of neuronal subpopulations in the GPe using transgenic mice

Authors: K. J. MASTRO[1], R. S. BOUCHARD[2], C. WINKLER[2], *A. H. GITTIS[3,4];
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Biol. Sci., [4]Ctr. for the Neural Basis of Cognition, [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Neurons in the external segment of the globus pallidus (GPe) participate in basal ganglia circuits that are critical for motor function. Heterogeneity of neuronal populations within the GPe has been described using various anatomical and functional criteria, but a rigorous classification scheme has yet to be established. Using transgenic mice, we define two non-overlapping cell populations in the GPe. Neurons labeled in Lhx6 transgenic mice make up 27% of GPe neurons and are more prominent in the medial portion of the GPe. In contrast, neurons labeled in PV transgenic mice make up 34% of GPe neurons and are more prominent in the lateral portion of the GPe. Anatomical targets of each GPe cell type were identified by expressing EYFP under viral transfection in either Lhx6-cre or PV-cre mice. As expected, axons from both cell types were found in downstream and upstream basal ganglia nuclei: subthalamic nucleus, susbstantia nigra, and striatum. Intriguingly, axons from both cell types were found in the reticular nucleus of the thalamus, and in PV-cre mice, a prominent collection of axons was also observed in a medial thalamic nucleus, likely the parafascicular nucleus. Electrophysiologically, PV neurons have lower input resistances and higher spontaneous and maximum firing rates than Lhx6 neurons. Combined, our data suggest that PV and Lhx6 neurons represent anatomically and physiological distinct neuronal populations in the GPe. These results provide a framework for the study of GPe circuits in basal ganglia function in both health and disease.

Title: Connectional evidence for multiple basal ganglia grasping loops in the macaque monkey

Authors: M. GERBELLA[1,2], E. BORRA[3], S. ROZZI[1,2], *G. LUPPINO[1,2];
[1]Neurosci., Univ. of Parma, Parma, Italy; [2]Rete Multidisciplinare Tecnologica, Italian Inst. of Technol., Parma, Italy; [3]Brain Ctr. for Social and Motor Cognition, Italian Inst. of Technol., Parma, Italy

Abstract: It is largely agreed that different sets of functionally related cortical areas project to different parts of the striatum, which are at the origin of largely segregated basal ganglia-thalamocortical loops. Specifically, caudal, corticospinal motor areas (M1, SMA, and caudal premotor areas) are a source of partially overlapping projections to a large putaminal sector caudal to the anterior commissure (AC). This sector is at the origin of a "motor" loop involved in modulating the cortical motor output during the execution of voluntary movements. In contrast, the distribution of the striatal projections of frontal and parietal areas involved in selecting and organizing voluntary actions is still largely unknown. To address this issue, we analyzed the corticostriatal projections of the inferior parietal (AIP and PFG), ventral premotor (F5a and F5p), and ventrolateral prefrontal (intermediate 12r and rostral 46vc) areas forming a network (lateral grasping network) involved in selecting and controlling goal-directed hand actions, based on visual and memory-based information and on behavioral goals. The results, based on anterograde neural tracer injections (12 injections, 9 macaques) showed that after injections in all the studied areas but F5p, patches of dense labeled terminals were observed in two distinct putaminal zones located at different rostrocaudal levels. One zone was located in the mid-ventral part of the putamen and extended for about 4 mm from the AC in rostral direction, i.e. just rostral to the putaminal sector of the "motor" loop. The other zone was located in the caudalmost part of the putamen and extended for about 3 mm in rostrocaudal direction, ventral to the putaminal sector of the "motor" loop. Additional labeled zones were observed in other striatal sectors, varying in

location according to the injected area. Specifically, after injections in F5a, the labeling also involved the putaminal sector of the “motor” loop. In contrast, the corticospinal area F5p, which in the lateral grasping network represents the gateway for the access of signals related to the selection of hand motor acts to M1, differently from the other areas of the lateral grasping network, displayed projections mostly involving the putaminal sector of the “motor” loop. The present data indicate that areas of the lateral grasping network are a source of projections likely overlapping in two striatal zones distinct from the putaminal sector targeted by corticospinal motor areas. Accordingly, these data provide evidence for multiple grasping basal ganglia loops, possibly differentially involved in controlling goal-directed hand actions.

Title: FACS-array profiling identifies Ecto-5’ nucleotidase as a striatopallidal neuron-specific gene involved in striatal-dependent learning

Authors: *S. N. SCHIFFMANN, S. ENA, J.-F. DE BACKER, A. DE KERCHOVE D'EXAERDE;
Lab. of Neurophysiol., Univ. Libre De Bruxelles (ULB), Brussels, Belgium

Abstract: The striatopallidal (STP) and striatonigral (STN) neurons constitute the main neuronal populations of the striatum. Despite the increasing knowledge concerning their involvement in multiple tasks associated to the striatum, it is still challenging to understand the precise differential functions of these two neuronal populations and to identify and study new genes involved in these functions. Here, we describe a reliable approach, applied on adult mouse brain to generate specific STP and STN neuron gene profiles. STP and STN neurons were identified in the same animal using the transgenic Adora2aCre-Z/EG mouse model combined with retrograde

labeling, respectively. Gene profiling were generated from FACS-purified neurons leading to the identification of new STP and STN neuron specific genes. Knockdown models based on Cre-dependent lentiviral vector were developed to investigate their function either in striatal or in STP neurons. Thereby, we demonstrate that ecto-5'-nucleotidase (NT5e) is specifically expressed in STP neurons and is at the origin of most of the extracellular adenosine produced in the striatum. Behavioral analysis of striatal and STP neuron knockdown mouse models as well as NT5e knockout mice demonstrates the implication of this STP neuron enzyme in motor learning. and therefore highlights the central role of the neuronal NT5e associated to adenosine receptors in striatum-dependent learning.

Title: Midbrain dopaminergic neurons acquire GABA through plasma membrane uptake, not synthesis

Authors: *N. X. TRITSCH[1], W.-J. OH[2], C. GU[2], B. L. SABATINI[1];
[1]Dept of Neurobio., Harvard Med. School, HHMI, Boston, MA; [2]Dept of Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Synaptic transmission between dopamine-containing neurons in the midbrain and target neurons in the striatum plays an essential role in the selection and reinforcement of voluntary movements based on contextual information. Although the importance of dopamine release for these processes is well established, recent evidence indicates that dopaminergic neurons additionally influence striatal circuit function through co-release of fast-acting neurotransmitters along with dopamine. In particular, we recently showed that nigrostriatal afferents in mice exert a rapid and potent inhibitory influence on the activity of striatal projection

neurons (SPNs) by releasing a neurotransmitter that activates $GABA_A$ receptors (Tritsch *et al.*, 2012). We now extend these findings by showing that this phenomenon also applies to mesolimbic afferents, and by providing additional functional evidence that the released neurotransmitter is GABA. Surprisingly, we did not detect the GABA synthetic enzymes GAD65 or GAD67 in dopaminergic neurons of the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc) using either *in situ* hybridization or immunolabeling in transgenic mice. However, VTA/SNc dopaminergic neurons expressed mRNA for the membrane GABA transporters mGAT1 (*Slc6a1*) and mGAT4 (*Slc6a11*) and pharmacological antagonism of these transporters prevented GABA release from these cells. Thus, these findings indicate that GABA co-release is a general feature of midbrain dopaminergic neurons that depends on membrane uptake of GABA from the extracellular milieu but not on GABA synthesis. This unusual mechanism may confer dopaminergic neurons the flexibility to differentially control GABAergic transmission locally across its extensive axonal arbors.

Title: Chronic pain reduces motivation through depression of the indirect pathway

Authors: *N. SCHWARTZ, S. JURADO, B. K. LIM, J. S. POLEPALLI, R. C. MALENKA; Psychiatry and Behavioral Sci., Nancy Pritzker Laboratory, Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Comorbidities of chronic pain include fatigue and symptoms of depression. Despite the large impact these symptoms have on patients' quality of life, little is known about the neural circuit adaptations underlying their development. To address this issue we used the well-established models of CFA-induced chronic inflammatory pain, and of injury-induced neuropathic pain. In both of these models, we observed reduced motivation as measured by a decrease in operant responding for food reward. This reduction could not be explained by reduced mobility or a change in the value of the food reward. Ex vivo recordings from slices

revealed that both chronic pain models were accompanied by a depression of excitatory synaptic transmission in medium spiny neurons (MSNs) of the indirect pathway in the nucleus accumbens (NAc) core. Suppression of calcineurin dependent LTD in the NAc core rescued the chronic pain-induced deficit in motivation. These results suggest that chronic pain depresses excitatory synaptic transmission in the NAc core indirect pathway, and that this depression is required for the decreased motivation caused by these pain models. Thus, neural circuit adaptations within the NAc may contribute to the fatigue and energy malaise that often accompany chronic pain syndromes.

Title: Non-linear dynamical analysis of EEG time series distinguishes patients with Parkinson's disease from healthy individuals

Authors: C. LAINSCSEK[1], M. E. HERNANDEZ[2], J. WEYHENMEYER[3], T. J. SEJNOWSKI[1], *H. POIZNER[4];
[1]Computat. Neurobio. Lab., The Salk Inst. for Biol. Studies, La Jolla, CA; [2]Inst. for Neural Computation, UCSD, La Jolla, CA; [3]Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Inst. Neural Computation, Univ. Calif, San Diego, LA JOLLA, CA

Abstract: Objective, automatic methods of classifying, assessing, and tracking the progression of Parkinson's disease (PD) could prove of great use in the clinic. The pathophysiology of PD is known to involve altered patterns of neuronal firing and synchronization in cortical-basal ganglia circuits. Rather than using spectral-based methods, we used data models based on delay differential equations (DDE) as non-linear time-domain classification tools to distinguish resting

state electroencephalographic (EEG) recordings from PD patients on and off dopaminergic therapy and healthy individuals. Two sets of 50 1-s segments of 64-channel EEG activity were recorded from nine PD patients on and off medication and 9 age-matched controls. The 64 EEG channels were grouped into 10 clusters covering frontal, central, parietal, and occipital brain regions for analysis. DDE models were fitted to individual trials, and model coefficients and error were used as features for classification. Classification performance was measured using 3-fold cross validation across subjects. We found that even short segments of resting state EEG in PD patients and controls contained dynamical structure, and, moreover, that PD patients exhibited a greater dynamic range than controls. DDE model output on the means from one set of 50 trials provided nearly complete separation of PD patients off medication from controls: across brain regions, the area under the receiver operating characteristic curves, A′, varied from 0.97 - 1.0. For distinguishing PD patients on vs. off medication, classification performance (A′) ranged from 0.86 - 1.0 across brain regions. Moreover, the generalizability of the model to the second set of 50 trials was excellent, with A′ ranging from 0.74 - 0.92 across brain regions for controls vs PD off medication, and from 0.62-0.82 for PD on medication vs off. Finally, model features significantly predicted individual patients' motor severity, as assessed with standard clinical rating scales.

Title: Non-linear dynamical classification of short time series of the Rossler system in high noise regimes

Authors: C. LAINSCSEK[1,2], M. E. HERNANDEZ[3], J. WEYHENMEYER[5,1], H. POIZNER[3], *T. J. SEJNOWSKI[6,4];
[1]Howard Hughes Med. Inst., The Salk Inst. for Biol. Studies, La Jolla, CA; [2]Inst. for Neural Computaiton, [3]Inst. for Neural Computation, [4]Div. of Biol. Studies, UCSD, La Jolla, CA; [5]Sch. of Med., Indiana Univ., Indianapolis, IN; [6]Salk Inst., Howard Hughes Med. Inst., LA JOLLA, CA

Abstract: Time series analysis with delay differential equations (DDEs) reveals non-linear properties of the underlying dynamical system and can serve as a non-linear time-domain classification tool. In a companion paper, we apply the DDE model developed here to classify short segments of encephalographic (EEG) data recorded from patients with Parkinson's disease and healthy subjects. Here global DDE models were used to analyze short segments of surrogate time series from a known dynamical system, the Rossler system, in high noise regimes.
Nine simulated subjects in each of two distinct classes were generated by varying the bifurcation parameter b and keeping the other two parameters (a and c) of the Rossler system fixed. Data segments of 512 samples were used. All choices of b were in the chaotic parameter range. We diluted the simulated data using white noise ranging from 10 dB to -20 dB signal-to-noise ratios (SNR). Structure selection was supervised by selecting the number of terms, delays, and order of nonlinearity of the model DDE model that best linearly separated the two classes of data. The distances d from the linear dividing hyperplane was then used to assess the classification performance by computing the area under the receiver operating characteristic (ROC) curve, A'. The selected model was tested on untrained data using 3-fold cross-validation.
DDEs were able to accurately distinguish the two dynamical conditions, and moreover, to quantify the changes in the dynamics. There was a significant correlation between the dynamical bifurcation parameter b of the simulated data and the classification parameter d from our analysis. This correlation still held for new simulated subjects with new dynamical parameters selected from each of the two dynamical regimes. Furthermore, the correlation was robust to added noise, being significant even when the noise was greater than the signal (SNR = -10 dB for single trials A' = 0.6 and for means over 50 trials A' = 0.9; SNR = -15 dB for means of 50 trials, A' = 0.75.
We conclude that DDE models may be used as a generalizable and reliable classification tool for even small segments of noisy data, if the data have an underlying nonlinear dynamical structure.

Title: Position-dependent modulation of digit forces: Temporal evolution of anticipatory and feedback control interactions

Authors: *Q. FU, M. SANTELLO;
Arizona State Univ., Tempe, AZ

Abstract: Previous studies have shown that humans can adjust digit forces to compensate for trial-to-trial variability in digit position, thus resulting in consistent task performance. However, it was not clear whether this digit force-position coordination was accomplished through feed-forward planning (i.e., position and forces are both planned before contact) or feedback corrections (i.e., making corrections after sensing actual digit positions). We speculated that motor commands for digit forces and position are initially planned in a feed-forward fashion but digit forces can be adjusted after making contact with the object if a discrepancy between actual and planned positions is perceived. We tested this hypothesis using a virtual reality (VR) environment consisting of two haptic devices and a monitor. Subjects' thumb and index finger were attached to the haptic devices and interaction forces between the digits and the virtual object were simulated. Subjects were initially trained to perform a two-digit unconstrained torque production task using both small and large virtual boxes (widths = 42 or 72 mm; S or L, respectively). Subjects were required to apply a torque (±90 Nmm) to the box to control a horizontal moving cursor to the left or right of the center position to catch a downward moving ball. They had to adapt their digit force as function of box width, i.e., small and large forces for L and S box width, respectively. After learning the task, subjects were tested with a random sequence of box widths (1) with (Test A) or (2) without (Test B) visual information about box width. Importantly, in Test A subjects could have planned manipulation forces prior to making contact with the box by using visual width cues. In contrast, in Test B subjects had to make corrections to their motor plan after contact if the actual box width did not coincide with the width they had planned for. Consistent with our hypothesis, we found that subjects exerted digit forces that matched actual box sizes regardless of whether visual cues about box width were available prior to contact. A closer examination of the time course of the forces revealed that force development was delayed in all cases for Test B condition. Specifically, the development of the digit forces appropriate for the current box width, hence the relative digit positions, was delayed about 120-180 ms after initial contact. We propose that digit position-dependent force modulation can be explained by integrating pre-contact feed-forward anticipation and post-contact feedback control.

Title: Feature extraction from grip force for identification of sensorimotor control processes

Authors: *K. MOJTAHEDI[1], M. SANTELLO[2];
[1]Sch. of Biol. and Hlth. Systems Engineering,, [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Phoenix, AZ

Abstract: Previous work on the control of grasping has focused on the phenomenon of bell-shaped grip force rates as a feature indicating feedforward force control. However, this feature has not been assessed quantitatively. Furthermore, it is possible that the time course of grip force may contain additional features that could provide insight into sensorimotor control processes. In this study, we addressed these questions by verifying two computational approaches to extract features from grip force rates generated between contact and the onset of object manipulation (i.e. object lift) in humans. One approach consisted of fitting a Gaussian function to grip force rate and quantifying the goodness of the fit using the root mean square error (RMSE). The second approach consisted of applying continuous wavelet transform (CWT), which is based on the correlation of the grip force rate signal with a Mexican hat function. For this approach, we used the features of signal-to-summation of signal and noise. We applied both approaches to analyze grip force in two grasping tasks: (1) grasping an inverted T-shaped object whose center of mass (right, center, or left) was changed across blocks of consecutive trials (24 subjects), and (2) grasping an object whose mass (light or heavy) was pseudo-randomly changed on a trial-to-trial basis (24 subjects). For both tasks, subjects were asked to grasp the object at either predetermined (constrained) or self-selected (unconstrained) locations. The RMSE approach revealed that grip force rates during constrained grasping were better fitted by a Gaussian function than unconstrained grasping ($p < 0.05$ for both experiments). The wavelet approach confirmed this observation as revealed by signal-to-summation of signal and noise analyses ($p < 0.05$ for both experiments). Both analytical approaches suggest that grip force control is

mediated by feedback-driven corrections when subjects can self-select digit contacts on an object, as opposed to feedforward force development for constrained contact points. Future work will examine the application of CWT on a broader variety of manipulation tasks to extract digit force features that might provide insight into neural control of grasping.

Title: Parallel processes underlie learning of skilled tool use: Retention and interference

Authors: *M. SANTELLO, Q. FU;
Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., TEMPE, AZ

Abstract: A novel tool can be used in multiple contexts each requiring different hand-object interactions. Previous studies have shown an interference effect when switching between two opposite manipulation tasks performed on the same object, i.e., a change of manipulation context. As the source of the interference remains unclear, we quantified the extent to which dexterous manipulation in different contexts had to be learned and recalled. Subjects (n = 44) were asked to lift and balance an L-shaped object. A torque (320 Nmm) had to be produced on the handle at object lift onset to compensate for the object's asymmetrical mass distribution and prevent tilt. The direction of the necessary compensatory torque (Tcom) depended on the context, i.e., orientation of the object, which could be changed by the subject by rotating the object 180 degrees about the vertical axis of the handle. Subjects performed four blocks of eight trials and had to rotate the object after each block. We measured Tcom at object lift onset to quantify anticipatory grasp control. Subjects started with a moderate error of |Tcom| =192.67 ± 12.61 Nmm (mean ± SE), but learned the task equally well in the first two blocks of both contexts (|Tcom| = 288.7 ± 6.78 Nmm and 293.7 ± 7.45 Nmm for the last 5 trials of block 1 (context A) and block 2 (context B), respectively). After the first two blocks, subjects were divided into 4 groups and took breaks of different durations (0, 10, 20, or 60 minutes) before performing the third block in which they were asked to retrieve the manipulation learned in context A. We found a retrograde interference on the first retrieval trial for the 0-min break group (|Tcom| = 122.74 ± 15.22 Nmm). Most importantly, a significant effect of break duration

was found on the strength of the interference. Specifically, subjects produced |Tcom| of 182.60 ± 21.53 Nmm, 238.02 ± 21.53 Nmm, and 264.82 ± 17.56 Nmm for breaks of 10, 20, and 60 minutes, respectively. The time-dependent decay of the interference was found to have a half-life of 10.91 minutes. The 0-min break group came back after two weeks to recall the manipulation learned in context A. Subjects showed good retention of what they had learned by producing |Tcom| of 272.71± 22.91 Nmm in the first trial despite the two-week break. We propose that, when subjects are learning manipulation tasks, two components are learned in parallel: one is acquired by error-driven update of the internal model whereas the other is acquired by repetitive exposure to performing a task in the same context. The formation of the second component is context-independent and has a time-dependent inhibitory effect on the retrieval of the previously learned context-dependent first component.

Title: Motor commands distort perception of relative fingertip position

Authors: *D. SHIBATA[1], A. M. L. KAPPERS[2], M. SANTELLO[1];
[1]Arizona State Univ., Tempe, AZ; [2]VU Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Digit force modulation as a function of position for dexterous manipulation suggests that humans are skilled at sensing points of force application relative to the object and each other. However, the underlying sensorimotor transformations remain unclear. In this study we quantified subjects' ability to sense the relative position of the digits as a function of digit force without visual feedback of the hand or grasped object. Thirty subjects were asked to match perceived vertical distance between the center of pressure (CoP) of the thumb and index finger pads (d_y) of the right hand ("reference" hand) using the same hand ("test" hand). The digits of reference hand were passively placed collinearly (d_y = 0 mm). Subjects were then asked to exert normal and tangential digit forces (F*n* and F*tan*, respectively) using the reference hand, release the grasp, wait for 10 seconds, and then match the memorized d_y using the test hand. The reference hand exerted F*tan* of thumb and index finger in either same (both up or down) or opposite (thumb-index: up-down or down-up) direction. The magnitude of F*n* and F*tan* exerted

by each digit of the reference hand was the same across these four experimental conditions (4-5 N and 2.5-3.5 N, respectively). In two additional conditions, we also examined the effect of F*n* magnitude by asking subjects to exert either the same range of F*n* as for the above-mentioned conditions while exerting negligible F*tan* (4-5 N, 0 ± 0.25 N), or negligible F*n* and F*tan* (0.5-1 N, 0 ± 0.25 N). For the test hand, digit forces were either negligible (0.5-1 N, 0 ± 0.25 N; Experiment 1) or the same as those exerted by the reference hand (Experiment 2). We hypothesized that the perception of d_y would be (a) less accurate and (b) biased toward the direction of F*tan* only when the direction of F*tan* of the thumb and index finger was opposite. Subjects systematically misplaced d_y but only when digit F*tan* directions were opposite. Specifically, subjects positioned the thumb CoP higher than the index finger CoP when the F*tan* of the thumb and index finger were directed upward and downward, respectively, and vice versa ($p < 0.001$). In contrast, d_y was placed accurately when the direction of F*tan* was the same for both digits and when F*tan* magnitude was negligible. There was no difference in d_y estimation error regardless of whether the magnitude of F*n* and F*tan* of the test hand were significant or negligible. These findings indicate that the direction of F*tan* distorts the placement of the relative position of the digits. We speculate that the expected sensory consequence of motor commands (vertical separation of fingertips) overrides veridical estimation of fingertip position through actual sensory feedback.

Title: Role of anterior intraparietal sulcus in dexterous manipulation

Authors: *P. MCGURRIN[1], P. PARIKH[2], M. DAVARE[3], M. SANTELLO[2];
[1]Sch. of Life Sci., [2]Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ; [3]Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. of London, Univ. Col. of London, London, United Kingdom

Abstract: Fronto-parietal cortical networks are involved in visuomotor transformation of object properties for accurate hand shaping and sensorimotor control of digit forces. However, to date no study has investigated the neural mechanisms underlying coordination of digit position and

forces for dexterous manipulation in a natural task paradigm. When subjects perform a grasp using self-selected (unconstrained) versus predetermined (constrained) locations on an object, the trial-to-trial variability in digit position is compensated by a covariation in digit forces so as to apply appropriate compensatory torque on the object to preserve task dynamics. Manipulation with an unconstrained versus constrained grasp may require additional online monitoring and correction of digit forces in relation to where the digits make contact with the object. Here, we sought to understand the effects of temporary disruption of contralateral anterior intraparietal sulcus (aIPS) using repetitive transcranial magnetic stimulation (rTMS) on the digit position-force coordination during a constrained versus unconstrained manipulation task involving lifting an object with asymmetrical mass while preventing it from tilting. Five right-handed young subjects performed a visually-cued grasp and lift task using a precision (thumb-index) grasp at unconstrained versus constrained contacts marked on the object in separate blocks. Transient contralateral rTMS stimulation over aIPS in a given trial was either delivered prior to grasp onset, or at object contact in a random order. rTMS at either stimulation time had no effect on digit placement. However, subjects applied greater peak grip and load force rates when rTMS was delivered at object contact under both unconstrained and constrained grasp conditions ($p < 0.03$). Furthermore, rTMS to aIPS induced significant increase in preloading duration in the constrained condition when TMS was delivered at object contact ($p < 0.05$). Interestingly, we saw no disruption in the covariation between digit position and force or the compensatory torque at object lift onset. Thus, our preliminary data suggest that temporary disruption of contralateral aIPS interfered with individual grasp variables associated with digit forces, but not digit placement or digit position-force coordination. Future work will further elucidate the role of bilateral aIPS and contralateral premotor areas in dexterous manipulation.

Title: Reach-to-grasp: A single movement of the entire upper extremity

Authors: *A. G. ROUSE, A. T. ROUSSIN, M. H. SCHIEBER;
Neurobio. and Anat., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: During reach-to-grasp, rather than reaching first and grasping second, shaping of the hand to grasp an object evolves in parallel with reaching to the object's location. Nevertheless, reaching and grasping commonly are considered to be independent processes, with the motion of proximal joints depending solely on reach location and the motion of distal joints depending solely on object shape. Here, we examined the extent to which the motion of proximal joints also depends on the object grasped and the motion of distal joints depends on reach location.
Two monkeys reached from a center location to grasp one of four objects located at one of eight radial locations separated by 22.5° as 22 joint angles were tracked. The effects of object and location on each joint's motion as a function of time were analyzed with two-way ANOVA from before the instruction/go cue until after grasp. The discriminability of object and location also was assessed with linear discriminant analysis (LDA).
The 3 shoulder joint angles showed a dominant effect of target location, but also showed a smaller effect of object that evolved in parallel. LDA using only the 3 shoulder angles discriminated not only location but also object, increasing to near 100% accuracy before object contact. In contrast, the elbow angle showed little if any effect of location (all objects were equidistant from the shoulder), but a large object effect. The 3 wrist angles showed an early effect of location which fell away as the effect of object increased. In the fingers, flexion/extension at the MCP joints showed small early effects of location followed by a larger effect of object. MCP ab/adduction angles showed later, large object effects, and the PIPs showed object effects later still. LDA using either wrist or finger angles discriminated both object and location early, but discrimination of location fell away as the time of object contact approached.
The kinematics of all upper extremity DoFs, from the shoulder to the PIP joints, thus varied substantially depending on the object to be grasped. While location affected shoulder angles most strongly, small but statistically significant differences in wrist and finger angles at different locations for a given object were observed as well. Reach-to-grasp thus is a single movement that involves both proximal and distal joints, all affected by both location and object as the movement evolves in time. Proximal joints are adjusted to achieve an attitude of the hand that permits grasping an object with a relatively invariant hand shape formed by distal joints.

Title: Reach-to-grasp: EMG activity in both proximal and distal muscles is related to both location and object

Authors: *M. H. SCHIEBER, A. T. ROUSSIN, A. G. ROUSE;
Neurol. and Neurobio., Univ. of Rochester, ROCHESTER, NY

Abstract: In reach-to-grasp movements, proximal muscles act on the shoulder and elbow to transport the hand to its target while distal muscles shape the hand to grasp the object. However, given that shoulder angles also vary depending on the object, the activity of proximal muscles might vary depending on the object as well as its location. Conversely, given that wrist and finger angles vary to orient the hand toward the object, distal muscle activity might vary with location as well as object shape.

We therefore recorded EMG activity from up to 16 muscles in the arm and hand of two monkeys performing reach-to-grasp movements involving four objects in up to eight radial locations separated by 22.5°. In general, EMG activity occurred in two temporal epochs. A first burst of activity occurred around the onset of movement. After this initial burst, the overall level of EMG activity decreased. A second increase in EMG activity began shortly before and continued through object contact. In the initial epoch, EMG activity appeared predominately in proximal muscles, wrist extensors and extrinsic digit extensors. In the second epoch, proximal muscles along with wrist and extrinsic digit flexors were more active. Also during this second epoch, the intrinsic muscles of the hand became active, and their activity was maintained during contact with the peripheral object.

In proximal arm muscles, EMG activity during the first epoch varied predominantly with the location to which the subject reached, although some proximal muscles also showed some object-related activity. In the second epoch, surprisingly, proximal muscle activity varied primarily depending on the object being grasped. The wrist and extrinsic digit extensors' activity during the first epoch depended on both object and location. In contrast, wrist and extrinsic digit flexors became active in the second epoch with their activity being affected more by object than location. Finally, intrinsic muscles of the hand showed predominately object-related activity during the second epoch.

For the present reach-to-grasp movements, an initial epoch of EMG activity in both proximal and distal muscles appeared to transport and orient the hand toward the target object. A second epoch of EMG activity--comprised mostly of object-related variation not only in distal, but also in proximal muscles--positioned proximal joints to achieve the appropriate attitude of the hand and closed the hand on the object. Although occurring in differing proportions, in each epoch the activity of both proximal and distal muscles varied significantly depending on both the reach location and the object grasped.

Title: Pre-tensioning of musculotendons is necessary to achieve finger postures and slow finger motions

Authors: *S. BABIKIAN[1], E. KANSO[2], F. J. VALERO-CUEVAS[3,4];
[2]Aerospace and Mechanical Engin., [3]Biomed. Engin., [1]USC, Los Angeles, CA; [4]Biokinesiology and Physical Therapy, Univ. of Southern Calfornia, Los Angeles, CA

Abstract: While the mechanics and neural control of rapid limb movements is relatively well understood, it is currently unknown how individual muscles are controlled to produce slow finger motions. Our purpose is to identify the necessary conditions for which the dominant models of muscles as elastic force actuators [1] can hold an arbitrary posture in the finger workspace--and produce quasi-static finger motions across them. Our test system is a 2-joint, 4-muscle planar finger model. Our approach is to define the set of muscle stiffness parameters that make it feasible to hold specific postures and transition among them [2] [3]. That is, we identify whether or not muscle stiffness parameters exist to produce a strain (i.e., potential) energy minimum for every finger posture in the workspace. First we explore the combinations of muscle stiffnesses that can keep the finger in equilibrium across its workspace. We find that such biomechanical systems have no solutions if muscles are not "pre-stretched," i.e., that muscles must always have strain energy, even at their shortest lengths. By adding a fixed initial stretch to each of the muscles and thus making them pre-stretched, we observe the feasibility of holding any posture in the workspace, and smoothly transitioning across postures by simply tuning muscle stiffness. We then solve the inverse problem where we identify the range of stiffness values across muscles to hold every posture in the workspace, which also allows us to identify the most energetically efficient muscle activations. We find that many postures in the workspace can be achieved by a variety of values and combination of muscle stiffnesses, but other portions

of the workspace require very precise values and combination of muscle stiffnesses. These novel results begin to explain the types of neural strategies necessary for slow finger motions, and begin to provide a neuromechanical explanation for a variety of functional deficits and deformities seen in neurological disorders.

Title: Compensating for discrete contact forces through grip force modulation and choice of contact location

Authors: *J. S. DIAMOND[1], J. Y. NASHED[1], J. R. FLANAGAN[1,2];
[1]Ctr. for Neurosci. Studies, Queen's Univ. Ctr. For Neurosci. Studies, Kingston, ON, Canada;
[2]Dept. of Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: Many day to day actions involve the manipulation of objects. During basic manipulation tasks_such as when an object is held and moved around_we see that grip force (i.e., the normal force applied to the object surface by the contacting digits) modulates in synchrony with the acceleration-induced load forces resulting from object motion. Often times however, a discrete load may be superimposed on the basic manipulation task, such as when using a hand-held object to contact a second object. In this context, a person must accommodate these sudden changes in load force, induced by the contact event, through compensatory changes in grip force applied to the hand-held object. Indeed, these grip force adjustments must be scaled to the dynamics of the contacted object, which may render some contact locations preferable over others. We tested this presumption using a novel task that involved moving a hand-held object to

contact a bar that pivoted counterclockwise about a fulcrum. Participants held an object in a precision grip and moved it in the horizontal plane to contact the bar with sufficient force to cause it to rotate 90° from its resting orientation that was orthogonal to the long axis of movement. As a consequence of the dynamics of the pivoting bar, the force necessary to achieve this rotation decreased as a linear function of contact distance from the pivot. Participants were instructed to contact the bar at a location that felt comfortable and natural. Two conditions were performed in which the centre of the bar was shifted either left or right of the midline, positioning the fulcrum either more distant or closer to the midline. Preliminary results from these conditions suggest that participants bias their reach location to a position on the bar that required less contact force to rotate it. That is, participants biased their endpoint to a location on the bar away from the fulcrum. Notably, participants did not simply reach for the position most distant to the fulcrum on each movement. This finding may indicate that participants tradeoff the impact force required for rotation and movement distance in choosing their contact location. Preliminary evidence also suggests that participants modulate their grip force to account for the position dependent changes in contact force along the bar. Furthermore, these changes are evident just prior to the contact event indicating that participants predictively modulate their grip force to account for the discrete loads.

Title: Motor control of the arm during voluntary collisions in inverted gravity field

Authors: *V. THEATE[1], C. PONSELET[2], T. JEAN-LOUIS[3], L. PHILIPPE[2];
[1]ICTEAM / IONS, Univ. Catholique De Louvain, Brussels, Belgium; [2]ICTEAM / IONS, Univ.

Catholique De Louvain, Louvain-La-Neuve, Belgium; [3]IONS, Univ. Catholique De Louvain, Brussels, Belgium

Abstract: Predictable collisions during object grasping are common in everyday life and previous studies have reported asymmetries between up and down collisions in the control of precision grip (White et al., 2011 & 2012). The aim of this study is to investigate the relative role of movement direction (to the head or to the feet) versus gravity (+1g versus -1g) in these asymmetries.
In our experiment, six subjects were seated and restrained in a chair. They performed collisions in direction of their head (H) or in direction of their feet (F), randomly interleaved. These collisions were, first, performed in a normal gravity configuration (+1g) and, second, in an inverted gravity configuration (-1g). The latter consisted in turning the subject with the head upside down. We recorded 300 collisions by subject for each of these 4 categories (+1gH, +1gF, -1gH, -1gF). Dynamics of precision grip, movement kinematics and muscular activities were recorded.
Our results show that the patterns of muscular activities adapt immediately to the gravity configuration (+1g versus -1g). Very interestingly, the kinematics of the upper limb is the same with respect to the allocentric frame of reference in both configurations (+1gH versus -1gF and +1gF versus -1gH). As a consequence, the load force at peak acceleration depends on the movement direction with respect to gravity, whatever the direction of the movement with respect to an egocentric frame of reference (to the head versus to the feet). Thus the load force at peak acceleration is the same when the movement is opposite to gravity (+1gH and -1gF) and is much larger than when the movement is in the direction of gravity (+1gF and -1gH). In contrast with this adaptation of movement kinematics, the dynamics of the precision grip does neither fully adapt during the transport phase (at peak acceleration) nor at collision (impact with target)

Title: Prehension force for lifting a light-weight object

Authors: *Y. HIRAMATSU[1], D. KIMURA[1], H. JINNOUCHI[1], T. ITO[2], K. KADOTA[1], H. KINOSHITA[1];

[2]Department. of Hlth. and Sport, Univ. of Mukogawa Women's, Hyogo, Japan

Abstract: Ability to manipulate small objects at the fingertips is an indispensable sensory-motor function in our daily lives. Previous studies of prehension force control commonly used a test object weighing greater than 100 g. In the present study, an attempt was made to develop an extremely light (6 g) test apparatus equipped with grip and lifting (load) force sensors. Using this apparatus and healthy young adults (N = 20), we examined grip-load force coordination in a light weight range. The subjects lifted the apparatus using the thumb and index finger, held it in the air for 10 sec, and drops it by slowly separating the fingers. Rayon and sandpaper grip surface, and weights of 6 g - 200 g were tested. Static grip force, slip force, a static grip force/load force ratio, safety margin relative to the static force, and the coefficient of static friction were evaluated. In both surfaces, the static grip force/load force ratio increased non-linearly with weight lighter than 30 g. The coefficient of friction also had a similar trend. The relative safety margin was quite large (> 80%) for the 6 g apparatus with both surfaces, which decreased non-linearly with load force, and reached about a half value while lifting the 200-g apparatus. When the subjects were asked to grip with smaller static grip force than usual force, static grip force was decreased by 40% on average due to a decreased safety margin. However, even with this controlled small static grip force, the higher relative safety margin during light object lifts remained. The findings suggest that force coordination for lifting of light objects (< 30 g) differs from that for heavier objects. Measurement of the area of finger-surface contact, and skin deformation in relation to grip force suggested that the high relative safety margin during manipulating light objects could be a strategic behavior to compensate decreased cutaneous input from the skin.

Title: Gaiting of cutaneo-muscular reflexes and somatosensory evoked potentials differs with the load compliance during maintaining constant finger force or position

Authors: *H. KIRIMOTO, T. MATSUMOTO, H. TAMAKI, M. SUZUKI, S. MIYAGUCHI, K. SUGAWARA, H. ONISHI;
Inst. for Human Movement and Med. Sci., Niigata Univ. of Hlth. & Welfare, Niigata, Japan

Abstract: Introduction; When an individual performs a submaximal statistic contraction, there are two different load types either to produce a constant force by pulling against a noncompliant restraint (force task) or to maintain a constant limb angle while supporting an equivalent isoinertial load (position task) . Sensorimotor modulation is crucial for executing smooth voluntary movements in humans, and many studies have examined this by using attenuation of cutaneo-muscular reflexes (CMR) and somatosensory evoked potentials (SEPs) during or even before the initiation of voluntary movement, which is known as 'gating'
Objective; The purpose of the current study was to determine the influence of load compliance during muscle static contraction tasks on the gating effect, i.e., attenuation of CMR and SEPs during the motor task.
Methods; Fourteen healthy subjects contracted the right first dorsal interosseus muscle by abducting their index finger 50 seconds either to produce a constant force against a rigid restraint by 10 degree (force task) or to maintain a constant position against a constant load of 20% of maximum contraction (position task). CMR and SEPs were recorded, following digital nerve stimulation of the index finger while subjects kept contraction. CMR were recorded from the first dorsal interosseous muscle and SEPs were recorded from C3' (2 cm posterior to C3). The stimulus was delivered using a constant current stimulator at a level 2.5 times above that required for perception (pulse duration 100 ms, frequency 5 Hz for CMR / 2Hz for SEPs). The amplified and filtered EMG and EEG signal were averaged time-locked to the stimulus for 250 sweeps
Results; The E2 component of the CMR and the P14/N20 components of the SEPs were significantly reduced during position task compared with force task ($p<0.001$). There was a significant (qualitative) relationship between the decrease in the size of the E2 component of the CMR and the P14/N20 components of the SEP (X2 test; $P < 0.05$).
Conclusions; We conclude that the decrease in size of the E2 component associated with position task results from gating of the digital nerve input. Larger gating effect in the position task could imply that the task to maintain the position of the index finger while supporting a constant load requires more afferent information with which the enhanced gating of centripetal mechanism would occur.

Title: Finger and arm control during interactions with multitouch devices

Authors: *D. L. JINDRICH[1], D. S. ASAKAWA[2], J.-H. LEE[3], C. LOZANO[4], J. T. DENNERLEIN[5];
[1]California State Univ. San Marcos, San Marcos, CA; [2]Kinesiology, California State University, San Marcos, San Marcos, CA; [3]Mechanical Engin., [4]Sch. of Computing, Informatics, and Decision Systems Engin., Arizona State Univ., Tempe, AZ; [5]Dept. of Physical Therapy, Northeastern Univ., Boston, MA

Abstract: Touchscreen and gestural computing devices, including tablets and smartphones, are commonly used for both personal and work purposes. These rapidly spreading devices involve complex finger and thumb movements whose motor control is poorly-understood. We are using experimental and modeling studies to better understand the control of multitouch interaction. We measured finger joint kinematics and arm muscle EMG during common one- and two-finger gestures used on a hand-held touchscreen computing device. Two-finger gestures involved larger changes in joint angles of the digits and greater muscle activity than one-finger gestures. Muscle activity was substantial, of magnitudes associated with risks for musculoskeletal disorders. Holding the device was associated with increased EMG relative to interacting with a device supported on a surface. Surprisingly, turning the device on and providing contextual feedback resulted in decreased EMG relative to interacting with a device that was turned off. To better understand the specific neuromuscular control strategies associated with multitouch gestures, we are using detailed musculoskeletal models of the hand and arm. We have incorporated intrinsic hand muscles into an existing musculoskeletal model of the arm using techniques for data-driven optimization to determine attachments. Optimization methods can reproduce measured moment arms for intrinsic and extrinsic muscles and tendons of the index finger. Our combined experimental and modeling approach will contribute to understanding the motor control of complex gestures, designing interfaces that increase performance, reducing risks for musculoskeletal disorders, and improving accessibility to motor-impaired populations.

Title: Does abrupt inversion of visual feedback influence grip force adjustments during object transportation? Implication for forward models

Authors: *F. DANION[1], F. SARLEGNA[2];
[1]CNRS, INT, Marseille, France; [2]CNRS, ISM, Marseille, France

Abstract: It has been proposed that goal-directed movements are executed by means of a central controller, an inverse model which can convert
desired hand or object motion into adequate motor commands (Wolpert and Kawato, 1998), in conjunction with a predictor (forward model) that can estimate the sensory consequences of the movement (Desmurget and Grafton 2000). Forward models have been hypothesized to be useful in the context of visuomotor tasks (Miall et al. 1993; Mehta and Schaal 2002) and object manipulation tasks (Flanagan et al. 2003; Danion and Sarlegna 2007), as both would allow controlling the motion of the object and adjusting grip force adequately. The goal of the current study was to investigate how independent are these two types of forward model, by means of a task requiring adaptation of visuo-manual tracking but no adaptation of grip force control. Thirteen healthy adults tracked a randomly-moving target by moving a handheld object that was restrained by an elastic cord. The set-up is similar to that used in Sarlegna, Baud-Bovy and Danion (2010). The ongoing position of the object was displayed as a cursor on a screen along with the visual target. The ability to manipulate the cursor/object was monitored through the accuracy of visuo-manual tracking and the coupling between the grip force and the load force resulting from the tension of the elastic cord. As expected, the sudden inversion of the Relationship between the hand displacement and the cursor displacement resulted in lower tracking performance. However, as participants had more and more experience with the sudden inversion, tracking performance increased, suggesting that the related forward model was updated. Surprisingly, at no point during the training course was the predictive control of grip force affected by the visuo-motor inversion. Overall, these results suggest that the forward model underlying visuo-manual tracking can be updated independently of the forward model underlying the predictive control of grip force.

Title: Neural representation of an invariant object mass is spatiotemporally changing during object manipulation

Authors: *G. KONG, K. L. WEI;
Dept. of Psychology, Peking Univ., Beijing, China

Abstract: We need to estimate the properties of objects when we interacts with the external world. This kind of estimation is especially important when we manually manipulating objects. For example, appropriate estimate of inertial properties of a hand-held coffee cup is essential for successful and efficient lifting and transporting it to our mouth. A wrong estimate of mass distribution will tilt the cup and spill the coffee; an overestimation of its mass will incur excessive force on the cup. How the nervous system represents the object estimate has not been systematically investigated.
We address this question with a novel motor perturbation paradigm. We asked subjects to perform center-out hand reaching task while holding a water-filled cup. After several attempts subjects learn the cup mass as such the movement trajectory becomes straight in 3D space. However, when the cup is unexpectedly emptied or filled in between trials, subjects will make vertically-curved reaches. This height change can be quantified as a surrogate of subjects' estimates about the object mass (Yan et al., 2013). In Experiment 1, we find that the mass estimate, learned in one reaching direction, can be generalized to other directions. Surprisingly, despite of repetitively lifting constant mass, this spatial generalization is not full and uniform across directions: the more deviated from the learning direction, the less generalization can be seen. This Gaussian-shaped generalization function is similar to what have been shown in other motor generalization tasks involving complex dynamic perturbations. In Experiment 2, when the test trials for probing the mass estimate are performed 30 or 60 seconds after the training trials, the mass estimate is significantly altered as if the sensorimotor memory of the object mass decays. In Experiment 3, when subjects explicitly observe (and verbally inform about) the change of object mass, they still cannot fully generalize the learning from one direction to other directions.
Our results indicate that when the inertial property of an object is learned via movements its correct representation is only available for subsequent actions performed near the learning

direction and within a short timing window. Verbal knowledge or visual observation is not sufficient for establishing correct representation of object inertial properties. It thus suggests that while the high-level cognitive representations of an object are spatially invariant and temporally sustainable, the neural representations of movement-related object properties might have their unique spatiotemporal patterns.

Title: Physiologically-based control of a robotic tendon-driven system

Authors: *J. ROCAMORA[1], C. M. NIU[1], J. BUCHLI[2], T. D. SANGER[1], F. J. VALERO CUEVAS[1];
[1]USC, Los Angeles, CA; [2]ETH Zürich, Zürich, Switzerland

Abstract: We have proposed a synthetic analysis approach to validate our models and hypotheses of neural control. We focus on tendon-driven systems to experimentally replicate the neuromechanical function of the fingers. However, such systems are generally high-dimensional and nonlinear, which require a careful strategy for their control.
In previous work [1], we explored theoretical control strategies for these systems by developing the first stochastic optimal controller applied to a simulated index finger model. Recent work [2] led to the actual implementation of such an approach in a tendon driven robotic finger.
We present the extension of our modeling work by including additional physiological elements such as generic muscle excitation-contraction dynamics and muscle spindle models [3]. To control this expanded system, we use the Reinforcement Learning approach PI2-CMA algorithm

(Policy Improvement with Path integrals with Covariance Matrix Adaptation) as described in [4] that allows more autonomous tuning of control and learning parameters, resulting in better convergence. This non-physiological machine learning approach identifies the constraints and boundary conditions for future neuromorphic control, which incorporates spiking neurons and realistic neural circuitries. It eventually allows us to test which minimalist structures are needed to achieve dexterous hand control, as well as the origins of upper-limb neuropathology.

Title: Kinematic and reflexive finger-thumb coupling during pinch

Authors: C. L. JONES[1,2], *D. G. KAMPER[1,2];
[1]Biomed Engin., Illinois Inst. Technol., CHICAGO, IL; [2]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: The ability to precisely and dynamically coordinate activity of the thumb and fingers is fundamental to our development as humans. Use of day-to-day objects such as scissors or pens requires dynamic coordination between the digits. Unfortunately, this critical coordination

between the fingers and thumb is significantly impaired following stroke. The nature of these deficits, however, is not yet well understood due to the difficulty of precisely measuring and acting on the hand under dynamic conditions. In this study, we employ a high bandwidth, precise finger exoskeleton to deliver perturbations to the index finger during pinching movements of the finger and thumb. The exoskeleton provides for full control of either torque or angle at each flexion/extension joint of the index finger. Servomotors located proximally to the hand transmit torque through a set of cables to the joints of the exoskeleton which are aligned with those of the finger. Both torque and reflex-inducing perturbations are applied in order to analyze the extent of kinematic and reflexive finger-thumb coupling involved in motor control of pinch. Preliminary results show that in slower movements (10s) when a perturbation is delivered to one digit with no outside interference in the other, a corresponding pause arises in the trajectory of the unperturbed digit (Fig. 1). Thus, substantial non-reflexive coupling between the index finger and thumb was apparent during movement. Knowledge of this coupling will inform future rehabilitation strategies and may be utilized to reduce the cost of take-home assistive and therapeutic devices.

Fig. 1 - Example of finger-thumb endpoint path (left-right traces) during unperturbed pinch (left) and including perturbation of the thumb during close (right). Onset of perturbation is marked with an ‘X’ and direction of motion is indicated by arrows.

Title: The effects of gender and hand strength differences on the relative contribution of efference copy and sensory feedback to the sense of effort

Authors: *D. E. ADAMO[1], S. SCOTLAND[2], B. J. MARTIN[2];
[1]Dept. of Hlth. Care Sci., Wayne State Univ., Detroit, MI; [2]Industrial and Operations Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Considering asymmetry in the sense of effort, a possible peripheral modulation of the sense of effort, and gender dependence of sensory asymmetry; the aim of this study was to investigate the effects of gender and hand strength differences between the dominant and non-dominant hand on the relative contribution of efference copy and sensory feedback to the sense of effort. Thirty-two (22 F and 10 M) right-handed, healthy adults performed grasp force matching tasks while seated in a standard posture with their forearms supported. Individuals were grouped according to grip strength differences between dominant and non-dominant hands, as either; positive (dominant at least 5% stronger than non-dominant), equal (dominant - non-dominant grip strength less than 5%), and negative (non-dominant at least 5% stronger than dominant). Participants reproduced a right or left hand 20% MVC reference grasp force with the same (ipsilateral remembered, IR) or opposite (contralateral remembered, CR) hand, with or without reference force visual feedback and, with or without reference hand vibration (60Hz) applied to flexor tendons at wrist level. A marker controlled by the reference force signal and presented on a vertical scale was displayed on a video screen when visual feedback was permitted. In the absence of visual feedback the reference force was learned from verbal qualitative and quantitative feedback. Feedback was never provided for the matching hand. Since vibration alters sensory coding of ongoing motor activities and muscle tension, it was hypothesized that vibration-induced changes in sensory information would influence the magnitude of force matching errors that, further, would be influenced by gender, grip strength differences between hands and the availability of visual feedback. The results revealed inconsistencies in the matching constant error expressed in both % MVC and Newtons. Variations in matching asymmetries found for different conditions suggest that the contribution of efference copy and sensory feedback to the sense of effort reflect complex interactions between gender and hand strength differences. The findings further emphasize the context dependent and multifaceted nature of grasp force production and control.

Title: Temporal aspects of grasping apertures with different tools

Authors: *Y. ITAGUCHI, C. YAMADA, K. FUKUZAWA;
Waseda University, Psychology Dept., Shinjuku-Ku Tokyo, Japan

Abstract: The present study investigated motor control of hand aperture in the process of grasping an object. Previous studies have suggested that an effecter-independent motor representation is used in grasping an object. Finger pre-shaping aperture was equally scaled as a function of object size. Temporal aspects of the grasping movements were, however, different between hand and tool use. To further elucidate how a grasping movement is affected by different effectors, the present study examined
the temporal transitions of grasping aperture using two different tools.
Methods
Five participants reached and grasped an object with (1) a hand (thumb and index finger), (2) chopsticks, and (3) a scissors-like tool. Diameters of the target object was 1.5cm, 2cm, and 2.4cm, with 2cm in height. The object and a start position of the movements were located a 20cm distance away on the midline of the participants. The start point was located at a point 25cm from the participants. The participants carried out a total of 180 trials (20 trials × 3 objects × 3 grasping conditions). The order of the objects grasped was randomized among the participants.
Results
(1) Maximal grip aperture (MGA) was equally scaled to object size in the three grasping conditions, i.e., the size of MGA increased as the object size increased. The size of MGA in the hand condition was larger than in the two tool-use conditions. (2) Timing of the MGA did not vary among the three conditions; MGA appeared at about 75% of the movement time. (3) When participants used tools, a grip aperture plateau was followed by MGA, and its duration was most prolonged in the scissors-like tool condition; 90% or more of MGA was maintained for 25%, 17%, and 13% of the movement time before the MGA in the scissors-like tool, chopsticks, and hand onditions.
Discussion
The present study provided mainly two new findings. First, sizes of MGA were modulated equally by object size, but the sizes of MGA were not the same among the grasping effecters. This finding suggests that absolute size of MGA was not a critical index in the motor planning processes. Second, a plateau in the temporal transition of grasping aperture was evident in the tool use conditions *before* the timing of MGA. This result was partially inconsistent with a previous study (Gentilucci et al. 2004) where a plateau *followed* MGA. This apparent disagreement may be attributed to the mechanical characteristics of the tools. In sum, the present results showed what aspects are effecter-independent and effecter-dependent in the temporal transition of grasping aperture.

Title: Psychophysical limitations and biases in the perception of tactile direction

Authors: *J. C. TANNER[1], N. NEWMAN[2], N. ZAUTRA[3], S. HELMS TILLERY[1];
[1]SBHSE, [2]CLAS, [3]SOLS, Arizona State Univ., Tempe, AZ

Abstract: Some of the tactile cues which arise from our interactions with objects have an element of directionality. These cues can inform grasp intent, adjustment, and in some cases may even modulate a response. In order to quantify perceptual limits of tactile direction, we investigated the perception of two types of tactile direction: oriented edges pressed passively into the skin and ulno-radially directed slip during precision grip. In both experiments, subjects are presented a reference stimulus and then a test stimulus at a randomized angle at 5° increments up to 30° relative to the reference. For the oriented edges, 8 subjects placed their right hand in a device that held the index finger over the stimulus bar. Subjects received a 1 second reference stimulus of 0°, parallel to the subject, or 90°, perpendicular to the subject, followed with the 1 second test stimulus after a randomized time. For the slip experiment, 4 subjects placed their arm in a mount that allowed for digital movement, but restrained the wrist to eliminate induced wrist, elbow and shoulder movement. Movement of each joint was monitored via PhaseSpace motion capture. The subject was presented with a 2”x2” textured object and instructed to use two grips: loaded, as if to control the object, and unloaded, as if the object were slipping. The object was translated 1 cm in 0° (proximal), 90° (up), 180° (distal), and 270° (down). This reference stimulus was followed by a 1 cm test stimulus at the same angular increments as in the previous experiment. A bias for distal and downward movements is hypothesized as physiological experiments exhibit sensitivity to those directions, shown via lower latency reaction times and higher force grip responses. After each pair of stimuli, subjects responded “Same” or “Different,” indicating if they perceived the experimental stimuli to be a repeat of or deviation from the reference. We found that the threshold for detecting a change in the orientation of the oriented bar was at approximately -15° and 20°. There is a slightly lower threshold for perpendicular stimuli (-20° and 20°) versus the horizontal stimuli (-20° and 25°). Presently, there is no significant difference between subjects’ perception of change in the stimulus for the second experiment. The data demonstrates a reverse bell curvefor the psychometric curve (% Response Different vs Angular increment), but the variation in data is high. Preliminary experiments that used larger angular increments and only one grip type indicated a threshold of 20° and a bias in the vertical directions. However, the renovated experiment requires more subjects as n=3 is inadequate for a sample population.

Title: Effects of force production and working memory on pain perception

Authors: *S. COOMBES, T. PARIS, G. MISRA, D. B. ARCHER;
Univ. of Florida, Gainesville, FL

Abstract: The goal in the current study was to examine the analgesic effects of a pinch grip-force production task and a working memory task when pain-eliciting thermal stimulation was delivered simultaneously to the left or right hand during task performance. Control conditions for visual distraction and thermal stimulation were included, and force performance measures and working memory performance measures were collected and analyzed. Our experiments revealed three novel findings. First, we showed that accurate isometric force contractions elicit an analgesic effect. Second, the magnitude of the analgesic effect was not different when the pain-eliciting stimulus was delivered to the left and right hand during the force task or the working memory task. Third, we found no correlation between analgesia scores during the force task and the working memory task. Our findings have clinical implications because they show that acute force production by one hand has an analgesic effect on pain that is simultaneously experienced in the other hand. From a theoretical perspective we interpret our findings on force and memory driven analgesia in the context of a centralized pain inhibitory response.

Title: Sequence-dependent hand kinematics by professional and amateur pianists

Authors: *S. A. WINGES[1], S. FURUYA[2];
[1]Kinesiology, Louisiana State Univ., Baton Rouge, LA; [2]Inst. for Music Physiol. and Musicians Med., Hannover Univ. of Music, Drama, and Media, Hannover, Germany

Abstract: Long-term musical training enables dexterous finger movements. Behavioral studies using the individuated finger movements demonstrated that trained pianists move fingers more independently than the untrained individuals. By contrast, studies using a transcranial magnetic stimulation revealed loss of surround inhibition of the finger muscles, which suggested a larger covariation of movements across fingers for more skilled players. To address this issue, the present study aimed to describe skilled finger movements during musical performance by professional and amateur pianists. Five professional pianists and five amateur pianists were asked to play thirteen musical pieces for ten successive trials at a certain tempo (inter-keystroke interval = 125 ms). Timing and force of each keystroke were recoded as MIDI information with a time resolution of 2 ms, and dynamic hand posture was recorded using sensors embedded in a right-handed glove (CyberGlove) with a time resolution of 12 ms. In order to assess effects of fingering on the finger movements, our analysis focused on three successive keystrokes, in which the central keystroke was with each of the five digits. The results of MIDI data showed that spatiotemporal features of the keystrokes were not independent of fingering. For example, during a keystroke with the thumb, the finger-key contact duration was shorter when the preceding finger was the little finger than the index finger for both of the two groups ($p<0.01$). In addition, the variability of rhythm and force of the keystrokes was overall larger for the amateurs than the professionals, which confirmed finer control of finger movements in more skilled players. The kinematic information also varied in relation to fingering and group at some joints. Of particular interest is that a group difference in the correlation coefficients of the movements between two fingers was dependent on the fingering, which indicates that the professionals moved the fingers more and less independently than the amateurs depending on the fingering. It is therefore likely that skilled pianists flexibly change the finger joint coordination across movement sequences.

Title: Effects of task complexity on grip force production

Authors: *A. N. KHAN, S. L. GORNIAK;
Hlth. and Human Peformance, Univ. of Houston, Houston, TX

Abstract: Previous studies of fine motor control have focused on the ability of participants to match their grip force production to a visually provided template. Widespread use of this technique ranges from studies of healthy control participants to evaluation of interventions for movement disorders. Typical visual templates have included both constant and variable force production values (eg. sine waves). The use of variable force production templates has been viewed as providing a challenging motor task in comparison to constant force production; however, the complexity/difficulty of these tasks has not been evaluated to date. In the current study, we investigated the behavioral differences exhibited in fine grip force control during several variable force production templates. Our results indicate that behavioral differences exhibited in variable force production tasks can be detected by using non-linear analyses. Use of these non-linear techniques allows for detection of behavioral differences reflecting task differences in non-Fitts-type tasks.

Title: The functional topology of large-scale brain networks relates to the efficiency of short-term skill acquisition training

Authors: *Z. ZANG[1], L. GEIGER[1], M. ZANGL[1], A. SCHAEFER[1], H. CAO[1], J. REIS[3], M. RUF[2], A. MEYER-LINDENBERG[1], H. TOST[1];
[1]Dept. of Psychiatry and Psychotherapy, [2]Dept. Neuroimaging, Central Inst. of Mental Health, Heidelberg Univ., Mannheim, Germany; [3]Dept. of Neurol., Albert-Ludwigs-University, Freiburg, Germany

Abstract: The acquisition of complex motor skills involves rapid plasticity-related reorganization of large-scale brain functional networks linked to movement control, working memory, and spatial attention, but the relationship to brain functional network properties derived from graph theory methods is largely unexplored. Here, we examined the relationship between the efficiency of skill acquisition training and the brain functional topology during resting state in 54 healthy volunteers (mean age 27.1 ± 7.9 years, 27 males). Prior to neuroimaging, motor skill learning was induced in a single training session involving 30 minutes repeated practice of a sequential visual isometric pinch task, an established behavioral marker for healthy and disturbed motor skill learning linked to cortical-striatal function and the effects of plasticity genes (Fritsch et al., 2010). Skill acquisition was defined as practice-induced changes in the speed-accuracy tradeoff function over time, which accounts for training-induced variations in sequence errors and movement speed (Reis et al., 2009). Resting state fMRI data were acquired in a 5 minute scan at 3T. Mean time series from 264 functional regions of interest (Power et al., 2011) were extracted after regressing out head motion effects, white matter and cerebral spinal fluid signals. Pairwise temporal correlations matrices were calculated and thresholded at in 10% intervals over a range of 5 densities (10% - 50%). Connectivity and graph properties were calculated using the Brain Connectivity Toolbox (Rubinov & Sporns, 2010). Partial correlation analysis of Global network properties (i.e., smallworldness, global efficiency, modularity, mean path length) with skill increase over training was performed while controlling for the effects of age and sex. The analysis of the behavioral data confirmed a significant training-induced increase in skill over time ($p = 4.7 \times 10\text{-}12$). Smallworldness, global efficiency, and modularity were significantly positively correlated with individual short-term skill acquisition abilities across all examined densities (range of r's = 0.28 to 0.47, range of p's = 0.041 to 0.003). Moreover, mean path length showed a significant negative correlation with skill acquisition across densities (range of r's = -0.338 to -0.484, p's = 0.014 to 0.0003). These data demonstrate the value of fMRI-based graph theory methods for the exploration of the neural correlates of learning and plasticity and suggest that individuals with more integrated, efficient and economic brain functional topologies are better equipped to learn complex motor skills in a short amount of time.

Title: Decoding grasp-relevant dimension of 3D objects in the Lateral Occipital Complex in grasping and viewing tasks

Authors: *S. MONACO[1], R. KAMRAN-DISFANI[2], K. FIEHLER[3], D. Y. HENRIQUES[1]; [1]Ctr. for Vision Res., [2]York Univ., Toronto, ON, Canada; [3]Justus-Liebig Univ. Giessen, Giessen, Germany

Abstract: The lateral occipital complex (LOC) in the ventral visual stream is known to be involved in visual object recognition. Despite the well-established role of ventral visual stream areas in object representation, growing evidence highlights the contribution of these areas to action planning and execution (Gallivan et al. 2013). However, extent to which LOC encodes overall object properties (e.g. size) as opposed to action-relevant object information (e.g. grasp-relevant dimension) is still not fully understood. The aim of this study was to determine which object properties could be predicted by LOC activity when an object was grasped or passively viewed.

We addressed this question by using a slow-event related fMRI design. We manipulated size (S) and grasp-relevant dimension (D) of 3-dimensional (3D) objects in grasping and viewing tasks. The grasp-relevant dimension of each object coincided with the top-to-bottom axis of the object, according to which the grip had to be scaled. The objects were shaped as a square (small S, small D) and a rectangle presented vertically (large S, large D) or horizontally (large S, small D). The task (grasp, view), object grasp-relevant dimension (large, small), and object size (large, small) varied in successive trials, yielding a 2 x 2 x 2 factorial design.

Fourteen right-handed volunteers participated in this study. At the beginning of each trial, an auditory cue instructed participants about the task. After 2-s, an object was illuminated for 250-ms, cuing the participant to initiate the task. For the purpose of previous published analyses exploiting repetition suppression (Monaco et al, 2013), a second object was presented 4-s after the first one and was followed by a 16-s ITI. However, for the present study only the first object presentation was included in the analysis. Multivoxel pattern analysis was performed using a support vector machine binary classifier.

Results from five participants show that the activity pattern in LOC during grasping could be used to decode between large and small grasp-relevant dimension, regardless of whether object size differed. Moreover, the activity pattern in viewing conditions could be used to decode between objects only when both size and grasp-relevant dimension differed, but not when either one was the same. These results show that object dimensions that are critical for the execution of accurate grasping movements can be predicted by LOC activity. In addition, the different decoding abilities in viewing and grasping conditions suggest that the results for grasping are not merely an epiphenomenon of the visual stimulation, but rather a product of information processing specific to action.

Title: Wrist forces and torques during activities of daily living

Authors: *A. L. PANDO[1], J. N. HERNANDEZ[2], S. K. CHARLES[3];
[1]Mechanical Engin., [2]Neurosci., [3]Mechanical Engin. and Neurosci., Brigham Young Univ., Provo, UT

Abstract: The wrist is one of the most common sites of joint injury, sustaining two-thirds of injuries due to repetitive motion. Although excessive force/torque is thought to be the leading cause of injury, the forces and torques that the wrist encounters in everyday life are virtually unknown. The purpose of this study is to characterize the forces and torques encountered in normal, healthy wrist activity during activities of daily living (ADL). The findings will enhance our knowledge of natural wrist movement, normal ranges of wrist activity, and how to properly rehabilitate for ADL.

Eleven young, healthy subjects (5 male) participated in this study. Electromyographic (EMG) sensors recorded activity of the four primary wrist muscles. Subjects performed 25 ADL (5 repetitions apiece). The following measures were computed: muscle force, joint torque, and co-contraction. Muscle force was calculated from the experimental EMG data and a position-dependent proportionality constant (relating EMG to force). Analysis considered all ADL cumulatively and involved comparing muscular contraction levels, forces exerted by each muscle, torque magnitudes and directions, and co-contraction activity over various torque and contraction levels.

Each muscle exerted differing levels of activation compared to their maximum voluntary contraction (MVC). The extensors, on average, exerted more of their strength than the flexors (13% and 6% of MVC respectively). The most frequent level of contraction occurred at 5% of MVC. The average amount of force produced by each muscle was (in increasing order) 65 N by the extensor carpi ulnaris, 70 N by each flexor, and 125 N for the extensor carpi radialis brevis-longus complex. The average amount of torque exerted by the wrist was 2 Nm, and the most frequent amount was 0.3 Nm (maximum wrist torque is on the order of 12 Nm). More torque was exerted in radial-ulnar deviation (RUD) than in flexion-extension (FE) for all muscles except the flexor carpi radialis.

Frequent co-contraction occurred over all levels of contraction. The frequency of co-contraction

was directly proportional to muscle activation, except in RUD during moderate-to-high levels of torque (more than 1.8 Nm), where the frequency of co-contraction was similar for all contraction levels greater than 40% of MVC.
These findings characterize natural wrist motor control used in everyday life, which is essential for quantifying disorder diagnosis, improving rehabilitation programs, and moving toward more personalized treatments.

Title: Improved sensorimotor performance via stochastic resonance is related to increased corticomuscular coherence

Authors: C. TRENADO[1], I. MENDEZ-BALBUENA[2,3], E. MANJARREZ[3,4], F. HUETHE[1], J. SCHULTE-MOENTING[1], B. FEIGE[1,2], M.-C. HEPP-REYMOND[4], *R. G. KRISTEVA[1]; [1]Univ. Freiburg, Freiburg, Germany; [2]Facultad de Psicologia, Buap, Mexico; [3]Inst. de Fisiologia, Buap, Mexico; [4]Inst. Neuroinformatics, Univ. Zürich and ETH Zürich, Zürich, Switzerland

Abstract: Internal stochastic resonance is a phenomenon of nonlinear systems that refers to the increase in coherence produced by a particular level of internal or external noise, called optimum noise (ON). The purpose of the present study was to investigate whether the improvement of the performance by ON is related to increased long-range synchronization between motor cortex and muscles reflected in corticomuscular coherence and increased cortical motor synchrony reflected in spectral power (SP). Seven subjects performed a visuomotor task requiring to compensate isometrically with the right index finger a static force generated by a manipulandum on which stochastic noise could be applied. The finger position was displayed on-line on a monitor as a small white dot which the subjects had to maintain in the center of a green bigger circle. EEG from the contralateral motor area, EMG from the active muscles and finger position were recorded. The performance was measured by the absolute deviation from the zero position. The effects of ON were characterized by a better performance, higher cortical motor SP and higher

corticomuscular coherence, as compared to the zero noise condition when no noise was applied to the manipulandum. These data suggest an increase in local cortical motor and long-range synchronization between cortical motor and spinal circuits as the neuronal basis of the improved sensorimotor performance via stochastic resonance.

Title: Inhibitory processes during response preparation are observed when a muscle is part of the volitional action, but not if the same muscle is recruited for postural stability

Authors: *L. LABRUNA[1], I. GREENHOUSE[2], M. PALUY[2], R. B. IVRY[2];
[1]Pshycology, UC Berkeley, Berkeley, CA; [2]UC, Berkeley, CA

Abstract:
TMS studies have revealed the operation of two inhibitory mechanisms during the selection and preparation of a response. Motor-evoked potentials in the agonist for a forthcoming response (selected) are reduced prior to the onset of an imperative signal, a process referred to as impulse control (IC). MEPs are also attenuated in muscles associated with the non-selected response, a process referred to as competition resolution (CR). Prior studies have provided converging evidence that these inhibitory effects reflect separable processes. Moreover, the effects are limited to task-relevant muscles; they are absent in muscles irrelevant to the competition (Duque et al., 2010). We revisited the specificity question by comparing preparatory changes in excitability in a muscle that was either directly involved in the forthcoming action (e.g., agonist if the finger was selected) or contributed to the action through a required postural adjustment. At the start of the trial, participants used a pinch grip to hold two small objects, one in each hand. This starting state required abduction of the left and right index finger via the FDI. In the volitional conditions, a cue indicated if the object should be squeezed with the left or right hand. In the postural condition, the cue indicated if the object should be lifted with the right or left arm by flexion of the biceps. Here, FDI was modulated in an involuntary fashion as a postural

response to offset slip forces. We used two levels of squeezing in the volitional condition (soft and hard), with the intention to have these forces span the EMG change observed in the postural condition. TMS was delivered over right M1 prior to the onset of the imperative signal, with half of the pulses occurring after a left hand cue (selected) and half occurring after a right hand cue (non-selected). Consistent with previous results, IC and CR in the FDI were observed during the preparatory phase in the volitional condition, regardless of whether the block required soft or hard squeezes. In contrast, neither form of inhibition was observed in the postural condition, despite the fact that there was an increase in FDI due to the increase in grip force. This dissociation indicates that inhibitory mechanisms recruited during response preparation are selectively targeted at muscles that are associated with the volitional component of the action.

Title: Influence of delay period duration on inhibitory processes for response preparation

Authors: *F. LEBON[1], I. GREENHOUSE[2], L. LABRUNA[2], C. PAPAXANTHIS[1], R. B. IVRY[2];
[1]STAPS, INSERM U1093, DIJON, France; [2]Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: Transcranial magnetic stimulation (TMS) and peripheral nerve stimulation provide effective tools to probe inhibitory and facilitatory processes during response selection and initiation. When a cue precedes an imperative signal, corticospinal (CS) excitability decreases as the imperative signal approaches, with greater inhibition when the targeted hand is selected than non-selected. These effects are attributed to shaping the selection and timing of the forthcoming response. In the present study, we compared the operation of these processes when the delay was short (300 ms), medium (500ms) and long (900 ms) in a choice RT task (left vs right index finger movement). During the delay period, a single TMS pulse was delivered over right motor cortex to elicit motor evoked potentials in the left first dorsal interosseous muscle. In the medium and long delay conditions, CS inhibition increased over the delay period and was greater when

the targeted hand was selected for the forthcoming response. In the short delay condition, CS inhibition was observed immediately after the cue and was similar regardless of whether the targeted hand was selected or not selected for the forthcoming response. To directly probe excitability changes at the spinal level, median nerve stimulation was used to measure the H-reflex in the flexor carpi radialis muscle. The reflex showed greater attenuation when the targeted hand was selected for the forthcoming response, but only in the long delay condition: the H-reflex response was similar for the selected and non-selected hands in short delay condition. These results demonstrate dynamical constraints in the recruitment of inhibitory processes during response preparation. With short delays, inhibition was recruited in a similar fashion for both selected and non-selected responses, whereas with long delays, inhibition was greater when the targeted hand was selected for the forthcoming response. These results indicate that, when preparation time is limited, all potential responses are inhibited in a similar manner. With longer preparatory intervals, differential mechanisms are recruited to inhibit the selected and non-selected responses.

Title: Response sequence influences motor excitability during response preparation

Authors: *I. GREENHOUSE[1], F. LEBON[2], L. LABRUNA[1], C. PAPAXANTHIS[2], R. IVRY[1]; [1]Univ. of California, Berkeley, Berkeley, CA; [2]Univ. of Burgundy, Dijon, France

Abstract: Excitatory and inhibitory processes influence the level of motor excitability during the selection and initiation of a motor response. However, little is known about the influence of response history on these processes. We tested whether responses on the preceding trial of a two-choice delayed response task influenced levels of motor excitability during an early and late phase of response preparation. On each trial of the task, participants (n=16) were randomly cued to prepare a lateral abduction of the left or right index finger. After a 900 ms delay, an imperative stimulus instructed participants to execute the selected response. Trials were separated by a 2500-3500 ms inter-trial interval. We applied transcranial magnetic stimulation (TMS) over right

M1 at an early (100ms) and late (800ms) time point during the delay period and measured the amplitude of the resulting motor evoked potential (MEP) from the left first dorsal interosseous muscle, as an index of motor system excitability. To determine the influence of response history on motor excitability, we compared raw MEP amplitudes between the early and late time points when the left hand was selected vs. non-selected to respond during the preceding trial. MEP amplitude was significantly greater at the early than at the late pulse when the left hand was selected to respond during the preceding trial. However, there was no significant difference between the two time points when the left hand was not selected on the preceding trial. Moreover, this pattern of results was insensitive to whether the left hand was selected or not selected on the current trial. This result suggests that modulation of motor excitability over the course of a delay period depends upon the response executed on the preceding trial. This finding has implications for understanding the time course of excitatory and inhibitory processes that operate during the preparation of a response, as well as methodological implications for choosing appropriate inter-trial intervals when designing TMS experiments.

Title: Modulation of the intra-cortical LFP during action execution and observation

Authors: *S. WALDERT[1], R. PHILIPP[1], G. VIGNESWARAN[1], J. M. KILNER[1,2], R. N. LEMON[1], A. KRASKOV[1];
[1]Sobell Dept. of Motor Neurosci. and Movement Disorders, IoN, [2]The Wellcome Trust Ctr. for Neuroimaging, IoN, Univ. Col. London, London, United Kingdom

Abstract: It is well established that the neuronal activity in cortical motor areas can be changed by observation of movements without execution of actual movements by the observer. Human

EEG and MEG studies reported a decrease in the power of beta oscillations in the motor cortex during movement observation similar to the well-known phenomenon of beta power reduction during movement execution. A special class of motor neurons, called mirror neurons, which modulate their activity both during movement execution and observation of the same movement performed by the experimenter, were originally discovered in macaque ventral pre-motor cortex (PMv), area F5. This study focuses on mirror properties of the intra-cortical local field potential (LFP), which reflects the superimposed, mainly synaptic activity of neuronal clusters.
Using single electrodes and electrode arrays, we recorded intra-cortical LFPs in macaque PMv, M1 and areas on the convexity of the pre-central gyrus between PMv and M1. Monkeys were trained to reach, grasp, hold and release different objects and to observe the same actions performed by a human experimenter. Arm and hand EMGs were recorded simultaneously with LFPs.
We found that neuronal population activity in PMv and M1, reflected by the intra-cortical LFP, can be modulated by action observation. Importantly, no overt EMG activity was present during observation indicating that no covert movements were executed.
LFP modulations during observation were found in the low-pass filtered LFP (<7 Hz, the movement related potential (MRP)) when the experimenter grasped an object but could also be detected during object release. Beta activity decreased mainly during observation of the grasping movement and increased during observation of the hold period. Modulations in high-gamma were partly observed during observation of the grasping movement.
The modulations of the MRP during action observation were similar but weaker than those recorded during action execution. Decoding LFPs during action execution showed that M1-LFPs carry more information about grasp type than F5-LFPs. During action observation, decoding accuracies for the LFPs from both areas were lower but similar for both areas.
These findings might indicate that both F5 and M1 are involved in processes mediated by mirror activity. In addition, the presence of modulations in the low-pass filtered LFP during action observation corroborate the importance and the genuine neuronal origin of this signal component, which has been shown to be a suitable input signal for Brain-Machine Interfaces (BMI) because it carries substantial information about movement parameters in LFP, ECoG, EEG and MEG signals.

Title: Effector coding for motor planning: Dynamic activation and information topologies in posterior parietal cortex

Authors: *F. LEONE[1], T. HEED[2], I. TONI[3], W. MEDENDORP[3];
[1]Radboud Univ. Nijmegen, Donders Inst., Nijmegen, Netherlands; [2]Hamburg Univ., Hamburg, Germany; [3]Donders Inst. for Brain, Cognition and Behavior, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Neuroimaging in humans and neurophysiology in monkeys have suggested segregated processing in the posterior parietal cortex (PPC) for saccades and reaches. These findings have been interpreted to indicate an effector-specific organization of the PPC. However, when comparing eye, hand, and foot motor planning in humans using fMRI, we recently found that the activation in the PPC did not differ between hand and foot motor planning, whereas limb activation segregated from saccade activation (Heed et al. J Neuroscience 2011), suggesting a functional rather than an effector specific organization. Recent multivariate pattern analysis studies, however, have shown that effector-specific information (difference in the pattern of activation across voxels) can reside within the same brain area without showing effector-specific activation (difference in average activation across voxels). Here, we apply a combination of activation and information measures to explore the organization of the PPC.
Sixteen participants performed delayed (1.6-5.6 sec) goal-directed eye, right hand, or right foot movements in an fMRI scanner. Data were analyzed using a novel method combining effector-specific activation and information measures. To this end, search-spheres (radius: 2 voxels) were used to estimate both effector-related average activity and correlations between effectors, separately for stimulus-, delay-, and movement-related epochs in each trial. The activation index represented the magnitude of the effector-related effects; the correlation index characterized the independent information provided by those effector representations. Based on these indices, we revealed the effector-specific topologies (differentiating each effector from the other two) and functionally-specific topologies (differentiating eye and limb representations) across the cortical surface.
Large portions of PPC had a functionally-specific organization, distinguishing eye and limb, primarily during the delay period. In contrast, the anterior parietal cortex demonstrated an effector-specific organization. During the stimulus and movement periods, anterior parietal cortex as well as pre- and supplementary motor areas, including the frontal eye fields, showed effector-independent activations. We conclude that PPC contains a functional gradient in both activation and information, which is employed specifically during the planning of movements.

Title: The cortical bases of hand selection for object manipulation in humans: Insights from fMRI repetition suppression

Authors: *K. F. VALYEAR, S. H. FREY;
Dept. of Psychological Sci., Univ. of Missouri, Columbia, MO

Abstract: Choosing which hand to use to perform actions is one of the most commonplace decisions we make as humans, and yet very little is understood about how the brain resolves these choices. Here we used a novel fMRI repetition suppression (RS) paradigm to identify brain areas important for hand selection for object manipulation. *Methods.* Novel tools were presented to participants in the MRI scanner with their handles oriented vertically, facing downward with respect to the workspace. According to arbitrary rules defined by the shape of tools, participants used either their left or right hands to reorient tools so that their handles faced either to the left or right. To rotate tools to the left versus right participants performed distinct types of hand actions (Action Types) involving distinct movements, and this was true for actions made with either hand. Critically, individual trials comprised two actions - a prime and a probe, separated by a 2.5s delay interval. Four conditions were defined by the relationship between prime and probe: either the same actions were repeated (Identical Repeat, IR), hand was repeated but action type was changed (Hand Repeat, HR), action type was repeated but hand was changed (Action Type Repeat, ATR), or neither hand nor action type were repeated (No Repeat, NR). Trials were separated by 15s intervals. *Results*. Response times to initiate actions were faster for IR versus all other conditions, and for HR versus both ATR and NR conditions. While the former result may be attributable to the repetition of hand, action type, tools and/or tool-defined action rules, the latter result is attributable to hand repetition. We take this to reflect more efficient action planning when the same hand can be used for successive actions, independent of the movements involved in those actions. Bilateral parietofrontal and left-lateralized occipitotemporal cortex showed RS for IR versus all other conditions (IR < HR, ATR, NR). A subset of these areas, namely bilateral posterior intraparietal and cingulate as well as left dorsal premotor cortex, showed RS for HR versus ATR and NR conditions (HR < ATR, NR). These results are interpreted as evidence for abstract hand-specific representations for action planning in these areas. We hypothesize that hand selection is resolved by biasing the competitive activity between

these hand-specific representations. According to this view, the current results identify recent hand selection history as an important source of selection bias. When the same hand can be used for successive actions, competition within these areas is more efficiently resolved, and both response times to initiate actions and fMRI activity levels are reduced.

Title: Body-centered, mixed, but not hand-centered coding of visual targets in the medial posterior parietal cortex during reaches in 3D space

Authors: *K. HADJIDIMITRAKIS[1,2], F. BERTOZZI[1], R. BREVEGLIERI[1], M. G. ROSA[2], C. GALLETTI[1], P. FATTORI[1];
[1]Dept. of Pharm. and Biotech., Univ. of Bologna, Bologna, Italy; [2]Dept. of Physiol. and Monash Vision Group, Monash Univ., Melbourne, Australia

Abstract: The posterior parietal cortex (PPC) is crucially implicated in the reference frame transformations that underlie visually guided arm reaching movements. The classical view on these transformations holds that
each PPC area represents spatial information in a specific system of coordinates depending on its relative proximity to sensory input and motor output, so that caudal PPC areas use eye-centered and rostral areas hand-centered coordinates. Accordingly, the information about target location, while being transferred along the caudorostral PPC axis, is gradually transformed from eye- to hand-centered reference frames. However, numerous recent studies challenge this view by demonstrating that multiple reference frames can be present in the same region and that large populations of neurons in several PPC areas use intermediate frames of reference. In all these studies arm movements were performed to targets arranged on a frontal plane, so the presence of multiple reference frames and intermediate representations in 3D space is still an open issue. We

addressed this issue in the caudal PPC area V6A, where it had been shown previously that reach targets located on a single plane were encoded reach in an intermediate eye- and body-centered coordinates by most of the neurons, with smaller populations of cells using "pure" eye- or body-centered frames of reference. In the present study, we manipulated the initial hand position to test between body- and hand-centered representations. Single unit activity was recorded from V6A in two *Macaca fascicularis* monkeys while they performed reaches in darkness towards targets located at different distances and lateralities from the body. We found two major populations of V6A cells: a) neurons that encoded targets in intermediate body and hand-centered coordinates, and b) cells not affected at all by stating hand position, which used "pure" body-centered representations of target location. Interestingly, we only found very few neurons that represented targets in "pure" hand-centered coordinates, despite the fact that the manipulation of hand position in depth was expected to increase the influence of proprioceptive signals from the hand. These findings argue in favour of area specific reach representations in PPC. Our results also provide for the first time evidence that intermediate frames of reference are widely used to represent targets in depth.

Title: Reaching related neurons in the Superior Parietal Lobule are strongly modulated by hand-positional signals when movement is directed to memorized targets

Authors: *E. BRUNAMONTI, A. GENOVESIO, M. A. GIUSTI, R. CAMINITI, P. PANI, S. FERRAINA;
Dept Human Physiol. & Pharm, Sapienza Univ., Rome, Italy

Abstract: In a previous report using a delayed reaching-in-depth (RID) task (Ferraina et al., J Neurosci 2009) we showed that reaching related neurons in parietal area PE are modulated by target depth and that the initial hand position had a strong effect on the neural activity as well. Most important, we provided evidence that PE modulation was mainly explained by the component in depth of the motor error, i.e., the vector of the planned arm movement that depends on the representation of both arm position and target location in space. Here, by

comparing data obtained in both a visual and memorized versions of the task we examined the role of the hand-related signal in relation to whether the target was visible or not during motor preparation.
Monkeys were trained to reach towards either visual (RIDvis) or memorized (RIDmem) targets located at different distances, after a delay of variable duration. Of 179 neurons recorded from area PE in both tasks, 116 (69%) were classified as reaching related of which ninety-four (81%) were modulated by changes in the initial hand position. Additionally, 38 (40%) of the hand-modulated neurons were influenced by the task.
We estimated the time in which the hand position information started to be used differently in the RIDmem and RIDvis respectively and, within each task and behavioral epoch, we quantified the influence of the hand initial position on the neural discharge. For each neuron we first identified the initial hand position associated to the highest activity in both tasks, and then we performed a time dependent analysis calculating the area under the ROC (AUROC) to identify when the activity in the two tasks started to differ. On average the hand modulated neurons started to use differently the hand position signal, 455 (64) ms before the movement onset. In the last 300 ms of the delay epoch we computed the AUROC for the hand positions in each task finding a 10 % of decrease in accuracy in estimating the initial hand position in the RIDvis compared to the RIDmem. Overall these results indicate that the hand position signal is less important for the PE's neural computation of the motor plan toward visible than memorized targets and highlights the flexibility of this parietal area to weight the available contextual information.

Title: The influence of gaze on the activity of macaque M1 and F5 mirror neurons

Authors: *R. PHILIPP, G. VIGNESWARAN, S. WALDERT, R. LEMON, A. KRASKOV; Sobell Dept. of Motor Neurosci. & Movement Disorders, Box 28, UCL Inst. of Neurol., London, United Kingdom

Abstract: Paying visual attention to an object which is going to be manipulated is an essential requirement for most tasks performed in everyday life of primates. In the mirror neuron literature, it is generally assumed that the observer is paying attention to what the actor is doing. Here, we will present data showing that this is indeed the case. We correlate the gaze behaviour i.e. the time spent by a macaque monkey looking at the object, with the neuronal firing rate of M1 and F5 mirror neurons while the monkey executed visually-guided grasps, and during observation of the same grasps mirrored by a human experimenter.
We monitored the eye movement pattern of the monkey by means of a non-invasive infra-red eye tracking system (ISCAN ETL-200, 120Hz). The monkey executed and observed three different types of skilled grasp: precision grip (trapezoid object), hook (small ring) and whole hand grasp (sphere). After an inter-trial waiting period, one of the three objects was presented either in the monkey's peripersonal space (execution trials) or in its extrapersonal space (observation trials). After a short observation period (epoch 1, presentation), a green light around the object (Go cue) (epoch 2, reaction time) instructed either the monkey, or the experimenter sitting opposite the monkey, to reach out and grasp the object, displace it against a spring load (epoch 3, movement), and hold it for 1s (epoch 4, hold), and then release it. The task did not require any particular eye movement or fixation, which allowed us to investigate the natural eye movement pattern during both execution and observation of the task.
Compared to its own actions, the monkey spent less time looking at the object during observation than during execution. However, the object fixation patterns between both conditions were highly correlated (0.92, $p<0.05$) emphasising that the monkey paid attention to the experimenter's actions during observation trials although this was not explicitly required in the task design. We simultaneously recorded mirror neurons in M1 (n=18) and F5 (n=36) in 28 sessions. Comparing neuronal firing rates for trials when the monkey attended the object for longer vs. shorter periods of fixation revealed that during observation trials 19% of the 54 recorded mirror neurons exhibited a higher discharge rate during epoch 3 the longer the monkey spent looking at the object while 9% showed the opposite effect. During execution trials 10% of the units were accounted for each of the effects.
The overall finding is that there are gaze-related changes in the activity of M1 and F5 mirror neurons, but many mirror neurons do not show any gaze-dependent activity changes.

Title: Precuneate cortical connections in the macaque monkey

Authors: L. PASSARELLI[1], *S. BAKOLA[2], M. GAMBERINI[1], K. J. BURMAN[2], K. E. RICHARDSON[2], P. FATTORI[1], M. G. P. ROSA[2], C. GALLETTI[1];

Abstract: The posterior parietal cortex in the macaque precuneate region (BA 7m, or PGm) has remained relatively unexplored, in part due to difficult access. Recent human imaging studies have ascribed a multitude of visuospatial and cognitive functions to this field, suggesting possible anatomical heterogeneity, and detailed histological analysis in macaque monkey demonstrated distinct rostral and caudal cytoarchitectonic fields within area PGm. The aim of this study was to examine the cortical connections of PGm, including possible variations in projections to different sectors of this region. Seven retrograde fluorescent tracers were placed in PGm in three macaque monkeys anesthetized with alfaxan (10 mg/kg). The distribution of labelled cells was visualized with fluorescence microscopy, and presented in computer-assisted reconstructions of the cortical surface. The principal sensory input to the PGm as a whole arrived from high-order medial extrastriate cortices (V6Av, and a yet to be characterized area located adjacent to peripheral V2), from oculomotor-related areas of the inferior parietal lobule (PG, Opt), and from visual area MST. Strong projections also stemmed from caudal cingulate area 23. Frontal projections arose mainly from the dorsal premotor cortex (F7), and from prefrontal areas 8 and 46. Rostral PGm received additional somatomotor input, from superior parietal areas PEci and V6Ad, whereas caudal PGm received stronger visual inputs. The present results indicate that PGm receives consistent input from high-order sensory, motor, and limbic cortices, in line with the proposed associative role of the area. The regional variations in the architectural structure and connectivity patterns likely reflect functional specializations within PGm.

Title: Probing corticospinal excitability at point of object contact during constrained vs. unconstrained grasps

Authors: *M. DAVARE[1], P. PARIKH[2], P. MCGURRIN[2], M. SANTELLO[2];
[1]Sobell Dept., Inst. of Neurol., London, United Kingdom; [2]Arizona State Univ., Tempe, AZ

Abstract: For successful object manipulation, the brain needs to precisely scale fingertip forces based on a prediction of digit positioning. When lifting an object with an asymmetrical center of mass, it has been shown that load force development varies as a function of digit positioning on a trial-by-trial basis. The question arises as to how information about digit positioning shapes corticospinal output, which in turn generates an appropriate load force pattern. To address this issue, we asked subjects to lift without tilting an object with an asymmetrical center of mass. Subjects could grasp the object either at self-chosen (unconstrained) or predetermined (constrained) locations. Our rationale was that unconstrained and constrained grasps would require the primary motor cortex (M1) to assign a different weighting to sensory feedback about digit positioning since these grasp conditions rely on a different balance between open- vs. closed-loop motor control mechanisms. To do so, we probed corticospinal excitability (CSE) at different time points, during grasp planning and at object contact, by using single pulse transcranial magnetic stimulation (spTMS) with an intensity of 80 and 120% of resting motor threshold, respectively. Subjects (n=7, right-handed) lifted the object using a precision grip (thumb-index) in an unconstrained or constrained fashion in two pseudorandomly distributed blocks. Digit positioning in the constrained condition was adapted to each subject's average digit placement, measured during practice trials prior to the experiment, so as to ensure any CSE change was not due to simple hand shaping differences. We found that when spTMS was delivered at object contact, CSE was greater for the unconstrained compared to the constrained grasp condition, although digit positioning was identical in both conditions. There was no difference in CSE for these two grasp conditions prior to object contact, i.e. during grasp planning or in the middle of the reaching phase. This shows evidence that M1 integrates context-dependent sensorimotor information about digit positioning differently at object contact, a time point when processing of online feedback is crucial for controlling fingertip forces.

Title: Visual monitoring of hand actions in AIP neurons

Authors: *P. PANI, T. THEYS, P. JANSSEN;
Lab. voor Neuro- en Psychofysiologie, Katholieke Univ. Leuven, Leuven, Belgium

Abstract: The macaque Anterior intraparietal area (AIP) is involved in the visuomotor control of grasping . Recent data (Pani et al., Program No.852.08 Society for Neuroscience 2011, Abstract viewer, online) showed a convergence between visual and motor responses in single AIP neurons, i.e. the same neurons fired both during grasping execution and grasping observation (grasping and observation neurons). This type of neurons could be involved in the monitoring of the interaction of the hand with the object . To investigate this hypothesis we selected grasping and observation neurons using a delayed visually-guided grasping (VGG) task (to test their motor properties) and an observation task in which the monkey observed a movie showing a grasping action in 1st person perspective (to test for visual responses). We selected 51 AIP grasping and observation neurons out of 183 neurons recorded. These neurons were further tested in one out of two observation tasks: a static hand observation task (SHOT), and a dynamic grasping observation task (DGOT). In the SHOT 4 static images of different phases of the grasping action were presented (object alone, hand reaching, hand on the object, hand holding the object).We found that 14/29 neurons (48%) detected the presence of the hand on the scene (Global aspect) by distinguishing between the object alone and at least one of the other three conditions. Furthermore almost all of them distinguished between at least two different hand configurations on the monitor (13/14, Detailed aspect). We compared their ability to distinguish between global and detailed aspects by comparing the Effect size obtained for each of the 14 selective cells. Overall the neurons were more strongly modulated by Global aspect (Es:1.37 vs 0.9, p=0.01).
In the (DGOT) a movie started showing a grasping hand moving toward the object to grasp. When the hand was covering the object but not yet grasping it (changing frame) the action evolved in 1 out of 4 possible actions, divided in two categories: hand absent (hand retracting or

disappearing) and hand present (hand still or grasping).We recorded 21 cells and contrasted their mean firing rates in the 500ms following the changing frame. Most neurons (18/21) distinguished between conditions with hand present or absent (Global aspect). Of those 10 neurons were also able to distinguish between conditions inside each category (Detailed aspect). Also in this task the cells were more able to distinguish between global than specific aspects (Effect sizes: 1.15 vs 0.72, p=0.002).
Thus, grasping and observation neurons in AIP can monitor the grasping action in terms of both global and specific aspects, but global aspects are more represented.

Title: The functional connectivity of macaque area AIP

Authors: *E. PREMEREUR[1], I. C. VAN DROMME[1], W. VANDUFFEL[1,2,3], P. JANSSEN[1]; [1]Lab. voor Neuro- & Psychofysiologie, KU Leuven, Leuven, Belgium; [2]Athinoula A. Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp, Charlestown, MA; [3]Dept. of Radiology, Harvard Med. Sch., Boston, MA

Abstract: A previous electrophysiology study identified two separate locations in monkey area AIP which contained neurons selective for disparity-defined depth structure: one located more anteriorly (aAIP), and a posterior spot (pAIP) neighboring area LIP (Van Dromme et al., SFN 2012, New Orleans, 264.03/Z14). The goal of our current research was to examine the functional connectivity of both stereo-sensitive AIP spots using electrical microstimulation during fMRI. In interleaved blocks, two macaque monkeys performed a memory-guided saccade task and a passive fixation task. Stimulation blocks for both tasks were interleaved with no-stimulation blocks. During stimulation blocks, area AIP was stimulated in every trial, at 200 micro-amperes.

Stimulation started together with target or distractor onset, and lasted for 500 ms (pulsewidth: 0.48 ms, frequency: 200 Hz). Both monkeys were injected with a contrast agent and scanned at a 3T Siemens MR scanner with an 8-channel phased-array coil. Before every scan session, a platinum-iridium electrode (impedance: 40-150 kΩ) was inserted in the recording grid, and fixed at a depth which had previously been determined based on single- or multi-unit responses. We analyzed the effects of microstimulation by comparing stimulation blocks with no-stimulation blocks averaged across tasks (memory saccades and passive fixation).
Electrical microstimulation of the most anterior part of area AIP (aAIP) caused increased fMRI activations in the stimulated area itself and in a network of areas implicated in reaching and grasping: the medial bank of the intraparietal sulcus corresponding to area MIP (the parietal reach region); somatosensory area S2; parietal areas PFG and 7a and premotor area F5. Similar results were obtained when stimulating aAIP under ketamine/medetomidine anaesthesia (1mA, 250 ms stimulation).
A largely different pattern of activations was observed when stimulating more posteriorly located pAIP: we obtained increased fMRI-activation in pAIP, in area TEO and in the Caudal Intraparietal area (CIP), while no stimulation-induced activation was obtained in area MIP, and only modest increased activation in premotor area F5. Similar results were obtained in anaesthetized animals. Furthermore, the results were verified in a third monkey in which pAIP was previously identified by the presence of selective single-unit responses to images of objects.
Our results thus suggest that area AIP consists of two subdivisions with different functional connectivity: while aAIP is embedded in a network of areas implicated in reaching and grasping, pAIP is connected with areas typically more implicated in object processing.

Title: The causal role of the posterior parietal cortex in online feedback control of visually-guided reaching movements

Authors: *E. HWANG, M. HAUSCHILD, R. A. ANDERSEN;
Div. of Biol., CALTECH, PASADENA, CA

Abstract: The parietal reach region (PRR) in the posterior parietal cortex (PPC) consists of neurons that are activated selectively during planning and execution of reaching movements. Inactivating the macaque PRR impairs reaches to eccentric visual targets, the major symptom of human optic ataxia (OA) caused by lesions in PPC (Hwang et al., 2012). Taken together, these findings suggest that PRR, a functionally defined area within PPC, may be the critical site for OA.

Besides misreaching to static visual targets, OA patients fail to make smooth adjustments when the target unexpectedly jumps to a new location during the course of a reaching movement. The degraded in-flight adjustments are an indication of an impairment of the feedback control system that updates motor commands based on the difference between the current hand location and the new target. It is unknown whether the same neural substrate contributes to both misreaching and diminished online feedback control in OA, or alternatively whether the two classes of deficits are observed together due to lesions spanning PRR and adjacent areas.

To investigate this issue, we inactivated PRR using muscimol and examined its effects on two non-human primates' movements in a target jump task in which the visual target unexpectedly jumped to a new location upon reach onset. We found that PRR inactivation affected reach endpoints in target jump trials similarly to reach trials with static targets, i.e., reaches ended short of the jumped target. Under PRR inactivation,

movement duration and the peak velocity decreased, in proportion to the shorter movement length. However, the frequency of trials lacking in-flight adjustments, reaction time to the target jump, and the variability of trajectories remained unchanged. This is in contrast to degraded online movement control resulting from area 5d inactivation, as indicated for example by delayed trajectory correction.

In summary, PRR inactivation did not abolish online feedback control, but affected it by distorting the difference vector between the current hand location and the new target location. Our results suggest that PRR represents a subset of neural circuits affected in OA, and that the lack of automatic feedback control is attributable to other PPC areas, with area 5d being a possible candidate.

Title: Corticospinal excitability during planning of a dexterous grasp

Authors: *P. J. PARIKH[1,2], P. MCGURRIN[3,1], M. DAVARE[4,5], M. SANTELLO[2,1];
[2]Sch. of Biol. and Hlth. Systems Engin., [3]Sch. of Life Sci., [1]Arizona State Univ., Tempe, AZ;
[4]Sobell Dept. of Motor Neurosci. and Movement Disorders, [5]Univ. Col. London, London, United Kingdom

Abstract: Humans are able to coordinate the amount of finger forces applied on an object in relation to where it is grasped for successful manipulation. However, the neural mechanisms underlying the planning of these grasp parameters are unknown. Furthermore, it is not clear *what* is being planned prior to grasp execution. In this study, we probed corticospinal excitability (CSE) using single-pulse transcranial magnetic stimulation (spTMS) over the primary motor cortex (M1) during two tasks. Young right-handed subjects (n = 11) were visually-cued to plan digit placement on the object at specific locations followed by exertion of either negligible (task "position"; P) or 10% of their maximum pinch force (task "position and force"; P&F) on the object. We hypothesized that planning to perform these tasks influences CSE differently prior to the grasp onset. To quantify the temporal evolution of this modulation, we delivered spTMS over left M1 at one of eight latencies from the '*task*' cue in a random order: 500, 750, 1000 ('*go*' cue), 1100, 1200, 1300, 1400, and 1500 ms. Consistent with previous literature (Cattaneo et al, 2005; Prabhu et al, 2007), the CSE assessed during movement preparation but prior to reach onset was suppressed when compared with the resting state CSE. Moreover, modulation of the CSE based on task characteristics was observed when the TMS pulse coincided with the signal to initiate the grasp, i.e., the '*go*' cue at 1000 ms after cue presentation. Specifically, significantly greater suppression of motor-evoked potentials, assessed in the first dorsal interosseus ($p = 0.001$) and abductor pollicis brevis ($p = 0.053$) muscles, was observed when subjects planned for task P&F versus task P. Similar task-dependent effects were not observed in abductor digit minimi and flexor carpi radialis muscles. In a control experiment, we demonstrated that this task-dependent modulation in the CSE was not related to the amount of force planned and applied to the object following contact. Overall, our findings suggest that planning force following contact versus making contact with an object engages different brain networks and/or reflects higher gain of inputs from the same brain network to M1. Future work will assess the contribution of premotor and anterior intraparietal areas on CSE during planning of dexterous manipulation.

Title: Selective modulation of interactions between areas of the dorsomedial pathway during the transport and grip formation of goal-directed hand actions

Authors: *M. VESIA[1], M. BARNETT-COWAN -[2], B. ELAHI[1], J. L. NEVA[3], M. DAVARE[4], W. R. STAINES[3], J. C. CULHAM[2], R. CHEN[1];
[1]Univ. of Toronto, Toronto Western Res. Inst., Toronto, ON, Canada; [2]Dept. of Psychology, The Brain and Mind Institute, Univ. of Western Ontario, London, ON, Canada; [3]Dept. of Kinesiology and Fac. of Applied Hlth. Sci., Univ. of Waterloo, Waterloo, ON, Canada; [4]Sobell Dept. of Motor Neurosciences and Motor Disorders, Univ. Col. London, Inst. of Neurol., London, United Kingdom

Abstract: Neural control of goal-directed hand actions is thought to rely on two specialized parieto-frontal pathways: 1) the dorsomedial stream (namely, superior parieto-occipital cortex, SPOC, in humans and the dorsal premotor cortex, PMd) involved in programming arm transport during reaching and 2) the dorsolateral stream (namely, anterior intraparietal sulcus, aIPS, and ventral premotor cortex, PMv) involved in programming hand grip during grasping - both of which send output to primary motor cortex, M1. Recent evidence has argued that macaque dorsomedial stream, specifically V6A (the putative homologue of human SPOC) and PMd, code both hand transport and grip. In humans, functional imaging studies also show evidence that SPOC and PMd differentiate grasping versus touching, but it is not clear whether these brain areas also code the details of the grip. We used dual-site transcranial magnetic stimulation (dsTMS) to test the functional interactions between SPOC-M1 and PMd-M1 in the left hemisphere during different hand actions. Subjects performed an event-related delayed movement task toward a single peripherally located object (consisting of a small cylinder attached atop a larger cylinder). For each trial, after visual presentation of the object, one of three hand movements was instructed: 1) grasp the top cylinder (precision grip); 2) grasp the bottom cylinder (whole hand grasp); or 3) reach-to-touch the side of the object (without preshaping the

hand). We found that motor-evoked potentials (MEPs) were facilitated by SPOC-M1 dsTMS applied at two specific time intervals (150 and 200 ms) after a cue to select a manual response. Specifically, 150 ms after the cue, MEPs were facilitated for all hand actions, whereas 200 ms after the cue, the facilitatory influence occurred only for reach-to-grasp actions, suggesting that over the course of a reach-to-grasp action SPOC-M1 interactions become functionally specific to the process of grip formation. We are currently testing the functional specificity of human PMd-M1 cortical interactions during these hand actions. Consistent with findings reported in the monkey, these results suggest that the human dorsomedial parieto-frontal stream may play a critical role in all phases of reach-to-grasp action. Critically, they challenge the view that the reach and grasp components are processed independently.

Title: Single trial neural correlates of grasping movement preparation in macaque areas AIP and F5

Authors: *J. A. MICHAELS[1], B. WELLNER[1], H. SCHERBERGER[1,2];
[1]Neurobio., German Primate Ctr., Göttingen, Germany; [2]Biol., Georg-August-Universität Göttingen, Göttingen, Germany

Abstract: The neural networks of the brain involved in the planning and execution of grasping movements are not fully understood. The network formed by macaque anterior intraparietal area (AIP) and hand area (F5) of the ventral premotor cortex is implicated in the generation of grasping movements. However, the differential role of each area in this fronto-parietal network is unclear. Previously, data collected from these areas were limited to single neuron electrophysiological recordings. Single neuron recordings are not sufficient to elucidate the interaction of neurons at a population level during the formation of a motor plan. To capture network dynamics, we recorded single and multi-unit activity in parallel from chronically implanted electrode arrays in AIP and F5 while two monkeys performed a delayed grasping task (using one of two grip types) that also involved a grip selection component. Implementing the

'initial condition hypothesis' of movement preparation developed by Afshar et al. (2011), we predicted behavior of the animal on a single trial basis. This hypothesis posits that neural population activity prior to movement on a single trial is predictive of the subsequent reaction time. Supporting the results of Afshar et al., who recorded on the border of dorsal premotor cortex and primary motor cortex in a reaching task, we found this method was able to explain significantly more variance in reaction time compared to previously published methods. No difference was found between conditions where the grip type was instructed and when the monkey chose freely. Furthermore, we were able to compare the information content of areas AIP and F5. We found that F5 was able to predict reaction time significantly better than AIP. This result lends support to the hypothesis that AIP represents an earlier step in the visuo-motor transformation and does not well encode the temporal characteristics of upcoming movements.

Title: Decoding reveals planning-related signals underlying object grasping and manipulation

Authors: *J. P. GALLIVAN[1], J. S. CANT[2], M. GOODALE[3], J. R. FLANAGAN[1];
[1]Queen's Univ., Kingston, ON, Canada; [2]Univ. of Toronto, Scarborough, ON, Canada; [3]Western Univ., London, ON, Canada

Abstract: Skilled manipulation requires the ability to predict the weights of viewed objects based on learned associations linking the extrinsic properties of an object, such as shape, size and texture, to the intrinsic property of weight. Although it is well established that extrinsic object properties are represented in regions within occipitotemporal cortex (OTC), the neural mechanisms involved in extracting weight information from these properties are unknown. Here, using functional MRI and pattern classification methods, we tested and confirmed the novel hypothesis that object weight is represented in visually defined object-selective regions within OTC. We used an event-related task in which participants first prepared and then executed lifting actions with objects of varying weight. In Experiment 1, participants lifted visually identical objects presented in blocks of trials such that weight could be reliably predicted. In Experiment 2, the same participants lifted objects of varying weight that differed in surface material. Across

both experiments, the activity patterns that formed in object-selective OTC areas prior to movement onset predicted the weight of the object to be lifted and, in Experiment 2, this effect was independent of the mapping between surface material and weight. In addition, we found that activity patterns in material-sensitive OTC regions coded object weight but only when weight could be reliably predicted from material. Our results indicate that the integration of visual and motor-relevant object information occurs at the level of single OTC areas and provide evidence that the ventral visual stream is actively engaged in processing object information for the purposes of action.

Title: Neural substrates for allocentric versus egocentric representation in memory-guided reach

Authors: *Y. CHEN[1], S. MONACO[2], P. BYRNE[2], X. YAN[2], D. Y. P. HENRIQUES[3], J. D. CRAWFORD[4];
[1]Kinesiology and Hlth. Sci., Ctr. For Vision Research, Canadian Action and Perception Network, York Univers, Toronto, ON, Canada; [2]Ctr. for Vision Research, York Univ., Toronto, ON, Canada; [3]Ctr. for Vision Research, Kinesiology and Hlth. Sci. and Psychology, York Univ., Toronto, ON, Canada; [4]Ctr. for Vision Research, Psychology, Kinesiology and Hlth. Sci. and Biology, Canadian Action and Perception Network, York Univ., Toronto, ON, Canada

Abstract: The location of a remembered reach target can be encoded in egocentric or allocentric reference frames, but the neural mechanisms for allocentric reach representations are essentially unknown. We utilized an event-related fMRI design to explore the brain regions that support these two types of representation for memory-guided reach. Twelve participants reached with their right hand toward a remembered target location in complete darkness. A reach target and an additional landmark were always presented at the beginning of each trial, at several positions to the left or right of a fixation target. A recorded voice instructed participants either to 1) remember target location relative to the landmark (Allo condition), or 2) ignore the landmark and only remember target location in space (Ego condition). During the following 12s delay period participants had to remember the target location in the appropriate reference frame. In a non-

spatial control condition (Color), participants were instructed to remember (and later report) the color of the target. At the end of the delay the landmark re-appeared at its original or a novel location (left or right). After the landmark disappeared, an auditory go signal instructed participants to reach or report target color according to the initial instruction, and in the Ego condition, participants were signalled to reach toward or opposite to the target. Thus, egocentric motor direction could not be planned during the delay in any task before the go signal. During the delay period, Ego and Allo conditions elicited significantly higher activation compared to the Color control in: bilateral dorsal premotor cortex (PMd), superior parieto-cccipital cortex (SPOC), midposterior intraparietal sulcus, and extrastriate cortex, inferior frontal gyrus, medial frontal gyrus, pre-supplementary motor area in the left hemisphere. The Ego condition produced more activation in bilateral SPOC and right PMd, whereas the Allo condition produced greater activation in early visual cortex. Significant egocentric spatial selectivity (target location relative to gaze) was observed in occipital cortex during the delay, only emerging in the frontoparietal cortices when participants were informed of the reach direction. Significant allocentric spatial selectivity (target location relative to landmark location) was observed in early visual cortex and bilateral inferior temporal gyrus. These results demonstrate 1) a complete parieto-frontal network for reach, 2) a special role for early visual cortex in spatial memory dissociated from reach direction, and 3) a special role for early visual cortex and the ventral stream for allocentric memory.

Title: Decoding of movement states and continuous kinematics of hand and arm motions from primate motor, premotor, and parietal cortex

Authors: *V. K. MENZ, S. SCHAFFELHOFER, H. SCHERBERGER;
German Primate Ctr., Göttingen, Germany

Abstract: The primate motor, premotor, and parietal cortex play a crucial role in the planning and execution of hand movements. It has been shown that area F5 in the ventral premotor cortex

and the anterior intraparietal area (AIP) carry information about grip type, wrist orientation, and hand shape during movement planning and execution. Here, we are investigating whether AIP and F5, in addition to this categorical information, also encode continuous movements by using spike signals from these areas to detect and predict complete hand and arm movements with 27 degrees of freedom (DOF) and compare these to results obtained with signals from primary motor cortex (M1).

Rhesus monkeys (Macaca mulatta) were trained to grasp and lift ~50 objects of different shape, size, and orientation that were presented in front of them in a delayed grasping task. Hand and arm kinematics were monitored with a sensor glove that can track 27 DOF of all fingers, wrist, and arm joint angles continuously (Schaffelhofer et Scherberger, 2012). At the same time, spiking activity was recorded in parallel with 64 chronically implanted microelectrodes (FMAs, Microprobe Inc.) in each of the areas F5, AIP, and the hand area of M1, and then spike-sorted offline (WaveClus, Plexon Offline Sorter). From these population spike data, we detected time periods during which the monkey rested or moved its hand or arm using a weighted support vector machine. Furthermore, we predicted continuous hand and arm kinematics with a Kalman filter.

Classification of movement vs. resting could be done almost equally accurately from signals in M1 or F5 (96% correct classification with M1, 95% with F5), whereas movement detection was significantly worse from AIP (85% correct). When decoding continuous hand and arm angles, differences between M1 and F5 became more apparent: the mean correlation coefficient (CC) (± standard deviation) between real and decoded trajectories across all 27 DOF (across 2 sessions of a first animal) was 0.74±0.14 when using signals from M1 for decoding, whereas the CC was 0.64±0.16 for signals from F5 and 0.55±0.16 for AIP. In contrast, we determined a chance-level CC of -0.005±0.023 when spiking data was temporally shuffled so that the causal link between movement and neural activity was destroyed.

These results indicate that both F5 and AIP carry information about continuous hand movements and movement timing, whereas AIP is less suited for continuous movement predictions. These findings suggest a fundamental difference in the coding of continuous movement information in AIP and the (pre-) motor areas F5 and M1, which could be useful for future hand prosthetic designs.

Title: Local field potentials are influenced by cooperative joint-action in frontal and parietal cortex of macaque monkeys

Authors: *O. PAPAZACHARIADIS, S. FERRARI-TONIOLO, F. VISCO-COMANDINI, R. CAMINITI, A. BATTAGLIA-MAYER;
Dept. of Physiol. and Pharmacol., SAPIENZA Univ., Rome, Italy

Abstract: The importance of social interaction in human and cultural evolution is only surpassed by the extreme complexity of social brain functions, making neural processes underlying social behavior difficult to study. Actions are identified as own or alien and in some cases alien actions trigger the same neural activity as own actions. However, evidence of neuronal activity associated to joint action in a social context is scant.
We studied extracellular local field potentials (LFPs:1-100 Hz) from premotor cortex (PM) and inferior parietal lobule (IPL) in two rhesus monkeys, during a joint-action task. Our goal was to determine not only the relationship between behavior and LFPs, but more importantly the context influence of an obligatory joint-action with a partner on neural activity.
Monkeys were trained in a center-out task in two conditions. In the first condition (SELF) each monkey, individually, had to move its cursor from the center toward a peripheral target, by applying a force on an isometric joystick, while the partner monkey observed the action. In the second condition (cooperative joint action: COOP), both monkeys had to move their cursors simultaneously toward the same peripheral target, constrained by a maximum inter-cursor distance limit visualized as an outlined circle encompassing the two cursors. Thus, in this condition they had to cooperate to reach a common goal.
We recorded neural activity from 236 PM and 166 IPL sites together with behavioral key events, simultaneously from homologous areas of both monkeys, by using two multiple-electrode arrays. Offline, we defined two epochs of interest, reaction time (RT: 0.2 s from target onset) and movement time (MT: 0.2 s from movement onset). For each trial we calculated the peak-to-peak LFP amplitude in each epoch. Finally we compared these values between the self-acting (SELF) and joint acting (COOP) and between peripheral target directions.
Behavioral analysis of reaction time and movement time showed that monkeys adapted their behavior during the joint-action condition in order to accommodate the partner's behavior. A two way ANOVA showed a significant difference of LFP activity during RT or MT between SELF and COOP conditions in 25.8 % PM and 21.1% IPL sites and between peripheral target directions in 41.9% PM and 36.7 % IPL sites with an interaction factor that resulted significant in 11% PM and 13% IPL sites.
Our data show that there exists in the parieto-frontal system an action cooperation network which is set in motion during cooperative joint-action. We also show that LFP, reflecting cell assembly coordination, can disclose executive and higher-order neural processes.

Title: Neural activity associated to joint-action during social cooperation in frontal and parietal cortex of macaque monkeys

Authors: *F. VISCO-COMANDINI, S. FERRARI-TONIOLO, O. PAPAZACHARIADIS, R. CAMINITI, A. BATTAGLIA-MAYER;
SAPIENZA Univ. of Rome, Roma, Italy

Abstract: The neural mechanisms related to the ability of humans and non-human primates to interact through joint-action are still poorly investigated. In the domain of motor functions, the study of goal-directed movement showed that no obligatory relationship exists between neural activity and movement, but rather movement-related activity is context-dependent and linked to different cognitive states. So far, neural activity in different cortical areas has been studied in a single brain in action, thus missing all information typical of interacting brains through a joint action task.
Two monkeys sat together in front of a display and they were trained in a center-out task in two intermingled conditions. In the first (SELF), each monkey had to move individually a visual cursor from a central position toward 8 different peripheral targets, by applying a force on an isometric joystick while its partner observed the action. In the second condition (cooperative joint action: COOP), both monkeys had to move their cursors together toward the same peripheral target, under the constraint of a maximum inter-cursor distance limit, which was visualized as an outlined circle incorporating the two cursors. Thus, in this context monkeys had to cooperate to reach a common goal.
Extracellular single-unit activity (SUA) was recorded from premotor cortex (PM) and inferior parietal lobule (IPL), simultaneously from homologous areas of both monkeys by using two multiple-electrode arrays.
Preliminary results showed that kinematic parameters, such as amplitude and direction of the force applied on the joystick, were overall similar in the COOP and SELF conditions. However,

analysis of temporal aspects related to COOP trials showed a tendency of each monkey to adapt its own behavior in order to accommodate partner's behaviour. In 540 PM and 258 IPL neurons studied during Reaction- and Movement Time, a 2-way ANOVA showed a significant difference of SUA between SELF and COOP conditions in 28.5 % PM and 22.1% IPL cells, and between final target directions in 42.6% PM and 39.2 % IPL cells with an interaction factor that resulted significant in 13.7% PM and 14.3% IPL cells. Therefore, in these areas similar actions performed in different social contexts (such as in absence or presence of social interactions), modulates SUA in a different way.
These findings represent a first step toward the description of the neural operations underlying motor functions in a cooperative context and suggest that within this action cooperation network different areas encode joint-action during different behavioural epochs.

Title: Reciprocal interactions between distal and proximal upper-limb segments in humans

Authors: *D. S. SOTEROPOULOS[1], M. A. PEREZ[2];
[1]Inst. Neurosci, Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Systems Neurosci. Inst., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Previous evidence suggested that the primary motor cortex controls different upper-limb segments as a whole rather than individually. However, electrophysiological interactions between distal and proximal arm segments in the same limb remain poorly understood. In the present study, we examined the effect of voluntary activation of a proximal arm muscle onto the excitability of corticospinal projections targeting distal intrinsic hand muscles. The effect of distal muscle activation onto corticospinal projections of proximal muscles was also tested. Non-invasive transcranial magnetic stimulation was used to elicit motor evoked potentials (MEPs) in the first dorsal interosseous (FDI), abductor pollicis brevis (APB), abductor digiti minimi (ADM), flexor carpis radialis (FCR), biceps brachii (BB), and triceps brachii (TB) muscles while subjects were instructed to complete an isolated ~3-5% maximal isometric voluntary contraction

(MVC) with either the elbow into flexion or the index finger into abduction. To examine the specificity of these effects, MEPs in arm muscles were tested during ~3-5% of MVC with foot dorsiflexors muscles. We found that voluntary contraction with the BB increased MEP size in several of the hand muscles tested including the FDI (by 43.1±25%), APB (by 45.2±27%) and ADM (by 62.5±62%). Similarly, voluntary contraction with the FDI increased MEP size in proximal muscles including the BB (104.9±34%) and TB (44.8±27%). No effects were found of dorsiflexion on MEPS in the muscles tested. Our findings demonstrate bidirectional facilitatory interactions between corticospinal projections targeting distal and proximal arm muscles in intact humans - whether these interactions occur at the level of the cortex and/or spinal cord remains to be determined.

Title: Ipsilateral corticospinal responses are modulated during bilateral voluntary contractions in humans

Authors: *T. TAZOE[1,2], M. A. PEREZ[2];
[1]Dept. of Rehabil. for Movement Functions, Res. Institute, Natl. Rehabil. Ctr. For Persons With Disabilities, Tokorozawa, Japan; [2]Systems Neurosci. Inst., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Bilateral voluntary contractions involve functional changes in both primary motor cortices. However, the contribution of ipsilateral corticospinal neurons to the control of bilateral upper limb movements remains poorly understood. Here we investigated whether ipsilateral motor evoked potentials (iMEPs) elicited by transcranial magnetic stimulation (TMS) were modulated by bilateral muscle contractions, and whether this modulation was influenced by the direction of the bilateral contraction. Single supra-maximal TMS pulses were given to the left motor cortex during 30% and 100% of maximal isometric voluntary contraction (MVC) with the left biceps brahii muscle into flexion while the contralateral side remained at rest or performed 30% or 100% of MVC into elbow flexion or extension. We found that iMEPs were suppressed during bilateral activation of homologous (biceps-biceps) muscles compared to a unilateral contraction. In contrast, iMEPs were facilitated during bilateral activation of antagonistic

(biceps-triceps) muscles compared to a unilateral contraction. In an additional control experiment, we found that when the head was rotated by 90° leftward (i.e. towards the side of the muscle tested) iMEPs were facilitated. Whereas, when the head was rotated rightward iMEPs were suppressed. The contralateral MEP showed the opposite modulation, suggesting that iMEPs and contralateral MEPs were mediated by different pathways. Our findings support the hypothesis that neural activity in ipsilateral corticospinal pathways is driven, at least in part, by limb kinematics.

Title: Feedback responses enforce trajectory control when required by the goal of the ongoing task

Authors: *T. CLUFF, S. H. SCOTT;
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Trajectory control models were introduced in motor neuroscience almost 30 years ago to explain our tendency to perform straight reaching movements. These models have led to the longstanding view that the motor system controls the desired position or trajectory of the limb during ongoing movements. However, recent studies have highlighted that the motor system compensates for perturbations in a way that maintains task performance rather than produce stereotyped movement patterns. Thus, it is still unclear whether there are circumstances where feedback responses enforce a desired limb trajectory. Here we investigate how the behavioural goal affects feedback responses during upper limb reaching movements. We predicted that feedback responses would only produce stereotyped movement patterns when they are required by the task. Participants (n = 6) performed 10 cm reaching movements with their arm supported in a robotic exoskeleton device (KINARM, BKIN Technologies). The subjects were instructed to reach slowly to the goal target (radius = 1 cm) within 800-1200 ms of movement onset. We probed feedback responses on random trials by applying step torque perturbations that displaced

the elbow during the ongoing reach (±0.5, ±1Nm, ±2 Nm with 10 ms ramp-up profile). Subjects completed two blocks of trials (in random order) where they were instructed either to resist the perturbation and complete the reach within the allotted time (mean reach time = 992±161 ms), or track a target that moved with a bell-shaped velocity profile along a straight path from the start position to goal target in 1000 ms. The radius of the moving target was adjusted for each individual subject based on the variability of his or her nominal (i.e., unperturbed) reaching movements. For each perturbation amplitude and direction (±0.5, ±1, ±2 Nm), we found that subjects reduced their maximum elbow and hand displacements to intercept the moving target before completing the reach, but corrected directly to the goal target when the task did not require precise control of the movement trajectory (all p's < 0.05). In a subsequent experiment, we found that verbal instructions were not sufficient to evoke feedback corrections along a desired trajectory. Our results highlight goal-directed feedback corrections that selectively compensate for errors that influence the outcome of the task. These goal-directed corrections can be modified to produce straight trajectories when required by the ongoing motor task.

Title: Neural correlates of online reaching control in primary motor cortex

Authors: *F. CREVECOEUR[1], T. HERTER[3], S. H. SCOTT[1,2];
[1]Ctr. For Neurosci. Studies, [2]Dept. of Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada; [3]Dept. of Exercise Sci., University of South Carolina, SC

Abstract: It is generally accepted that sensory feedback is essential to control voluntary movements. However, the neural mechanisms underlying feedback control remain highly debated amongst researchers who study voluntary movements such as reaching. One view argues that feedback control is performed by low-level structures (including the spinal cord), which

maintain the limb close to a desired state or trajectory. An alternative hypothesis suggests that the cortical network engaged during motor planning is equally engaged during motor execution, allowing online goal-directed motor adjustments. Here we present data supporting the latter hypothesis. We analyzed firing patterns of neurons in Primary Motor Cortex (M1) of non-human primates performing reaching movements to visual targets (3 monkeys, 117, 306 and 141 cells collected). Monkeys performed centre-out reaching towards one of eight targets uniformly distributed around the starting position. Movement amplitude was 6 cm. We selected cells displaying significant directional tuning during the agonist activity (-50 ms to 100 ms relative to reach onset). This criterion allowed us to include 54 (46%), 137 (44%) and 37 (26%) cells in the analyses, respectively. We concentrated on the reaching movements orthogonal to the cells' preferred directions and compared their activities across trials in which movements initially deviated towards or away from the preferred directions. We reasoned that, if the cell is linked to the generation of movement towards its preferred direction, then it should be engaged in controlling trial-to-trial variability along this axis. We found that the cells' firing rates during the movement (from 0 to 0.5 s relative to reach onset) were greater when the hand was initially moving away from the preferred direction (paired t-test, $t = 2.9$, $P < 0.005$). In addition, the trials displaying greater corrective displacements towards the preferred direction were associated with an increased activity during the reaching movement ($t = 2.7$, $P < 0.01$). Hence, the modulation of single cells' activities during the movement was compatible with the compensation for trial-to-trial variability, and the amplitude of the modulation correlated with the distance travelled along the preferred direction. Altogether, these results support a direct contribution of M1 to online control of reaching movements.

Title: Rapid Feedback Responses: Rapid switching between multiple goals during movement execution

Authors: *J. Y. NASHED, F. CREVECOEUR, S. H. SCOTT;
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Recent work has highlighted that corrective responses to mechanical perturbations consider the shape of behavioural goals (Nashed et al, 2012 JNP). This work highlights the ability to make goal-directed corrections across a spatially distributed goal. However, what if this end goal was a series of discrete goals as opposed to a continuous one? Using a novel obstacle avoidance paradigm we examined if rapid feedback responses differed when reaching to a continuous bar target or multiple discrete dots spanning the same spatial position as the continuous goal.
In the single-long target experiment (SLT), subjects performed reaches (KINARM, BKIN Technologies) from a start target (ST; radius 1cm) close to the body to a bar located directly in front of ST. Participants were instructed to avoid two virtual circular obstacles (radius 1cm) placed strategically to the left and right of the straight path between the start and end goals. Importantly, the obstacles were positioned such that they did not impede the unperturbed reaching trajectories to the center of the end target(s). On random trials subjects were perturbed with 1 of 4 possible joint torques (-0.5,-1,-2 or 0.5 Nm) which displaced the hand leftward or rightward towards the obstacles. The key to the experiment was the medium perturbation (-1Nm), which directed their hand towards the obstacle and forced them to make online decisions. In the multiple target experiment (MLT), subjects performed the same experiment as in SLT, except, the long bar was replaced with three circular targets located at the centre and two ends of the bar's location in the SLT experiment. Obstacles and loads were identical across the two tasks.
In the SLT group, for the medium perturbation (-1Nm), subjects had a diverse mixture of strategies with some movements passing between the obstacles and finishing at the middle of the bar, whereas other movements passed around the obstacles and landed near the end of the bar. We found that long-latency stretch responses (R2 and R3 time periods) were altered across these two strategies, with larger responses generated to direct the hand back between the two obstacles. For the MLT group we found similar patterns of corrective movements for the each perturbation magnitude. However, changes in the long-latency response were found to be only significant during the R3 but not the R2 period. As corrective responses were generated to roughly the same spatial location for the long-bar and the multiple targets, this data suggests that the ability to make corrective responses to a different spatial goal requires additional processing time by the motor system.

Title: Decoding the representations of grasp types and object properties in the human brain

Authors: *S. FABBRI[1], R. CUSACK[1,2], J. C. CULHAM[1,2];
[1]Brain and Mind Inst., [2]Dept. of Psychology, Univ. of Western Ontario, London, ON, Canada

Abstract: Macaque neurophysiology has suggested a special role of ventral premotor cortex (PMv) and the anterior intraparietal sulcus (AIP) in processing both grasp type and object type. Studies in humans have demonstrated that the putative human homologues of these macaque areas -- PMv and aIPS-- are also involved in the grip component of reach-to-grasp actions and that temporary lesions in these areas cause impairment in preshaping the hand appropriately for the shape and size of the object. It remains unknown to what extent visual and sensory information about shape and size of the objects and the specific grip type are represented and interact in these regions. We recorded human brain activation using functional magnetic resonance imaging (fMRI) and applied multivariate pattern analysis (MVPA). Specifically we utilized a representational similarity approach (Kriegeskorte, Mur, & Bandettini, 2008), to correlate the spatial representations of different grasps and objects in the human brain.
We measured brain activity while participants were passively observing or grasping with 3 grip types (precision grip with 2 digits, precision grip with 5 digits, or a whole-hand grasp) 6 objects (bar, cube, plane, cylinder, sphere, disc) of different sizes (small, medium, and large), for a total of 72 conditions. We collected a rich dataset with 12 repetitions for each of the 72 conditions. We measured how dimensions like task and object size were represented in the human brain by computing correlations between spatial patterns of activation across voxels during odd and even runs in the 72 conditions.
We found that both PMv and aIPS encoded information about the specific task, distinguishing the three grasps from passive viewing. The way in which the three grasps were represented differed between regions: while aIPS showed similar response patterns across all three grasp types, PMv showed greater similarity between the 5-digit and whole-hand grasps than between

either of those grasps and the 2-digit precision grip. Moreover, the representation of the size of the objects depended upon the task, suggesting an interaction between grasp type and object size. Overall, our results indicate that human aIPS and PMv distinguish between grasps to different extents and that this information interacts with information about the size of the object to grasp.

Title: How far is it? BOLD fMRI activity encodes reach amplitude during planning and execution

Authors: *A. PILACINSKI, A. LINDNER;
Hertie Inst., Tuebingen, Germany

Abstract: Unlike ballistic saccadic eye movements, always executed along stereotyped movement paths, reaching a target with the hand can be realized in various ways. This is needed, for instance, because physical obstacles might be blocking the most direct path. Therefore, as opposed to saccades, the planning of reaching movements needs to also consider movement trajectory information - not just define the movement endpoint. This means that neural activity encoding reaching movements should likewise reflect the basic properties of their trajectories such as movement amplitude. Neural correlates of this component, however, have been difficult to capture especially when using noninvasive brain imaging techniques such as fMRI. We tackled this problem. In a series of experiments we studied reach amplitude effects on BOLD fMRI-signals during movement preparation and execution. All experiments were based upon delayed response tasks, implemented in a MRI-compatible virtual reality reach setup and all statistical analyses were performed on a single-subject basis. In the first experiment we successfully demonstrated a significant modulation of BOLD signals by reach amplitude during both movement planning and execution in posterior parietal and in premotor cortex. In contrast, the hand area of primary motor cortex showed amplitude representation solely during reach execution. Specifically, the larger the amplitude the stronger was the BOLD signal in these areas.

In the second experiment we confirmed these results and moreover we ascertained that the reported differences in BOLD signals do not depend on the eccentricity of target position but instead reliably reflect movement amplitude.

Title: A role for ventral stream brain areas in understanding errors in tool manipulation

Authors: *J. C. MIZELLE[1,2], R. KELLY[1], L. A. WHEATON[1];
[1]Sch. Applied Physiol, Georgia Tech., ATLANTA, GA; [2]Rehabil. Res. and Develop., Atlanta VA Med. Ctr., Atlanta, GA

Abstract: The successful completion of complex action goals often relies on the use of tools. For this, we must know which tools to use for a specific action goal. Further, we must also know how to manipulate those tools in meaningful way to achieve the goal of the action. Our previous work has highlighted a role for ventral stream brain areas in support of understanding errors in the context of tool use (e.g., identifying that a hammer is not the appropriate tool for stirring coffee). Although clinical observations suggest that dorsal stream areas may be important for understanding errors in the physical usage of tools (e.g., hammers must be grasped and manipulated a certain way to best drive a nail), this has not been fully evaluated in the healthy brain. As such, the purpose of this study was to identify the regions of the brain critical to supporting the process of understanding errors in tool manipulation. Using event-related fMRI, neural activations were recorded while participants silently evaluated whether images showed correct (e.g., hammer held by its handle with the head oriented towards a nail) or incorrect (e.g., hammer held by its handle but with the handle oriented towards a nail) tool manipulation. The context of the action scene was always correct (e.g., hammer used on a nail). We expected similar regional activations (i.e., parietofrontal areas) for both conditions, but with greater activation for identifying incorrect over correct tool manipulation. As expected, both conditions elicited robust activation of parietal and frontal areas. However, greater activation was seen for correct over incorrect tool manipulation along the canonical parietofrontal action network, while activations for identifying incorrect over correct tool manipulation were primarily seen at superior temporal areas and insula. These findings support a fundamental role for ventral brain

areas in functional action understanding. Accordingly, we expand our hypotheses about ventral brain networks identifying contextual error to include mechanisms for understanding functional tool actions, which collectively we regard as functional affordances.

Title: Effects of verb presentation on motor preparation and motor action

Authors: *M. YUKI[1], S. MORIOKA[2];
[1]Tatuminishi, Murata Hosp., Osakashi, Japan; [2]Grad. school of health science,Kio university, Nara, Japan

Abstract: Introduction
Humans perform motor actions by their own intentions, and also perform preparation and planning prior to motor action. The efficiency of neural circuits is enhanced by motor preparation, enabling more efficient motor control. “Intention” is important in motor preparation, and language is involved in the formation of “intention”. In fact, verbs which are associated with parts of the body have effects on motor action (Ricardo, 2009). Therefore this study considers whether verb presentation affects the motor preparations.
Methods
The subjects were three healthy adults. The protocol of presentation was as follows: A point of fixation, “×”, was displayed for 5sec and, as the conditioned stimulus (S1), either a hand-related verb or an abstract verb was displayed for 2sec. Following S1, either “Go” or “No” was displayed as the discriminative stimulus (S2) for 1sec. With each trial comprising the period of eight seconds from the display of a point of fixation to the presentation of S2, 100 trials were conducted. With 100 trials as a set, three sets were conducted. Fifty times each of hand-related and abstract verbs were presented as S1. As S2, “Go” was presented 60 times and “No” was presented 40 times. Instruction was given to press a button only when “Go” is presented. Reaction times following the presentation of S2 were measured, and the times for the hand-related verbs and for the abstract verbs were tested by Student’s t-test. EEG measurements were made with a digital electroencephalograph with advanced features, the ActiveTwo system(BioSemi). The record of the EEG assumed 32ch, sampling frequency 1,024Hz, band pass

filter 0.05-50Hz. Event-related potential (ERP) data were taken beginning at 1sec in advance of, and ending 4sec after, the presentation of S1, and signal averaging was carried out for each condition of the hand-related verbs and the abstract verbs. The EEGs were analyzed using EMSE Suite (Source Signal Imaging Inc.), and CNVs as well as changes in the amplitude of N400 were examined.
Results/Discussion
Although there was a tendency for the response time to be short when hand-related verbs were presented, a significant difference was not found ($p<0.05$). The average amplitude of the CNV was large when hand-related verbs were presented, and the average amplitude of N400 was large when abstract verbs were presented. From these results, it is considered that the efficiency of neural circuits is enhanced by the presentation of hand-related verbs, which tends to shorten the response time. Further, it is considered that the mental load of apprehending the meaning is increased by the presentation of abstract verbs, which tends to lengthen the response time.

Title: Effect of sensory attenuation on cortical movement related oscillations

Authors: *J. LEE, B. D. SCHMIT;
Marquette Univ., Milwaukee, WI

Abstract: Changes in cortical oscillations associated with motor commands after spinal cord injury (SCI) may result from the loss of proprioceptive sensory feedback. After SCI, beta frequency (15-35 Hz) oscillations have been observed to be significantly attenuated compared to control subjects over sensorimotor areas of the cortex. These neural oscillations have been theorized to facilitate communication between different segments of the brain, and their amplitude has been shown to modulate during motor tasks. We hypothesized that changes in amplitude of beta frequency modulation after SCI result from the loss of proprioceptive sensory feedback and that a similar alteration in cortical patterns can be induced in controls with the use of muscle vibration. During this experiment, we measured the effects of attenuated proprioceptive feedback on electroencephalography (EEG) signals in ten young, healthy control

subjects during a simple ankle motor task using prolonged tendon and muscle vibration, previously demonstrated to depress Ia afferents. Participants were instructed to briskly dorsiflex their ankle after a visual cue from a comfortable seated position. Four conditions were randomly interleaved across 5 blocks and consisted of the following: no vibration before the visually cued ankle dorsiflexion, vibration (10 s ± 1 s of 70 Hz) of the tibialis anterior (TA) before the visual cue, electrical stimulation (Estim) of the TA, and vibration of the TA followed by Estim. Signals from a 64 channel EEG actiCAP were sampled at 2000 Hz and band-pass filtered between 1 and 500 Hz. Offline data analysis was conducted using the Fieldtrip and EEGLAB lboxes, and custom Matlab scripts. Electromyography (EMG) recordings (band-passed 10-350 Hz) were taken from the TA and the medial gastrocnemius (MG) muscles. A beta band time frequency (TF) decomposition of the Cz electrode was calculated, averaged across epochs and referenced to a baseline rest period as a percent change in power. Event related synchronization (ERS), the synchronized increase in beta band power after a cortical motor command, was attenuated ($p=0.0199$) after prolonged vibration compared to ankle dorsiflexion without vibration. Event related desynchronization (ERD), an event related decrease in spectral power found during movement initiation, was also observed to be attenuated ($p=0.0557$) after prolonged vibration. The attenuation of beta band cortical oscillations following prolonged vibration of the TA, despite no significant change in the EMG activity of the resulting ankle movement, lends evidence towards a change in cortical sensory processing during movement after proprioceptive attenuation.

Title: Increased activation in premotor and prefrontal cortices relates to poorer motor action selection performance after stroke

Authors: *J. C. STEWART, S. C. CRAMER;
Univ. of California, Irvine, Irvine, CA

Abstract: Action selection (AS) is a critical feature of voluntary movement. After stroke, damage to the motor system often leads to compensatory brain activation for the performance of simple movement tasks. It is not known, however, how the motor system responds after stroke when additional AS requirements are placed on movement and whether variability in task performance between individuals relates to neural resource utilization. The purpose of this study was to determine the relationship between AS task performance and brain activation in individuals post-stroke. Ten individuals with right-sided hemiparesis (mean (SD): age: 66.3 (5.7); Upper Extremity Fugl-Meyer motor score: 52.3 (9.1); time post-stroke: 42.5 (24.7) months) and 16 age-matched controls (age: 65.0 (9.0)) performed a right or left joystick movement with the dominant, right hand under two conditions. In the *action selection (AS) condition*, participants moved right or left based on a visual cue. In the *execution only (EO) condition*, participants repeated a simple movement in the same direction on every cue. After a practice period (3 blocks of 36 trials), the two conditions (AS, EO) were performed during functional MRI in a 3T scanner with an MRI compatible joystick. In both subject groups, reaction time (RT) for the AS condition was significantly longer than for the EO condition (p<0.001). RT was longer in the stroke group, but RT cost (AS RT normalized to EO RT) did not significantly differ between groups and did not correlate with degree of motor impairment. Across groups and tasks, movement activated a motor network that included left primary motor, PMd, supplementary motor area (SMA), and parietal cortices and right cerebellum; right PMd and parietal cortex were also active in the stroke group. Regression analysis during AS revealed three significant clusters that had a significant positive correlation with RT cost: left PMd, dorsal lateral prefrontal cortex, and SMA (p<0.001), i.e., individuals with higher cost had greater activation in these regions during AS. Interestingly, these relationships were independent of group. In summary, increased activation in left premotor and prefrontal regions during the AS task was associated with slower task performance suggesting greater utilization of these regions reflects compensatory activation to maintain task performance. The brain-behavior relationship in individuals post-stroke varied in a similar manner as controls, suggesting common compensatory mechanisms across stroke and normal aging. Future work will investigate whether neural recruitment during AS predicts motor learning in complex conditions of practice that target AS processes.

Title: Neural correlates of reaching movements in virtual environments designed for neuro-rehabilitation

Authors: *G. GARIPELLI, V. LIAKONI, D. PEREZ-MARCOS, T. TADI;
Mindmaze SA, Ecublens, Switzerland

Abstract: Recent advances in neurorehabilitation research have shown that virtual reality (VR) based cognitive therapy may induce cortical plasticity and promote recovery using goal-directed arm/hand movements. Through an immersive VR setting, it may be possible for a system capable of appropriately stimulating the action observation system to encourage plasticity and repair. Since task-oriented rehabilitation is known to be beneficial, in the current study, we designed a virtual reality (VR) paradigm in combination with EEG through a novel VR platform (MindMaze, Switzerland) to investigate the behavioral and neural mechanisms associated with the observation and execution of self-generated movements in healthy participants.
64 Channel scalp EEG was recorded from 9 healthy participants (mean ± SD; 29±5 years) during a reaching task in a VR platform (MindMaze). Participants' were instructed to reach 5 equidistant targets in a virtual environment following a linear path. Their movements were recorded and mapped onto an avatar in real time. We analyzed EEG activity (Slow Cortical Potentials (SCP; 0.1-5Hz); and beta (18-30Hz) band), as well as behavioral data (reach time and trajectory accuracy) across three conditions: a) 1-to-1 mapping: right arm mapped onto the virtual right arm; b) mirror mapping: right arm mapped onto the virtual left hand; and c) video control: pre-recorded reaching movements.
Analysis of behavioral data revealed a significant main effect (Anova) of mapping with longer reach times ($F(1,8)=16.48$, $p<0.01$) and reduced trajectory accuracy ($F(4,32)=4.99$, $p<0.01$) in the mirror mapping across all the targets. Analysis of the SCP over central electrodes before movement onset showed a significant negative shift in the mirror condition compared to the other two (ANOVA, $p<0.001$). Furthermore, SCP at C1 electrode during movement correlated positively with trajectory accuracy ($\rho=0.86$ in 1-to-1; $\rho=0.48$ in mirror; Pearson coeff). We also observed higher beta activity suppression in electrodes C3, CP3 and CP1 electrodes during the movement execution in the 1 to 1 compared to the mirror condition (t-test, $p<0.001$).
Behavioral data shows that the mirror condition was more complex to perform & depending on the mapping, the same targets were accessed differently. Data from SCP suggests that the upcoming task complexity is encoded in the preparatory activity and may predict task difficulty. Additionally, weaker contralateral beta activity during the mirror mapping may be due to the increased multisensory incongruence. Further studies in patients will provide valuable insights into these manipulations signatures for concrete prognosis and diagnostics.

Title: The role of primary motor cortex beta activity in the control of force output

Authors: *E. PROKIC, G. WOODHALL, I. STANFORD, S. HALL;
Life and Hlth. Sci., Aston Univ., Birmingham, United Kingdom

Abstract: Beta frequency (15-30Hz) oscillatory power in the motor network is modulated during motor control and has been linked to specific movement phases, such as movement preparation and execution. However, experimental results and opinions on the involvement of beta in force output are varied.
Excessive synchronization of neuronal activity in the beta range is characteristic of patients with Parkinson's disease (PD) and beta oscillations are thought to produce the motor impairment associated with the disease. Stimulation at 20Hz in the subthalamic nucleus (STN) and motor cortex stimulation at 20Hz has been shown to impair force development (Chen et al., 2011; Joundi et al., 2012) providing a link between excessive neuronal synchronization at beta frequencies and motor impairment in PD. However, the effects of these experiments are modest. Here, we used a source-level magnetoencephalography (MEG) approach to investigate the hypothesis that beta power suppression in primary motor cortex (M1) co-varies with motor force generation. Ten healthy participants used their dominant hand to produce specific isomentric force output, measured using a MEG compatible force transducer. Four target levels were generated (35, 50, 65 and 80% of each participants maximum force output). Participants were required to elicit the target force as quickly and accurately as possible in response to four randomly presented visual cues and maintain each force level for 5 seconds. M1 cortices were localised with synthetic aperture magnetometry beamforming analysis. Virtual electrode analysis was used to reconstruct the spontaneous and movement-related oscillatory activity in bilateral

M1 cortices, before and during force output.
We demonstrate that there is no difference in the ampitude of beta desynchronisation from pre-movement baseline at the four different force outputs. These data suggest that beta desynchronisation does not encode force output. Further experiments are underway to explore the role of beta desynchronisation in relation to force control over time, movement speed, between cue and onset of movement and between onset to target force reached.

Title: Separable components of object-related gesture production in the left hemisphere

Authors: *L. J. BUXBAUM[1], A. D. SHAPIRO[1], H. B. COSLETT[2];
[1]Moss Rehabil. Res. Inst., Elkins Park, PA; [2]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: A great number of functional neuroimaging studies suggest that gesture production is associated with a widely distributed bilateral frontal, parietal, and posterior temporal network. Evidence from patients with ideomotor apraxia after left hemisphere stroke suggests, in contrast, that the left posterior temporal and inferior parietal lobes are a critical locus of gesture representations, particularly those for skilled object use. We performed voxel-based lesion symptom mapping with data from 73 left hemisphere stroke participants to assess the critical neural substrates of 3 types of gestures performed with the less-impaired left hand: gestures produced in response to viewed objects (VO), imitation of object-specific gestures demonstrated by the examiner (IO), and imitation of meaningless gestures (IM) matched to the other two types for complexity. Gestures were scored separately for postural (hand/arm positioning) and dynamic (amplitude/timing) accuracy. Lesioned voxels in the left posterior middle temporal gyrus (pMTG) were significantly associated with lower scores on the posture component for both of the object-related gesture types (VO and IO). In contrast, this region was not associated with posture scores for the meaningless gestures (IM). Moreover, lesioned voxels in the pMTG remained significant predictors of low VO and IO even when controlling for IM performance. Poor performance on the dynamic component of all 3 gesture types was significantly associated

with relatively more dorsal regions in the left inferior parietal and frontal cortices. These data confirm prior claims that the left hemisphere is a critical substrate of gestural action, and extend prior findings by demonstrating separable loci for postural and dynamic components of object-related (but not meaningless) gesture. Finally, the pMTG substrate of object-use postures suggests that these representations may have co-evolved with semantic systems encoding relational (thematic) object knowledge.

Title: Attention modulated resting state neural activity predicts future performance on a complex multimodal glider landing task

Authors: *D. E. CALLAN[1], C. TERZIBAS[2], D. CASSEL[3], A. CALLAN[4], H. ANDO[2]; [1]Ctr. For Information and Neural Networks NICT, Osaka, Japan; [2]Multisensory Cognition and Computation Lab. NICT, Kyoto, Japan; [3]Hosp. for Sick Children, Toronto, ON, Canada; [4]Ctr. for Information and Neural Networks NICT, Osaka, Japan

Abstract: The goal of this study is to determine internal states that are difficult to record behaviorally that may predict future performance. There has been considerable debate about the role of resting state brain networks in modulating task processing and performance. Most of these studies, however, utilize tasks and conditions that are far removed from real-life experience and may not translate to real-world application. In this study we utilize a neuroergonomics approach in which it is maintained that in order to investigate complex real world behavior it is necessary to understand the processes within the context of the underlying interacting brain networks rather than under reduced isolated conditions typical of brain imaging experiments that only occur in the laboratory. In accomplishing this goal an extremely robust virtual glider flight simulator is used within fMRI to investigate neural processes underlying complex perceptual, motor, and cognitive processing. Specialized MRI compatible fiber optic devices were used to duplicate the same flight controls as are used in a real glider: control stick (right hand) manipulating the aileron (roll) and elevator (pitch), rudder pedals (yaw; both feet), and dive brake (left hand). The task for the subjects (consisting of 14 pilots recruited from local university

glider clubs) was to land the glider as close to a red x on the runway as possible from a first person perspective. The fMRI results show that activity in action planning brain regions are parametrically modulated by behavioral performance on the landing task. These brain regions include the basal ganglia, primary motor cortex, premotor cortex, dorsolateral prefrontal cortex, and the parietal cortex. Of considerable interest, is the finding that in the resting condition, starting 25 seconds before each trial, these same brain regions showed an inverse parametric modulation with behavioral performance. These results suggest that modulation of brain networks on a complex task by internal states such as alertness, vigilance, attention can be determined long before the task begins. It is unlikely that these internal brain states can be measured through behavioral or physical measures that don't involve monitoring brain activity. The proposed research has far reaching implications for advancement in knowledge of brain processes involved with complex real world tasks as well as development of neuroergonomic technology that can be used in a wide variety of applications such as vehicle/machine operation, medical/psychological diagnosis, and rehabilitation/treatment.

Title: Pathways of processing tool information during actual use

Authors: *M.-L. BRANDI[1,2,5], J. HERMSDÖRFER[3], C. SORG[1,2,4], G. GOLDENBERG[6], A. WOHLSCHLÄGER[1,2,5];
[1]Dept. of Neuroradiology, [2]TUM-NIC Neuroimaging Ctr., [3]Sport and Hlth. Sci., [4]Dept. of Psychiatry, Technische Univ. München, Munich, Germany; [5]Grad. Sch. of Systemic Neurosciences, Ludwig-Maximilians-Universität München, Munich, Germany; [6]Dept. of Neuropsychology, Klinikum Bogenhausen, Munich, Germany

Abstract: In order to use tools like a scissor, a spoon or a pen properly we need to process, connect and integrate different information in order to reach the planned goal of cutting, scooping or writing. A tool related network including parietal, frontal and temporal regions has been shown in studies investigating the imagination, pantomime or observation of tool use. The

pathway in which the semantic aspects and action relevant information is transported through this network during actual tool use and action planning is yet not fully clear. Dynamic causal modeling (DCM) is a method for the analysis of such networks in functional magnetic resonance imaging (fMRI) data with regard to changing patterns of effective connectivity among brain areas due to experimentally induced contextual modulation. The aim of this study was to define a tool use specific network during actual tool use and analyze how this network is connected and processes the tool specific information.
A special apparatus in the MRI scanner was used to present different stimuli. One set of stimuli included ten tools regularly used in daily life (e.g. scissor, spoon or pen), the other comprised ten neutral objects. The task was to either use or transport the tools and objects with the right and left hand. A signal triggered the start of the action and divided each trial in a planning and execution phase. The fMRI activation analysis revealed a tool specific activation-pattern in temporal, parietal and frontal regions representing semantic aspects, the processing of tool-knowledge and the realization of motor actions. Different models were tested to investigate how the tool related network is constructed and how the semantic information of tool use is distributed within this network.
With DCM and Bayesian model selection it was possible to detect a model of effective connectivity, which describes a network including brain regions of the dorsal and ventral stream. This network is involved in the processing of tool use specific information during the planning and the execution of an action. Additionally the analysis revealed that semantic information from the ventral stream is connected to the processes of the dorsal stream via a strong temporal parietal link.
Not only is this essential for the general knowledge about the neuronal processes of action planning and tool use but can also be relevant for certain clinical investigations. The impaired use of tools and objects can be the result of brain lesions after a stroke and is seen in patients with apraxia. In order to understand the neuroanatomical correlates of apraxia it is important to know the neuronal networks which are important for planning complex actions like tool use.

Lab, ETH, Zurich, Switzerland; [3]Inst. of Neuroinformatics, Univ. of Zurich and ETH, Zurich, Switzerland; [4]Inst. of Neuroradiology, Univ. Hosp. Zurich, Zurich, Switzerland

Abstract: Mental imagery is a valuable tool in motor learning due to its endogenous nature, ability to complement physical training, and its proven effectiveness. It has been shown that motor imagery improves motor performance and the improvement is associated with cortical changes in primary and secondary motor areas. Yet, it is unclear how changes in each motor area represent the putative mechanisms behind motor imagery's improvement of performance.
The aim of the present study is to define the role of the primary motor cortex (M1) in motor learning by guiding mental imagery within this area using neurofeedback training. To this extent, we used real time functional magnetic resonance imaging (rtfMRI) to measure activity of the M1 hand area online and then fed this information back to the participant for the purpose of self-regulation. The M1 hand area was functionally localized in every participant during a visuomotor isometric precision grip task. Participants attempted to up-regulate the target area while performing motor imagery of pinching. Before and after M1 up-regulation, outcomes of the precision grip task were evaluated. Changes between the two assessments were analyzed to measure motor performance. We found short-term performance improvements in the isometric force-matching task to be proportional to the ability to up-regulate the BOLD signal of the target region. The endogenous self-regulation employed in this paradigm is both useful as a scientific tool to investigate the involvement of M1 in motor imagery, but also has implications towards refining mental training strategies for targeted motor improvements in motor performance.

Title: Dissociating intrinsic and extrinsic reference frames in the human motor system

Authors: *D. A. BARANY[1], V. DELLA-MAGGIORE[2], M. CIESLAK[1], S. VISWANATHAN[1], S. T. GRAFTON[1];
[1]UC Santa Barbara, Santa Barbara, CA; [2]Dept. of Physiol. and Biophysics, Sch. of Med., Univ. of Buenos Aires, Buenos Aires, Argentina

Abstract: Hand movements can be defined in relation to intrinsic and extrinsic references frames. Single-neuron recordings of movement-related activity in motor regions of monkeys have shown a mixed representation of muscle activity and posture (intrinsic), and movement direction (extrinsic). We hypothesized that intrinsic and extrinsic movement codes are differentially expressed in the human motor system. Rather than remapping reference frames using a manipulandum, we directly tested the hypothesis by exploiting two properties of movements about the wrist: (1) wrist movements involve two distinct muscle groups (ulnar-radial and extension-flexion) and (2) rotation of the forearm changes the muscle group required to produce a movement in a given direction. In a rapid event-related functional magnetic resonance imaging (fMRI) design, we measured blood oxygen level dependent (BOLD) brain activity as participants used free right-handed wrist movements of variable amplitudes to move a cursor to targets at different locations. In each run, participants maintained either a palm-down posture or palm-mid posture and moved to horizontal or vertical targets on each trial of that run. We applied multivoxel pattern analysis (MVPA) to successfully classify movements on single trials from parietal, premotor and motor areas. In each region, the classifier's generalization performance was used to dissociate target location, direction of movement, forearm posture, and muscle used. Both target location and movement direction were decodable from ventral premotor cortex (PMv). However, target location was more decodable than movement direction in the superior parietal lobule (SPL). The decoding of target location in PMv and SPL was robust to posture differences, and to targets presented in the vertical and horizontal plane. Furthermore, muscle- and posture-related information was widely decodable independent of external-space related coding, suggesting a mixed pattern of movement encoding in the human motor system.

Title: Neural dynamics of the prehension system

Authors: *L. TURELLA[1], R. TUCCIARELLI[1], R. RUMIATI[2], A. LINGNAU[1];
[1]Ctr. For Mind/Brain Sci. (CIMeC), Univ. of Trento, Mattarello, Italy; [2]2.Scuola Internazionale Superiore di Studi Avanzati (SISSA), Trieste, Italy

Abstract: In everyday life, we continuously interact with people and objects within our social and physical environment. The most powerful and versatile tools we adopt within these complex interactions are our hands. Prehension, the capability to reach and grasp objects, is a clear example of the capacity of our hands to manipulate our environment. Even if this ability appears effortless and simple, the whole-brain network dynamics underlying its sophisticated control are still largely unknown.
Here we used magnetoencephalography (MEG) to record brain activity of nineteen subjects performing non-visually guided reaching and grasping movements on an object, using either the left or the right hand. The experimental paradigm comprised a planning and an execution phase. We observed spectral modulations induced by the experimental conditions in different frequency bands (alpha, beta) within the 'prehension' network. These modulations were not only evident within the execution phase but also during the planning phase. Changes in spectral power during the planning phase were evident both with respect to the effector used (left or right hand) and the performed action (grasping or reaching). This overview of whole-brain spectral modulations contributes towards a better understanding of the dynamics within the prehension system during the planning and execution of actions.

Title: The EEG activity of the prefrontal cortex in the visual reaction task

Authors: *A. MORI[1], R. KOSHIZAWA[1], K. OKI[1], M. TAKAYOSE[2], Y. KITA[3];
[1]Col. Human & Sci., Nihon Univ., Tokyo, Japan; [2]Col. of Industrial Technol., Nihon Univ., Chiba, Japan; [3]Dept. of Human Life and Envrn. Studies, Fac. of Human and Social Studies, Keisen Univ., Tokyo, Japan

Abstract: Recently, we have that the frequency of electroencephalogram (EEG) component β band is synchronized with a probability of 100% in the prefrontal cortex just before the start of voluntary movement.
The EEG frequency monitoring showed that only a beta band synchronized in approximately 14 ms before the muscle discharge.
In the present study, we examined the occurrence pattern of beta band in the prefrontal cortex in the relationship between wrist extension and a ankle extension using visual stimulation task.
The subjects included seven kendo players all healthy male college students(19-21 years, mean age 20.3 years) and all right-hand. Experiments were carried was done using selected reaction assignment by visual stimuli. Using (17 inches) LCD display set up to 1.3 m in front of the subject was maintains a seated posture in the experimental easy chair in the inter-stimulus interval of ,3000-8000ms target stimulus for the standard stimulation (Target) stimulus image is the (Standard). The stimulus was presented randomly. To present a diamond as the Standard, the incidence of Target was 20%. The recording of EEG, was used (Electrical Geodesics, Inc. Ltd.) 128 channel digital EEG. The EEG recorded from the scalp for 128chs, was filtered through 3-30Hz, separated into the theta band (4-7 Hz), alpha band (8-12 Hz), beta band (13-30 Hz).
The frequency of EEG component beta band is synchronized with a probability of 100% in the prefrontal cortex in the visual reaction before the onset EMG.
The exact areas of beta activity site were shown in two locations in the hemisphere of the prefrontal cortex, as well as in a pinpoint area of the right hemisphere near the midline. We found a localized activity area in the left prefrontal area approximately 14 ms before the EMG onset of the wrist extensor muscle or ankle extensor muscle.
Our results show that in the selective reaction task, the activity of beta band was confined to the side of the left hemisphere and the frontal pole area of the prefrontal cortex with wrist extension or a ankle extension.
There was no significant difference between the wrist extension and a ankle extension for the latency period.These results suggest the possibility that there is recognition of the motor output in the motor cortex.

Title: Postural effects on cortical activity during swallowing: A fNIRS study

Authors: *M. YAMAWAKI, S. SHIBANO, E. YOKOZEKI;
Med. Educ. & Primary Care, Kyoto Prefectural Univ. of Med., Kyoto, Japan

Abstract: (Backgrounds)
The swallowing center in the medulla is the key integrator of swallowing performance. There are subcortical and cortical centers above the brainstem that induced swallowing movement, however, their specific role and connections are not well understood. There are technical limitations of conventional neuroimaging techniques that require subjects to be in a supine position and/or restrict head movements. Such limitations narrow the range of experimental task options for swallowing. To challenge these issues, we applied functional near-infrared spectroscopy (fNIRS), an optical method that noninvasively measure cortical hemodynamics, for brain mapping in swallowing.
(Methods)
Eighteen of right-handed healthy male were analysed. Subjects, on the chair or in supine position were put 34-channel holder of OMM-2000 Optical Multichannel Monitor (Shimadzu, Kyoto, Japan). An increase in oxyHb is used as an indicator for brain activation. Sensorimotor cortex and frontal lobe were set as the region of the interest. Data analysis was performed according to our previous study. Optode positions were measured using a 3D magnetic space digitizer (FASTRAK-Polhemus, Colchester, VT). Probabilistic method was used to register NIRS data to MNI (Montreal Neurological Institute) standard brain space. The statistical method used was a general linear model employing a two-level summary statistics approach for random effects analysis with a one-tailed t test.
(Results)
Activation areas in each task were detected separately in SMI ($p < o.o5$ by Student t, one-tailed, FDR controlled). During swallowingin supine, activation was detected in tongue SMI and BA 40 ($p < o.o5$, one-tailed, FDR controlled). The haemodynamic pattern observed during swallowing was different in sitting versus supine position in BA 6 and BA 40 ($p < o.o5$, one-tailed, FDR controlled).
(Conclusions)

The haemodynamic pattern during swallowing appeared different in sitting versus in supine position in BA 6 and BA 40. Our findings suggest that the sensory input is more important in supine than in sitting posture. Since fNIRS measurements are limited to the cortical surface, determining cortical connections to insula and basal ganglia in swallowing requires continued research.

Title: Variability of skillful motor performance is stemmed from variability of neuronal activity in wider range of brain regions recruited during motor execution

Authors: *N. MIZUGUCHI[1], S. UEHARA[1], S. HIROSE[1], S. YAMAMOTO[2], E. NAITO[1,3]; [1]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communications Technol., Suita, Japan; [2]Grad. school of Human and Envrn. Studies, Kyoto Univ., Kyoto, Japan; [3]Grad. school of Med., Osaka Univ., Suita, Japan

Abstract: Human motor performances vary across trials even when people perform well-trained motor skills. In non-human primate study, it is shown that the variability of reaching movements is originated from the variability of spikes in the premotor cortex (Churchland et al. 2006). However, we hypothesized that variability of motor performance is also derived from variability of neuronal activity in other brain regions recruited during motor execution. In the present study, we focused on a skillful motor task and investigated brain activity that generates variability of its motor performance using functional magnetic resonance imaging (fMRI). 15 right-handed participants repeated a sequence of 5 button-presses (one sequence = ring-middle-little-index-ring) with their right hand for 10 seconds (= epoch) as fast and accurate as possible. Ten epochs were completed with inter-epoch-intervals of 12 seconds in each fMRI scan, and the participants completed 15 fMRI scans in the experiment. We calculated the number of correct sequences for each epoch as an index for the variability of motor performance, and performed parametric modulation analysis. As the participants well-trained the task before the experiment, no

consistent performance improvement was observed in the scanner. But we found that the performance (the number of correct sequences) varied across epochs. In the fMRI analysis, we found that the lower performance was associated with the higher activities in bilateral premotor cortices, dorsolateral prefrontal cortices, cingulate cortices, insular cortices and parietal cortices. Thus, the present findings suggest that variability of motor performance is stemmed not merely from variability of premotor activity but from the activity in wider range of brain regions that are recruited during motor execution.

Title: Hierarchical movement coding within the prehension network

Authors: *A. LINGNAU[1], R. RUMIATI[2], L. TURELLA[1];
[1]Ctr. for Mind/ Brain Sci. (CIMeC), Univ. of Trento, Mattarello, Italy; [2]Intl. Sch. for Advanced Studies (SISSA), Trieste, Italy

Abstract: Prehension is thought to consist of two main components: reaching, i.e. the transport of the hand toward an object, and grasping, i.e. the preshaping of the hand with respect to object's properties [1]. Reaching and grasping have been suggested to rely on two distinct pathways, a dorsomedial pathway, consisting of area V6A in the medial wall of the parietal cortex and the dorsal premotor cortex (PMd), and a dorsolateral pathway, consisting of anterior intraparietal sulcus (aIPS) and the ventral premotor cortex (PMv) [2-4]. Less is known, however, about the representation of hand orientation [5, 6].
Here we used multivariate pattern analysis (MVPA) of functional magnetic resonance imaging (fMRI) data to investigate the neural representations of non-visually guided prehension movements using two different grip types (precision grip, whole-hand grip) and two different hand orientations (0 degrees rotation, 90 degrees rotation). Patterns of fMRI data within parietal

and premotor nodes of the prehension system demonstrated the existence of different movement representations: bilateral aIPS and contralateral primary motor cortex were sensitive to muscular activity coding for specific prehension movements (i.e. specific combinations of grip type and hand orientation), whereas PMv seemed to be more sensitive to wrist orientation. Our results support the view of a hierarchical representation of movements within the prehension system.

Title: Separating the Means from the End: Differentiating Motor Actions from their intended consequences

Authors: *R. GILRON[1], A. KRASOVSKY[2], Y. YESHURUN[2], R. MUKAMEL[1];
[1]Psychology, [2]Computer Sci., Tel Aviv Univ., Tel Aviv, Israel

Abstract: To reach a certain goal, multiple actions can be executed. For example, in order to draw a circle one can perform a clockwise or counterclockwise pen trace. Thus the same goal

(drawing a circle) can be achieved by different motor actions. Here we examined the neural networks that dissociate intention from action. Using fMRI, we scanned 10 right handed subjects during a visuo-motor task. Subjects tracked a figure moving on the screen either vertically or horizontally. Tracking was performed with a cursor that was controlled by pen traces on an MR compatible digital tablet. During congruent trials (50%) the direction of cursor movement on the screen and direction of pen traces on the tablet were compatible (e.g. horizontal pen traces resulted in horizontal cursor movement). In incongruent trials the direction of pen traces and cursor movement were orthogonal (e.g. in order to move the cursor horizontally, subjects had to perform vertical pen traces). This design allowed us to dissociate the goals (directional cursor movement) from motor actions (horizontal/vertical pen traces). We used multi-voxel pattern analysis (MVPA) and a whole brain searchlight algorithm to examine brain regions discriminating the different experimental conditions. In agreement with previous findings, activity patterns in left motor, left parietal, and right motor cortices discriminated direction of pen traces regardless of cursor movement (performance accuracy of 80%, 73% and 73% respectively). Interestingly, activity patterns in the right parietal, right pre-motor, and left fronto-polar cortex discriminated sensory goals (horizontal from vertical cursor movement) regardless of pen traces (performance accuracy of 77%, 75% and 75% respectively). These results point to a network of brain regions involved in high order goal selection that is dissociated from specific motor plans.

Title: Change in resting-state functional connectivity after motor skill learning in humans

Authors: *S. UEHARA[1,2], N. MIZUGUCHI[1], S. YAMAMOTO[2,3], S. HIROSE[1,2], E. NAITO[1,4]; [1]Ctr. For Information and Neural Networks (CiNet), Natl. Inst. of Information and Communications Technol., Suita City, Osaka, Japan; [2]Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Grad. Sch. of Human and Envrn. Studies, Kyoto Univ., Kyoto, Japan; [4]Grad. Sch. of Medicine, Osaka Univ., Osaka, Japan

Abstract: Motor memories are stabilized and consolidated during resting-state after motor practice. Here, we investigated change in functional connectivity after motor practice using functional magnetic resonance imaging. Thirty-two right-handed healthy volunteers practiced two different types of sequential finger-tapping tasks with their left hands. They were subdivided into two groups; one group practiced two tasks in a randomized order (random practice; n = 16), while the other group practiced one task first and then practiced the other task next (blocked practice; n = 16). We analyzed resting-state functional connectivity before and after the motor practices.
When we analyzed the connectivity after the practices, we found that the activities between the right dorso-lateral prefrontal cortex (DLPFC) and precuneus were coupled only after random practice. As this activity coupling was not observed before either type of motor practice, the activity coupling between DLPFC and precuneus was confined after the random practice. The present findings indicate that resting-state functional connectivity after motor practice may reflect change in spontaneous brain activity associated with memory consolidation process, which is distinct between random and blocked practices.

Title: Ablation of arcuate KNDy neurons amplifies the LH surge in steroid-primed, ovariectomized rats

Authors: S. J. KRAJEWSKI-HALL[1], M. A. MITTELMAN-SMITH[1], N. T. MCMULLEN[2], *N. E. RANCE[1,2,3];
[1]Pathology, Univ. of Arizona Col. of Med., TUCSON, AZ; [2]Cell. and Mol. Med., Univ. of Arizona Col. of Med., Tucson, AZ; [3]Evelyn F. McKnight Brain Inst., Tucson, AZ

Abstract: KNDy (kisspeptin, neurokinin B and dynorphin) neurons in the arcuate nucleus play an important role in the reproductive axis. We have developed a method to selectively ablate KNDy neurons in the rat using NK_3-SAP, a neurokinin 3 receptor agonist conjugated to saporin (Mittelman-Smith, Endocrinology 2012). Ablation of KNDy neurons results in cessation of

estrous cycles, ovarian atrophy, a decrease in tonic LH secretion and loss of the rise of serum LH after ovariectomy. Given these profound effects, we tested if we could induce an LH surge in KNDy-ablated rats using a well-established steroid replacement regimen. Rats were maintained on a 14:10 light cycle (lights on at 0500). Using stereotactic surgery, NK_3-SAP or Blank-SAP was injected in the arcuate nucleus and rats were allowed to recover for one month before ovariectomy. Seven days after ovariectomy they were implanted with silastic capsules containing 17β-estradiol. Two days later, they were implanted with progesterone capsules (~0830h). Rats were sacrificed in the afternoon at a time previously shown to exhibit peak LH surge levels (~1600h) and the brains were processed for immunohistochemistry. Ablation of KNDy neurons was verified by near complete loss of NKB-immunoreactive neurons in the arcuate nucleus in NK_3-SAP rats. At 0830h, tonic levels of serum LH were significantly lower in KNDy ablated rats, consistent with our previous studies. Unexpectedly, the surge in serum LH at 1600h was more than 3-fold higher in NK_3-SAP-treated rats compared to Blank-SAP controls (53.5 $\pm$ 16.5 ng/ml vs 16.5 $\pm$ 2.1 ng/ml, respectively). To determine if this change was associated with increased activation of GnRH neurons, dual-labeled GnRH-fos immunocytochemistry was performed in rostral hypothalamic sections. There was no significant difference in the total number of GnRH cells counted in 4 matched sections (NK_3-SAP, 85.8 $\pm$ 9.8 vs Blank-SAP, 84.9 $\pm$ 4.6) or in the percentage of GnRH cells that were activated, as measured by GnRH-fos coexpression (NK_3-SAP, 22.4 $\pm$ 1.8% vs Blank-SAP, 16.6 $\pm$ 4.9%). In addition, there was no difference between NK_3-SAP and Blank-SAP controls in the number of fos-ir cells counted in the AVPV. These data indicate that arcuate KNDy neurons are not required for the induction of an LH surge. The marked increase in the LH surge in KNDy-ablated rats, however, suggests that KNDy neurons are important for regulating the magnitude of the surge.

Title: Co-treatment with either insulin sensitizer or androgen antagonist blocks the effect of prenatal testosterone on AgRP cell number in female sheep hypothalamus

Authors: *M. CERNEA[1], L. M. COOLEN[1], V. PADMANABHAN[2], M. N. LEHMAN[1];
[1]Neurobio. and Anatom. Sci., Univ. of Mississippi Med. Ctr. (UMMC), Jackson, MS;
[2]Pediatrics, Obstetrics and Gynecology, and Reproductive Sci. Program, Univ. of Michigan, Ann Arbor, MI

Abstract:
Similar to women with polycystic ovarian syndrome (PCOS), prenatal testosterone (T) treated ewes develop metabolic defects such as insulin resistance and compensatory hyperinsulinemia. Previous findings from our lab have found that prenatal T-treated ewes also display alterations in hypothalamic metabolic control neurons manifested as increased numbers of immunoreactive agouti-related peptide (AgRP) neurons with no change in number of pro-opiomelanocortin (POMC) cells. In addition, we demonstrated that co-treatment of T with androgen antagonist (Flutamide, F) reversed this effect. Since AGRP cells also express insulin receptors, the current study determined whether pre- or postnatal treatment with the insulin sensitizer, Rosiglitazone (R), would reverse the effects of prenatal T on these neuronal populations. Pregnant Suffolk ewes were administered twice weekly injections of T propionate (T; 100 mg i.m.) from days 30 to 90 of gestation. In addition, separate groups of pregnant ewes received prenatal T combined with either R (8 g/ewe/day, oral) or F (15mg/kg/day, s.c.). An additional group of prenatal T-treated offspring received postnatal R (0.11 mg/kg/day, oral), beginning at 8 wk of age. Control groups received pre- or postnatal R treatments without prenatal T. At 21 months of age, all adult female offspring were ovariectomized and received hormonal implants to produce an artificial follicular phase prior to sacrifice, and brains were processed for AgRP immunocytochemistry. Confirming our previous findings, prenatal T treatment significantly increased the number of AgRP neurons ($p=0.001$), and prenatal F treatment reversed this effect, reducing cell number to control levels ($p<0.001$). Moreover, prenatal ($p<0.001$), but not postnatal ($p=0.709$), treatment with insulin sensitizer (R) reversed the effect of prenatal T on AgRP neuron number. The finding that prenatal treatments with either insulin-sensitizer or anti-androgen reverses the effect of prenatal T indicate that a common mediator involving both androgen and insulin signalling is responsible for the long-term alteration in AgRP cell number. Given the role of AgRP in regulation of energy homeostasis and body weight, we hypothesize that this effect of prenatal T on AGRP neurons may contribute to increased risk of obesity and metabolic syndrome associated with PCOS.

Title: Neurokinin B signaling in the retrochiasmatic area is essential for the full preovulatory LH surge in ewes

Authors: K. L. PORTER, S. M. HILEMAN, S. L. HARDY, *R. L. GOODMAN;
West Virginia Univ., MORGANTOWN, WV

Abstract: The effects of inactivating mutations indicate that neurokinin B (NKB) is essential to human reproduction, but its physiological roles in control of GnRH secretion remain unclear. Recently, we observed that senktide, an NKB receptor (NK3R) agonist, stimulates surge-like LH secretion in ewes when given in the retrochiasmatic area (RCh) or preoptic area (POA). Thus NKB may play a role in E2 positive feedback to induce the preovulatory LH surge. The aims of this study were to determine: 1) if RCh or POA senktide treatment activates kisspeptin neurons in the arcuate nucleus (ARC), and 2) if NKB-NK3R signaling in the RCh or POA is necessary for the preovulatory LH surge. For Exp. 1, bilateral senktide-containing or empty microimplants (n=3/treatment group) were placed in the RCh or POA in anestrous ewes. Ewes were killed and brains perfused 3 h later, tissue collected, and sections encompassing the ARC used for dual immunocytochemistry to assess the percentage of kisspeptin-ir neurons that were activated, based on coexpression of cFos. In prior crossover experiments, senktide stimulated surge-like LH secretion in all 6 RCh and 5/6 POA ewes. cFos in ARC kisspeptin neurons was induced by senktide in the RCh (59.0 ± 8.6% vs. 4.0 ± 0.5% in controls, $P < 0.05$) and, albeit to a lesser extent, in the POA (26.8 ± 5.0% vs. 4.8 ± 1.1%, $P < 0.05$). In Exp. 2, ewes were OVX and chronic guide tubes were placed in the RCh or POA. At the time of surgery, a 1 cm E2-containing silastic implant and progesterone-containing controlled internal drug-releasing devices (CIDRs) were inserted sc and intravaginally, respectively. After 10-14 days, CIDRs were removed and four 3 cm E2 implants were inserted 24 h later. Microimplants containing SB222200, an NK3R antagonist, or empty control microimplants , were immediately inserted in the RCh or POA (n=5/group). Jugular blood samples were collected every 2 h for a period of 48 h. Microimplants and the longer E2 implants were removed, CIDRs reinserted and the protocol repeated in a cross-over design. Microimplants of SB222200 in the RCh significantly decreased the amplitude of the LH surge from 185.2 ± 10.2 ng/ml with empty implants to 108.4 ± 17.5 ng/ml. In contrast, SB222200 treatment in the POA had no effect on LH surge amplitude (79.7 ± 15.2 vs. 78.3 ± 17.4 ng/ml, control vs. SB222200, respectively). No effects on timing of the LH surge were observed. Together with tract tracing data (Coolen et al., SFN abstr 2013), these findings indicate that NKB signaling in the RCh, but not the POA, is essential for the full preovulatory LH surge, and that the effect of NKB in the RCh on the LH surge is likely mediated, at least in part, by direct projections to ARC kisspeptin neurons.

Title: Effect of progesterone on kisspeptin and neurokinin B cell numbers in the arcuate nucleus of the female pig

Authors: S. M. HILEMAN[1], L. J. MEADOWS[1], K. L. PORTER[1], *L. M. COOLEN[2], C. FERGANI[2], L. A. REMPEL[3], R. A. CUSHMAN[3], W. T. OLIVER[3], E. C. WRIGHT[3], J. R. MILES[3], C. A. LENTS[3];
[1]Physiol. and Pharmacol., West Virginia Univ., Morgantown, WV; [2]Physiol. & Biophysics, Univ. of Mississippi Med. Ctr., Jackson, MS; [3]USDA, ARS, U.S. Meat Animal Res. Ctr., Clay Center, NE

Abstract: Progesterone acts at the hypothalamus to inhibit LH secretion in the pig, but the mechanism for this is unknown. Kisspeptin and neurokinin B (NKB) have both been shown to influence GnRH/LH secretion and mediate steroid negative feedback in several species and to be critical for normal reproductive function in humans. This study examines the influence of progesterone on kisspeptin and NKB expression in the pig and their potential colocalization in neurons of the arcuate nucleus of the hypothalamus (ARC). The hypothesis was tested that progesterone would reduce LH secretion in association with a decrease in ARC kisspeptin or NKB cell number. White crossbred, postpubertal gilts (106 ± 1.5 kg) were surgically fitted with an indwelling jugular catheter and either ovariectomized (OVX; n=3) or ovariectomized and treated with progestin (Altrenogest, 15 mg/d; OVX+P; n=4) for 10 days beginning 2 to 3 weeks after OVX. Blood samples were collected at 12 min intervals for 4.6 hours on day 9 of treatment. On day 10 of treatment, gilts were euthanized and brain tissue collected for immunocytochemical analysis of kisspeptin and NKB expression across five or three sections, respectively, of the caudal ARC. Progesterone treatment reduced ($p<0.05$) mean LH (OVX, 1.58+/-0.20 ng/ml;

OVX+P, 0.70+/-0.23 ng/ml) and increased ($p<0.05$) LH interpulse interval (OVX, 43.5+/-5.1 min; OVX+P, 184.5+/-44.7 min) without significantly affecting LH pulse amplitude. Contrary to our hypothesis, kisspeptin cell numbers were increased ($p<0.05$) in progesterone-treated gilts (OVX, 334.7+/-26.5 cells; OVX+P, 446.5+/-47.5 cells). A similar trend was noted for NKB cell numbers, but this difference was not significant ($p>0.20$). Dual immunofluorescence revealed that kisspeptin and NKB were highly colocalized in the ARC. These data indicate that reduction of LH secretion by progesterone in the pig does not involve a decrease in kisspeptin or NKB expression. The USDA is an equal opportunity provider and employer.

Title: Prenatal testosterone alters KNDy cell peptides in the arcuate nucleus of pre-pubertal male and female lambs

Authors: *C. FERGANI[1], L. M. COOLEN[2], V. PADMANABHAN[3], M. N. LEHMAN[1]; [1]Neurobio. and Anatom. Sci., Univ. of Mississippi, Jackson, MS; [2]Physiol., Univ. of Mississippi Med. Ctr., Jackson, MS; [3]Obstetrics and Gynecology,Pediatrics and Reproductive Sci. Program, Univ. of Michigan, Ann Arbor, MI

Abstract: Female sheep exposed to excess testosterone (T) during prenatal life, display an array of symptoms similar to those observed in women with PCOS. Such perturbations include early onset of puberty followed by disruption of estrous cyclicity and impaired steroid feedback mechanisms in adulthood. These deficits are associated with an imbalance in Kisspeptin-Neurokinin B (NKB)-Dynorphin (KNDy) neuropeptides in the ARC nucleus of the hypothalamus of adult ewes. However, it is unknown if the alterations in KNDy peptides precede and potentially contribute towards prenatal T induced pubertal advancement. We tested the hypothesis that prenatal T treatment would alter the expression of KNDy peptides in prepubertal

females to the magnitude seen in control males. Pregnant Suffolk ewes were given injections of T propionate (100mg/kg i.m. twice weekly) from day 60 to 90 of gestation and their male and female offspring together with a group of offspring from control pregnant ewes, (n=5/group) were perfused at 10 weeks of age. Hypothalamic sections were processed for kisspeptin, NKB, and dynorphin, and numbers of immunopositive cells counted in the ARC. Sex differences in kisspeptin and NKB, but not dynorphin, were observed in control lambs, with greater numbers of kisspeptin (189 ± 13 vs. 125 ± 30, mean±SEM) and NKB (108 ± 20 vs. 62 ± 11, mean±SEM) cells in females compared to males. Prenatal T treatment significantly reduced the number of kisspeptin-positive cells in female lambs (from 189 ± 13 to 122 ± 23, mean±SEM) but had no effect on males. By contrast, prenatal T treatment increased the number of NKB cells in both females (108 ± 20 to 180 ± 17, mean±SEM) and males (from 62 ± 11 to 126 ± 21, mean±SEM). Dynorphin cell numbers were low, but prenatal T decreased the number of dynorphin-positive cells (from 12 ± 1 to 4 ± 1, in both sexes, mean±SEM). The results of the present study provide evidence that prenatal T treatment causes a masculinization of the female kisspeptin system prepubertally whereas the early onset of puberty in female lambs is accompanied by an increase in NKB and a decrease in dynorphin. Given the role of NKB in puberty, we speculate that KNDy peptide imbalance, consisting of increased stimulatory NKB and decreased inhibitory dynorphin may contribute to the early onset of puberty that occurs as a consequence of prenatal T excess.

Title: Arcuate KNDy neurons receive afferent projections from the retrochiasmatic area in the ewe

Authors: L. M. COOLEN[1], T. G. SMITH[1], *M. N. LEHMAN[2], S. M. HILEMAN[3], J. M. CONNORS[3], R. L. GOODMAN[3];

Abstract: Gonadotropin-releasing hormone (GnRH) secretion is controlled by steroid hormones via negative and positive feedback actions on interneurons. One critical population for steroid feedback action in the ovine brain is a group of arcuate (ARC) neurons that co-express kisspeptin, neurokinin B (NKB), and dynorphin: KNDy neurons. Several groups have proposed that within this cell group, kisspeptin is the stimulatory output to GnRH neurons; NKB is stimulatory to other KNDy cells, while dynorphin inhibits KNDy activity. However, we recently demonstrated that NKB may also act in the retrochiasmatic area of the hypothalamus (RCh) to regulate LH secretion. RCh neurons express NK3 receptors (NK3R) and microimplants of a NK3R agonist produces a surge-like increase in LH. The pathways by which RCh neurons ultimately control GnRH and LH release are unclear. Here, we test the hypothesis that RCh neurons have direct projections to KNDy neurons. To address this, the anterograde tracer, biotinylated dextrane amine (BDA), was injected into the RCh of ewes during anestrus (n=3). Ten days after injection (to allow for transport) ewes were perfused intracranially with 4% paraformaldehyde and brains were sectioned. Dual immunoperoxidase and fluorescence techniques were used to visualize BDA and kisspeptin. All three ewes had BDA injections restricted to the RCh, but the spread of the BDA infusion within the RCh varied and one animal had very limited labeling of cell bodies. In all animals, BDA-labeled axon terminals could be traced to the ARC, ipsilateral to the injection site, and were found in close apposition with kisspeptin cells. Moreover, a large portion (70-80%) of ARC kisspeptin cells received RCh inputs and often more than one input was noted. These results demonstrate that KNDy neurons receive direct input from neurons in the RCh. Consistent with this observation, administration of the NK3R agonist senktide into the RCh induces cFos expression in KNDy neurons (Porter et al, SFN abstract 2013). It remains to be determined whether the inputs to KNDy cells derive from NK3R-expressing or other neurons in the RCh. Moreover, we are currently testing whether connections between RCh and KNDy cells may be reciprocal.

Title: Interactions between substance p, neurokinin a and kisspeptin in the control of gnrh release

Authors: *V. M. NAVARRO[1], S. SIMAVLI[1], M. WU[2], R. S. CARROLL[1], M. ALREJA[2], U. B. KAISER[1];
[1]Med., Brigham and Women's Hosp. / Harvard Med. Sch., Boston, MA; [2]Psychiatry, Yale Univ., New Haven, CT

Abstract: Kisspeptins (encoded by Kiss1) are the most potent elicitors of GnRH identified to date; yet, what regulates kisspeptin release is only starting to be deciphered. Recent studies showed co-localization of kisspeptin with neurokinin B (NKB) and dynorphin in neurons of the hypothalamic arcuate nucleus (ARC) in rodents, so-called KNDy neurons. Importantly, NKB belongs to the tachykinin family of neuropeptides that also includes substance P (SP) and neurokinin A (NKA). Studies in rodents, sheep and monkeys have documented a kisspeptin-dependent stimulatory action of NKB on gonadotropin release under physiological levels of sex steroids. However, the reproductive roles, if any, of SP and NKA remain unknown. In this work, we aimed to characterize and compare the actions of SP, NKA and NKB on gonadotropin release by using specific agonists for their corresponding receptors - SP: neurokinin receptor 1 (NK1R, GR73632); NKA: NK2R (GR64349) and NKB: NK3R (senktide) - through a series of functional and electrophysiological studies in mice. Central administration of NK1R and NK2R agonists (600 pmol) resulted in an increase in serum LH in adult intact males and adult ovariectomized and estradiol-replaced (OVX+E2) females 25 min after treatment, similar to the previously reported action of senktide. Interestingly, in the absence of circulating estradiol (OVX+sham), central injection of NK2R agonists_but not NK1R agonists_replicated the inhibitory action of senktide on LH release in this model. Additionally, we assessed the regulation of Tac1 (encoding SP and NKA) by sex steroids in the mouse brain. Tac1 mRNA was widely detected in the brain and was significantly inhibited by E2 in the arcuate nucleus (ARC), but did not co-localize with Kiss1. In order to assess a likely direct action of SP and NKA on kisspeptin release, we studied the electrophysiological effects of tachykinin receptor agonists (1-10 μM, 15-30 s) using whole-cell recordings of Kiss1-GFP neurons. All 3 agonists activated Kiss1-GFP neurons. NK1 and NK2 agonists activated 37% (n=33) and 15% (n=20) of KNDy neurons, respectively. Importantly, GnRH-GFP neurons remained unresponsive to the same challenge, suggesting a specific effect on Kiss1 neurons. In sum, we document the ability of all three members of the tachykinin family to regulate gonadotropin release through, at least in part, a stimulatory action on upstream KNDy neurons, in line with previous reports of NKB action.

Title: Investigating circadian regulation of Rfrp (GnIH) neurons in male and female mice

Authors: *M. C. POLING, E. Y. LUO, A. S. KAUFFMAN;
Reproductive Med., UC San Diego, La Jolla, CA

Abstract: RFamide-related peptide 3 (RFRP-3, encoded by *Rfrp*) is the mammalian ortholog to gonadotropin-inhibiting hormone (GnIH) and thought to be a negative regulator of the reproductive axis due to its inhibitory effects on GnRH neurons and LH release. However, the regulatory roles that endogenous RFRP-3 plays in reproductive physiology are unclear. In rodents, RFRP-3 neurons receive projections from the suprachiasmatic nucleus (the circadian clock), and both *Rfrp* gene expression and *Rfrp* neuronal activation are reduced during the circadian-timed preovulatory luteinizing hormone (LH) surge in female hamsters. However, similar experiments have not yet been performed in mice. Nor is it known if the circadian changes in *Rfrp* expression and neuronal activation seen during the LH surge are specific to this neuroendocrine event or represent a normal daily fluctuation of RFRP-3. We therefore examined *Rfrp* expression and neuronal activation of *Rfrp* neurons in LH surge and non-LH surge paradigms in female and male mice. First, we used *in-situ* hybridization (ISH) to evaluate possible circadian changes in *Rfrp* expression in adult male mice over the course of day. There were no significant temporal changes in the number of detectable *Rfrp* neurons or the amount of *Rfrp* mRNA produced in each cell. Next, we performed double label ISH for *cfos* mRNA induction in *Rfrp* neurons of these same male mice, but observed no significant changes in the number of *Rfrp* neurons co-expressing *cfos* across time points. Nearly 50% of all *Rfrp* neurons co-expresses *cfos*, regardless of time of day, indicating a high level of *Rfrp* neuronal activation throughout the day and suggesting that *Rfrp* neurons are not circadian-gated in adult male mice. However, this does not exclude the possibility of circadian regulation of RFRP-3 neurons in females during the LH surge. To address this, we gonadectomized and estradiol-replaced female and male mice to generate an evening LH surge in females (male mice do not produce an LH surge, even with estradiol treatment). We are currently analyzing the brains of these mice to determine if *Rfrp* expression and/or neuronal activation decreases during the LH surge in female mice, as has been reported previously in hamsters. Male mice will also be examined to see if similar temporal changes occur under these conditions, or if any observed circadian decrease in

Rfrp expression or neuron activation is a sexually dimorphic feature. Overall, these findings will provide further insight into possible roles and regulation of RFRP-3 in the murine brain.

Title: Vax1 is required for migration of hypothalamic GnRH neurons and normal reproductive function in mice

Authors: *H. M. HOFFMANN[1], I. KIMURA[1,2], A. TAMRAZIAN[1], A. S. KAUFFMAN[1], P. L. MELLON[1];
[1]Dep. of Reproductive Med., UC San Diego, La Jolla, CA; [2]Kyoto Univ. Grad. Sch. of Pharmaceut. Sci., Kyoto, Japan

Abstract: Sexual maturation and fertility are regulated by a small population of neuroendocrine cells localized in the hypothalamus, the gonadotropin-releasing hormone (GnRH) neurons. In humans, disruption of the GnRH system leads to reduced fertility or complete infertility owing to hypogonadotropic hypogonadism. GnRH neurons originate in the olfactory placode at embryonic day 11.5 (e11.5), from where they
initiate their migration through the cribriform plate to the hypothalamus. Any alteration in GnRH neuron migration, survival or maturation is prone to result in hypogonadotropic hypogonadism. As a result, biological factors regulating these cellular functions are of critical interest for the treatment of GnRH-associated fertility disorders. GnRH neuron development is dependent on the sequential activation of an array of homeobox genes. Alteration of their expression causes cell death, incorrect localization, incomplete maturation and/or faulty functioning of these neurons. Here, we identified the homeodomain
transcription factor Ventral anterior homeobox1 (Vax1) as a critical regulator of GnRH neuron

function in mice. $Vax1^{-/-}$ mice had normal GnRH neuron numbers at e13.5, whereas no GnRH neurons were detected at e17.5 in $Vax1^{-/-}$. Interestingly, $Vax1^{+/-}$ retain 50% of this neuronal population at e17.5. Since $Vax1^{-/-}$ mice die soon after birth; we conducted a fertility study in $Vax1^{+/-}$ mice. $Vax1^{+/-}$ male mice fathered smaller litters than wild-type males. Analysis of sperm quality revealed that the sub-fertility was attributed to an 88% reduction of motile sperm. $Vax1^{+/-}$ females mothered smaller and less litters in 3 months than wild type. In addition, they had prolonged estrus cycles, spent more time in metestrus, and had a 60% reduction in corpora lutea number. They also exhibited increased levels of luteinizing hormone and estradiol. Surprising, despite the reduced number of GnRH neurons, we found that adult $Vax1^{+/-}$ mice had normal or slightly increased GnRH transcription levels in the hypothalamus, suggesting an important role for Vax1 in regulating GnRH transcription in vivo. To evaluate the transcriptional role of Vax1 in GnRH neurons we transiently transfected the mature GnRH cell line GT1-7 with Vax1 siRNA. qRT-PCR revealed Vax1 to be a repressor of GnRH transcription, supporting the increased transcriptional levels of GnRH found in $Vax1^{+/-}$ mice. In conclusion, reduced expression of Vax1 is associated with sub-fertility in adulthood of both male and female mice. We hypothesize that mutations in one Vax1 allele are sufficient to affect fertility and are likely responsible for cases of sub-fertility in humans.

Title: Neurokinin B induces c-fos transcription via serum response factor (SRF) and signal transducer and activator of transcription (STAT) in gonadotropin-releasing hormone neurons

Authors: *C. A. GLIDEWELL-KENNEY, P. P. SHAO, P. L. MELLON;
Reproductive Med., Univ. of California San Diego, LA JOLLA, CA

Abstract: A small population of hypothalamic neurons secretes gonadotropin-releasing hormone (GnRH), the hormone responsible for puberty and reproduction. GnRH stimulates the secretion of the pituitary gonadotropin hormones luteinizing hormone (LH) and follicle-stimulating hormone (FSH) to control reproduction. Mutations in Neurokinin B (NKB) and its receptor, the Neurokinin 3 receptor (NK3R), were identified in patients with hypogonadotropic hypogonadism, a disorder characterized by lack of puberty and infertility. Treatment with exogenous GnRH restored hormone levels and fertility, indicating that NKB regulates reproduction via a hypothalamic mechanism. Senktide, an NK3R agonist, given by intracerebroventricular (i.c.v) injection into rodents induces c-fos mRNA, a marker of neuronal activation, in kisspeptin neurons by in situ hybridization. In addition, NK3R is expressed in a subset of GnRH neurons, suggesting there is also a potential for NKB to directly regulate GnRH secretion. Previously, we showed that NKB induces c-fos mRNA and GnRH secretion in an in vitro model of the GnRH neuron (GT1-7 cells). Here, we elucidate the signal transduction pathways activated downstream from NK3R in GnRH neurons. Using truncation analysis of a well-characterized murine c-fos promoter, we find that the induction of c-fos gene transcription by senktide maps to between 400 and -200 bp upstream from the transcription start site. Using cis-mutations within this region, we find that the STAT (-345) and SRF (-310) binding sites are required for induction in addition to a potential modulatory role for the Ets site (-318). Using a multimer reporter and inhibitors, we show that the SRF site is sufficient for induction and utilizes a PKC-dependent mechanism. Furthermore, PKC activation leads to decreased binding of phosphorylated SRF to the -310 site and increased binding of phosphorylated Elk-1, its accessory protein, to the -318 Ets site by electromobility shift assay. In conclusion, NKB may induce c-fos transcription in GnRH neurons by a PKC-dependent mechanism involving changes in the binding of phosphorylated SRF and Elk-1 to the c-fos promoter.

Title: Vasoactive intestinal peptide modulation of steroid-induced lh surge involves kisspeptin signaling in young but not in middle-aged female rats

Authors: *Y. SUN[1], A. KAUFFMAN[2], J. KIM[2], A. R. KHAN[2], J. SHU[1], G. NEAL-PERRY[1]; [1]Ob/Gyn, Albert Einstein Col. of Med., New York, NY; [2]Dept. of Reproductive Med., Univ. of California, San Diego, CA

Abstract: Female reproductive aging is characterized by a delayed and attenuated LH surge. We previously reported age-related LH surge dysfunction reflects reduced input from kisspeptin. Vasoactive intestinal peptide (VIP) neurons located in SCN excite GnRH cells and affect the LH surge. Of note, age-related LH surge dysfunction is characterized by reduced SCN VIP transcript. The SCN receives inhibitory input from RFamide-related peptide-3 (RFRP-3) cells in the DMN. VIP neurons project to GnRH neurons and to AVPV neurons, raising the possibility that VIP neurons may regulate GnRH neurons through effects on Kiss1 cells located in the AVPV or from RFRP-3 input. *We hypothesize RFRP-3 regulates VIP and VIP regulates GnRH and AVPV Kiss1 cell activation in young (Y) and middle-aged (MA) females.* Awake and freely moving Y (3-4 mon) and MA (9-11 mon) SD rats (n=14) with a 3rd ventricle cannula were infused with VIP (6 nmol) or saline (control) on the day of LH surge between 1300 and 1600h. Rats were killed between1600 to 1700h, brains collected and sectioned for double-label *ISH* for *GnRH/cfos*, *Kiss1*/*cfos*, and *Rfrp/cfos*. 2-way ANOVA determined group differences. $P<0.05$ = significant. *Post hoc* tests = Bonferroni or *Turkey's* test. **Results:** 55% *GnRH* cells in preoptic area (POA) and 39% *Kiss1* cells in AVPV express *cfos* in E+P primed, control Y rats. Compared to Y controls, VIP infusion reduced the percent of *GnRH* (30%) and *Kiss1* (22%) cells expressing *cfos* ($P<0.01$). The percent of *GnRH* (30%) and *Kiss1* (20%) cells expressing *cfos* was reduced in control MA rats ($P<0.01$). MA control rats also had less *Kiss1* mRNA per cell compared with Y controls ($P<0.01$). Unlike Y rats, VIP infusion in MA females increased the percent *GnRH/cfos* neurons (45%) ($P<0.01$). In contrast, VIP infusion did not affect the percent of *Kiss/cfos* cells or *Kiss1* mRNA content per cell in MA rats ($P=0.08$). VIP infusion did not affect *GnRH* or *Kiss1* cell density in Y or MA rats. *Rfrp/cfos* (9%) was not affected by age or VIP treatment. **Conclusion:** Reproductive age affects many E-regulated neurotransmission. We report VIP reduces the percent of *GnRH/cfos* and *Kiss1*/*cfos* cells in Y, suggesting that VIP-induced effects on Kiss1 cells disrupts GnRH cells. VIP increased the percent of *GnRH/cfos* but not *Kiss1/cfos* cells in MA, suggesting a direct effect on GnRH cells or other non-kisspeptin circuits that modulate GnRH cell activation. Age-related differences in VIP's effects on *Kiss1* neurons suggests that changes in GnRH neuron activation may also reflect, in part, an age-related decline in *Kiss1* neuron responsiveness to VIP.

Title: Kisspeptin antibody crossreactivity with GnIH: Further questions about the identity of kisspeptin in birds

Authors: *F. N. MADISON, G. F. BALL;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Kisspeptin (KP; product of Kiss1 gene) and its receptor (GPR54) have been shown to play a critical role in the regulation of reproduction in many vertebrate species. It has been shown for example that KP directly innervates and stimulates gonadotropin releasing hormone (GnRH) neurons that in turn stimulate luteinizing hormone (LH) release from the pituitary in mammals. Over the past several years, substantial evidence has accumulated establishing KP's role in the neuroendocrine regulation of reproduction in mammals. Genomic methods have identified KP in many non-mammlian species, but curiously not in birds. We investigated the possible presence of KP in songbirds and quail by employing an antibody that had previously been successfully used to label kisspeptin-like-immunoreactivity (KP-ir) in the medial preoptic area of a seasonal breeding avian species, the Mallard drake. The purpose of this study was therefore to characterize the distribution of KP-ir in several avian species. The brains of two female zebra finches, canaries, and Japanese quail were extracted and post fixed in acrolein. The brains were sectioned and stained via immunocytochemistry and labeled for KP using a commercial polyclonal antibody raised against the human kisspeptin-10 peptide. We found dense KP-ir fibers and perikarya in the paraventricular nucleus (PVN) and the preoptic area (POA) in all three species in addition to KP-ir fibers in the median eminence. However, while investigating the specificity of the KP antibody in tissue from all three species, we ran a control by preabsorbing the primary antibody at a 10-fold molar excess (relative to our IgG concentration) of either the KP or gonadotropin-inhibiting hormone (GnIH) antigen. GnIH is a neuropeptide (discovered in Japanese quail) that is expressed in cell bodies in the PVN and can inhibit luteinizing hormone release. GnIH-ir fibers project to GnRH neurons in the POA and to the median eminence. Interestingly, preabsorbing the KP antibody with KP and GnIH eliminated all KP-ir in both the PVN and POA in the songbird and quail tissue. Our studies suggest that this KP antibody derived from mammalian KP is detecting GnIH in birds. This finding is consistent

with the questions raised by other studies employing other methods as to whether KP is present in avian species. It is interesting to note that central injections of KP have been shown to stimulate the release of LH in the Mallard drake, suggesting that the structure of mammalian KP may share some properties in common with an unidentified novel neuropeptide responsible for modulating GnRH secretion in birds.

Title: 17β-Estradiol regulation of the mRNA expression of tachykinins in the guinea pig hypothalamus during positive feedback

Authors: *M. A. BOSCH[1], Y. FANG[1], M. J. KELLY[1,2], O. K. RONNEKLEIV[1,2];
[1]Dept. Physiol. & Pharmacol., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Oregon Natl. Primate Res. Ctr, Div. of Neurosci., Oregon Hlth. & Sci. Univ., Beaverton, OR

Abstract: Kisspeptin and neurokinin B (NKB) are essential for reproductive function. Similar to these peptides, substance P (SP)-expressing neurons are also localized in the mediobasal hypothalamus and believed to be involved in the control of reproductive functions. The NKB receptor, tac3, is expressed in Kiss1 neurons and its mRNA is reduced following E2-treatment, at least in rodent models. The guinea pig, similarly to primates, has a long ovulatory cycle with an estrogen-dominated follicular phase and a progesterone-dominated luteal phase and is therefore an excellent model for studying E2 regulation of positive and negative feedback. Although, the distribution and E2-regulation of Kiss1 neurons have been explored in GP (Bosch et al., J. Comp Neurol. 2011), the role or E2-regulation of the tachykinins and their receptors have not been investigated. Using cell harvesting of arcuate neurons and single cell (sc) RT-PCR we determined that NKB was expressed in approximately 63% of Kiss1-identified neurons, and the tac1 receptor was co-localized in 50% of the neurons. We have found previously that immunoreactive SP neurons are highly localized in the arcuate nucleus (Rønnekleiv et al., J. Comp. Neurol., 1984). For a quantitative analysis of E2 regulation of mRNA expression, we

used real-time quantitative (q)PCR of RNA extracted from micro-dissected periventricular (pv)POA and arcuate tissues in ovariectomized (OVX) oil- and E2-treated GP. This analysis revealed that NKB mRNA expression was significantly reduced ($p<0.01$; n=6) in the arcuate nucleus, but not in the pvPOA in E2-treated animals. Similarly to that found in the rodent for the tac3 receptor, the tac1 receptor was significantly reduced ($p<0.0005$; n=6) in the arcuate nucleus in E2 compared to oil-treated GP. Interestingly, the tac1 receptor mRNA levels were increased ($p<0.05$; n=5-6) in the pvPOA in E2-treated GP. These findings suggest a significant role for both NKB and SP systems in mediating E2-feedback to the hypothalamic areas involved in the control of reproduction and other homeostatic functions.

Title: Conductances underlying the burst firing of kisspeptin neurons in the rostral periventricular area of the third ventricle (RP3V)

Authors: *C. ZHANG[1], K. J. TONSFELDT[1], J. QIU[1], R. A. STEINER[2,3], M. J. KELLY[1,4], O. K. RØNNEKLEIV[1,4];
[1]Dept Physiol & Pharmacol, Oregon Hlth. & Sci. Univ., PORTLAND, OR; [2]Dept Obstetrics & Gynecology, Univ. of Washington, Seatle, WA; [3]Dept Physiol & Pharmacol, Univ. of Washington, Seatle, WA; [4]Div. of Neurosci., Oregon Natl. Primate Res. Ctr., Portland, OR

Abstract: Kisspeptin (Kiss1) neurons in the rostral periventricular area of the third ventricle (RP3V) provide excitatory drive to gonadotropin-releasing hormone (GnRH) neurons to control fertility. Using whole-cell patch clamp recording and scRT-PCR techniques targeting Kiss1-CreGFP neurons, we characterized the biophysical properties of these neurons and identified the critical molecular constituents required for burst firing in estrogen-treated female mice.

Approximately 25% of the neurons exhibited burst firing, but all Kiss1 neurons in this region expressed a kinetically fast pacemaker current, (I_h) with mean amplitude of 31.3 ± 4.8 pA. Single-cell PCR analysis of Kiss1- neurons revealed abundant expression of the HCN1 channel transcript, which was 3-fold greater than either HCN2 or 3. The rapidly inactivating T-type Ca^{2+} current was prominent in these neurons, with a mean amplitude of 41.5 ± 5.8 pA, and molecular analysis revealed that $Ca_V3.1$ mRNA was highly expressed in these cells. Interestingly, Kiss1 neurons in RP3V have much higher (2.4 GΩ) input resistance in comparison to Arc Kiss1 neurons (0.65 GΩ), which lowers the rheobase for generating burst firing. Kiss1 neurons also expressed a persistent sodium current with a variable amplitude and activation threshold. We found that T-type calcium channels plays a critical role in driving the low threshold burst firing, but the h-current and the persistent sodium current also help drive burst firing. Therefore, the interaction of multiple conductances facilitates the burst firing of Kiss1 neurons in the RP3V.

Title: Changes in RFamide related peptide-1 (RFRP-1)-immunoreactivity during postnatal development and estrous cycle

Authors: *M. D. ANDERSEN, S. R. JØRGENSEN, A. OVERGAARD, J. D. MIKKELSEN; Neurobio. Res. Unit, Rigshospitalet, Copenhagen, Denmark

Abstract: Gonadotropin releasing hormone (GnRH) is a key player in the hypothalamic control of gonadotropin secretion from the anterior pituitary gland. GnRH secretion is governed by a dynamic interplay between excitatory and inhibitory signals to GnRH neurons in the brain and the median eminence. Several lines of evidence have shown that two hypothalamic neuropeptides, kisspeptin and RFamide related peptide (RFRP), are present in distinct nervous input to the GnRH neurons. While kisspeptin is a strong stimulator of GnRH secretion, RFRP is merely considered as inhibitory in most species. The mammalian RFRP precursor is processed into two biological active peptides, RFRP-1 and RFRP-3, which are characterized by a conserved C-terminal motif Arg(R)-Phe(F)-NH2. We raised a specific antiserum against the rodent RFRP-1, and used this antiserum to identify the RFRP-1 neurons in the rat brain using

immunohistochemistry. The first aim was to analyze the distribution of RFRP-1 immunoreactive (ir) neurons in the rat brain during the postnatal development (juvenile, pre-pubertal, pubertal, and adult) with special emphasis on changes at puberty onset in males and females. The second aim was to investigate if RFRP-1 neurons were affected during the estrous cycle using simultaneous detection of c-Fos in RFRP-1-ir neurons at metestrus, diestrus, proestrus and estrus. RFRP-1-ir neurons were found to be distributed along the third ventricle from the caudal part of the medial anterior hypothalamus throughout the medial tuberal hypothalamus and were localized in, as well as in between, the intermediate periventricular nucleus, dorsomedial hypothalamus, ventromedial hypothalamus and arcuate nucleus. Both the number of RFRP-1-ir neurons and the density of RFRP-1-ir/cell were unchanged during the postnatal development in male rats. However, both parameters were increased significantly in the adult (P60+) female rat. This strongly indicates a gender difference in the developmental control of RFRP-1 expression. The percentage of c-Fos positive RFRP-1-ir neurons was significantly ($P < 0.05$) higher in diestrus as compared to proestrus and estrus. This suggests that RFRP-1 neurons are indeed activated under events relevant for reproduction. All together, our data indicate that RFRP-1 plays a role in female reproduction, but whether this is manifested as inhibitory or stimulatory has still to be ruled out.

Title: Kisspeptin analogues produce different effects on GnRH neurons

Authors: *J. D. MIKKELSEN[1], M. LIE[1], V. SIMONNEAUX[2], A. OVERGAARD[1]; [1]Neurobio. Res. Unit, Univ. Copenhagen - Rigshospitalet, Copenhagen, Denmark; [2]Inst. des Neurosciences Cellulaires et Intégratives, Univ. de Strasbourg, Strasbourg, France

Abstract: Kisspeptins are peptides derived from the *Kiss1* gene and are key upstream regulators of the hypothalamic-pituitary-gonadal (HPG) axis. They are all potent stimulators of gonadotropin-releasing hormone (GnRH) secretion and considered to play an essential role in regulation of pubertal maturation and reproduction. However, when kisspeptins are administered

systemically increase in LH and testosterone has been reported suggesting that kisspeptin acts directly on GnRH terminals located outside the blood-brain barrier. We here investigated the effect on the HPG axis in male rats of different (mouse (m), rat (r) and human (h) forms) kisspeptins (m/rKp10, mKp13 mKp14, mKp16, rKp16, mKp52, or hKp16) and the kisspeptin analogues (Kiss1-305 (D-Tyr-D-Pya(4)-Asn-Ser-Phe-AzaGly-Leu-Arg(Me)-Phe-NH_2), m[dY]^{1}Kp10, or h[dY]^{1}Kp10) after intraperitoneal administration. Injection of 150 nmol/kg of m/rKp10, mKp52, or hKp16 as well as the kisspeptin analogues Kiss1-305, m[dY]^{1}Kp10, or h[dY]^{1}Kp10) all produced an increase in plasma testosterone levels. Also, the other kisspeptins increased testosterone, though without reaching significance. We also examined the effect on GnRH neurons, by determining the level of c-Fos in the GnRH neurons in rats transcardially perfused 45 minutes after the injection. Interestingly, only Kiss1-305 was able to activate GnRH neurons located in the region around the organum vasculosum lamina terminalis, as well as in more distant locations in the medial preoptic area. These data suggest that kisspeptins act on GnRH terminals in the circumventricular organs i.e. the median eminence, but that more stable analogues activate GnRH neurons via another target and/or mechanisms perhaps located inside the blood-brain barrier.

Title: Modification of prolactin signaling in the arcuate nucleus of the mouse during lactation

Authors: *S. J. BUNN[1], S. H. YIP[2], S. E. KIRK[1], P. E. GUSTAFSON[1], D. R. GRATTAN[1]; [1]Anat., [2]Physiol., Univ. of Otago, Dunedin, New Zealand

Abstract: Prolactin is a pleotropic hormone, which acts at targets throughout the body including the mammary gland, heart, liver, muscle and brain. Its secretion from the anterior pituitary is regulated by a feedback loop in which prolactin activates the tuberoinfundibular dopaminergic (TIDA) neurons located in the arcuate nucleus of the hypothalamus. In response to prolactin these neurons synthesize and release dopamine into the hypophyseal portal system, which in turn inhibits further prolactin secretion by the pituitary lactotrophs. During lactation this negative-

feedback mechanism becomes refractory allowing circulating levels of prolactin to rise. We have demonstrated lactation is associated with a change in the phenotype of a subpopulation of TIDA neurons. By day 7 of lactation the number of enkephalin-immunoreactive cells in the arcuate nucleus of the C57/B6J mouse had risen approximately 10-fold. This response appears to be driven by prolactin in that it was suppressed by prior bromocriptine treatment (200µg/mouse every 8h for 24h) but maintained if ovine prolactin was co-administered (200µg/mouse). Over 80% of the enkephalin-positive cells seen during lactation were also immunoreactive for tyrosine hydroxylase indicating that they are TIDA neurons. Conversely these dual-labeled cells represented approximately 35% of the total TIDA neuron population. Thus prolactin stimulation of TIDA neurons may drive enkephalin synthesis during lactation but dopamine synthesis at other times. Our data suggest that a change in prolactin-activated signaling pathways may underlie this plasticity. Prolactin administration to bromocriptine-treated virgin mice generated a concentration-dependent increase in the level of both activated signal transducer and activator of transcription-3 (phospho-STAT3), and extracellular receptor regulated kinase 1/2 (phospho-ERK1/2) in TIDA neurons. The same treatment of lactating mice resulted in a phospho-STAT3 response of similar magnitude, although it required a 3-fold higher prolactin concentration, but a complete loss of phospho-ERK1/2. In conclusion these data demonstrate a lactation-associated change in the manner TIDA neurons respond to prolactin. This alteration in signal-transduction may be responsible for the switch from a dopaminergic to enkephalinergic phenotype in a subpopulation of these neurons. The physiological significance of this event is yet to be fully investigated but is likely to have implications in supporting the elevated prolactin levels essential for lactation.

Title: Anatomical substrate for the neuroendocrine role of the incerto-hypothalamic area

Authors: D. N. M. BUENO, R. J. DA SILVA, J. M. DA SILVA, J. C. BITTENCOURT, *L. V. SITA;
Dept Anat., Inst. Biomed Sci., Sao Paulo, Brazil

Abstract: The incerto-hypothalamic area (IHy) is a diencephalic region characterized by the presence of melanin-concentrating hormone (MCH)-producing neurons. Recent studies suggest that MCH-ir cells of the IHy are probably involved in the neuroendocrine control of female reproduction in specific metabolic states. In this way, our aim is to study the anatomical substrate to the neuroendocrine function of the IHy in normal female Sprague-Dawley rats. Using the retrograde neuronal tracer Fluorogold (FG) and anterograde neuronal tracer Biotinylated Dextran Amine (BDA), we observed that, in diestrus female rats, IHy is predominantly innervated by the lateral septal nucleus, median preoptic nucleus and thalamic paraventricular nucleus. IHy neurons projects mainly to the lateral septal nucleus, anteroventral periventricular nucleus, periventricular hypothalamic nucleus, medial preoptic area, medial preoptic nucleus and arcuate nucleus. Our previous studies in males have failed to show IHy projections to these neuroendocrine control areas, suggesting that IHy presents sexual dimorphic connections. Further studies are needed to unravel the neurochemical characteristics of this dimorphic innervation provided by the IHy in female rats and its role in the neuroendocrine control. Besides, there is a relative increase in the preproMCH mRNA expression in the IHy during the proestrus compared to the diestrus phase as showed by the *in situ* hybridization. The increase in the expression of the mRNA precursor is also accompanied by an increase in the number of MCH immunoreactive cells in the IHy. These data indicate that MCH is a potential candidate to mediate the neuroendocrine role exerted by the IHy.

Title: Expression and immunoreactivity of mchr1 in mammary gland of the rat during lactation

Authors: *D. S. BATAGELLO[1,3], R. J. DA SILVA[1], H. C. DA COSTA[1], J. M. DA SILVA[1], C. F. P. LOTFI[1], L. V. SITA[1], E. M. A. F. BEVILACQUA[2], J. C. BITTENCOURT[1,3];
[1]Dept. of Anat., [2]Dept. of Cell and Developmental Biol., Univ. of Sao Paulo, Sao Paulo, Brazil; [3]Dept. of Exptl. Psychology, Inst. of Psychology, Sao Paulo, Brazil

Abstract: Introduction: The melanin-concentrating hormone (MCH) mRNA, as well as the MCH, are located predominantly in hypothalamic nuclei. Novel sites of MCH mRNA expression and immunoreactivity during lactation final period have been identified in other hypothalamic nuclei, such as the ventral part of medial preoptic area (MPOAv). The MCH receptor 1 (MCHR1) is an orphan G protein-coupled receptor detected in many regions of the rat brain, but there are no descriptions of MCHR1 expression in the mammary glands of non-lactating or lactating dams. Objective: this project was designed to detect MCHR1 mRNA expression and immunorreactivity in the mammary glands of lactating and non-lactating rats, correlating MCH mRNA expression in the MPOAv with the consequent MCHR1 mRNA expression in the mammary gland, thereby, increasing the knowledge regarding the control of maternal behavior (MB). Material and methods: We used in situ hybridization and immunohistochemistry to detect MCHR1 in mammary gland tissue from four groups of rats : virgins; dams of lactation day 5; dams of lactation day 12; and dams of lactation day 19. Results: We detected MCHR1 mRNA in the mammary glands of dams, in the lactation days 12 and 19, a comparable expression in the controls, in the stroma; a differential expression was found in the glandular tissue of dams of lactation day 12 compared with day 19. By immunohistochemistry, we found MCHR1-ir cells in hair follicle in skin. In glandular tissue we found cells MCHR1-ir bordering the acini, compatible with mRNA expression of MCHR1 seen in lactation day 12, but not in the day 19. Conclusion: Once that there is a differential expression of MCHR1 mRNA and MCHR1-ir cells in different parts of the mammary gland during the lactation days, this data suggests that MCHR1 is involved at the end of the lactation process.

Title: Morphological characterization of tuberoinfundibular dopamine (TIDA) neurons in rodents

Authors: *A. HELLYSAZ[1], D. J. LYONS[2], C. BROBERGER[1];
[1]Karolinska Institutet, Stockholm, Sweden; [2]Dept. of Neurosci., Uppsala Univ., Uppsala, Sweden

Abstract: Tuberoinfundibular dopamine (TIDA) neurons, located in the dorsomedial arcuate nucleus (DM-ARC) of the hypothalamus, control milk production and other aspects of reproduction by tonically releasing dopamine into the portal capillaries in the median eminence to inhibit prolactin secretion from the pituitary. The electrophysiological properties of rat TIDA neurons have recently been described, including a robust gap junction-dependent membrane potential oscillation that is synchronized between cells. To better understand the anatomical substrate for TIDA network oscillations we are studying the morphological features of these neurons in the rodent. During whole-cell recording of coronal male rat hypothalamic slices (P21-30), oscillator neurons in the DM-ARC were filled with neurobiotin and subsequently recovered with avidin-fluorescence histochemistry. Recorded slices were also counterstained through immunofluorescence using antibodies against tyrosine hydroxylase (TH) to ascertain the catecholaminergic nature of oscillator neurons. Three-dimensional reconstruction and the visualization were performed through fluorescence and confocal microscopy. In addition 6-12 w-old male Sprague-Dawley rats and C57BL/6 mice were perfused with a formalin-based fixative and the brain was sectioned on a cryostat. Hypothalamic sections were stained with immunofluorescence for TH to determine the rostrocaudal distribution of neurons. In sections from perfused animals, TH-immunoreactive (-ir) cell profiles could be observed at Bregma -1.7 to -3.5, *i.e.* the entire rostrocaudal extent of the arcuate nucleus with the exception of the caudal pole. Overall, the total number of TH-ir cell profiles was lower in mice compared to rats. All (n = 29) recovered oscillator neurons were TH-ir. They have an oval soma shape with the dimensions 9.8±0.6 x 16.7±0.8 µm (mean ± SEM, n = 7). No significant difference could be observed in soma size between recorded oscillator neurons and nearby TH-ir neurons (n = 18). On average, oscillator neurons have three primary dendrites (range: two-six; n = 20) which branch sparsely within the ARC. Spines are rarely, if ever, observed on the dendrites. These data reveal several distinguishing features of oscillating TIDA neurons. The sparse branching and paucity of dendrites indicate morphological characteristics that may impact on the electrical repertoire of these cells.

Title: Oxytocin excites rat tubero-infundibular dopamine (TIDA) neurons *In vitro*

Authors: *V. BRIFFAUD, C. BROBERGER;
Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Lactation, and other functions that allow mothers to care for their offspring, is stimulated by the hormone, prolactin (PRL). Under most conditions PRL release from the pituitary is under tonic inhibition by neuroendocrine tubero-infundibular dopamine (TIDA) neurons of the hypothalamic arcuate nucleus. Successful nursing requires not only production of breast milk, stimulated by PRL, but also its ejection, promoted by the hormone, oxytocin (OT), suggesting that the release of these two hormones is coordinated. Here, we have explored the actions of OT on TIDA neuron electrophysiology. Whole-cell patch-clamp recordings were performed at room temperature from TIDA cells in acute hypothalamic slices from 21-30 day-old male rats. As previously shown, TIDA neurons exhibited a spontaneous robust ~ 0.05 Hz oscillation of the membrane potential between quiescent states and periods of depolarization crowned by action potentials. In the presence of OT (1 µM), TIDA cells depolarized and rhythmic activity switched to tonic firing (n = 6/6). This effect was mediated by a direct post-synaptic mechanism since it persisted when fast ionotropic transmission was pharmacologically blocked. In the presence of tetrodotoxin (500 nM, which abolished the rhythmic activity), OT (1 µM) induced a depolarization (+10.4 ± 2.4 mV, n = 6/8). This depolarization was abolished in the presence of the OT receptor antagonist, (d(CH2)51,Tyr(Me)2,Thr4,Orn8,des-Gly-NH29)-Vasotocin. The conductances underlying the OT effect were studied in voltage clamp recordings where OT induced a net inward current (13.16 ± 3.61 pA at a holding potential of -60 mV; n = 8/8). Preliminary findings indicate that this OT-induced current is diminished when extracellular Na^+ is substituted with Tris-HCl, and abolished in the presence of 2-Aminoethoxydiphenyl

borate (2-APB). The OT-induced current was, however, not significantly affected when extracellular Ca^{2+} was reduced to near-zero concentration. Together these results indicate that OT-induced depolarization of TIDA cells is mediated via a canonical transient receptor potential (TRPC)-like conductance. These findings suggest that OT may modulate PRL secretion by exciting TIDA neurons leading to increased dopamine release and, in turn, inhibition of PRL secretion. This work was support by grants from the European Research Council, the Swedish Research Council to C.B and internal funds from Karolinska Institutet.

Title: Dopamine autoregulation of tuberoinfundibular dopamine (TIDA) neurons in the male rat: Electrophysiological studies *In vitro*

Authors: *A. S. STAGKOURAKIS, D. J. LYONS, C. BROBERGER;
Karolinska Institutet, Stockholm, Sweden

Abstract: Neuroendocrine tuberoinfundibular dopamine (TIDA) neurons in the hypothalamic arcuate nucleus regulate reproduction by providing tonic inhibition of pituitary release of the hormone, prolactin. As in all neuroendocrine axes, feedback regulation at several levels is key to maintaining appropriate serum hormone concentrations. Unlike other dopamine neurons TIDA cells have, however, been proposed to lack autoreceptors. Yet, the effects of dopamine receptor activation have not been studied on the passive and active membrane properties of the TIDA network.

Here, whole-cell recordings were performed on male rat (P21-30) hypothalamus slices maintained in oxygenated artificial cerebrospinal fluid at room temperature under differential interference contrast visualization. In the dorsomedial arcuate nucleus a neuron population exhibiting a robust oscillation (0.05 Hz) between depolarized states crowned by action potentials

and quiescent hyperpolarized states has been previously identified as TIDA cells (DJ Lyons et al., 2010, Neuron). Application of dopamine (20μM; n=5/5) significantly increased the duration of the slow depolarizing phase of the hyperpolarized state to 165.3±18.3% (average±SD) of control, the duration of the depolarized state (160.8±46.6% of control), the number of action potentials per cycle (210.5±111.1% of control) and decreased the frequency of the TIDA oscillation (71.4±9.5% of control). Application of the broad-spectrum dopamine agonist, apomorphine (20μM; n=5/5), as well as the D2-like receptor (D2R) agonist, quinpirole (20μM; n=5/5), resulted in similar changes, whereas application of the D1R-like agonist, SKF81297 (10μM, n=5/5), did not affect TIDA oscillation properties. In the presence of tetrodotoxin (500nM) application of quinpirole resulted in hyperpolarization (-3.4±1.9mV; n=7/7), suggesting the involvement of direct post-synaptic mechanisms. During application of the D2R antagonists, eticlopride (20μM; n=5/5) or haloperidol (10μM; n=5/5), TIDA behaviour changed dramatically; the 0.05Hz oscillation was replaced by a faster fluctuation at a depolarized membrane potential (ca. -45mV) and action potential discharge ceased, possibly due to depolarization block. These findings indicate that the D2R pathway is constitutively active on the TIDA network in our slice preparation, and that dopamine may regulate its own release by modulation of TIDA electrophysiological properties.

Abstract: In the mature rat the tubero-infundibular dopamine (TIDA) secretion regulates pituitary prolactin (PRL) release. Likewise, TIDA system is modulated by serotonin from dorsal raphe nucleus (DRN). According to Ugrumov et al. (2010, 2012), during the first two weeks of life dopamine (DA) and serotonin (5-HT) serum levels are higher than those observed in adult rats. During this short period, blood brain barrier is open and close at 14 th day. In addition, at this period both maternal cares, such as milk products, are well known to be crucial for social and neuroendocrine development. We have observed low levels of serum PRL at 14 postnatal day (pnd) in male pups, but not at 7 or 21 pnd, in rats reared in artificial condition (AR) in comparison to males reared by their mother (MR) (Toriz et al., 43rd SfN Annual Meeting). Then, we asked if the TIDA and the hypothalamus 5-HT levels are affected in the neonatal rat under artificial reared condition. In order to answer this question we use the paradigm of AR. Male rat pups of 3 pnd were reared by their mother (MR, control) or under artificial reared condition (AR). At pnd 7, 14 or 21 we measured 5-HT and its metabolite 5-HIAA, dopamine (DA) and its metabolite DOPAC by HPLC-electrochemical detection in the hypothalamic tuberal and infundibular regions, as well as in the DRN and pituitary gland. In the DRN we found a decrease in 5-HT concentration in AR animals at 14 and 21 pnd with respect to MR animals (T test, P=0.09, P=0.02, respectively). However, hypothalamic and pituitary 5-HT concentrations did not show differences. On the other hand, DA and DOPAC levels in the pituitary were higher in AR pups of 14 pnd (T test, P=0.03, P=0.006, respectively).The present study shows that artificial rearing condition increases DA concentration in pituitary, while 5HT exhibits no-change at this level suggesting immaturity of the serotonin TIDA regulation. On this account, the low PRL serum levels observed in AR animals could be the result of the high dopamine levels observed at pituitary levels.

Title: Changes in SK3 channel and associated proteins during pregnancy and lactation in the rat supraoptic nucleus (SON)

Authors: *G. CHANDAKA[1], L. WANG[1], S. E. SENOGLES[2], W. E. ARMSTRONG[1]; [1]Dept. of Anat. and Neurobio. and Neurosci. Inst., Univ. of Tennessee, Memphis, TN; [2]Dept. of Mol. Sci., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: The physiological demands of parturition and lactation lead to the increased pulsatile release of oxytocin (OT) into the circulation from the neurohypophysial axons of OT neurons in the supraoptic (SON) and paraventricular nuclei. Calcium-dependent afterhyperpolarizations (AHPs) are enhanced in OT neurons during these periods, which would sculpt bursts underlying the pulsatile release. The plasticity of these AHPs is dependent on central OT receptor activity, mimicked by exposure to OT and estrogen, and occurs in the absence of detectable changes in voltage-gated somatic or proximal dendritic calcium currents. The calcium calmodulin (CaM) sensor of some SK3 channels plays a major role in modulating these channels via the CaM binding proteins, casein kinase 2 (CK2, which phosphorylates channel-bound CaM) and protein phosphatase 2A (PP2A, which dephosphorylates channel-bound CaM). Enhancement of AHPs could be due to an increase in the channel number (e.g., SK3 channels) or conductance, and/or due to an increase in the calcium sensitivity of the channels. We are investigating the differences in the expression pattern of SK3 channels, CK2, PP2A among virgin, late pregnant (E20-21) and lactating rats using western blots. To date, we have found that SK3 protein levels from the SON across the three groups of rats did not significantly change relative to beta-tubulin, suggesting that an increased channel density may not play a major role in the AHP enhancement. Analysis of CK2 and PP2A are in progress along with phospho-MAPK (phospho-ERK1/2), the latter of which we previously have observed upregulated in OT neurons in late pregnant rats using immunocytochemistry. Supported by NIH grant R01-HD072056 (WEA).

Title: Fasting decreases tuberoinfundibular dopaminergic neurons and induces PRL secretion

Authors: *T. KUBOTA, M. FURUTA, A. FUKUSHIMA, C. KAKEHASHI, T. FUNABASHI, T. AKEMA;
Dept. of Physiol. St.Marianna Univ. Sch. of Med., Kawasaki/Kanagawa, Japan

Abstract: Dopamine neurons located in the arcuate nucleus (ARC) and adjacent periventricular region of the mediobasal hypothalamus are called tuberoinfundibular dopaminergic (TIDA) neurons (A12). A part of their functions is to inhibit prolactin (PRL) release from the anterior pituitary as a PRL inhibitory factor. Sulpiride, a dopamine D2 receptor blocker, acts as an antidepressant and stimulates food intake, suggesting that TIDA neurons are involved in the controlling feeding behavior but its role on feeding states is not documented. We first investigated TIDA neurons during fed and fasted condition. Transgenic mice carrying green fluorescent protein under the control of the rat tyrosine hydroxylase gene (Matsushita et al, J Neurochem 2002) were used. In fed and fasted male mice at the age of 8 weeks, whole-cell voltage-clamp techniques in acute slice were applied. TIDA neurons were identified by fluorescence microscopy. The amplitude of miniature excitatory post synaptic current (mEPSC) in fasted mice was significantly decreased compared to that in fed mice, but the mean frequency of mEPSC was not different. We next investigated Fos expression by fasting in TIDA neurons. 24-fasting induced c-fos expression in the ARC, but the number of Fos-positive TIDA neurons were decreased by fasting. Low amplitude and decreased Fos expression of TIDA neurons by fasting showed that fasting lowered TIDA neurons activations. We finally measured PRL and the negative feedback of PRL since PRL acts at TIDA neurons and activates signal transducer and activator of transcription 5 (STAT5). PRL level was increased and expression of phosphorylated STAT5 was increased by fasting. All together, the present study revealed that fasting decrease excitatory synaptic inputs to TIDA neurons. As the result, PRL was high and this phosphorylated STAT5. However, pSTAT5 did not stimulate TIDA neurons. We assume that this status was a PRL resistance. Since Cytokine-Inducible SH2 Domain-Containing Protein (CIS) was not changed in the hypothalamus during feeding condition, a mechanism for PRL resistance is currently unknown, but synaptic input may be dominant role for controlling TIDA neuronal activity to release dopamine.

Title: The role of suckling or non-suckling stimulation on the prolactin effects upon wide dynamic range cells of male rats

Authors: *A. GONZALEZ-HERNANDEZ[1], F. MENA[2], N. NAVARRO[2], A. CASTILLA[2], T. MORALES[2], G. ROJAS-PILONI[1], G. MARTINEZ-LORENZANA[1], M. CONDES-LARA[1]; [1]Neurobiologia del Desarrollo y Neurofisiologia, [2]Neurobiologia Celular y Mol., Inst. de Neurobiologia, UNAM, Queretaro, Mexico

Abstract: Since its discovery, considerable literature has built up describing more than 300 biological actions of prolactin. More recently it has been shown that PRL generated during peripheral inflammation could act as a mediator to reduce the pain threshold. Furthermore, in cultured trigeminal nociceptive neurons, exogenous PRL is able to sensitize TRPV1 channels and consequently a potential pro-nociceptive effect was suggested. Paradoxically it has been reported that an increase of prolactin secretion by suckling reduces pain sensitivity. We hypothesize that this difference could be attributable to the fact that PRL secreted from the adenopituitary (AP) is transformed into several molecular variants by suckling stimulation. Indeed, PRL has as a number of molecular isoforms produced by posttranslational modifications, and it has been proposed that this molecular heterogeneity is one of the mechanisms involved in the pleiotropic activity of this peptide.
In order to test the potential effect of PRL from the AP of suckled (S) or non-suckled (NS) rats on the neuronal activity of nociceptive fibers, we recorded in anaesthetized male Wistar rats the nociceptive responses evoked on the wide dynamic range (WDR) neurons. The WDR neurons are large, second-order neurons that are widely distributed in the dorsal horn spinal cord and receive input from the first-order non-nociceptive (Aβ-fibers) and nociceptive (Aδ- and C-fibers) neurons. These cells represent an important connector between primary afferent nociceptive fibers and higher nociceptive centers. Our results show that spinal administration of NS-PRL or S-PRL had no effect on the neuronal activity corresponding to activation of non-nociceptive Aβ-fibers. However, the firing of Aδ-fibers and C-fibers (both nociceptive) were: (i) increased by

NS-PRL and (ii) diminished by S-PRL. Finally, either NS-PRL or S-PRL enhanced the post-discharge activity.
These findings provide a basis for addressing the physiological relevance of the prolactin variants induced by suckling and might help to explain the differences observed in several experiments related to nociception.

Title: Behavioral effects in the offspring of maternal protein malnutrition during lactation

Authors: *J. D. SILVA, M. C. F. FRAGA, F. N. NUNES, E. G. DE MOURA, P. C. LISBOA, C. C. FILGUEIRAS, Y. D. VILLAÇA, A. C. MANHÃES;
Ciências Fisiológicas, Univ. Do Estado Do Rio De Janeiro, Rio De Janeiro, Brazil

Abstract: Neonatal undernutrition in rats results in short- and long-term metabolic and endocrine alterations in the offspring. It is known that some of these alterations, such as adrenal catecholamines content and hypercorticosteronemia, are associated with behavioral alterations in adult animals. However, it is not known whether the alterations are present since the original insult or if these arise at some specific point after it. In this sense, in the present work, we analyzed, in Wistar rats, the effects of protein restriction programing during lactation on behavioral parameters associated with anxiety, locomotor activity and memory/learning at different time points during development and maturation. Progenitors were separated into 2 groups after delivering: PR (protein restriction) group - which received hipoproteic chow (8% protein) from birth to weaning [postnatal day (P) 21], and CONT (control) group - which received normoprotein chow during this period. The following behavioral tests were used to analyze offspring behavior (21 animals per group/age) at P21, P45, P90 and P180: 1) elevated plus maze (EPM) - to assess anxiety related behaviors; 2) open field (OF) - to assess locomotor

activity; 3) radial arm water maze (RAWM) - to assess memory and learning. After the behavioral tests, animals were decapitated and blood and the adrenal glands were collected for the analyses of catecholamine content and serum corticosterone level. In the EPM, PR animals had a significant increase in the values of the anxiety-associated variables when compared to the control group at P21. In the OF, a significant reduction in the number of traversed rectangles was observed in the PR group at P90. In the RAWM, we did not identify significant differences between groups during the first four days of testing in all ages. On the fifth day (probe trial), the PR group had a significant reduction in the latency to find the scape platform at P21 and P180. As for the endocrine data, the PR group had a significant reduction in serum corticosterone level at P90. Catecholamine content was increased in the RP group at P21 and P180. Our data indicate that animals in the PR group display: 1) a reduction in anxiety-like behaviors at weaning; 2) a reduction in locomotor activity as young adults; 3) an improvement in memory/learning performance both at weaning and as mature adults. Moreover, our results indicate that there is an association between behavioral and endocrine alterations. We can conclude that protein restriction during lactation in rats affects behavior at different time points during the animal's life and that the temporal profile of the effects varies as a function of the behavior that is being assessed.

Title: Each individual isoform of the dopamine D2 receptor protects from lactotroph hyperplasia

Authors: D. RADL, H. LEE, *E. BORRELLI;
Univ. California, IRVINE, CA

Abstract: Dopamine acting through D2 receptors (D2R) controls lactotroph proliferation and prolactin (PRL) levels. Ablation of this receptor in mice results into lactotroph hyperplasia and prolactinomas in aged females. Alternative splicing of the Drd2 gene generates two independent isoforms, a long (D2L) and a short (D2S), which are present in all D2R expressing cells. Here, we addressed the role of D2L and D2S on lactotrophs physiology through the generation and analysis of D2S-null mice and their comparison to D2L-null animals.
These mice represent a valuable tool to investigate dopamine-dependent isoform-specific signaling in the pituitary gland. We sought to assess the existence of a more prominent role of D2L or D2S in controlling PRL expression and lactotroph hyperplasia. Importantly, we found that D2L and D2S are specifically linked to independent transduction pathways in the pituitary. D2L-mediated signaling inhibits the AKT kinase activity while D2S is instead required for the activation of the ERK 1/2 pathway. Under normal conditions, presence of only one of the two D2R isoforms in vivo prevents hyperprolactinemia, formation of lactotroph's hyperplasia and tumorigenesis that is observed when both isoforms are deleted as in D2R-/- mice. However, the protective function of the single D2R isoforms is overridden when single isoform knockout mice are challenged by chronic estrogen treatments as they show increased prolactin production and lactotroph hyperplasia. Our study indicates that signaling from each of the D2R isoforms is sufficient to maintain lactotroph homeostasis in physiological conditions, however signaling from both is necessary in conditions simulating pathological states.

Title: Alterations in the endocannabinoid machinery in alternative microglia *In vitro*

Authors: M. MECHA[1], A. FELIÚ[1], F. CARRILLO-SALINAS[1], *C. GUAZA[2];
[1]Cajal Inst., Madrid, Spain; [2]Inst. Cajal, CSIC, Madrid, Spain

Abstract: The regulation of inflammation in the central nervous system (CNS) is necessary to prevent the irreversible cellular damage that occurs in neurodegenerative diseases like Multiple

Sclerosis. Under pathological conditions, much is known about how microglial cells play a pivotal role becoming rapidly activated, changing both phenotype and morphology, and displaying several functions like antigen presentation, phagocytosis and cytokine production. On the other hand, little is known about how microglial cells serve a protective role in the CNS, acquiring an alternative state (also referred to as M2-type microglia) that is associated with tissue repair, anti-inflammatory cytokine production and extracellular matrix reconstruction. Compared to classically activated microglia, NOS2, IL-12, IL-1b, IL-6 and TNFa induction are suppressed in alternative activated microglia when stimulated with IL-4 and IL-13, whereas repair genes like Arginase1 and Ym-1 are activated. However, the participation of the endocannabinoid machinery in the acquisition of the M2-type microglia phenotype has not been addressed yet.

In this study, we have investigated the possible alterations of the endocannabinoid system in the alternative activated primary microglia *in vitro*, stimulated with the anti-inflammatory cytokines IL4 and IL13. M2-type microglia cells showed an increase in the Arginase-1 and IGF-1 levels, as it has been previously described in M2-type macrophages. Using RT-PCR, we analyzed the mRNA levels of the endocannabinoid classical immune receptor (CB2), and of the enzymes of synthesis (NAPE and DAGL) and degradation (FAAH and MAGL) of AEA and 2-AG, respectively. M2-type microglia express a higher expression of CB2 and of the synthesis enzyme of AEA (NAPE); moreover, this alternative activated cells express lesser expression of both degradation enzymes (FAAH and MAGL), suggesting a change in the endocannabinoid system towards an increase in the production and signaling of classical cannabinoids like AEA and 2-AG .

Our results highlight the importance of the endocannabinoid system in the alternative state of microglia, and open a new field of study in the repair functions of immune cells in the CNS.

Abstract: Microglia are myeloid cells of the central nervous system (CNS) that participate both in normal CNS function and disease. A barrier to the study of microglia is the lack of markers that distinguish them from infiltrating monocytes during disease. The distinction between resident microglia and recruited mononuclear phagocytes is crucial, because it provides an approach to understand the biology of microglia and their relevance to disease. We have identified a microRNA/gene/protein signature that is uniquely expressed in resident adult microglia in mice and humans. This molecular microglial signature was not observed in classically studied microglial cell lines or embryonic preparations of microglia, nor in peripheral immune cells or recruited mononuclear cells in animal models of MS, AD or ALS. We identified 239 genes and 8 microRNAs that are uniquely or highly expressed in microglia. We found unique microglial surface markers related to the TAM system and targeting of these receptors modulated the microglial phenotype. Furthermore, we found a crucial role for TGF-β in microglial biology including the absence of microglia in CNS-TGF-β deficient mice. We also identified unique patterns of microglial dysfunction associated with CNS disease in EAE, SOD1 and APP/PS1 mouse models. Most of the identified unique microglial genes were downregulated during acute or chronic phases in EAE mice or during disease progression in SOD1 and APP/PS1 mice. Our identification of a unique microglial signature provides a new understanding of microglial biology and the possibility of targeting microglia for the treatment of CNS disease.

Title: Morphological differences in microglia in the mouse brain through development may contribute to vulnerability to stressors during puberty

Authors: *M. K. HOLDER, J. D. BLAUSTEIN;
Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: The peak age of onset for diseases of mental health is during puberty, with extremely stressful or traumatic experiences during this period contributing to a increased risk for affective disorders. In female mice, the experience of shipping from a supplier or a single injection of the bacterial endotoxin, lipopolysaccharide (LPS) during pubertal development alters the behavioral response to estradiol in adulthood as demonstrated by perturbations of estradiol's anxiolytic and anti-depressive properties. Microglia, the primary type of immunocompetent cell, contribute to brain development and respond to stressors with dramatic and long-lasting morphological and functional changes. Recently, we have begun to investigate the role that microglial cells may play in mediating the alteration in hormone response that results from pubertal stressors. We first examined the basal morphology of microglia during (6 wks old) and after (10 wks old) the pubertal period of female mice using immunohistochemistry for ionized calcium binding adaptor molecule 1 (Iba1), which is constitutively expressed in microglia in areas implicated in anxiety and depression. Interestingly, age of animal was without effect on the total number of microglia in each brain area. However, we observed more hyper-ramified, or activated, microglia in the hippocampus and amygdala at 6 wks than at 10 wks. These data suggest that the developmental status of the microglia may underlie the alteration in hormone-responsive affective behaviors. We are currently examining the microglial morphology following the experience of either an immune (LPS) or a shipping stressor in pubertal female mice. Title: The role of microglial-specific MyD88-dependent signaling after LPS stimulation

Authors: *C. M. MILLER[1], K. BHASKAR[2], C. PARKHURST[3], D. LITTMAN[3], W.-B. GAN[3], R. RANSOHOFF[1], B. LAMB[1];
[1]Neurosciences, The Cleveland Clin. Lerner Res. Inst., Cleveland, OH; [2]Univ. of New Mexico, Albuquerque, NM; [3]New York Univ., New York, NY

Abstract: As the resident immune cells of the CNS, activated microglia strongly influence the state of neuroinflammation by the cytokines and chemokines they produce, thus polarizing a response toward either pro- or anti-inflammatory depending on the stimulus. Peripheral stimulation with lipopolysaccharide (LPS) signals through *t*oll-*l*ike-*r*eceptor *4* (TLR4) on microglia and promotes their activation and a pro-inflammatory response. Interestingly, stimulation with LPS can also enhance intraneuronal *m*icrotubule-*a*ssociated *p*rotein *t*au (MAPT) pathologies, including increases in phosphorylation and aggregation of MAPT, both characteristic of tauopathies like Alzheimer's disease. TLR4 is an innate immune receptor, whose downstream signaling converges through the universal adaptor protein *my*eloid *d*ifferentiation primary response gene *88* (MyD88). Notably, MyD88-dependent signaling activates transcription factors responsible for the regulation of many downstream pro-inflammatory cytokines and chemokines. However, the relationship between MyD88-dependent signaling within microglia and development of neuronal MAPT pathologies has not been explicitly tested, due to the fact that most studies have utilized MyD88 knock-out mice that remove MyD88 from all cell types within the brain and periphery.
In order to assess the role of MyD88-dependent microglial activation on the development and progression of MAPT pathology, we generated mice in which MyD88 can be conditionally removed specifically from microglia ($Cx3cr1^{CreER/+}$; $MyD88^{flox/flox}$) after tamoxifen administration. We hypothesize that abrogation of the microglial MyD88 signaling will reduce pro-inflammatory cytokine/chemokine production and attenuate MAPT pathologies after LPS injections. To test this hypothesis, $Cx3cr1^{CreER/+}$; $MyD88^{flox/flox}$ mice were administered tamoxifen at six weeks of age and two weeks later treated with LPS. Twenty-four hours after LPS stimulation, microglial MyD88-deficient mice were examined for alteration in microglial activation and neuronal MAPT pathologies. This study provides proof-of-concept for using $Cx3cr1^{CreER}$ mice as a tool to abrogate microglial signaling molecules (including MyD88) in the development and progression of neurological diseases.

Title: Lectin-based passive and active dendritic cell immunotherapies against experimental autoimmune encephalomyelitis/multiple sclerosis, and Glioblastoma

Authors: *D. SAGAR[1], C. FOSS[2], Z. K. KHAN[3], J. SHIRAZI[3], M. G. POMPER[2], P. JAIN[3]; [1]Neurobio. & Anat., Drexel Univ. Colleged of Med., Doylestown, PA; [2]Johns Hopkins Univ., Baltimore, MD; [3]Drexel Univ. Col. of Med., Doylestown, PA

Abstract: The potential of dendritic cells (DCs) as sentinels for immunotherapy is emerging against various diseases such as HIV, multiple sclerosis (MS) and various cancers. DC immunotherapy remains a promising therapeutic approach and warrants further exploration to enhance its immunogenicity. Here, we seek to utilize a specific aspect of DC biology involving the expression of surface lectin receptors that play variable roles including cell-cell adhesion and innate pathogen recognition. While studying molecular mechanisms of how circulating DCs gain access to the CNS, we found that lectins play crucial role in transmigration of DCs across the blood-brain barrier (BBB). The near-infrared imaging (NIRF) of DCs in experimental autoimmune encephalomyelitis (EAE, the model for MS), indicated that DCs' accumulation into areas of CNS correlate with the severity of inflammation. Further studies confirmed the involvement of the chemokine CCL2 in this process involving a cross talk between actin cytoskeleton and lectins. Profiling of different DC subsets- myeloid (mDC), plasmacytoid (pDC) and monocyte-derived (MDDC) revealed a unique enrichment of lectin receptors on each DC subset. Subsequently, in the presence of CCL2, each DC subset was found to utilize a different lectin type in order to adhere and transmigrate across the BBB. While lectins can be specifically blocked on DCs to prevent transmigration, they can also be harnessed to enhance cytotoxic response against tumors. Glioblastoma multiforme (GBM) is one of the most common and malignant types of brain tumor with mean survival time of 1 year or 2-3 years in case of anaplastic astrocytoma. Therefore, we used a GBM as model to test a glycotargeting approach for the uptake of glioblastoma tumor antigens via specific lectin recepors on DCs. Further, anti-HIF1α (hypoxia inducible factor 1α) shRNA was transduced into DCs to revert the effect of hypoxia. We first confirmed that hypoxic environment affects the expression of antigen-presentation, -uptake and migratory receptors on DCs that hampered their antigen presentation capability. Futher, anti-HIF1α transduced DCs were shown to efficiently migrate in vivo using NIRF. Our dual approach of lectin-targeting and hypoxia-reversal showed potentiation of DC migration and functionality under hypoxic conditions and has further potential to be tested in vivo. In conclusion, both aspects of our study will further substantiate the promise of current

DC-based immunotherapies to battle diseases that overpower the body's immune capabilities, and generate lectin-targeted therapies that can be directed to inflammatory lesions or tumors.

Title: Rapid stimulation of IFN-regulated genes and JAK/STAT signaling in the brain following peripheral administration of IFN-γ

Authors: *J. WANG, Y. DAI;
Dept Pharmacol, Univ. Missouri-Kansas City, KANSAS CITY, MO

Abstract: Interferon-gamma (IFN-γ) is a pleiotropic cytokine and implicated in inflammatory and degenerative CNS disorders. Nevertheless, recent studies have identified a direct crosstalk of IFN-γ with morphogen sonic hedgehog (Shh) in neuronal precursor cells, indicating a potential importance of IFN-γ in neurodevelopment and/or neurogenesis. As a key antiviral cytokine and immune regulator, IFN-γ is produced mainly by T lymphocytes and NK (natural killer) cells in the periphery. It remains unresolved whether systemic IFN-γ acts on the brain directly or not. Here, we took an approach to analyze the expression of IFN-γ target genes in the CNS as a measurement of direct action of IFN-γ in the brain following peripheral administration. We found that systemic administration of IFN-γ by intraperitoneal injection induced a rapid and profound stimulation of IFN-stimulated genes (ISGs) both in the CNS and peripheral tissues in mice. Dose response studies showed a significant upregulation of ISGs, including CTIIA (MHC class II trans-activator gene), TGTP (T-lymphocyte GTPase) and OAS (2', 5'-oligoadenylated synthase) in brain by IFN-γ at doses as low as 0.1 μg. Doses of IFN-γ higher than 1.0 μg did not further enhance its stimulatory activity on ISG expression in both the brain and liver. Time course studies revealed that expression of ISGs in the brain peaked at around 2 hours, was attenuated at 8 hours, and returned to baseline after 24 hours following treatment. Immunoblot detected an increase in expression and phosphorylation of both STAT1 and STAT3 in the brain regions following peripheral IFN-γ treatment. In conclusion, our studies indicate a direct access of peripherally administered IFN-γ to the brain and activating IFN-γ-initiated JAK/STAT

signaling in the CNS. Together, direct action of circulatory IFN-γ on the brain underscores the significance of systemic IFN-γ in brain development and function.

Title: The effects of calorie restriction on fever and neuroimmune communication pathways in mice

Authors: *S. KENT, M. RADLER, G. SMITH, M. W. HALE;
Psychological Sci., La Trobe Univ., Melbourne (Bundoora), Australia

Abstract: Calorie restriction (CR) has been shown to increase longevity and elicit many health promoting benefits, including delaying the development of diabetes, improving learning and memory, and reducing anxiety. In addition, CR has been shown to attenuate fever and sickness behaviour in response to systemic immune challenges. However, it is unclear how the neuroimmune pathways that relay immune signals between the brain and the periphery are affected by CR. The current study examined the expression of c-Fos, the protein product of the immediate early gene (IEG) *c-fos*, in brain regions known to be involved in neuroimmune communication pathways. Twenty-two male C57BL-6J mice were either fed ad libitum or were subjected to a CR dietary regimen for four weeks. Following the CR period, mice were injected with saline or 50 μg/kg of lipopolysacharide from *Escherichia coli* (serotype 0111:B4). Immunohistochemistry was conducted and cells that expressed c-Fos were counted in five regions of the medulla and pons, including the lateral parabrachial nucleus, locus coeruleus, nucleus of the solitary tract and the area postrema. Lipopolysaccharide increased c-Fos expression; however, CR did not alter c-Fos expression
in the regions examined. This indicates that CR attenuation of fever and sickness behavior does not occur peripherally, but is instead moderated by central mechanisms. Neuroinflammation was also examined as a possible mechanism and data will be presented at the meeting.

Title: Harnessing the benefits of polarized macrophages for CNS functions

Authors: *M. K. MISHRA, M. KEOUGH, V. W. YONG;
Clin. Neurosci., Univ. of Calgary, Calgary, AB, Canada

Abstract: Monocytoid cells (circulating monocytes, tissue infiltrated macrophages and CNS-resident microglia) are very plastic and heterogeneous cells of innate immunity that have important roles in homeostasis and defense. While an overactive and uncontrolled inflammatory response directed towards the CNS is detrimental, it is increasingly recognized that some components of the immune response may be beneficial. Recent lines of evidence suggest that macrophage activation state can switch from a proinflammatory (M1) to an anti-inflammatory (M2) state, depending on the microenvironment. As with peripheral macrophages, microglia respond to the prevailing cytokine milieu and display markers of M1 and M2 cells. Macrophages are involved in various functions including extracellular matrix (ECM) remodeling; these ECM has inhibitory components such as chondroitin sulfate proteoglycans (CSPGs) that inhibit neuronal adhesion and neurite outgrowth. We have characterized macrophages and microglia in culture into M1 and M2 subsets by qPCR, western blot, ELISA and by nitric oxide and arginase assays. We have also examined the proteolytic properties of M1 and M2 macrophages particularly their capacity to overcome the inhibitory effects of CSPGs. We have found that M1 and M2 polarized macrophages produce different spectrum of matrix metalloproteinases, TIMPs and cytokines. The conditioned media from M1 and M2 macrophages have differential effect on neuronal survival, with M1 being toxic. Moreover, these conditioned media process CSPGs differentially, and M2 conditioned media overcome the inhibition by CSPGs on neuritic outgrowth. We have also found that vitamin D and minocycline at low concentrations reduce the proinflammatory M1 phenotype of BMDMs, and favor cells towards the M2 subset. Overall, our data suggest that the polarization of macrophages and microglia is a tool to reduce detrimental neuroinflammation and to harness the beneficial aspects of neuroinflammation to favor recovery in various CNS diseases.

Title: Age-related changes induced by Lipopolysaccharide on α2,3-Na,K-ATPase activity, cyclic GMP levels and oxidative status in rat hippocampus

Authors: *A. R. VASCONCELOS[1], L. M. YSHII[1], A. E. BÖHMER[1], L. S. LIMA[1], R. ALVES[1], D. Z. ANDREOTTI[1], T. MARCOURAKIS[2], C. SCAVONE[1], E. M. KAWAMOTO[1,3]; [1]Dept. of Pharmacol. - Inst. of Biomed. Sci., [2]Dept. of Clin. and Toxicological Analysis - Fac. of Pharmaceut. Sci., Univ. of Sao Paulo, Sao Paulo, Brazil; [3]Natl. Inst. on Aging Intramural Res. Program, Baltimore, MD

Abstract: Chronic neuroinflammation is a common characteristic of neurodegenerative diseases, such as Alzheimer's and Parkinson's diseases, that may contribute to loss of function and cell death. Sodium, potassium pump (Na,K-ATPase) plays an important role to maintain cell ionic equilibrium. Disruption of Na,K-ATPase activity and cyclic GMP signaling could lead to oxidative stress process which could be detrimental to the cells. In this project we compared the effects of an inflammatory stimulus induced by Lipopolysaccharide (LPS, 1 mg/kg) administration on the activity of isoforms α_1 and $\alpha_{2,3}$-Na,K-ATPase, cyclic GMP and TBARS levels in hippocampus of young (4-month-old), adult (12-month-old) and aged (24-month-old) male Wistar rats. The results showed that Aging induces a progressive decrease in hippocampal total-Na,K-ATPase activity at 12 and 24 months when compared with the values detected at 4 months, which is due to a reduction in $\alpha_{2,3}$-Na,K-ATPase activity, since α_1-Na,K-ATPase and Mg-ATPase activities are not changed. Also, LPS caused a decrease of the total-Na,K-ATPase activity 2 h after intravenous injection at 4 and 12 months. This effect was also specific to $\alpha_{2,3}$-Na,K-ATPase. We also showed that cyclic GMP levels decrease at 12 and 24 months when compared to 4-month-old animals. TBARS determinations showed that aging is linked to progressive increase in products of lipid peroxidation at 12 and 24 months when compared to 4-month-old rats. Moreover, LPS treatment decreased cyclic GMP levels at 4 and 12 month-old animals but not at 24 months when compared with respectively aged control groups. On the other

hand, TBARS levels were increased after LPS at 4, 12 and 24 month-old animals when compared to respectively aged control groups. Taken together, these findings suggest that aging is associated with a progressive decrease of protective signaling related to an increased risk for deficits on brain function and neurodegenerative disorders which are aggravated by inflammation.

Title: IL-2 activated natural killer cells interact with but do not lyse adult DRG neuron targets

Authors: *A. J. DAVIES[1], J. LEE[1], J. LEE[2], J. CHOI[1], M. KIM[2], K. LEE[2], S. OH[1]; [1]Natl. Res. Lab. for Pain, Dept. of Physiol., Sch. of Dentistry, Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Global Res. Lab, Col. of Med., Korea Univ., Seoul, Korea, Republic of

Abstract: Natural Killer (NK) cells are cytotoxic lymphocytes typically involved in cell lysis of tumour or virus-infected target cells. It has previously been shown that NK cells are cytotoxic against embryonic dorsal root ganglia (DRG) neurons and can restrict neurite outgrowth central neurons *in vitro*, however very little is known about the interactions between NK cells and the nervous system. We observed NK cell-like immunoreactivity in sections of adult mouse DRG in close-proximity to neurons and glia suggesting possible functional interactions. We first confirmed the ability of IL-2 activated NK cells to lyse embryonic mouse DRG neurons using a Cr^{51}-release assay. NK cell activity is co-ordinated by a fine balance of stimulatory and inhibitory signals. We go on to show that cytoxicity against embryonic DRG neurons is dependent on the activating NK cell receptors NKG2D and 2B4 using antibody blocking and receptor knock-out strategies. In contrast, DRG neurons cultured from adult mice were resistant

to cytotoxicity suggesting possible inhibitory receptor function. Instead we show that IL-2 activated but not resting NK cells physically interact with adult DRG neurons in co-culture by immunocytochemistry and live confocal microscopy. We also tested the ability of NK cells to lyse primary-cultured microglia. IL-2 activated NK cells showed significant cytotoxicity against resting microglia but unlike embryonic DRG lysis was not dependent on 2B4 receptor function. Conversely, prior activation of microglia with lipopolysaccharide was protective against NK cell-mediated lysis. Our results suggest that NK cell activation within the nervous system may lead to differential effects on neurons and glia respectively.

Title: Recruitment of interferon-producing killer dendritic cells to the viral-induced encephalitic brain is IL-15 dependent

Authors: *A. TROCHTENBERG, P. M. D'AGOSTINO, K. BULLOCH;
The Rockefeller Univ., New York, NY

Abstract: Interferon-producing killer dendritic cells (IKDC), defined by their $NK1.1^+$ $CD49b^+$ $B220^+$ IL-$2R\beta^+$ $CD11c^{int}$ phenotype, have been recognized in the periphery as a novel tumoricidal cell capable of both cytotoxicity and antigen presentation. However, these cells have remained uncharacterized in the infected brain. Using intranasally administered Vesicular Stomatitis Virus (VSV) as a model for viral-induced encephalitis, we identified a population of cells bearing the IKDC phenotype in the olfactory bulb (OB) 4 days post-infection (dpi). In initial studies performed on *CD11c-eyfp* mice, a transgenic C57BL/6 mouse in which enhanced yellow fluorescent protein (YFP) expression is linked to the CD11c promotor, we identified putative IKDC based on YFP expression. We observed a rare IKDC subset in the OB that was both $TRAIL^+$ and IFN-γ producing 4 dpi, substantiating our hypothesis that the identified population represented putative IKDC. In our current study, we focus on further characterizing the lineage and function of IKDC in the encephalitic brain. In order to assess the origin of these putative

IKDC, we infected IL-15$^{-/-}$ (a C57BL/6 transgenic mouse lacking cells of the NK lineage) and C57BL/6 wild-type (WT) mice using our VSV protocol. Recruitment of putative IKDC cells by VSV-infected WT and IL-15$^{-/-}$ mice was analyzed by flow cytometry, which required use of an anti-CD11c antibody (clone N418) to evaluate the CD11c^{+} population in the absence of the YFP selection marker. Our data clearly demonstrate recruitment of a large population of putative IKDC by 4 dpi in WT mice, whereas cells bearing the IKDC phenotype are absent from the olfactory bulb of IL-15$^{-/-}$ mice. This finding strongly implies that IKDC are derived from a NK precursor, reminiscent of a recently reported peripheral B220^{+} NK population (Guimont-Desrochers, *Blood*, 2012). Interestingly, we also observe that the putative IKDC population on 4 dpi is significantly larger in WT mice than that reported in *CD11c-eyfp* transgenic mice. Further flow cytometry analysis of VSV-infected *CD11c-eyfp* mice, using an anti-CD11c antibody in conjunction with the YFP reporter, demonstrates a large population of putative IKDC that are CD11c^{+} but YFP^{neg}, suggesting that this population of interest: 1) has down-regulated the CD11c promoter while retaining surface expression of CD11c protein and 2) composes a larger fraction of cells recruited to the OB than previously recognized. Identification of the expanded population of CD11c^{+} NK1.1^{+} CD49b^{+} B220^{+} IL-2Rβ^{+} cells will facilitate our further functional analysis of their cytotoxic and antigen presenting potential in VSV-induced encephalitis.

Title: Spinal cord injury in aged mice resulted in increased lesion length and limited functional recovery associated with impaired interleukin-(IL)4 receptor-alpha mediated regulation of microglia

Authors: *A. M. FENN[1], J. C. HALL[2], J. C. GENSEL[3], P. G. POPOVICH[2], J. P. GODBOUT[2]; [2]Neurosci., [1]The Ohio State Univ., Columbus, OH; [3]Physiol., Univ. of Kentucky, Lexington, KY

Abstract: Older individuals have a poorer prognosis, worse functional recovery, and higher mortality rate after spinal cord injury (SCI). Limited studies, however, have investigated the mechanism by which SCI is worse with age. Our previous work indicates that activated microglia from aged mice are less sensitive to anti-inflammatory and reparative (M2a) signals.

Therefore, we hypothesize that impaired M2a-mediated regulation of active microglia in the aged plays a pivotal role in SCI severity. To begin to test this hypothesis, adult (3-4 mo) and aged (18-19 mo) mice were subjected to mid-thoracic (T_9) SCI. Here, we show that functional recovery after SCI was limited in aged mice compared to adults with lower Basso Mouse Scale (BMS) scores and failure to regain plantar stepping. Moreover, lesion length was 38% longer in aged mice compared to adults. To assess the reparative potential of resident and infiltrating microglia/macrophages after injury, protein expression of the M2a-driven enzyme, arginase, was determined. Coinciding with worsened functional recovery, the number of arginase$^+$ microglia/macrophages was reduced in the injured spinal cord of aged mice. Because arginase is driven by interleukin-4 (IL-4), expression of its corresponding receptor, IL-4 receptor-alpha (IL-4Rα), was determined on microglia and infiltrating monocytes after injury. Microglia from aged mice failed to increase IL-4Rα protein expression after SCI associated with a reduction in cytokines, chemokines, and trafficking of IL-4Rα$^+$ monocytes. To better understand IL-4Rα-mediated regulation of inflammatory activated microglia, a series of intracerebroventricular (i.c.v.) IL-4 infusion studies were completed. Mice were injected peripherally with lipopolysaccharide (LPS) to induce an acute inflammatory response and drive IL-4Rα expression on microglia, followed by an i.c.v. injection of IL-4. These studies show that functional IL-4/IL-4Rα interactions were critical in re-directing inflammatory activated microglia towards an M2a phenotype. Indeed, only LPS-activated microglia with upregulated IL-4Rα expression had increased arginase expression after i.c.v. IL-4. Furthermore, enhanced IL-4Rα expression on active microglia was required for IL-4-dependent neurite growth *ex vivo*. Thus, inflammatory-induced IL-4Rα expression is necessary for IL-4-driven M2a responses by microglia. Collectively, these studies indicate that impaired IL-4Rα upregulation on active microglia of aged mice limits IL-4-mediated M2a redirection contributing to increased tissue damage and worse functional outcome after SCI.

Title: Interleukin-1beta excites rat histaminergic neurons

Authors: *H. L. HAAS, Y. YANOVSKY, O. A. SERGEEVA;
Neurophysiol., Heinrich-Heine-University, Dusseldorf, Germany

Abstract: Members of the inflammatory cytokine interleukin-1 (IL1) family, interleukin-1beta (IL1β) and IL1 receptor antagonist (IL1RA) affect body temperature in response to systemic inflammation through the hypothalamus. Neuronal histamine prevents amplification of IL1β signalling in the hypothalamus and suppresses fever (Tringali et al., 1997; Kang et al., 1995). It was reported previously that IL1β enhances histamine turnover, histidine decarboxylase (HDC, histamine-producing enzyme) and histamine release (Niimi et al., 1994,1997). We recorded now from identified histaminergic neurons in the tuberomamillary nucleus of the hypothalamus (TMN) in cell-attached mode in rat (P22-26) brain slices during IL1β (1.7nM) bath perfusion and report an increased firing, to 200±48 % (n=5) of control. Single-cell RT-PCR revealed expression of the IL1β receptor (IL1R) by 30% of the TMN neurons. In 60% of IL1R-negative TMN neurons mRNA encoding for the IL1β peptide was detected. IL1RA transcripts were not detected in individual neurons, but were found in the whole TMN region used as positive control. Bath application of IL1RA prevented the increase of neuronal firing by IL1β (n=4). Moreover, GABA (10-30µM, n=4) or ammonium chloride (5mM, n=5) given prior to IL1β significantly suppressed excitation, most likely by inhibiting the amplification of IL1β signalling by glia or neurons. Mechanisms of glia-TMN neuron interaction may involve release of glutamate (Huang et al., 2010) and activation of metabotropic glutamate receptors of type I as we have shown previously for the response to protons (Yanovsky et al, 2012). Thus direct activation of histaminergic neurons by IL1β and amplification of interleukin signalling in the TMN region provide a cellular basis for feed-back control of the inflammatory fever response.

Title: Spatial, temporal and phenotypic differences in GFP^+ bone marrow cells repopulating central autonomic nuclei

Authors: *Y. SUGIYAMA[1], G. FARACO[1], A. MORAGA[2], L. GARCIA BONILLA[1], J. ANRATHER[1], C. IADECOLA[1];
[1]Brain and Mind Res. Inst. Weill Cornell Med. Col., New York, NY; [2]Univ. Complutense, Madrid, Spain

Abstract: Trafficking of circulating bone marrow (BM)-derived cells into the hypothalamic paraventricular nucleus (PVN) has been implicated in critical autonomic functions, such as stress hormone responses (Neuron 65:94, 2010) and sympathetic activation during cardiac failure (Hypertension 55:652, 2010). Transplantation of GFP+ BM has been used extensively to localize BM-derived cells in the mouse brain. However, the regional distribution and the phenotypic characteristics of GFP+ cells in brain regions involved in autonomic regulation have not been clearly defined. We transplanted GFP+ BM into lethally irradiated C57Bl/6 mice (n=5/group) and examined phenotype and regional distribution of the cells 7 and 14 weeks later in brain sections by confocal microscopy. GFP+ cells were observed in brain regions involved in autonomic regulation, such as the PVN, nucleus tractus solitarius (NTS), area postrema (AP), and subfornical organ (SFO), but also in the somatosensory cortex. However, in PVN and NTS the number of cells increased markedly between 7 and 14 wks (e.g., PVN: 7 wks: 49±10; 14 wks: 210±45, $p<0.05$), whereas in cerebral cortex, SFO and AP the number of GFP+ cells did not change significantly (e.g., cortex: 7 wks: 106±20/section; 14 wks: 129±22/section, $p>0.05$). Next, we characterized GFP+ cells based on location, morphology and expression of myeloid markers. Two distinct populations were identified: (a) elongated cells, closely associated with blood vessels and expressing the perivascular macrophage marker CD206 (GFP+/CD206+) and (b) stellate cells with dendritic ramifications resembling microglia, not associated with blood vessels and expressing the microglia/macrophage marker Iba1 (GFP+/Iba1+). At 14 weeks, GFP+/CD206+ cells were most abundant in cortex, AP and SFO, whereas GFP+/Iba1+ cells were most abundant in PVN and NTS. The increase in GFP+ cells in PVN and NTS was entirely attributable to expansion of the GFP+/Iba1+ population (e.g., PVN: 7 wks: 21±7; 14 wks: 124±37). Furthermore, GFP+/CD206+ cells, but not GFP+/Iba1+ cells, were able to take up fluorescent dextran injected intracerebroventricularly, demonstrating a difference in phagocytic activity between the two groups. We conclude that there are fundamental regional and phenotypic differences in BM-derived cells repopulating the brain, non-phagocytic microglia-like cells predominating in the PVN and NTS, and phagocytic perivascular macrophages in neocortex and circumventricular organs (SFO, AP). It remains to be established whether these phenotypic differences are induced by regional molecular cues or reflect distinct homing programs intrinsic to BM-derived cells.

Title: Dendritic cell vaccine-induced immune activity in gliomas elicits ependymal gene expression and differentiation

Authors: *M. C. JHUN[1], N. YEAGER[1], R. CORDNER[2], A. RENTSENDORJ[1], A. MARDIROS[4], A. PANWAR[3], Y. HIRAKAWA[3], D. K. MORRIS-IRVIN[1], C. WANG[4], K. L. BLACK[1], C. J. WHEELER[1];
[1]Maxine Dunitz Neurosurgical Inst., [2]Biomed. Sci., [3]Cedars-Sinai Med. Ctr., Los Angeles, CA; [4]City of Hope, Los Angeles, CA

Abstract: Glioblastoma Multiforme (GBM) is the most aggressive form of primary brain cancer. Even with aggressive surgical and chemical therapies, the overall prognosis is the most dismal of central nervous system cancers. In efforts to identify better treatment options, several subclasses of malignant gliomas are now distinguishable by global gene expression profiling, which can also identify tumor differentiation status. Microarray gene expression studies have identified differentiation profiles of tumor cells before and after Dendritic-Cell (DC) Vaccination. These profiles accompanied with fluorescence imaging of characteristic profile markers, track movement away from an astrocytic, mesenchymal profile after DC vaccination in both human GBM and mouse GL26 gliomas, towards a more ependymal-like profile. The decreased astrocytic and increased ependymal tumor gene expression taken together suggests heightened neuroepithelial differentiation. Furthermore, Fas-L deficient (Gld) mice and mice deficient for T cell functions showed evidence of increased invasive properties, while treatment with CD8 T-Cells, or prior exposure to CD8 T-Cells with temozolomide (TMZ) showed significantly similar decreased invasiveness. Dendritic-Cell Vaccination-elicited selection pressure may cause the ependymal-like differentiation which confers protection against immune predation of gliomas. Further identifying factors to perturb may possibly lead to development of longer times until tumor treatment-resistance resulting in longer survival for patients.

Title: The CD200L-CD200R interaction is essential for the repair process following spinal cord injury

Authors: *M. COHEN, H. BEN-YEHUDA, M. SCHWARTZ;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: The isolation of the central nervous system (CNS) from the periphery results in unique defense mechanisms that protect the CNS from uncontrolled inflammation. During homeostasis, the interaction between CD200L (OX2), expressed on neurons, and CD200R, expressed on resting microglia inside the CNS, is one of the most important axes to regulate microglial function, and delivers an inhibitory signal. Here, we probed the role of this interaction following spinal cord injury (SCI). Recovery of CD200-/- mice following SCI was impaired compared to wild type (WT) mice. CD200L expression by resident CNS cells, and not by the peripheral infiltrating cells, was essential for the repair process. On day 7 following SCI, CD200R was highly expressed by IB4+ activated microglia and macrophages, which were localized at the center of the lesion site. Moreover, while injured neurons down-regulated CD200L expression, CD31+ and CD34+ endothelial cells elevated its expression at the site of injury. CD200 deficiency in injured mice led to dysregulated organization of IBA1+ activated microglia compared to controlled localization of IBA1+ microglia in WT mice, which was also in close proximity to the CD200L+CD31+CD34+ endothelial cells. mRNA analysis of the cytokine milieu within the site of the injured spinal cords indicated that CD200L expression in the CNS might play a role in regulating the inflammatory response during the first 3 days following SCI. Furthermore, its deficiency seemed to affect the ability of the residing immune cells to express matrix metalloproteinases (MMPs), which have an important role in the degradation of the extracellular matrix following SCI. Thus, following SCI, CD200L expression by CNS endothelial cells compensates the down-regulation of its expression by neurons. Moreover, CD200L not only regulates inflammation, but also the induction of MMP expression.

Abstract: Microglia are the resident immune effector cells in the central nervous system. Microglia can be activated by endotoxins, lipopolysaccharides (LPS) upon phagocytosis of invading bacteria, and produce pro-inflammatory radical mediators including nitric oxide (NO). Excess NO is thought to induce nitrosative stress and contribute to neuronal injuries leading to the progression of neurodegenerative diseases. There is a long-standing interest in botanicals as potential sources for the prevention of neuroinflammation and treatment of neurodegenerative diseases. Botanical compounds, aged garlic extract (AGE) and its active component D-fructose-L-arginine (FruArg), have been shown antioxidative activity. In this study, we investigated the effects of AGE and FruArg on LPS-induced neuroinflammatory response in immortalized murine microglial BV-2 cells by a quantitative proteomic approach. BV-2 cells were exposed to 100 ng/mL LPS for 20 hours in the presence or absence of 1% AGE or 3 mM FruArg. A Griess assay indicated both AGE and FruArg inhibited NO production in LPS-activated BV-2 cells, while no significant toxicity appeared in the cells as determined by MTT assay. Cell lysates of the samples (untreated, LPS-treated, LPS+AGE, LPS+FruArg) in biological triplicates were then labeled with CyDyes (using GE minimal labeling) and resolved by two dimensional difference

in-gel electrophoresis (2D-DIGE). Using Progenesis SameSpot software, we detected a total of 1,925 protein spots on the 2D-DIGE gels. Compared to LPS-treated conditions, 21 and 18 protein spots showed significant protein expression level changes (fold changes > 1.5, $p < 0.05$) after treatment with AGE and FruArg, respectively. Protein identification by liquid chromatography tandem mass spectrometry determined 24 proteins from the 21 spots and 20 proteins from the 18 spots. Ingenuity Pathway Analysis (IPA) with these proteins suggested oxidative stress and Nrf2-mediated antioxidative response were among the top toxicity and canonical pathways targeted by both AGE and FruArg. These results revealed the ability of AGE and FruArg to attenuate LPS-induced neuroinflammatary response in microglial cells.

Title: Mitochondrial dynamics modulate the expression of pro-inflammatory mediators in microglial cells

Authors: *J. PARK[1], H. CHOI[2], D.-S. LEE[1];
[1]Col. of Natural Sci., Kyungpook Natl. Univ., Daegu, Korea, Republic of; [2]Korea Res. Inst. of Biosci. and Biotech. (KRIBB), Daejeon, Korea, Republic of

Abstract: Over-activation of microglia cells contributes to neurodegenerative processes. Recent evidence demonstrated that mitochondrial dynamics are an important constituent of cellular quality control and function.
In the present study, we found that LPS stimulation induced excessive mitochondrial fission in BV-2 microglia cells. Drp1-Ser637 phosphorylation as key regulator of mitochondrial fission was decreased. Furthermore, inhibition of LPS-induced mitochondrial fission by Mdivi-1, a

mitochondrial fission inhibitor, attenuated the production of pro-inflammatory mediators via reduced NF-κB, ERK, and p38 MAPK signaling, thereby suppressing mitochondrial fission-induced ROS production.
We therefore suggest that mitochondrial dynamics may regulate activation of microglia cells in brain.

Title: Active microglia are modulated by TGFb that is produced by IL-10 re-directed astrocytes

Authors: *D. M. NORDEN, A. M. FENN, A. DUGAN, J. P. GODBOUT;
The Ohio State Univ., Columbus, OH

Abstract: Following immune challenge, active microglia in the aged brain produce exaggerated levels of both pro- and anti-inflammatory cytokines, including interleukin (IL)-10. Under normal conditions, IL-10 acts to resolve inflammatory processes within the CNS. High IL-10 production in the aged brain, however, did not correspond with reduced inflammation. We interpret these results to indicate that responsiveness to IL-10 is impaired in the aged brain. To begin to address this notion, we investigated the ability of IL-10 to regulate microglia and astrocytes using adult mice and series of cell culture experiments. In initial studies, expression of IL-10 receptor (IL-10R) was determined on astrocytes and microglia. While a subset of astrocytes expressed IL-10R, microglial expression of IL-10R was limited. Moreover, surface expression of IL-10R was increased on astrocytes, but not microglia, 24 h after immune challenge. Corresponding with these receptor results, primary cell culture experiments showed that astrocytes were more sensitive to the anti-inflammatory effects of IL-10 than microglia. For example, IL-10 stimulation of active primary astrocytes reduced the expression of inflammatory mediators (IL-1b, TNFa, IL-6). IL-10, however, had little effect on the pro-inflammatory profile of active microglia. To determine whether microglial activation could be indirectly modulated by IL-10 signaling in astrocytes, expression of anti-inflammatory cytokines induced by IL-10 treatment of astrocytes was determined. We show that activated astrocytes increased TGFb mRNA and protein expression which was significantly augmented in the presence of IL-10. Next, the ability

of TGFb to modulate microglia activation was investigated. In primary microglia, TGFb attenuated LPS induced expression of IL-1b and IL-6 and increased expression of two key regulatory receptors CX3CR1 and IL-4R. Using astrocyte-microglia co-culture systems, we confirmed that astrocytes mediate the anti-inflammatory effects of IL-10 on microglia via the production of TGFb. For instance, only when astrocytes were present did IL-10 stimulation result in lowered expression of IL-1b and increased expression of CX3CR1 and IL-4R. Importantly, all of these IL-10-astrocyte dependent effects on microglia were blocked by a TGFb inhibitor. Thus, we postulate that IL-10 re-directs active astrocytes to augment the production of TGFb, which in turn, attenuates microglial activation. Overall, these findings provide novel insight into the mechanisms by which astrocytes modulate microglia, and may provide new avenues to understand impaired regulation of microglia in the aged brain.

Title: Homeostatic and injury-induced microglial behavior in the aging brain

Authors: *J. K. HEFENDEHL[1,2], J. J. NEHER[2], R. SÜHS[2], S. KOHSAKA[3], A. SKODRAS[2], M. JUCKER[2];
[1]Cell. Neurol., Brain Res. Centre, Universtiy of British Columbia, Vancouver, BC, Canada; [2]Hertie Inst. for Clin. Brain Res., Tuebingen, Germany; [3]Natl. Inst. of Neurosci., Tokyo, Japan

Abstract: Microglia cells are essential for brain homeostasis and have essential roles in neurodegenerative diseases. Because aging is the main risk factor for most neurodegenerative diseases, microglia aging may contribute to the susceptibility of the aged brain to dysfunction and neurodegeneration. Microglia aging in the past has been studied in postmortem brain tissue. Today we know, however, that microglia are highly dynamic surveying cells that continuously scan their environment every few hours and respond dynamically to disturbances in the brain (Nimmerjahn et al., Science 2005; Davalos et al., Nature Neuroscience 2005). Thus, postmortem microglia analysis alone is arguably not an appropriate method to assess microglia aging. In the present study we have analyzed microglia behavior in vivo in young adult (3 mo-old), adult (11-12 mo-old) and aged (26-27 mo-old) mice using in vivo 2-photon microscopy. Our results show

that surveying microglial cells in the neocortex exhibit age-related soma volume increase, shortening of processes, and loss of homogeneous tissue distribution. Furthermore, the baseline microglial process speed significantly decreased with age. While only a small population of microglia showed soma movement in adult mice, the microglia population with soma movement was drastically increased in aged mice. However, in response to tissue injury the dynamic microglial response was age-dependently diminished. These results provide novel insights into microglial behavior and indicate that microglial dysfunction in the aging brain may contribute to age-related cognitive decline and neurodegenerative diseases.

Title: Urban particulate matter selectively affects primary human neurons

Authors: K. MENDOZA[1], C. SIOUTAS[3], P. PAKBIN[3], *A. G. CAMPBELL[2];
[1]Pharmaceut. Sci., [2]Western Univ. Hlth. Sci., POMONA, CA; [3]Civil Engin., USC, Los Angeles, CA

Abstract: Exposure to particulate matter (PM), found in urban air pollution, is considered a risk factor in many respiratory and cardiovascular diseases. More recently it has been speculated that PM exposure may also cause adverse effects in the brain. Although the exact mechanisms involved are unknown, enhancement in both oxidative and inflammatory responses has been reported. Since the main route of exposure to particulate matter is through inhalation, there is a potential for compounds to rapidly enter the brain through the cribriform plate of the ethmoid bone, resulting in direct activation of CNS inflammatory responses. The purpose of this study was to use normal human brain cells to assess cell type specific effects of PM exposure. We hypothesized that particles would activate microglial cells. Reactive oxygen species formation and the proinflammatory cytokine tumor necrosis factor alpha (TNF-α) were measured as markers of oxidative stress or inflammation respectively. Human microglia, neurons, and astrocytes were grown separately or as co-cultures and then exposed to PM collected from a site in Los Angeles. Surprisingly, the only human CNS cell type which was responsive to PM was

neuronal. Exposed cells showed a decrease in ROS formation but an increase in TNF-α production. This is contrary to what is seen in primary rodent CNS cells. Thus, the CNS response in normal human cells may be different compared to primary rodent cells. This is not surprising since a new report indicates that mouse models poorly reflect human inflammatory diseases. Thus the use of human cells may be more predictive than animal models in determining risk assessment of environmental factors.

Title: Microglia mediate chemotherapy induced neuroinflammation and cognitive deficits in female mice

Authors: *B. L. JARRETT[1], M. B. LUSTBERG[2], A. HINZEY[1], C. L. SHAPIRO[2], A. C. DEVRIES[1];
[1]Neurosci., [2]Intrnl. Medicine, Div. of Med. Oncology and the Breast Program, Ohio State Univ., Columbus, OH

Abstract: Although improvements in cancer detection and treatment have substantially increased the survival rate for breast cancer patients, the treatment regimens often impair quality of life. Chemotherapeutic drugs, particularly anthracyclines, have potentially toxic side effects in the brain affecting memory, processing time, and verbal fluency. More than 30% of patients undergoing chemotherapy for breast cancer report cognitive deficits during and after treatment. Despite the high incidence and significant impact on quality of life, little is known about the cause of the cognitive deficits and no effective treatment currently exists. Our hypothesis is that chemotherapy induces neuroinflammation and related cognitive impairment side effects that can be ameliorated though treatment with minocycline, an anti-inflammatory drug. Adult female BALB/C mice were ovariectomized and then two weeks later injected intravenous (IV) with a single dose of chemotherapy (45 mg/m^{2}doxorubicin + 450 mg/m^2 cyclophosphamide) or vehicle (n=10-12/group). The mice were trained for three trials per day across six days in the Barnes Maze, a well-characterized spatial memory task.
Both the chemotherapy-treated and vehicle-treated mice were able to acquire the task by the final

day of training. However, the chemotherapy-treated mice took significantly longer to find the escape box than the vehicle-treated mice on training days 2-5 ($p<0.05$). In contrast, there were no group differences in overall locomotor activity level, suggesting that the observed difference in maze performance was not due to fatigue. ($p>0.05$) In addition, chemotherapy increased proinflammatory cytokine expression (TNF-, IL-1, and IL-6) and altered neuronal morphology in the hippocampus ($p<0.05$), a region of the brain that is critical for spatial learning and memory. Likewise, microglia from chemotherapy-treated mice exhibited increased expression of MHCII and CD80 relative to vehicle-treated mice ($p<0.05$), thereby suggesting a proinflammatory phenotype.
A second cohort of mice was given minocycline (80 mg/kg/day) dissolved in the drinking water, or normal drinking water, before injection of chemo or saline. Chemo treated mice receiving minocycline improved learning and memory, similar to that of the control mice and also decreased proinflammatory and microglial activation markers. Together, these data suggest that the administration of doxorubicin and cyclophosphamide produce neuroinflammation, including microglia activation, and concomitant cognitive deficits in female mice and that these side effects can be eliminated with minocycline treatment.

Title: Differential modulation of bacteria-induced sickness and inflammation by double stranded RNA-dependent protein kinase (PKR)

Authors: *D. C.-H. POON[1], Y. S. HO[1,4], C. K. M. LOK[1], S. M. C. LEUNG[1], K. CHIU[1], R. C. C. CHANG[1,2,3];

Kong, China; [4]State Key Lab. of Quality Res. in Chinese Med., Macau Univ. of Sci. and Technol., Macau, China

Abstract: Sickness refers to a set of adaptive, physiological (e.g. fever) and behavioral (e.g. malaise, anorexia, social withdrawal, and fatigue) changes in response to systemic inflammatory insults, e.g. infection and injury. While these responses collectively serve to facilitate an organism to recover, increasing lines of evidence indicate that sickness, if exacerbated, may precipitate depression and delirium. Hence, it will be beneficial to discover suitable approaches to modulate sickness so as to maximize its benefits and minimize its side effects. As double-stranded RNA-dependent protein kinase (PKR) is key kinase regulating inflammation, the aim of this study is to investigate whether PKR also plays a regulatory role in sickness. PKR+/+ and PKR-/- mice were infected subcutaneously with live Escherichia coli (*E. coli*.) or vehicle. Sickness was assessed by monitoring fever, food consumption, burrowing, and open field activity for five days. Moreover, the brain and the liver were collected for quantitative polymerase chain reaction (qPCR) of the inflammatory markers interleukin-1β (IL-1β) and cyclooxygenase (COX-2).After being challenged by *E. coli*., PKR-/- mice developed prolonged fever (2-3 days) as compared to PKR+/+ mice (3-4 days). Moreover, PKR-/- mice showed greater hypophagia during the early phase of sickness (day 1-2), which was followed a more pronounced hyperphagia in the late phase of sickness (day 4-5). While both types of mice displayed similar decreases of burrowing activities, PKR-/- mice exhibited a greater reduction in open field activity than PKR+/+ mice. Furthermore, IL-1ß and COX2 in PKR +/+ and PKR-/- mice were differentially expressed in the brain and the liver following *E. coli.* challenge.It has been known that PKR participates in up-regulating inflammatory responses in immune cells, and that inflammatory factors such as IL-1β and COX-2 are key players in causing sickness during systemic inflammation. Our data is consistent with the literature that deficiency of PKR could lower the expression of systemic inflammatory markers after immune challenge. These findings shall (1) shed light on the suitability of PKR as a target to modulate sickness, and (2) stimulate us to refine the current concepts relating infection, systemic inflammation, and sickness.

Title: Perturbation of the innate immune system in neurons leads to depression in mouse

Authors: *K. KEYHANIAN[1,3], X. ZHOU[3], N. R. PANDEY[3], Z. QIN[1,3], T. HO[2], K. WEN[4], A. F. R. STEWART[5], H.-H. CHEN[3];

Abstract: Brain inflammation has been linked to chronic depression. Viral infection may act as a trigger preceding chronic depression. Half of patients who receive interferon alpha therapy to treat hepatitis infection develop depression. Interferon alpha is activated as part of the innate immune response to viral infection and this depends on the activity of the interferon regulatory factor transcription factors (IRF1, IRF3, IRF7). In contrast, IRF2 acts to suppress interferon alpha expression and limits the inflammatory response via the co-repressor IRF2-binding protein 2, IRF2BP2. To study the role of interferon alpha and inflammation on depression, we ablated IRF2BP2 in neurons of the forebrain. This leads to elevated interferon alpha expression. In behavioral studies, the sucrose preference test revealed a marked depression phenotype in these mice compared to littermate controls. Our studies further indicate that IRF2BP2 protein levels in neurons are regulated in response to metabolic perturbations and ischemia-reperfusion. The regulatory mechanisms that control IRF2BP2 protein levels are being elucidated. Disrupted expression of IRF2BP2 may affect the duration and extent of the inflammatory response and underlie chronic depression associated with metabolic and ischemic brain disorders.

Title: Electroconvulsive therapy changes the plasma cytokine profile in patients with depressive disorder

Authors: *L. SCHWIELER[1], M. SAMUELSSON[2], H. LITWIN[1], S. ERHARDT[1];
[1]Karolinska Inst., Stockholm, Sweden; [2]Section of Psychiatry, Fac. of Hlth. Sci., Dept of Clin. and Exptl. Med., Linköping, Sweden

Abstract: Introduction
Depression is a severe, life-threatening illness exposing the patient to direct risks, such as suicide and lower quality of life. The pathogenesis of depression is still not fully understood but recent studies point to an involvement of the inflammatory system. In particular, activation of cytokines is suggested to play an important role in the pathophysiology. Electroconvulsive therapy (ECT) is regarded as an effective treatment of drug-resistant depression. The mechanism of action of ECT is unclear, although studies have investigated its effects on neurotransmitters and their receptors, neuropeptides, hormones, and neurotrophic factors. The aim of the present study is to investigate peripheral levels of cytokines in patients suffering from depression before and after treatment with ECT.
Methods:
Plasma cytokine concentrations (Interleukin (IL)-1β, IL-2, IL-4, IL-6, IL-8, IL-10, TNF-α, GM-CSF and INF-ϒ) were analyzed with electrochemiluminescence biosensor immunoassay (Meso Scale Discovery) in 27 patients with depression. The majority (n=23) of these patients had been treated with oral antidepressants but had not responded to drug treatment, and four were treatment naïve. Diagnosis was based on clinical interviews by a senior psychiatrist and the severity of symptoms was rated with Brief Psychiatric Rating scale (BPRS) and global assessment of functioning (GAF). To estimate the severity of depression during the course of the ECT treatments, the psychiatrist performed a Montgomery-Åsberg Depression Rating Scale (MADRS) scoring before the first and after the third ECT administration.
All patients where treated with right unilateral ECT treatments after at least 6 h of fasting. Plasma samples were collected before first ECT (n=27), after third (n=23) and sixth (n=12) ECT. All samples where stored at − 70 °C until analysis.
Results:
Preliminary data show that plasma levels of IL-6, IL-8 and TNF-α increase after ECT treatment with the most tangible effect after the sixth ECT. The mean MADRS score for all patients was 36.9± 1.5 before the ECT therapy started and 19.5 ± 2.0 after three ECT administrations. When data are subgrouped according to the treatment outcome into responders (MADRS score ≤ 15; n = 7) and non-responders (MADRS score > 15; n = 15) the effects on plasma cytokines are even

more pronounced, especially with regard to IL-6.
Conclusion:
The present results suggest that ECT changes the plasma levels of various cytokines in patients with depression. Therefore, cytokines might play a specific role within the treatment and pathogenesis of affective disorder.

Title: L. reuteri-induced modulation of behavior in C57BL/6J mice

Authors: *M. J. EIMERBRINK, E. E. JOHNSON, G. W. BOEHM;
Psychology, Texas Christian Univ., Fort Worth, TX

Abstract: There is a well-established communicative link between the immune system and central nervous system by which each has regulatory influence over the other. This bidirectional communication facilitates adaptive behaviors during peripheral immune activation commonly known as sickness behaviors. Sickness behaviors include a variety of responses, but there are specific behaviors that are mediated by an increase in pro-inflammatory cytokines, including IL-1β, IL-6, and TNF-α. Interestingly, recent studies also indicate that the microbiota of the gut can interact with the immune system to indirectly exert influence on an organism's behavior. The purpose of this research was to manipulate the gut microbiota to produce alterations in the immune system of C57 BL/6J mice that protect against the immune response to LPS. To achieve this goal, we utilized a treatment of the probiotic Lactobacillus reuteri to buffer the inflammatory response to LPS. Additionally, we used direct injections of IL-10 as a positive control against LPS-induced proinflammatory cytokine expression to test the efficacy of both treatments in rescuing burrowing behavior, as well as learning and memory. We hypothesize that behavioral changes will also be corroborated with subsequent decreases in hippocampal decreases in pro-inflammatory cytokines. In summation, this research looked to identify the effects of L. reuteri and IL-10 on LPS-induced sickness behavior and memory alteration.

Title: Role of inflammation in high-fat diet-induced cognitive deficits and alterations in hippocampal neurogenesis

Authors: K. M. BAUMGARNER, C. DIAZ, A. JONES, *R. A. KOHMAN;
Psychology, Univ. of North Carolina Wilmington, Wilmington, NC

Abstract: Obesity is a risk factor for several life-threatening diseases and neurological disorders including cardiovascular disease, diabetes, metabolic syndrome, dementia and Alzheimer's disease. One factor that may contribute to the increased risk for these conditions is the development of chronic inflammation. The current study evaluated whether consumption of a high-fat diet affects cognitive performance, measures of neural plasticity, and alters the inflammatory response to an immune challenge. Two experiments were conducted using adult male C57BL/6J mice that were fed ad libitum either a high-fat diet (HFD; 60% fat) or a control diet (CD; 10% fat) for 2 or 5 months. Initial results indicate that consumption of the HFD impaired acquisition of a spatial learning task relative to mice consuming the CD. Further, in response to the endotoxin lipopolysaccharide (LPS) mice fed the HFD showed higher splenic and hippocampal levels of the proinflammatory cytokine interleukin-1β relative to mice fed the CD. Additional work is underway to assess the impact of consuming the HFD on LPS-induced alterations in hippocampal neurogenesis, as measured by new cell survival and cellular differentiation. We hypothesize that consumption of the HFD in combination with an immune challenge will further reduce new cell survival relative to each treatment alone. Further, the lab is currently investigating the potential effects of consuming a HFD on the behavioral response to LPS administration as well as additional measures of immune activation within the brain. Presently, the data indicate that HFD consumption can disrupt cognitive function and exaggerate the inflammatory response within both the periphery and the brain.

Title: More pain than gain with chronic codeine: The first evidence of codeine-induced hyperalgesia

Authors: *J. L. JOHNSON[1], M. R. HUTCHINSON[2], D. B. WILLIAMS[3], P. ROLAN[1,4]; [1]Discipline of Pharmacol., [2]Discipline of Physiol., Univ. of Adelaide, Adelaide, Australia; [3]Sch. of Pharm. and Med. Sci., Univ. of South Australia, Adelaide, Australia; [4]Pain and Anaesthesia Res. Clin., Adelaide, Australia

Abstract: Background: Chronic opioid therapy is associated with opioid-induced hyperalgesia and allodynia, paradoxically increased pain sensitivity. Codeine is a widely used opioid that relies upon partial metabolism (approximately 10%) to morphine to elicit analgesia, owing to codeine's poor opioid receptor affinity. Chronic morphine exposure can exacerbate pain by activating the spinal innate immune system in a toll-like receptor-4 (TLR4) dependent manner. In silico docking simulations indicate codeine also docks to TLR4, suggesting potential to induce TLR4-dependent pain enhancement independent of conversion to morphine or opioid receptor activity.
Hypothesis: Codeine and morphine will cause TLR4-dependent hyperalgesia/allodynia that is independent of their opioid receptor-dependent analgesic rank potency.
Aims: Compare chronic codeine and morphine induced hyperalgesia/allodynia in mice and investigate mechanisms contributing to increased pain sensitivity.
Methods: Hyperalgesia and allodynia were assessed using hot plate and von Frey tests respectively, at baseline, day 3 and day 5 in male BALB/c mice receiving equimolar codeine 21 mg/kg (n=8), morphine 20mg/kg (n=8) or saline (n=8), twice daily (i.p.). The impact of Interleukin-1b on pain behavior was assessed on day 5 with the administration of interleukin-1 receptor antagonist (IL-1RA) prior to testing.
Results: Hot plate latency (s) was reduced, in codeine (-9.5, CI:4.7-14.3) and morphine (-7.3, CI:2.3-12.3) groups compared to saline at day 5. An increase in von Frey paw withdrawals (out of 10), only reached significance in the morphine group on day 5 (2.3, CI: 0.6-4). IL-1RA reversed codeine- (8.6, CI:5.1-12.2 and -2.1, CL:0.6- 3.6) and morphine-induced (10.4, CI:6.9-14 and -1.8, CI: 0.2-3.3) changes in hot plate latency and paw withdrawals, respectively.
Conclusions: Equimolar doses of codeine and morphine induce similar degrees of Interleuklin-1b-dependent hyperalgesia and allodynia, suggesting codeine does not rely upon conversion to morphine to increase sensitivity to noxious stimuli, emphasising the non-opioid receptor dependent nature of opioid-induced hyperalgesia. Ongoing studies examining priming with partial nerve injury, TLR4 knockout mice, a glial attenuator (ibudilast), and proteomic analysis

of collected spinal cord samples will explore the underlying cellular and molecular mechanisms further.

Title: Amyloid-beta induces a neuroinflammatory response and indoleamine 2,3-dioxygenase-dependent neuropsychiatric-like behaviors in mice

Authors: *J. M. PARROTT, L. REDUS, A. GREEN, J. C. O'CONNOR;
Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstract: Retrospective studies indicate that about one-third of Alzheimer's disease (AD) patients were previously diagnosed with depression prior to developing AD symptomology. Amyloid-beta (Aβ) plaques and neurofibrillary tangles begin to accumulate long before overt cognitive symptoms develop in humans, so early accumulation of Aβ may stimulate a neuroinflammatory response and subsequent neuropsychiatric symptoms.
Here, we sought to determine if acute administration of Aβ42 would induce a neuroinflammatory response and precipitate depressive-like behaviors in mice. Using the young (2-month) "triple-transgenic" mouse model of AD (3xTg-AD) with no overt cognitive deficits, Aβ42 levels and the expression of several neuroinflammatory markers in the hippocampus, striatum, frontal cortex and amygdalae were measured. Compared to age-matched wild-type (WT) control mice, 3xTg-AD mice had detectable increases in Aβ42 in the hippocampus and amygdala. Further, in all of the brain regions assessed, 3xTg-AD mice exhibited a marked neuroinflammatory response, characterized by up-regualtion of pro-inflammatory cytokines and kynurenine pathway enzymes. To determine whether Aβ42 could directly induces a similar neuroinflammatory response, WT mice were administered 400pmol Aβ42, or vehicle, directly into the lateral ventricles, followed

by assessment of neuropsychiatric-like behaviors and tissue collection for analysis of neuroinflammatory status. Three days post-injections, Aβ42-treated mice exhibited a significant reduction in sucrose preference. After 7d, Aβ42 administration caused mice to spend less time in the central area of an open field and more time floating during the forced swim test. Further, an increase in pro-inflammatory cytokines and kynurenine pathway enzymes was present at 1 and 3 days post Aβ42 infusion.
To determine whether increased kynurenine pathway metabolism mediates the behavioral effects of acute Aβ42, indoleamine 2,3-dioxygenase (IDO) deficient mice, mice pretreated with the competitive IDO inhibitor, or WT vehicle mice received intracerebroventricular infusion with Aβ42 or vehicle. Interestingly, both genetic and pharmacological inhibition of IDO protected mice from the Aβ-induced decrease in sucrose preference, increase in central area duration, and increase in floating behavior observed in the forced swim test. Together, these data suggest that very early AD pathogenesis may drive comorbid depressive symptoms in an IDO-dependent manner.

Title: Effects of mold exposure on anxiety, conditioned fear, motor performance and spatial memory

Authors: *C. F. HARDING[1,2], K. DENISOVA[1], T. DESAI[3], R. DESTEFANO[4], T. ROA[5], E. SHTRIDLER[1], C. PYTTE[2,6];

Abstract: The common estimate is that approximately 40% of American buildings are moldy. Exposure to mold can cause neurological problems, increased anxiety, and cognitive deficits. However, no animal research has been published examining how mold exposure causes these problems. We developed a mouse model to determine how mold exposure can lead to neurobehavioral dysfunction. Our basic hypothesis is that mold inhalation, like bacterial infection, activates an innate immune response triggering sickness behavior with resultant behavioral dysfunction. There is controversy over whether only toxic molds, like *Stachybotrys chartarum*, can cause health problems, or if exposure to skeletal elements common to all molds is sufficient. We therefore compared mice treated with 1) intact, toxic *Stachybotrys* spores (IN), 2) extracted *Stachybotrys* spores that had their toxins removed and proteins denatured (EX), or 3) vehicle (VEH). Mice were treated with relatively low spore doses 3X per week. Three weeks of treatment led to significant increases in anxiety as measured by the elevated plus maze among EX mice compared to both VEH and IN mice. EX mice had a significantly lower percentage of open arm entries, percent duration in the open arms, and percent distance traveled in the open arms. All groups performed similarly on the training trial of an auditory-cued conditioned fear test. However, IN mice moved significantly less than VEH mice on the auditory test a day later, suggesting they were more fearful. Among mice that learned to find the platform in the Morris water maze after four visible platform training trials, IN mice took slightly longer to reach the hidden platform the following day and their paths to the platform were longer. Results of a subsequent probe trial suggested that IN mice were using a thigmotactic, rather than a spatial strategy to find the platform. After six weeks of mold treatment, IN mice also fell off the rotorod significantly earlier than VEH mice. These data indicate that mold exposure increases both general anxiety and fearful behavior, alters learning strategies, and interferes with motor performance. Contrary to popular opinion, skeletal elements are sufficient to elicit adverse effects. Increased anxiety, increased fearfulness, deficits in learning and memory, and deficits in motor performance have all been documented in mold-exposed patients. Other studies from our laboratories suggest that these problems are mediated by mold-induced microglial activation and resulting brain inflammation.

Title: Repeated exposure to environmental mold increases cytokine interleukin-1β expression in the mouse hippocampus

Authors: *L. BLACHORSKY[1,2], K. PAGE[3], G. MANES[4], C. HARDING[4,3], C. PYTTE[3,1]; [1]Psychology, Queens College, CUNY, Flushing, NY; [2]Macaulay Honors Col., New York, NY; [3]Behavioral and Cognitive Neurosci. Doctoral Program, CUNY, New York, NY; [4]Psychology, Hunter College, CUNY, New York, NY

Abstract: Prolonged exposure to indoor mold can cause severe cognitive impairment, anxiety, and depression. However, the neural mechanisms underlying these symptoms have not been identified. Towards this aim, we have developed a mouse model to determine how inhaled mold spores affect the brain, leading to neural damage and cognitive and affective impairment. Our work focuses on the toxic "black" mold *Stachybotrys chartarum*, which is a common contaminant of damp and water-damaged buildings. Previous work from our labs has determined that repeated exposure to spores (3x per week for 3 weeks) caused striking deficits in hippocampal memory and increased anxiety compared to controls. Here we tested the hypothesis that these effects are mediated by central inflammation. Adult male C57BL/6 mice were given intranasal instillations of low doses of intact mold spores (IN), extracted spore skeletons (EX), or saline vehicle (VEH) 3x per week for 6 weeks. Extracted *Stachybotrys* spores have had their toxins remove and proteins denatured in order to test effects of exposure to non-toxic spore elements common to all molds. Moreover, extracted spore elements remain after killing mold in buildings with commercial products. Mice were tested with behavioral tests beginning at week 3, and were anesthetized and perfused after 6 weeks of treatment. Brains were processed for immunohistochemistry to label the pro-inflammatory cytokine Interleukin-1β (IL-1β) which is expressed primarily by microglia. Numbers of cells expressing IL-1β, and numbers of IL-1β - positive cellular processes, per area sampled were quantified throughout the CA1 and the whole hippocampus. We found significant differences in numbers of IL-1β-expressing cells and processes between IN, EX, and VEH groups in both the CA1 and throughout the entire hippocampus (ANOVA, $p<0.05$). On all measures, IN mice showed significantly more IL-1β expression than VEH mice (Tukey's posthoc test) while EX groups had intermediate values. These findings support our model that cognitive and affective impairment following repeated or prolonged exposure to mold triggers an innate immune response leading to central inflammation.

Title: Environmental mold decreases new neuron survival in the adult mouse hippocampus

Authors: *E. NORMAND[1,2], D. BEECH[5], S. RIBEIRO[5], K. PAGE[6], C. F. HARDING[3,7], R. DESTEFANO[1,4], D. MORRIS[2], C. PYTTE[5,6];

Abstract: Indoor mold is known to cause systemic health problems and sometimes severe learning and memory impairments. To understand the effects that mold may have on the central nervous system, we have developed a mouse model to study neural and behavioral consequences of exposure to *Stachybotrys chartarum*, a species of "black" mold found in water-damaged buildings. *Stachybotrys* is a toxin-producing mold and it is controversial whether the toxins per se cause cognitive problems or whether basic components of the spore found in all molds are sufficient to trigger cognitive deficits. In our standard protocol, C57BL/6 mice are exposed to low doses of intact spores (IN), extracted spore casings (EX) in which the intact spores were treated with ethanol to remove toxins and denature proteins, or saline vehicle as a control (VEH). In previous work, we found that mice treated with EX spores or IN spores showed equivalent impairment of hippocampal-dependent learning and memory. We then tested the hypothesis that deficits in hippocampal-dependent tasks may be due to decreased survival of new neurons in the dentate gyrus. Interestingly, we found a decrease in doublecortin (DCX)-expressing young neurons in the dentate gyrus only in EX treated animals, suggesting that IN spores are acting via a different mechanism, or perhaps impact a different neuronal cohort, than EX spores. DCX is

expressed in post-mitotic migratory and young neurons up to about 1 month of age. Here we quantified new neuron survival of older neurons in IN, EX, and VEH treated groups. Adult male C57BL/6 mice were intranasally exposed to spores or vehicle 3x per week for 6 weeks. The mice were injected with BrdU (2 x day, 4 days) 34-37 days before perfusion to label mitotically active cells and then underwent behavioral testing to assess hippocampal-dependent learning and memory. To quantify new neurons in the hippocampus, cells containing BrdU and NeuN, a marker of mature neurons, were labeled using immunohistochemistry. We found a significant difference across groups (ANOVA, $p=0.02$). Moreover, mice treated with IN spores showed fewer new neurons than the VEH-treated group (Tukey's post hoc, $p<0.05$). The EX group was not significantly different from IN or VEH groups. Together, these results suggest that EX spores lead to decreased numbers of new neurons less than one month of age whereas IN spores result in decreased survival of neurons in a cohort 32-37 days of age. These findings are consistent with the hypothesis that EX and IN spores have different effects, or different time courses of effects, following exposure; both lead to decreased survival of new neurons and hippocampal learning and memory deficits.

Title: Exercise alters the adaptive immune profile in mice

Authors: K. POINSATTE[1], A. MCPARTLIN[1], A. J. M. MEEUWISSEN[1], D. CHEN[1], E. SHUBEL[1], X. KONG[1], N. MONSON[1], R. ZHANG[2], *A. M. STOWE[1];
[1]Neurol. and Neurotherapeutics, [2]Intrnl. Med., UT Southwestern Med. Ctr., Dallas, TX

Abstract: Objective: Exercise provides neuroprotection from stroke-induced injury, as demonstrated in previous animal studies. Clinically, patients with high physical activity prior to stroke present with milder strokes and decreased deficits. However, the mechanisms for this protection remain unclear. This study used a voluntary exercise protocol to test the hypothesis that exercise induces adaptive immune mechanisms, which may be protective prior to stroke

onset.
Materials/Methods: Male Swiss Webster mice (6-12 wks old) were individually housed in cages with monitored running wheels (n=11) or locked running wheels (i.e. sedentary controls; n=11). Following three weeks of exercise, leukocytes were isolated from peripheral blood and spleen, stained with antibodies, and profiled on a BD-FACS Aria flow cytometer, while brains were collected for quantitative rt-PCR. Student's t-test or linear regression analysis determined significance ($p<0.05$). Additionally, sorted CD19+ B cells were isolated from spleen by flow cytometry (n=5/group), analyzed on an Illumina MouseWG-6 V2 Bead Chip, and final gene pathways determined using Ingenuity Pathway Analysis (IPA).
Results: Voluntary exercise decreased CD4 T cell representation ($p=0.05$) in the peripheral blood, with no other differential effect on CD8 T cells, neutrophils, B cells, or monocytes in the blood or spleen when compared to sedentary controls. Average weekly individual wheel rotations, however, were inversely proportional to the number of leukocytes ($p=0.06$), CD8 T cells ($p<0.05$), neutrophils ($p<0.05$) and neutrophil representations ($p<0.01$) in the spleen. Only B cells increased representation ($p<0.01$) in mice with higher levels of exercise. Mice with sustained levels of exercise over 3 wks also exhibited a unique clustering pattern in the CD19+ B cell microarray data. Microarray showed a significant upregulation of 1844 genes and downregulation of 1333 genes in the resident splenic B cells. Exercise upregulated genes associated with increased B cell maturation, generation and differentiation, with simultaneous downregulation of genes responsible for apoptosis and B cell death.
Conclusion: Three weeks of voluntary exercise in mice results in a change in the immune profile with enhanced expression of a unique, exercise-induced B cell phenotype. Downregulation of neutrophils and cytotoxic T cells also suggests that this alteration in immunity is anti-inflammatory. Further studies will determine the significance of these immune adaptations and their role in decreased neurovascular injury and functional deficits following stroke.

Title: Sex differences in hippocampal cytokine expression and signaling after myocardial infarction

Authors: *N. C. TRONSON, I. C. SPEIRS;
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Activation of the innate immune system by chronic illness or injury is correlated with depression, anxiety and PTSD. In patients of heart attack (myocardial infarction, MI), rates of major depression and PTSD diagnoses are two- and three-fold higher, respectively, than the population at large. Consistent with other patients of PTSD and depression, post-MI incidence of these disorders is correlated with increased levels of circulating pro- inflammatory cytokines. In addition, women are more susceptible to both PTSD and depression. The effects of systemic inflammation in causing cytokine expression in the brain, and the role of their intracellular signaling cascades on memory and depression-like behavior in females and males, remains unknown. In this study, we used a surgical model of myocardial infarction in mice to investigate the role of sustained peripheral inflammation on sex differences in learning, memory and depression-like behaviors. Multiplex analysis of cytokines specifically within the hippocampus, and determination of JAK/STAT signal transduction was determined in male and female mice in the months after MI. These changes were correlated with alterations in memory and depression like behavior. Here, male, but not female mice exhibited enhanced fear conditioning soon after MI. In contrast, both males and females showed impaired memory and depression-like behavior at later time points. Thus we demonstrate differential cytokine expression and JAK/STAT signaling in the hippocampus in males and females, and determined their role in altered memory and affect. These findings suggest cytokine-dependent signaling in the brain after systemic inflammation as a candidate mechanism for susceptibility to, or development of depression, PTSD, and cognitive impairments.

Essen, Essen, Germany; [5]German Ctr. for Neurodegenerative Dis., Magdeburg, Germany; [6]Inst. of Exptl. Immunol. and Imaging, Essen, Germany

Abstract: The pathophysiology of ischemic stroke resulting from the occlusion of arterial vessels which leads to irreversible neuronal cell injury is further aggravated by invading peripheral immune cells. Recently, the common concept that early brain infiltrates are mainly neutrophil granulocytes is controversially discussed. However, all these studies are based solely on histological and flow cytometric analysis of ischemic brain tissue. But the cellular dynamics of neutrophil entry and the direct consequences for the affected brain area have remained unclear. We show by intravital two-photon microscopy in mice that neutrophils immediately recognize endothelial activation in stroke-related brain areas and start rolling and firm adhesion on such sites. We also show the extravasation into the impaired brain parenchyma and that microglia within the brain recognizes both, endothelial damage and neutrophil invasion. In a cooperative manner they form membrane processes to physically shield activated endothelia and trap infiltrating neutrophils. Further we demonstrate that the systemic blockade of Very-late-antigen 4 (VLA-4) effectively inhibits endothelial interaction as well as brain entry of neutrophils, which reduces behavioral impairmentsCollectively these data shows, that the anti VLA-4 treatment is neuroprotective and a critical receptor for neutrophil entry into the inflamed brain in the first 3 days after stroke.

Title: Long-term consequences of early life stress on immune function in rhesus macaques

Authors: *P. J. PIERRE[1], C. L. COE[2], A. J. BENNETT[2];
[2]Psychology, [1]Univ. of Wisconsin-Madison, Madison, WI

Abstract: Human and animal studies demonstrate many profound and long-lasting negative health consequences of early life stress experiences (ELS), including those that disrupt social attachment relationships. Little is known, however, about the specific biological mechanisms by which these experiences alter individual's health across the lifespan. In this study, we used a well-validated nonhuman primate model of ELS (nursery-reared monkeys, NR) to assess the effects of infant experience on health in middle-age. Nursery-reared (NR) nonhuman primates exhibit robust alterations in many aspects of behavior and physiology that parallel those observed in humans who experience early life adversity. These include significant differences in immune function and health; however, little is known about the persistence of these effects into middle and older adulthood in nonhuman primates. This study evaluated the consequences of early differential rearing in multiple aspects of immune function in twelve sub-adult and twelve middle-aged male rhesus macaques, with six NR and six mother-reared (MR) monkeys in each age group . Blood samples were collected from animals lightly anesthetized for routine clinical health examinations. Samples were analyzed to provide white blood cell counts, platelet counts, mononuclear cell counts, number of lymphocytes and neutrophils. Cytokine concentrations, including interleukin-1 (IL-1), interleukin-6 (IL-6), interleukin-8 (IL-8), and tumor necrosis factor alpha (TNF), were assayed in whole blood cell culture under both unstimulated conditions and in response to stimulation with LPS (E. coli derived). Key measures of immune function were significantly affected by early rearing experience in both sub-adult and adult monkeys. NR animals had lower neutrophil counts and significantly increased IL-6 concentrations in response to LPS challenge. The groups did not differ in cytokine concentrations of unstimulated cells. Age also influenced multiple immune measures, with increased white blood cell counts, increased percentage of lymphocytes and neutrophils, and decreased IL-8 concentrations. Together these results demonstrate that the effects of early social experience can have persistent effects on immune function into the middle-life period and in absence of subsequent differences in diet, medical care, or other environmental factors.

Title: Acute neuroinflammation disrupts context-object discrimination but not novel object recognition

Authors: *J. CZERNIAWSKI[1], J. F. GUZOWSKI[2];
[1]Neurobio. & Behavior, [2]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Neuroinflammation is now widely implicated in the deleterious effects on neuronal function due to aging, disease, and trauma. In the event of immune system activation, there is a robust and transient increase of immune molecules, such as cytokines and chemokines, in the brain. Emerging data indicate that cytokines, such as IL-1β, IL-6, and TNF-α, can affect synaptic plasticity and learning processes. The hippocampus in particular appears to be vulnerable since the induction of an immune response in rodents tends to disrupt hippocampus-dependent tasks such as the Morris water maze and contextual fear conditioning, while leaving hippocampus-independent tasks such as the cued version of the water maze or auditory fear conditioning intact. However, whereas most of these studies have examined the effect of immune challenge on the acquisition or consolidation of memories, humans with a variety of neuroimmune disorders can also have problems in memory retrieval. Therefore it is important to have a behavioral paradigm that can assess the impact of neuroinflammation on retrieval in order to develop potential therapeutic agents. We have implemented the use of novel object recognition (NOR) and context-object discrimination (COD) tasks in order to assess the effects of acute neuroinflammation on retrieval. Both of these paradigms exploit the animals' natural tendency to explore novelty but NOR tests the ability to remember a previously experienced object, whereas COD tests the ability to recognize that a previously experienced object is in a different context. Importantly, COD is widely considered to be dependent on the hippocampus whereas NOR is not. Male Sprague Dawley rats were trained in COD or NOR for two days, followed by testing on the third day. Subjects received a low-dose (100ug/kg) of lipopolysaccharide (LPS) systemically 6 hours prior to testing, a timepoint during which we observe peak levels of IL-1β, IL-6, and TNF-α in dorsal hippocampus. Subjects that received systemic LPS injections preferentially explored a novel object similar to controls. However, unlike controls, subjects injected with LPS did not exhibit greater exploration of a familiar object in a different context during COD testing. There no were differences in total exploration between LPS and control subjects for either experiment. These data indicate that acute neuroinflammation impaired the retrieval of context-object associations. Subsequent studies will use Arc/Homer catFISH in order to assess the effect of LPS administration on neural circuit activity in these tasks and explore potential therapeutic agents to block the deleterious effect of LPS on cognitive processes.

Title: Antipsychotic potential of thalidomide in immune/inflammatory model for schizophrenia

Authors: *M. MIZUNO[1], H. NAWA[2], K.-I. NAGATA[1];
[1]Inst. For Developmental Research, Aichi Human Service Center,, Aichi, Japan; [2]Mol Neurobiol, Brain Res. Inst., Niigata Univ.,, Niigata, Japan

Abstract: Most of conventional antipsychotic drugs target monoamine receptors such as dopamine D2 receptors. In the present research, we aimed at developing a new class of antipsychotic drugs using the animal models for schizophrenia, which were established with maternal immune activation. We challenged pregnant mice and rats with bacterial lipopolysaccharides(LPS). At post-pubertal stage, these animals exhibited behavioral abnormalities in prepulse inhibition and social interaction. We examined the antipsychotic actions of immunomodulatory agents, thalidomide, which are known to attenuate inflammatory cytokine signaling. Subchronic p.o. administration of thalidomide for a week significantly ameliorated deficits of social interaction and prepulse inhibition in the animal model established with maternal LPS challenge. However, thalidomide alone did not affect weight gain and locomotor activity, suggesting no apparent side effects. Currently we are investigating the behavioral effects of thalidomide in these animal models. These results suggest that immunomodulatory or anti-inflammatory agents may be a new class of antipsychotic drugs for schizophrenia.

Abstract:
Major depressive disorder (MDD) is one of the leading causes of disability worldwide associated with persistent feelings of sadness, depressed mood, anhedonia and suicidal thoughts. In addition to the traditional hypothesis of monoamine deficiency, inflammatory responses are emerging as potential contributors towards the development of
depression symptoms in humans. Earlier reports indicated that a single injection of *Bacillus Calmette-Guerin* (BCG) vaccine results in a brief period of serum sickness followed by a long lasting depression-like phenotype in mice; however the responsiveness of BCG-induced depressive behavior to pharmacological treatment has not been extensively characterized. In the present study we induced depression-like behaviors in male BALB/c mice by administering the BCG-vaccine at a dose of 10^9 cells/mouse, i.p. A single injection of BCG-vaccine produced an inflammatory response including elevation of plasma IL-6 and IFN-gamma levels 24-hours after administration. We also observed a robust decrease in body weight and a reduction in locomotor activity and voluntary wheel running in BCG-treated mice compared to saline-treated
animals. Time course analysis showed a gradual recovery from serum sickness followed by the development of a significant depression-like phenotype, namely increased immobility in the FST and TST tests, from day 14 onwards and lasting up to 28 days post-BCG administration. We also observed a significant increase in indoleamine 2, 3-dioxygenase (IDO) activity in the lungs on day-14 post BCG, which is the rate limiting enzyme involved in the synthesis of serotonin from tryptophan and plays major role in cytokine-induced depression. Investigation of acute antidepressant treatment showed that the depressive behavior was resistant to selective serotonin reuptake inhibitors (SSRIs; escitalopram, fluoxetine and citalopram) whereas dual (duloxetine and nomifensine) and triple monoamine reuptake inhibitors (AMR-002) showed an antidepressant effect. Resistance to SSRIs was observed despite achieving high levels of SERT occupancy in BCG-treated mice. In
summary, our results suggest that depression-like behaviors in BCG-treated mice are selectively resistant to acute SSRI treatment.

Title: Neuroinflammation as a consequence of cardiac ischemia-reperfusion

Authors: *B. JOHNSTON[1], M. E. YOUNG[2], L. L. MCMAHON[3], T. M. DESILVA[1];
[1]Dept. of Physical Med. and Rehabil., [2]Div. of Cardiovasc. Dis., [3]Cell, Developmental and Integrative Biol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: While procedural advances have greatly improved survival following heart failure over the past decade, a number of studies have presented evidence for an association between heart failure and cognitive impairment in survivors. Indeed, patients with heart failure have damage to the hippocampus, a brain region critical for normal learning and memory, and reduced volume in the parahippocampal gyrus which projects to the hippocampus. Clearly, further elucidation of the underlying pathophysiology is important for developing therapeutic strategies to prevent cognitive decline in heart failure patients. Ischemic heart disease is the primary cause

of heart failure, which is a chronic failing of the heart to efficiently supply blood to meet the needs of the body. To establish if heart failure results in hippocampal changes in an animal model we used an open and closed-chest acute myocardial ischemia/reperfusion injury. We observed an increase in hippocampal inflammation compared to sham animals within 72 hours of the ischemic event. Furthermore, four months after acute myocardial ischemia/reperfusion deficits in hippocampal learning and memory were observed compared to sham and control animals. We therefore hypothesize that following cardiac ischemia/reperfusion in mice, immediate inflammation ultimately results in cellular damage to the hippocampus, deficits in synaptic function and plasticity at hippocampal synapses, and impairment in hippocampal dependent learning and memory.

Title: REM Selective sleep deprivaction alters intestinal mucosa integrity of wistar rats

Authors: *E. G. IBARRA CORONADO[1], A. M. PANTALEÓN-MARTÍNEZ[1], J. VELÁZQUEZ-MOCTEZUMA[2], A. PÉREZ-TORRES[3], V. RODRIGUEZ-MATA[3]; [1]Inmunologia, Inst. De Investigaciones Biomedicas, UNAM, Mexico DF, Mexico; [2]Dept. de Biología de la Reproducción, Univ. Autonóma Metropolitana - Iztapalapa, México, DF, Mexico; [3]Dept. de Biología Celular y Tisular, Facultad de Medicina, UNAM, México, DF, Mexico

Abstract: Sleep is considered as a fundamental process to maintaining the physiological functions of an organism. It has been shown that sleep deprivation affects the development of and adequate immune response, since it decreased the antibody levels generated against the hepatitis A vaccine. Moreover, specific REM sleep deprivation, produces changes in both number of immune cells and cytokine levels (IL-1, IFNγ, TNFα, IL-6 and IL-17). Addittionally, it has been documented that sleep deprivation promotes the translocation of bacteria from the intestinal mucosa to extra-intestinal sites, compromising the immune system. These findings, show that sleep deprivation alters some of the components related to the immune system, and probably impaired an adequate immune response The aim of our work was to analyze whether REM sleep deprivation alters the mechanisms related to the innate immune response, such as the

integrity of intestinal mucosa, that is considered as the first line of defense against pathogens. Our results, demonstrate that REM sleep deprivation produces an inflammatory infiltrate in the lamina propria of the intestinal villi, which is characterized by an increase in the number of eosinophils and mast cells present in the periglandular area. Concomitantly, there is an increase in expression of IFN-γ and IL-1β. Additionally, epithelium shows an increase in villi detachment, and a decrease in the expression of occludins, which are part of the tight junctions in the intestinal epithelium. Our findings suggests that, the defense mechanisms related to innate immune responses are affected by selective REM sleep deprivation. In this way, translocation of pathogens from the gut, which has been reported in other work, can be mediated by the alteration produced on such molecules involved in maintaining the integrity of the intestinal mucosa, thus it may compromise the ability of the innate immune system to establish an adequate response to infection.

Title: Effects of repeated voluntary or forced exercise on rat brain thermosensitive serotonergic systems

Authors: *M. ARNOLD, B. N. GREENWOOD, J. A. MCARTHUR, P. J. CLARK, M. FLESHNER, C. A. LOWRY;
Integrative Physiol., Univ. of Colorado, Boulder, CO

Abstract: Exposure of rats to elevated ambient temperature activates subpopulations of brainstem serotonergic neurons in the dorsal raphe nucleus (DR), the main source of serotonergic innervation of the forebrain. Thermosensitive subpopulations of serotonergic neurons include those in the "lateral wings" of the DR, also referred to as the dorsal raphe nucleus, ventrolateral

part/ventrolateral periaqueductal gray (DRVL/VLPAG) and those in the interfascicular part of the dorsal raphe nucleus (DRI). DRVL/VLPAG serotonergic neurons are thought to be sympathomotor command neurons involved in inhibition of sympathetic outflow, while DRI serotonergic neurons project to forebrain areas involved in cognitive function and mood, such as the prefrontal cortex and hippocampus, and are thought to be involved in stress resilience. Prior studies have shown that either voluntary or forced wheel running for six weeks has stress resistance effects in rodent models, effects that are dependent on alterations in serotonergic function. It is unclear how voluntary exercise is associated with activation of the DRVL/VLPAG and DRI serotonergic neurons and how this activation is associated with the stress resilient effects of voluntary exercise. Considering the outcomes of the above studies, the objective of the current study was to determine if voluntary or forced wheel running activates DRVL/VLPAG and DRI serotonergic neurons. To investigate this question we conducted two studies. The first study examined expression of the protein product of the immediate-early gene, c-fos, and tryptophan hydroxylase (TPH) using immunohistochemistry in rats exposed to either 1) chronic voluntary exercise for 6 weeks or 2) sedentary control conditions for 6 weeks. The second study included a third treatment group in which rats were exposed to forced exercise for 6 weeks. In Study 1, rats exposed to repeated voluntary exercise had increased c-Fos expression in non-serotonergic neurons within the DRI, relative to sedentary controls. In Study 2, we replicated the findings in Study 1. In addition, rats exposed to repeated forced exercise, but not repeated voluntary exercise, had increased c-Fos expression in serotonergic neurons in the DRI. These results suggest that repeated forced exercise, but not repeated voluntary exercise, activates DRI serotonergic neurons, an effect that may contribute to the recently described stress resilience effects of forced exercise. These results also suggest that the stress resistance effects of chronic voluntary and forced exercise may involve different mechanisms.

Title: Neuronal Interleukin-1β expression initiates inflammation leading to neonatal brain injury induced by combined lipopolysaccharide and hypoxia-ischemia

Authors: *A. SAVARD, D. GRBIC, D. GRIS, G. SEBIRE;
Pediatry, Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: Background: Perinatal hypoxia-ischemia (HI) and infection-inflammation are the principal risk factors of cerebral injuries in newborns. Strikingly, clinical and pathological features of human perinatal brain lesions present variations according to gestational ages. Recently we developed a new preclinical rat model of perinatal induced brain injury at a neurodevelopmental stage equivalent to human term newborn. In this model, lipopolysaccharide (LPS) combined with HI, induced severe damage similar to human brain damage observed in term newborn. Interestigly, the brain lesions were spatially and temporally linked to the expression of IL-1β.
Objective: We hypothesize that neurons constitute the primary source of IL-1β during HI inflammatory challenge. In addition, this neuronal IL-1β triggers cascade of deleterious events leading to exacerbation of brain pathology.
Method: P12 (post-natal day 12) Lewis rat pups were injected with LPS or saline 4h before HI. The right common carotid artery is permanently ligated; 30 min later, pups are exposed to 8% O2 for 1h30.. Brains were studied at different time points for cytokine and chemokine immunoreactivity, polymorphonuclear neutrophil (PMN) infiltration and histological measures of the brain damage. Rats' behaviour assessment was documented after 5 months using Open field, Elevated body swing and Turning in alley tests.
Results: Our results show that IL-1β is strongly expressed early (4 h) after LPS+HI exposition in fronto-parietal neocortical neurones. This neuronal expression is maintained at 24 h and 48 h after LPS+HI exposition with a delayed contribution of glial cells (astrocytes) at 48 h. IL-1β expression then leads to chemokine (MCP-1 and CINC-1) activation and to massive gliosis and neutrophil infiltration starting at 48 h after LPS+HI exposition. LPS+HI-exposed rats showed long-term motor impairments that were prevented by IL-1β blockage. Throughout our experiments we noted only weak increases in the TNF-α expression in microglia and astrocytes.
Conclusion: These results show that neurons are the first cells to express IL-1β and initiate the neuroinflammatory cascades leading to severe brain damage and long term motor impairments in LPS+HI-exposed rats.

Title: Effects of morphine on inflammation and the blood-brain barrier in the LP-BM5 AIDS model

Authors: *V. D. MCLANE, L. CAO, C. L. WILLIS;
Col. of Osteo. Med., Univ. of New England, Biddeford, ME

Abstract: Even in the age of highly active antiretroviral therapy, ~20% of human immunodeficiency virus (HIV)-1 infected patients develop cognitive deficits ranging from mild memory loss to dementia. Opioid abuse accelerates cognitive deficit onset and increases central nervous system (CNS) viral load in HIV-1 patients. Opioids such as morphine facilitate the glial inflammatory response to HIV proteins, increasing production of proinflammatory cytokines (tumor necrosis factor-α, interleukin (IL)-1β, regulated on activation, normal T cell expressed and secreted (RANTES, aka CCL5), IL-6, etc.). These cytokines have been shown to reduce blood-brain barrier (BBB) integrity in vivo, which would allow increased access of peripheral virions and infected cells to the CNS, furthering the inflammatory state.
We hypothesized that morphine potentiates BBB breakdown through enhancing CNS inflammatory responses, leading to increased cognitive deficits. To test this, we examined the effects of chronic morphine administration in the LP-BM5-induced murine acquired immunodeficiency syndrome (MAIDS) mode in vivo. 8-week-old male C57Bl/6Ncr mice were injected intraperitoneally with 5x10^4 plaque-forming units of LP-BM5 retroviral mixture. At 7 wks post-infection, morphine (25 mg) or placebo pellets were implanted subcutaneously and replaced 3 days later. Tissues were collected at 8 wks. We then analyzed viral load, cytokine production, and BBB integrity through immunoassays and quantitative real-time (q-rt)PCR. Morphine treatment did not impede the peripheral progression of LP-BM5 infection, as measured by spleen weight, serum IgG and IgM, and tissue viral loads. Spleen cytokine levels did not differ significantly between morphine and placebo-treated LP-BM5 mice. However, CCL5 RNA expression decreased significantly in the frontal lobe of morphine-treated infected mice, suggesting a potential anti-inflammatory role for morphine in the CNS. CNS IL-1β and TNF-α did not show a significant change. Further, immunohistochemistry of the LP-BM5-infected hippocampus revealed increased leak of IgG into the brain parenchyma and loss of claudin-5, a tight junction protein, from the paracellular cleft of brain endothelial cells, indicating

compromised BBB integrity. Morphine treatment did not significantly modify BBB integrity in infected mice. Our work correlates elevated CCL5 with LP-BM5-induced BBB dysfunction. Chronic morphine treatment abolished the CCL5 response, yet did not improve BBB integrity and CNS viral load. There may therefore be a novel pathway for morphine-potentiated blood-brain barrier dysfunction in HIV infection.

Title: Plasma membrane progesterone receptors A and B do not complex with dopamine D1 receptor in the arcuate nucleus of the hypothalamus

Authors: *M. MAHAVONGTRAKUL, J. PHAN, K. SINCHAK;
Biol. Sci., California State University, Long Beach, Long Beach, CA

Abstract: Ovariectomized (OVX) rats primed with 2μg of estradiol benzoate (EB) and 26 hours later given 500μg progesterone show maximal sexual receptivity four hours later. EB primes some lordosis facilitative circuits through upregulation of classical progesterone receptors (PR-A & PR-B) necessary for facilitation of lordosis. These PR are classical transcription factors that are localized to the nucleus and cytoplasm. Although PR has been thought to signal primarily in the nucleus, *in vitro* PR expression studies have demonstrated presence of PR-A and PR-B on the plasma membrane (Pedram et al., 2007; Welter et al., 2003). Further, progesterone has been shown to facilitate lordosis within 30 minutes, indicating that a rapid PR signaling mechanism is involved. Similarly, estradiol rapidly activates an inhibitory lordosis circuit through estrogen receptor-α that is trafficked to the plasma membrane (mERα) that complexes with and transactivates metabotropic glutamate receptor-1a (mGluR1a) to activate a multisynaptic circuit originating in the arcuate nucleus of the hypothalamus (ARH). Subsequent progesterone deactivates this circuit to facilitate lordosis, presumably through classical PR signaling. PR are necessary for the estradiol + progesterone facilitation of lordosis, but without dopaminergic neurotransmission via the dopamine D1 receptor (D1), progesterone facilitation of lordosis does not occur (Mani et al., 1994; Mani et al., 1996). However, it is unclear where D1 signaling occurs and whether a direct PR-D1 interaction occurs as seen with mERα and mGluR1a. To

determine whether D1 complexes with PR-A or PR-B on the plasma membrane in the ARH and mediobasal hypothalamus (MBH), OVX rats were treated with oil or 2µg EB and plasma membrane fractions were extracted from block dissections of the ARH and MBH. Although Western blots revealed D1 and PR-A and PR-B were present in the plasma membrane, co-immunoprecipitation demonstrated neither PR-A nor PR-B complexes with D1. These results suggest that although classical PR are found on the plasma membrane in the ARH and MBH, progesterone does not appear to signal through these PR complexed with D1 to facilitate lordosis. Although D1 and PR signaling pathways act through the same lordosis regulatory circuit, D1 may regulate PR interacting with and signaling through Src kinase. Alternatively, progesterone may be acting on a recently discovered group of membrane PR that may be mediated by dopamine signaling.

Title: Free estradiol signals through G-protein coupled receptor 30 (GPER) to rapidly facilitate lordosis via deactivation of medial preoptic nucleus-µ-opioid receptors in estradiol primed rats

Authors: *N. P. LONG[1], C. S. SEREY[1], A. WELBORN[2], K. SINCHAK[1];
[1]Biol. Sci., [2]Psychology, California State Univ. Long Beach, Long Beach, CA

Abstract: Facilitation of sexual receptivity (lordosis) can be rapidly induced in a 2 µg estradiol benzoate (EB) primed female rat by a less used paradigm. Instead of progesterone, free 17β-estradiol (E2) can be given 47.5 hours after priming and 30 minutes later lordosis is facilitated. Previously, our research showed that the E2 given 47.5 hours is acting through the G protein coupled estrogen receptor 30 (GPER; aka GPR30) to facilitate lordosis. Antagonism of the opioid receptor-like receptor 1 (ORL-1) blocked the rapid E2 facilitation of lordosis. Estradiol priming initially inhibits lordosis through a multi-synaptic circuit in the arcuate nucleus of the hypothalamus (ARH) that stimulates β-endorphin release that activates and internalizes µ-opioid receptors (MOP) in medial preoptic nucleus (MPN) neurons. Deactivation of MPN MOP by

either 1) subsequent progesterone; 2) exposure to high levels of estradiol for 48 hours, or 3) activation of the ORL-1 (receptor of orphanin-FQ; OFQ) in the ARH facilitates lordosis. We tested the hypothesis that free E2 activation of GPER rapidly facilitates lordosis through deactivation of MPN MOP that is mediated by ORL-1 activation. Ovariectomized Long Evans rats implanted with a third ventricle (3V) cannula were primed with 2 µg EB. DMSO control or E2 was infused into the 3V 47.5 hours later, 30 minutes later rats were tested for sexual receptivity measured by lordosis quotient (LQ). E2 and G1 (GPER agonist) infused rats had a higher LQ compared to the DMSO controls ($P < 0.001$; E2 LQ 88.57 +/- 4.58; G1 LQ 90.00 +/- 7.56; DMSO LQ 6.00 +/- 4.00) which was blocked by pretreatment with G15 (GPER antagonist) or UFP101 (ORL-1 antagonist: $P < 0.05$; G15+E2 LQ 10 +/- 5.16; G15+G1 LQ 16.67 +/- 9.89; UFP101+E2 LQ 5.00 +/- 2.45). Four days later, drug treatments were repeated and brains were processed for MPN MOP immunohistochemistry and MOP activation as measured by MOP immunofluorescence staining intensity (MORi) levels. Infusions of E2 and G1 both deactivated MOP significantly as compared to DMSO controls and pretreatment with G15 and UFP101 ($P < 0.001$; E2 MORi 88.60 +/- 1.33; DMSO MORi 128.31 +/- 2.55; G1 MORi 90.49 +/- 1.27; G15+E2 MORi 127.46 +/- 3.38; G15+G1 MORi 132.09 +/- 1.37; UFP101+E2 MORi 134.81 +/- 1.39). Collectively, these data support our hypothesis that, E2 rapidly signals through GPER to deactivate MPN MOP and facilitate lordosis which is mediated by the activation of ORL-1. Thus, all three steroid priming paradigms signaling mechanisms converge to deactivate ARH β-endorphin neurons that project to the MPN facilitate lordosis.

Title: Localization of the nucleus accumbens in Japanese quail and European starlings based on hodological, immunohistochemical and functional criteria

Authors: *O. IYILIKCI[1], B. ALWARD[1], A. GILMOUR[1], J. BALTHAZART[2], G. F. BALL[1]; [1]Johns Hopkins Univ., Baltimore, MD; [2]Univ. of Liege, Liege, Belgium

Abstract: In mammals, nucleus accumbens (NAc) is a well-defined ventromedial forebrain structure that plays a critical role in regulating motivation and reward mechanisms. However, the

exact anatomical location of the NAc, its subdivisions and its function in avian species has been a controversial subject. The present study, therefore, aimed to investigate the exact anatomical location of the NAc and its subdivisions based on hodological and histochemical markers. Drawing on these anatomical findings we also aimed to elucidate if the avian NAc plays a role in female appetitive sexual responses similar to its mammalian homologue. Here we examined the hodology of the putative NAc by stereotaxically injecting a biotinylated dextran amine (BDA) as a neuroanatomical tracer in Japanese quail and in European starlings. One week after the injections, subjects' brains were prepared for immunohistochemical labeling of BDA. At low molecular weights (3kDa), BDA retrogradely labels cell bodies that send projections to the injection site. Our results demonstrated afferent inputs to NAc from hippocampus (Hp), ventral tegmental area (VTA), bed nucleus of stria terminalis (BNST), raphe pallidus (Rp), periaqueductal central gray (PAG), lateral preoptic area (lPOA), as well as ventral and dorsal corticoid plate region of mesopallium (MVcp and MDcp). We also examined the distribution of serotonin transporter (SERT) in order to histochemically demarcate NAc and BNST. Our localization of NAc via immunohistochemical markers is in concordance with previous avian studies, which used different immunomarkers. In addition, the afferent hodology of NAc in avian species indicated by the findings of the present study is congruent to its mammalian homologue. Building on these hodological and immunohistochemical findings, we examined the expression of the immediate early gene Zenk in female European starlings that had been exposed to sexually attractive male song. Our results demonstrated an increase in Zenk-immunoreactivity (ir) in response to male song, consistent with a role for the NAc in female sexual motivation. We are also testing Zenk-ir in female Japanese quail in response to conspecific male crows. Overall, the present study explicated the anatomical location of the avian NAc. Additionally, we demonstrated that the hodology and function of avian NAc is congruent with its mammalian homologue.

Title: Estrogens control female sexual motivation and receptivity in quail

Authors: C. DE BOURNONVILLE[1], G. F. BALL[2], J. BALTHAZART[1], *C. A. CORNIL[1]; [1]GIGA Neurosciences, Univ. Liege, Liege, Belgium; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Estrogens are known to regulate female sexual behavior in quail. Sexual behavior can be divided into different components: appetitive behavior (reflecting motivation) and consummatory behavior (copulatory performance). Recently, it was demonstrated that brain-derived estrogens acutely control male sexual motivation but not performance. In females, repeated peripheral administrations of tamoxifen (an estrogen receptor antagonist) decreases receptivity in females. Whether this effect on receptivity reflects estrogen's action on sexual motivation or performance is not known. To study this question, we designed sexual motivation tests for females in which they could either approach a tethered male in an empty arena or choose to approach either a male or a female that were similarly tethered. Experimental females were treated with tamoxifen (2mg/animal/day) or the vehicle for 15 consecutive days. Treatment was then stopped for 18 days to test for a possible recovery. Females were repeatedly tested for sexual motivation and sexual receptivity throughout the experiment. Female receptivity and motivation to approach a male were strongly decreased by the tamoxifen treatment. During the 18-day recovery period, tamoxifen-treated females significantly increased their receptivity but did not completely recover to their basal level of receptivity. In conclusion, these results suggest that the deficit in receptivity induced by estrogen blockade likely results from a reduction in sexual motivation in female quail. Future studies should investigate the source of the estrogens mediating these motivational effects. Indeed, although female ovaries produce large amounts of estrogens, the female brain also contains aromatase, the rate-limiting enzyme for estrogen synthesis. Brain aromatase in females is controlled by estrogens (inhibited by chronic tamoxifen treatment) and can be rapidly regulated by environmental stimuli. It is thus conceivable that, as in males, some of the neuro-active estrogens in females are produced locally.

Title: Differential effects of global versus local testosterone on song behavior and its underlying neural substrate

Authors: *B. A. ALWARD[1], J. BALTHAZART[2], G. F. BALL[1];
[1]Psychological and Brain Sci., The Johns Hopkins Univ., Baltimore, MD; [2]GIGA Neurosciences, Univ. de Liege, Liege, Belgium

Abstract: Testosterone (T) has multiple effects on sexually-motivated song in male songbirds, regulating both the motivation to sing as well as its quality. However, the brain region(s) where T acts to regulate these different aspects of song behavior have not been definitively characterized. One candidate site where T might exert its influence on song motivation is the medial preoptic nucleus (POM). POM lesions block male-typical sexual behaviors and the action of T in the POM is sufficient to activate male sexual motivation and performance in birds and mammals. We hypothesized that song, at least in part, is regulated by T action in the POM. We tested this by implanting T into the POM of castrated male canaries (Border strain) and assessing song rate and acoustic features as well as stereotypy, a measure of song quality. We also presented a female to males to assess the activation of sexual behaviors in her presence. We demonstrate that T in the POM was sufficient to induce song rate to levels similar to those in birds with globally circulating T, but took longer to exhibit a significant difference from baseline levels as compared to castrated birds with blank implants (about 9 days versus 3). On the other hand, T in the POM was unable to induce song stereotypy to levels of birds with global T. Castrated birds treated with T peripherally had larger volumes of song nuclei as compared to castrates with blank implants but strikingly canaries receiving T in the POM had song control nuclei volumes as large as birds receiving global T, suggesting activity-induced neuroplasticity. We also show that T in the POM is sufficient to activate copulation in canaries but not the number of calls or peri-copulatory songs made in her presence. These results suggest that while T in the POM is sufficient for activating song rate and copulation, T must act elsewhere to induce normal song latency, stereotypy, as well as vocalizations made in the presence of a female. These results support the conserved role of T actions in the POM in regulating male sexual behaviors specifically and that T acts at multiple brain loci to regulate specific aspects of singing behavior in songbirds.

Title: Androgen receptor protein is increased in the hypothalamus of male compared to female green anole lizards during the breeding season

Authors: *H. KERVER, J. WADE;
Neurosci., Michigan State Univ., East Lansing, MI

Abstract: Green anole lizards are seasonal breeders, with an annual rise testosterone (T) regulating male sexual behavior. T has dramatic effects on masculine behavioral, morphological, and biochemical functions during the breeding season (BS), but these effects are not mirrored in the non-breeding season (NBS) and are limited in females. Data suggest that T acts at androgen receptors (AR). Therefore, we hypothesized that increased AR protein expression in the hypothalamus in the BS facilitates the seasonal responsiveness to T in males. We also hypothesized that two AR coactivators, steroid receptor coactivator-1 (SRC-1) and CREB binding protein (CBP), are involved. Here we performed Western blot analyses on hypothalamic samples dissected from adult males and females from both the BS and NBS. Two experiments were completed, the first on gonadally intact animals and the second on gonadectomized animals that received either a blank or T-filled pellet. No significant effects of sex or season were detected for any of the three proteins in the intact animals (all $F \leq 1.47$, $p \geq 0.239$). Manipulated animals in the second study also exhibited no main effects of sex, season, or treatment for AR ($F \leq 2.23$, $p \geq 0.333$), but there was a significant sex x season interaction ($F=14.10$, $p<0.001$). A two-way ANOVA for sex and season confirmed this interaction ($F=15.20$, $p \leq 0.001$), and within the BS, AR was increased in the hypothalamus of males compared to females ($t=4.11$, $p<0.001$). There were no differences in AR expression between sexes in the NBS ($t=1.79$, $p=0.086$) or across seasons in males ($t=1.70$, $p=0.100$). Among females, more AR was expressed in the NBS than BS ($t=3.74$, $p=0.001$). Treated animals showed no effects on CBP ($F \leq 0.90$, $p \geq 0.347$) or SRC-1 expression ($F \leq 1.19$, $p \geq 0.282$). Differences between the two experiments may be due to increased sample size and/or removal of gonadal influences in the second study. Collectively, the results are consistent with the idea that relative levels of AR expression may facilitate sex differences in hypothalamic structure and function. However, it does not appear that AR, SRC-1 or CBP in this general region of the brain regulate seasonal differences in responsiveness to T.

Title: Effects of chronic RU486 on the sensitization of sexual behaviors by repeated estradiol benzoate in the ovariectomized Long-Evans rat

Authors: *S. JONES, J. GARDNER GREGORY, J. G. PFAUS;
CSBN/Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Sexual behaviors in the ovariectomized (OVX) rat are partially restored by an acute injection of estradiol benzoate (EB), and fully restored by a subsequent injection of progesterone (P). Repeated injections of 5µg or 10µg EB, but not 2µg EB, administered alone every 4 days to sexually-experienced OVX rats results in a the sensitization of sexual behaviors, since successively greater sexually appetitive behaviors (hops, darts, & solicitations) and lordosis quotients (LQ) are observed. Previous research has suggested that P receptors are not involved in the expression of sexual behavior by estradiol alone (Blaustein et al., 1987). Here we tested whether chronic injections of the P receptor antagonist, RU486, would alter the development of behavioral sensitization by repeated injections of EB. Females were treated with EB (5 or 10µg), and 5mg RU486 dissolved in 0.4mL vehicle (VEH; 80% sesame oil, 15% benzyl benzoate, 5% benzyl alcohol) 48 and 4 hours prior to each of 7 tests, respectively, occurring at 4-day intervals in unilevel 4-hole pacing chambers. Control animals were treated with 2, 5, or 10µg EB+VEH. As expected, sensitization did not occur in females treated with 2µg EB+VEH. LQ sensitized across tests in all other groups, however RU486 attenuated LQ on the two final test days. Appetitive behaviors sensitized in the RU486 groups, however this sensitization was also attenuated on the two final test days. Interestingly, appetitive sexual behaviors did not sensitize in females treated with VEH. In accordance with Pleim et al., (1990), RU486 given in combination with 5µg, or 10µg EB, facilitates sexual behavior by inducing more appetitive sexual behaviors, and higher LQ compared to VEH. Despite the initial facilitation, however, blocking P receptors by chronic administration of RU486 appears to inhibit, or disrupt the maintenance of, the sensitization of sexual behaviors by repeated administration of EB.

Title: Effects of progestins in the modulation of sexual receptivity in female mice

Authors: L. E. GRIJALVA[1], O. GONZÁLEZ-FLORES[2], F. J. CAMACHO[1], *N. F. DIAZ[3], S. K. MANI[4], R. G. PAREDES[1], W. PORTILLO[1];

Abstract: Progesterone (P) can be rapidly metabolized in the central nervous system to the ring A reduced metabolites progestins. These, steroids have low affinity for the P receptor (PR), but induce female sexual receptivity with a higher potency than P in estrogen primed rats. In addition, the receptivity induced by P is followed by a period in which female do not respond behaviorally to a second administration of P (sequential inhibition). The aim of the present study was to evaluate the role of several ring A reduced progestins to induce sequential inhibition in estrogen primed female mice. Female mice that were treated with estradiol benzoate (EB) plus P which 24 hours later received a second dose of P, were not sexually receptive. Female mice treated with EB plus 5b Pregnanedione (5b DHP), 5a3b or 5b3a Pregnanolone (5a3b PGL and 5b3a PGL respectively) a second P dose (24 hours later), induced high levels of receptivity. These observations indicate that progestins with low affinity for the PR do not induce sequential inhibition. We also evaluated the effect of ring A reduced progestins in mutant mice, which are deficient in PR (PRKO) and compared to their wild type (WT) littermates. WT females treated with EB plus P administration showed high levels of receptivity compared to the PRKO. Administration of EB plus 5b3a or 5a3b PGL facilitated high levels of receptivity in WT and

PRKO animals. Furthermore, WT females treated with EB plus 5b3a or 5a3b PGL that received P 24 h later showed high levels of receptivity. The same treatment failed to induce receptive behavior in PRKO females. Taken together, these data suggest that progestins do not induce sequential inhibition. They also show that 5b3a or 5a3b PGL can induce sexual receptivity by an independent mechanism of nuclear PR.

Title: Ovarian steroids modulate dopamine receptor binding in the medial preoptic area of female rats

Authors: *M. GRAHAM, D. HUSSAIN, W. G. BRAKE, J. G. PFAUS;
CSBN-Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Dopamine (DA) transmission in the medial preoptic area (mPOA) plays a critical role in the control of appetitive sexual behavior in the female rat. We have shown previously that a DA D1R-mediated excitatory state appears to occur in females primed with estradiol benzoate (EB) and progesterone (P), whereas a DA D2R-mediated inhibitory state appears to occur in EB-alone females. We have also found evidence of DA receptor (DAR) modulation by hormonal administration, through examination of protein levels using the Western blotting technique. These data indicate that females treated with EB+Oil show reduced DA D1R in the mPOA, while adding progesterone (EB+P) increases these receptor levels. A similar effect was found in the prelimbic cortex (PLC), but no differences were found in the caudate putamen (CP), control areas examined due to their role in female sexual behaviour and presence of high levels of DA. To better understand the changes that occur to DAR following hormone administration, the present experiment used in vitro quantitative receptor autoradiography to quantify the amount of DA D1R binding levels in the mPOA, CP, and PLC. Ovariectomized rats were randomly assigned to one of three steroid treatment groups: EB+P (10 μg and 500 μg, respectively), EB+Oil, Oil+Oil. Hormone injections were administered 48h and 4h prior to sacrifice, and the density of binding sites in the CP, PLC, and mPOA were compared following incubation periods

of 4, 6, and 12 weeks, respectively. Similar to the results of the Western blotting, hormonal administration alters DA D1R binding levels in the mPOA, as females treated with EB+Oil show decreased binding levels, and those in the EB+P group show increased binding levels. Binding levels did not differ in the other two areas examined. These data confirm the DA receptor protein changes observed in our previous studies, and provide further evidence that EB+Oil females may have a low DA D1R/D2R ratio, and EB+P females may have a high DA D1R/D2R ratio.

Title: Absence of pubertal ovarian hormone exposure induces higher activity, but not receptivity, in hormone-primed adult female rats

Authors: *S. H. MEERTS, M. E. FARRY-THORN, L. K. DAIRAGHI, W. KAY, N. MASON, R. S. SCHAIRER;
Carleton Col., Northfield, MN

Abstract: The female phenotype has long been thought to be the default developmental pathway, occurring in the absence of gonadal hormone exposure, but recent evidence has demonstrated prepubertal organizational effects of estradiol in females. The role of estradiol in organizing the female brain during puberty is not well understood. We hypothesized that without pubertal exposure to ovarian hormones, female rats would show more feminine behavior in adulthood when primed with estradiol benzoate (EB) and progesterone (P) due to a heightened sensitivity to EB/P. Here we tested whether pubertal ovarian hormones affect the display of lordosis and activity in adulthood following hormone treatments known to induce either full or partial receptivity. Female Long-Evans rats were ovariectomized before puberty (No-O@P) or after puberty (O@P). Four weeks after ovariectomy rats received two cycles of EB/P in the two weeks before experimental procedures began to facilitate vaginal opening in No-O@P rats. Receptivity was assessed with a 10-stimulation lordosis quotient (LQ) test followed immediately by a 10-min open field activity test. Rats were tested for receptivity and activity after full hormone priming (10 ug EB 48h and 1 mg P 4h prior to tests) and one week later after administration of subprime hormone treatment (2 ug EB 48h and 500 mg P 4h prior to tests).

O@P and No-O@P rats did not differ in terms of receptivity under either hormone-priming regimen, but with subprime hormone treatment No-O@P rats took significantly longer to receive 10 stimulations in the LQ test and exhibited significantly more arena crossings in the open field test than O@P rats. The elevated activity in No-O@P rats could either have been due to the absence of pubertal hormone exposure alone or in combination with the neuroendocrine cascade induced by the preceding mating. Therefore, the rats received two additional open field tests. First, rats received full hormone priming prior to mating and then activity was assessed after rats received 15 intromissions. One week later, rats were again fully EB/P-primed and activity assessed with no preceding mating. No-O@P rats only showed significantly elevated activity levels relative to O@P rats when tested immediately after mating, suggesting that some aspect of mating triggers elevated activity in No-O@P rats. Thus, the presence or absence of ovarian hormones during puberty affects activity, but not receptivity, indicating that the female rat brain is organized to some degree by pubertal ovarian hormones. Additional research is necessary to pinpoint the role of ovarian hormones in pubertal organization of the female rat brain.

Title: Vasopressin and dopamine neurons are activated in female rats that display conditioned mate-guarding behavior

Authors: *A. HOLLEY, S. BELLEVUE, S. ROORDA JR, D. VOSBERG, J. G. PFAUS; Concordia Univ., Montreal, QC, Canada

Abstract: Rats are often described as having a polygamous mating strategy, yet through simple Pavlonian conditioning paradigms, where neutral odors are paired with sexual reward states, rats can develop conditioned sexual partner preferences, where they prefer to solicit, copulate, and mate with scented familiar partners over unscented unfamiliar ones. We have previously shown that ovariectomized female rats primed fully with estradiol and progesterone do not need odors if they are paired with the same male for their first 10 paced sexual experiences: They are able to recognize their partner male based on primary cues alone and will display rudiments of mate-

guarding behavior when placed in a situation where defending their mate is required. In the present study we used double-immunocytochemistry to examine the induction of Fos protein within vasopressin neurons of the PVN and SON, or within the dopamine neurons of the ZI, VTA, and SN of females that display conditioned mate guarding in the presence of their familiar male and another female in an open field, relative to females that copulated with a random male and another female. Conditioned rats showed significant activation of vasopressin neurons in both regions relative to unconditioned, non-partner rats. Conditioned rats also showed significant activation of dopamine neurons in the ZI and VTA compared to unconditioned rats. These findings indicate that female rats are not hard-wired to be polygamous, and that early experience with sexual reward that is conditioned with the same male induces conditioned mate-guarding behavior in the presence of that male when a novel female is present as a competitor. This behavior is accompanied by significant induction of Fos within vasopressin and dopamine neurons relative to the near absence of vasopressin and dopamine activation in non-partner females who copulate but do not display conditioned mate-guarding behavior.

Title: Gene expression in the mPOA of copulating and sexually sluggish male rats

Authors: A. GONZÁLEZ-GALLARDO, *W. PORTILLO, C. GARCÍA-UGALDE, R. G. PAREDES, A. ANTARAMIAN;
NEUROBIOLOGIA CONDUCTUAL Y COGNITIVA, INSTITUTO DE NEUROBIOLOGIA, QUERETARO, Mexico

Abstract: Sexually sluggish males have been described in several species including rats. These animals take more than 30 min to ejaculate or they ejaculate inconsistently despite being tested

repeatedly with sexually receptive females. Different brain areas and hormones play an important role in the control of male sexual behavior. The aim of the present study was to determine the expression of the vitamin D receptor (VDR), the androgen receptor (AR), the estrogen receptor alpha (ERa), the progesterone receptor (PR), and the aromatase enzyme (P450) genes in the medial preoptic area (mPOA), the amygdala (AMG) and the olfactory bulb (OB) of copulating (C) and sexually sluggish (SS) male rats. Subjects were tested with sexually receptive females in 3-4 tests of sexual behavior. Those males that ejaculated within 30 min in all tests were included in the C group and those males that ejaculated in one or none of the 4 tests were included in the SS group. One week after the last test of sexual behavior, males were sacrificed by decapitation to obtain the different brain regions. RNA was isolated and cDNA synthesized from the areas described, with cortex (CTX) included as a control group. Samples were dissected from 8 C and 8 SS males. Expression of the VDR, P450, AR, ERa and PR genes was determined by qPCR. PCR efficiency of all genes was determined using serial dilutions of mPOA cDNA. The geometric mean of the Ct from two housekeeping genes, cyclophilin A and tyrosine 3-monooxygenase-tryptophan activation protein zeta, was used to determine relative gene expression using the 2-double dCt method. Gene identity was confirmed by sequencing. In the mPOA, P450 mRNA increased 1.35 fold in SS males versus C males. AR mRNA also increased 3.45 fold and VDR showed 79.55 fold increase in the mPOA of SS males; only ERa and PR exhibited no change in this area. P450 mRNA was reduced 0.399 fold in the AMG. VDR and AR were not detectable in the OB, nor was AR in the AMG. Neither VDR nor P450 were detectable in the CTX. In the OB the only mRNA expressed at different levels in SS males was ERa (0.68). In conclusion, expression of several genes involved in hormone responsiveness is altered in the mPOA of SS males that could be associated with the low levels of sexual behavior.

Title: Repeated sexual behavior and neurogenesis in the hippocampus of the female rat

Authors: M. G. ORTIZ, W. PORTILLO, D. M. ARZATE, M. C. SANCHEZ, *R. G. PAREDES;
Behavioral Neurosci., Institutod De Neurobiologia UNAM, Querétaro, QRO, Mexico

Abstract: The ability of female rats to control the rate of sexual interactions (pacing) has important physiological and behavioral consequences. We have previously shown that the first paced mating encounter increases the number of newborn cells in the accessory olfactory bulb (AOB) in the female rat. Furthermore, when the females are allowed to paced the sexual interaction once weekly for 4 consecutive weeks this effect is potentiated and a higher number of new neurons is observed in the accessory and main olfactory bulbs. In the present study we evaluated if the repetition of the stimulus (paced mating) could increase the survival of newborn neurons, in the dentate gyrus (DG), generated during the first session of paced sexual contact. Sexually-naive female rats were bilaterally ovariectomized, hormonally supplemented and randomly assigned to one of four groups: 1) without sexual contact, 2) one session of paced mating during 1h, 3) four sessions of paced mating of 1h each and 4) four sessions of non-paced mating during 1h. Results showed an increase in the number of newborn cells (BrdU immunoreactive) in the ventral, dorsal and total (ventral + dorsal) DG of the repeated paced mating group in comparison to the control group. These results indicate that repeated paced mating promotes newborn neurons survival in DG of the hippocampus, which is consistent with our previous results in the olfactory bulb. We thank Francisco Camacho for his technical assistance.

Title: Carbon monoxide neurotransmission in the MPOA plays a role in male rat sexual and anxiety-like behaviors

Authors: *C. L. ROBISON[1], J. A. MCHENRY[2], E. M. HULL[2];
[2]Psychology, [1]Florida State Univ., Tallahassee, FL

Abstract: Carbon monoxide (CO) has been implicated as a gaseous neurotransmitter involved in functions as diverse as synaptic plasticity, vasorelaxation, and neuroendocrine regulation. The primary source of CO in the brain is the enzyme heme oxygenase 2 (HO-2). Given its similarities with nitric oxide (NO) neurotransmission, we hypothesized that CO plays a role similar to that of NO in the medial preoptic area (MPOA) of male rats. We observed an increase in HO-2 immunoreactivity in the MPOA after repeated, but not a single, sexual experience, similar to the increase in the NO-producing enzyme NOS. Administration of the HO-2 antagonist, tin mesoporphyrin IX (SnMP) to the MPOA prior to each of seven non-contact exposure to a sexually receptive female impaired sexual behavior on subsequent copulatory behaviors 1-2 days after the last exposure compared to vehicle controls. SnMP administration also elicited unusual behaviors such as excessive climbing during the non-contact exposure but did not appear to affect locomotion or coordination. Animals administered SnMP to the MPOA ten minutes before a copulatory encounter did not express altered copulatory or locomotor behavior compared to controls, but displayed significantly longer latency to reach and intromit with a receptive female in an X-maze task, indicating that CO may facilitate motivational or learning aspects of sexual function, but unlike NO does not centrally affect copulatory performance. Conversely, animals administered SnMP to the MPOA ten minutes before an elevated plus-maze task spent significantly less time in open arms and more time in closed arms compared to controls while expressing normal locomotor activity. Thus, the blockade of CO neurotransmission in the MPOA inhibits learning and motivational aspects of copulatory function while increasing the expression of anxiety-like behaviors in the male rat.

Title: Pontine control of ejaculation and female orgasm

Authors: *G. HOLSTEGE[1], A. T. M. WILLEMSEN[2], H. K. HUYNH[3], T. A. LOVICK[4];
[1]Ctr. Uroneurol, Ctr. For Uroneurology, Haren, Netherlands; [2]Nuclear Med. and Mol. Imaging, Univ. Med. Ctr. Groningen, 9713 AV Groningen, Net, Univ. Med. Ctr. Groningen, Groningen,

Netherlands; [3]Ctr. for Uroneurology, Haren, Netherlands; [4]Sch. of Physiol. and Pharmacol., Univ. of Bristol, Bristol, United Kingdom

Abstract: Ejaculation is a key event and end point in male sexual activity. At the climax of coitus ejaculation propels seminal fluid containing sperm through the urethra and into the female vagina, the biological objective being to fertilize a female ovum. This event is effected by a highly synchronized pattern of rhythmic contractions of smooth and striated muscles within the pelvic region.
Although ejaculation is a purely male event, a homologue exists in females. During female orgasm, the vaginal smooth muscle and the striated bulbospongiosus muscle produce rhythmic contractions in the distal part of the vagina to draw semen into the vagina, making it easier for sperm to approach and fertilize the egg.
The physiological component of ejaculation shows parallels with micturition since both are essentially voiding activities. Both depend on supraspinal influences to orchestrate the characteristic pattern of activity in the pelvic organs. Unlike micturition, little is known about the supraspinal pathways involved in ejaculation and female orgasm.
Ejaculation in men and orgasm in women was induced by manual stimulation of the penis or clitoris by the participants' partners. Positron emission tomography (PET) with correction for head movements was used to capture the pattern of brain activation at the time of sexual climax.
Ejaculation in men and orgasm in women resulted in activation in a localized region within the dorsolateral pontine tegmentum on the left side and in another region in the ventrolateral pontine tegmentum on the right side. The dorsolateral pontine area was also active in women who attempted but failed to have an orgasm and in women who faked orgasm. The ventrolateral pontine area was only activated during ejaculation and physical orgasm in women.
Activation of a localized region on the left side in the dorsolateral pontine tegmentum, which we termed the pelvic organ stimulating center (POSC) occurs during ejaculation and physical orgasm in women. This same region, but on the right side, has previously been shown to be activated during micturition. The POSC, via projections to the sacral parasympathetic motoneurons, controls pelvic organs involved in voiding functions. In contrast, the ventrolateral pontine area, which we term pelvic floor stimulating center (PFSC), produces the pelvic floor contractions during ejaculation and physical orgasm in women via direct projections to pelvic floor motoneurons.

Title: A role of Lis1 in adult mice

Authors: *X. GAO, D. SMITH;
Univ. of South Carolina, Columbia, SC

Abstract: *Lis1* haploinsufficiency in humans results in a "smooth brain" phenotype called lissencephaly, and also causes severe cognitive and motor impairments and epilepsy. Various mouse models have been used to examine the role of Lis1 during brain development, and it is clear that Lis1 regulates a microtubule motor, cytoplasmic dynein. Intriguingly, Lis1 expression remains high in adult brains indicating that it plays a role in mature systems. Indeed, our group found that Lis1 and several related proteins regulate dynein-dependent axon transport in cultured adult rat sensory neurons. I am interested in examining Lis1 function in the adult mouse, and in order to bypass the embryonic impact of Lis1 loss I have utilized a tamoxifen inducible Cre-mediated recombination system to knock out Lis1 in adult mice (8 weeks). I chose to cross floxed Lis1 mice with mice in which Cre expression is driven by an actin promoter. I find that loss of Lis1 in adult mice causes severe malaise and ultimately death. The timing of the lethality is dependent on the tamoxifen dose. These phenotypes are not observed in any of a variety of control animals. Thus, Lis1 plays a crucial role in an adult mammalian system. I examined the pattern of Cre activation in experimental animals, and found that Cre is activated in several tissues including brain stem, heart and skeletal muscle. Lis1 is normally expressed at substantially higher levels in brain than in heart, and no Lis1 was detected in skeletal muscle. Cre activation led to reduced Lis1 level protein expression in brainstem and heart. We hypothesize that the sudden death of Lis1 conditional knock out mice may be related to the cardiorespiratory control network in the brainstem, but could conceivably reflect a hitherto unforeseen role for Lis1 in cardiomyoctes.

Title: Prazosin reverses acute apoptosis in a rat model of enterovirus 71 encephalitis

Authors: *C.-J. TSENG[1], W.-H. LU[2], K.-S. HSIEH[2], L.-P. GER[1];
[1]Veterans Gen Hosp-Kaohsiung, Kaohsiung, Taiwan; [2]Dept. of Pediatrics, Kaohsiung Veterans Gen. Hosp., Kaohsiung, Taiwan

Abstract: Children infected with enterovirus 71 encephalitis progressing abruptly to left ventricle dysfunction and neurogenic pulmonary edema die suddenly within hours. In our previous study, we identified a rat model with nucleus tractus solitarii lesion causing immediate excessive catecholamine release to mimic fulminant enterovirus 71 infections. In this study, we investigated the alpha-adrenergic blockers on survival in this rat model. 270-360g male Sprague-Dawley rats were divided into two groups. Group 1 was a control group that received microinjections of 6-hydroxydopamine into the nucleus tractus solitarii bilaterally. Group 2 was an intervention group with α-adrenergic blocker (prazosin). We found that prazosin can prevent cardiac hypercontracture and preserve cardiac output. It also reverses the pathological changes of contraction band necrosis, increased expressions of brain natriuretic peptide and troponin T in the heart and neutrophil infiltration in the lungs, leading to prevention of hyaline membrane formation and pulmonary hemorrhagic edema, increasing survival time. The time-dependently increased and strong expression of connexin 43, caspase3 and the apoptotic cells induced by the 6-hydroxydopamine lesion were decreased after prazosin treatment. Connexin 43 is involved in a novel apoptotic mechanism for speeding apoptosis within hours in the rat model. For translational research on fatal enterovirus 71 encephalitis, early prazosin treatment may prevent acute death from tissue apoptosis.

Title: Wnt signaling activation in nucleus tractus solitarii modulates insulin receptor substrate-mediated central blood pressure regulation

Authors: *W.-H. CHENG[1,2], C.-J. TSENG[1,2];
[1]Dept Med. Educ. & Res., Veterans Gen Hosp-Kaohsiung, Kaohsiung, Taiwan; [2]Inst. of Clin. Med., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract:
The cluster of pathologies known as metabolic risk factors, including high blood pressure, high fasting blood sugar, and insulin resistance, has become one of the most serious warnings of human health. The nucleus tractus solitarius (NTS), located at the dorsal part of the brainstem, was discovered to be an important sympathetic nervous system integral center in the central nervous system (CNS). Interestingly, our previous studies also mentioned that insulin plays a role in central cardiovascular regulation. Moreover, insulin signaling is defective in the NTS of hypertensive spontaneously hypertensive rats (SHRs) and fructose-fed rats. The Wnt signaling is involved in many physiological and pathophysiological activities. In addition, recent clinical and in vitro studies reveal that aberrant Wnt signaling is thought to play an important role in the onset of diabetes. Nevertheless, the relationship between Wnt signaling and insulin pathway and related modulation of blood pressure in the CNS has not been established. In light of these observations, we postulated that Wnt signaling pathway may improve neuronal insulin resistance and that neuronal insulin resistance is a key mechanism involved in triggering hypertension. Intracerebroventricular administration of Wnt3a produced depressor in both SHRs and fructose-fed rats. Pretreatment with a low density lipoprotein receptor-related protein (LRP) antagonist, Dickkopf-1 (DKK-1) significantly attenuated the depressor effect and nitric oxide production evoked by Wnt3a. Additionally, immunoblotting and pharmacological studies further showed inhibition of LRP6 activity by DKK-1 significantly abolished Wnt3a-induced glycogen synthase kinase 3beta (GSK-3beta)^{S9}, extracellular signal-regulated kinases 1/2 (ERK1/2)$^{T202/Y204}$, ribosomal protein S6 kinase (RSK)$^{T359/S363}$, Akt^{S473} and increased insulin receptor substrate-1 (IRS1)^{S332} phosphorylation. GSK-3beta was also found to direct bind to IRS1 and induced Ser332 phosphorylation in the NTS. Likewise, the addition of GSK-3beta inhibitor (TWS119) into the brain decreased blood pressure of SHRs and fructose-fed rats through enhancing IRS1 activity. Taken together, these results suggest that the Wnt-LRP6-GSK3beta signaling may as a key regulator of insulin pathway and a potential therapeutic target for essential hypertension.

Title: Genic expression of oxytocin in the paraventricular nucleus is altered by paroxetine in subchronic aortic regurgitation rats

Authors: *J. I. GOBBI[1], A. M. OMOTO[1], L. N. MORAES[2], M. G. ROSCANI[3], L. S. MATSUBARA[3], B. B. MATSUBARA[3];
[1]Dept. of Physiol., [2]Dept. of Morphology, UNESP, Inst. of Biosci., Botucatu, Brazil; [3]Dept. of Intrnl. Med., UNESP, Med. Sch., Botucatu, Brazil

Abstract: Aortic regurgitation (AR) leads to eccentric hypertrophy and eventually left ventricular dysfunction. Rheumatic heart disease is a leading cause of AR in developing countries, and its incidence is increasing in developed countries as a consequence of senile degeneration. Depression and heart disease are correlated states. Alterations in the metabolism of serotonin (5-HT) are particularly implicated. Selective 5-HT reuptake inhibitor (SSRI) are widely used as antidepressants. Treatments with 5-HT agonists or 5-HT releasers facilitate oxytocin (OT) and vasopressin (AVP) secretion in the plasma. OT regulates cardiac function and hydromineral balance. The hypothalamic-neurohypophyseal system is responsible for OT and AVP secretion. Thus, the present study was designed to test the hypothesis that paroxetine (a SSRI) treatment changes paraventricular hypothalamic (PVN) OT and AVP expression in rats with subchronic aortic regurgitation. Male Wistar rats (260 to 280 g) had sham or AR surgeries induced by retrograde puncture of the aortic valve leaflets, procedures were aproved by animal ethical commitee (386-CEUA/SBCAL). Presence of AR was confirmed by echocardiography (Eco) exams. Rats were randomly divided into 4 groups: AR+parox, AR+control, sham+parox and sham+control. Eco exams were conducted for collecting morphological variables at week 4 following AR surgeries. The groups started to be treated with parox (10 mg/kg 3 times in a week) or control subcutaneous injections till week 8, when Eco exams were conducted again in order to verify systolic function. Rats were deeply anesthetized. Fresh brains were frozen and sliced to isolate the PVN. Relative OT and AVP mRNA expression in the PVN was quantified by real-time PCR. As result fractional shortening was preserved in AR+parox, compared to AR+control (47.1 ± 1.5% vs 33.0 ± 4.0%, respectively). AR+parox had an increased in the OT expression (0.61 ± 0.16 vs 0.42 ± 0.08 relative quantification). AVP was not changed. The results suggests that increasing central 5-HT levels, determined by the antidepressant, may change oxytocin PVN expression which produces improvements to cardiovascular system exposed to volume overload.

Title: Diet-induced obesity is associated with angiotensin-dependent microglial activation, astrogliosis and inflammation in the hypothalamus

Authors: *A. D. DE KLOET[1], D. NGUYEN[2], D. J. PIOQUINTO[1], L. WANG[2], E. G. KRAUSE[2], C. SUMNERS[1];
[1]Physiol. and Functional Genomics, Univ. of Florida, Col. of Med., Gainesville, FL;
[2]Pharmacodynamics, Univ. of Florida, Gainesville, FL

Abstract: Obesity and co-morbid hypertension are epidemic health concerns and major risk factors for the development of cardiovascular disease. As a consequence, it is vital to determine effective strategies to treat or prevent these pathologies, and accumulating evidence has implicated proinflammatory factors and the renin-angiotensin-system as promising targets in this regard. To this end, obesity is accompanied by elevated inflammation in peripheral tissues and the brain. Furthermore, obesity leads to increased levels of angiotensin-II (Ang-II), which activates central angiotensin type 1a receptors (AT1a) to influence cardiovascular function. Based on these findings and the observation that Ang-II induces hypothalamic inflammation in hypertensive models, we hypothesized that during obesity, Ang-II contributes to recruitment and activation of immune cells within the CNS which then contributes to obesity-related hypertension.
In a first set of experiments, adult male C57BL/6 mice were given either high-fat diet (HFD) or low-fat diet for 8 weeks and the effect of HFD-feeding on microglial activation, astrogliosis, and RAS activity within specific brain nuclei was examined via IHC and RT-PCR. Consumption of HFD led to an increase in the size and number of microglia within the arcuate nucleus of the

hypothalamus (ARC), the subfornical organ (SFO), the parvocellular region of the paraventricular nucleus of the hypothalamus (PVN), but not within the magnocellular region of the PVN. Furthermore, glial fibrillary acidic protein (GFAP) immunoreactivity and gene expression were elevated within the ARC and PVN. Next, we used the Cre/lox system to delete AT1a from the PVN of mice and test the hypothesis that this population of AT1a mediates the increases in blood pressure, microglial activation and astrogliosis that are associated with obesity. Consistent with this hypothesis, PVN AT1a deletion reduced indices of hypothalamic inflammation and GFAP immunoreactivity within the PVN. In fact, although mice lacking AT1a in the PVN had an enhanced susceptibility to diet-induced obesity, deletion of AT1a from the PVN reduced systolic blood pressure, suggesting that this receptor population mediates the positive correlation between adiposity and blood pressure. Collectively, these studies demonstrate that HFD feeding initiates an AT1a-dependent inflammatory cascade within the PVN that contributes to increased blood pressure.

Title: Chronic treatment with phenytoin ameliorates the cardiac phenotype in a mouse model of Rett Syndrome

Authors: *J. A. HERRERA, JR[1,2], C. S. WARD[1,2], X. H. T. WEHRENS[2], J. L. NEUL[1,2]; [1]NRI 1250.01, Jan and Duncan Neurolog. Res. Instutite, Houston, TX; [2]Baylor Col. of Med., Houston, TX

Abstract: Eighteen percent of individuals with Rett Syndrome (RTT) have a prolonged QT (LQT) interval; a heart rhythm disorder that can lead to lethal cardiac arrhythmias. Mice deficient of Methyl CpG binding protein (MeCP2), *Mecp2*$^{Null/Y}$, recapitulate the cardiac phenotype seen in patients with RTT. The current standard therapy for patients with RTT and LQT are β adrenergic antagonist used to decrease sympathetic activity. We tested for the incidence of inducible arrhythmias with acute administration of propranolol, a β adrenergic antagonist, and did not prevent arrhythmias. Meanwhile, acute administration of phenytoin in

Mecp2$^{Null/Y}$ mice prevented induction of arrhythmias. We have designed a pre-clinical trial to investigate the physiologic and behavioral effects of chronic treatment with phenytoin or propranolol in *Mecp2*$^{Null/Y}$ mice.
Mecp2$^{Null/Y}$ and wildtype mice were randomly assigned to be treated twice a day for 28 days with either 30 mg/kg of phenytoin or vehicle. In a separate cohort, *Mecp2*$^{Null/Y}$ and wildtype mice were treated 10 mg/kg of propranolol via osmotic pump or vehicle. The experimenter was blinded for genotype and treatment. Mice were implanted with telemeters at 4 weeks and treatment was initiated soon after implantation. Programmed electrical stimulation (PES) was used to determine their susceptibility to inducible arrhythmias and to measure the electrocardiogram (ECG) for interval analysis. ECG analysis shows that *Mecp2*$^{Null/Y}$ vehicle treated mice have a prolonged QRS interval and QTc compared to the *Mecp2*$^{Null/Y}$ phenytoin treated mice. Treatment with propranolol did not correct the ECG abnormalities in *Mecp2*$^{Null/Y}$ mice. Propranolol treatment did not prevent arrhythmias in *Mecp2*$^{Null/Y}$ whereas phenytoin completely ablated arrhythmias in *Mecp2*$^{Null/Y}$ mice. Phenytoin treatment had no adverse behavior effects, and rescued the overweight phenotype in *Mecp2*$^{Null/Y}$ mice which was identified to be due to decreased abdominal fat accumulation. *Mecp2*$^{Null/Y}$ mice have a decreased basal heart rate compared to wildtype mice which was not affected by phenytoin treatment. However, treatment with phenytoin was identified to worsen the breathing phenotype seen in *Mecp2*$^{Null/Y}$ mice. Since phenytoin worsened the breathing phenotype, a more target therapy such as ranolazine should be tested to determine if it is effective in ablating arrhythmias with minimal side effects. Ranolazine has been identified to selectively block the late persistent sodium channel current which is seen in cardiomyocytes isolated from *Mecp2*$^{Null/Y}$ mice.

Title: Proteomic analysis of the caudal ventrolateral medulla in an animal model of renovascular hypertension reveals signalling and metabolic dysfunction

Authors: *A. K. GOODCHILD[1], M. MIRZAEI[1], A. DING[1], J. K. PHILLIPS[1], P. HAYNES[2]; [1]The Australian Sch. of Advanced Medicine, Macquarie Univ., Sydney, Australia; [2]Chem. and Biomolecular Sciences, Macquarie Univ., Sydney, Australia

Abstract: The caudal ventrolateral medulla (CVLM) contains cell groups that regulate blood pressure and heart rate via baroreceptor dependent and independent mechanisms, metabolism via connections with hypothalamic regions and respiration. Hypertension is present in those suffering polycystic kidney disease although the mechanisms responsible are unclear. Associated with hypertension is reduced baroreflex sensitivity which has been linked with oxidative stress (De Castro UG et al 2012) or angiotensin (Cangussu LM et al 2009) in the CVLM. The aim here is to determine what signalling pathways in the CVLM are altered in renovascular hypertension. A new Lewis rat model of polycystic kidney disease (LPK) and its genetic control were used (n=6 of each). At 12 weeks of age when severe hypertension was evident in the LPK (203 ± 15 mmHg LPK vs 100 ± 12 mmHg Lewis) the brains were rapidly removed under pentobarbitone anaesthesia and frozen. The brain was placed into a brain matrix and 1 mm coronal sections of the brain stem were taken. The CVLM region was dissected (1mm x 1.5mm) and frozen until analysis. Conventional protein preparation and digestion strategies were used and LC-MS/MS was used to identify proteins in the CVLM region of 3 LPK and 3 Lewis rats. In total 1212 proteins were identified of which 116 were differentially expressed. The distribution was relatively even with 54 proteins upregulated and 62 proteins down regulated in the LPK compared to Lewis. Key pathways were affected: Fatty acid beta oxidation was associated with changes in ACACA, FASN, ABCD3, CPT2 however this may not be linked with oxidative stress. Endocytotic changes include LAMP1, CLTA, VAC14, COP1B and EEA1. Glutamate/GABA signalling changes were associated with SLC32A1, ABAT/ DLG2, LIN7C, CAMK2A respectively. Plasticity associated changes with ARPC4, TPM4, CORO1B, ANLN, MACF1. In addition significant changes linked with GNAI3 and CNRIP1 were also present. Western blot analysis is currently being conducted. Novel targets associated with hypertension associated dysfunction could be elucidated.

Title: Baroreflex control of splanchnic, renal and lumbar sympathetic nerve activity is differentially regulated in chronic kidney disease

Authors: *Y. YAO, M. M. FARNHAM, P. M. PILOWSKY, J. K. PHILLIPS;
Australian Sch. of Advanced Med., Macquarie Univ., Sydney, Australia

Abstract: The pattern of sympathetic nerve activity (SNA) to individual target organs in chronic kidney disease (CKD) is an issue that has implications for the overall hypertensive state and target organ damage. Splanchnic SNA (sSNA) controls gastrointestinal blood flow and imposes a major influence on systemic total peripheral resistance and blood pressure (BP). Lumbar SNA (lSNA) also influences BP by regulating skeletal muscle blood flow. In comparison, renal SNA (rSNA) controls long-term BP by regulating renin release and Na^+ / water reabsorption in the kidneys. Our aim was to determine if there is differential activation and regulation of SNA to these vascular beds in CKD, recording from all three nerves simultaneously and determining their respective sensitivity to baroreceptor activation. We have examined these variables using the Lewis polycystic kidney (LPK) rat model of CKD.
Under urethane anaesthesia (1.3 g/kg i.p.), 12 week old male LPK or Lewis control rats (n = 8 per experimental group) were vagotomised, paralysed and maintained on artificial ventilation. Baseline values of smoothed arterial pressure (SAP), heart rate (HR) and rSNA and lSNA and/or sSNA were recorded. Baroreflex function was assessed using a 4-parameter sigmoidal fit of SNA responses to changes in MAP, induced by intravenous infusion of phenylephrine (10-40 µg/kg) or sodium nitroprusside (50-70 µg/kg). SNA was rectified and smoothed (t = 1 s) and normalised against baseline as 100% and death level as zero.
Compared to the Lewis controls, the baseline values of SAP (80 ± 2 *vs* 88 ± 4 mmHg), rSNA (3.4 ± 0.9 *vs* 8.5 ± 2.1 µV), lSNA (2.4 ± 0.5 *vs* 9.1 ± 2.8 µV) and sSNA (3.1 ± 0.8 *vs* 6.9 ± 1.4 µ) were significantly higher in the LPK rats (all $p < 0.05$). The baroreflex functional curves for all nerve beds were shifted to the right (as reflected by MAP_{50} values) in the LPK rats [rSNA (107 ± 4 *vs* 145 ± 8 mmHg), lSNA (114 ± 4 *vs* 132 ± 5 mmHg) and sSNA (118 ± 2 *vs* 144 ± 7 mmHg), all $p < 0.05$]. Whereas the gain and maximal range of baroreflex control of rSNA and sSNA (gain 2.2 ± 0.7 vs 0.4 ± 0.05 %/mmHg & range 71 ± 7 vs 54 ± 7%, and gain 1.9 ± 0.3 *vs* 0.8 ± 0.1 %/mmHg & range 74 ± 5 *vs* 41 ± 2%, respectively, all $p < 0.05$) were significantly lower in the LPK, these parameters were not different for the baroreflex control of lSNA between strains. The elevation of basal rSNA, lSNA and sSNA in the LPK rats suggest that there is a global elevation of sympathetic tone that contributes to the hypertensive state in CKD. The maintenance of normal baroreflex responses for lSNA, despite abnormal rSNA and sSNA function suggests differential central processing of baroreflex control of SNA to different target regions.

Title: Blunted pressor and renal sympathetic nerve stress response in a conscious rodent model of chronic kidney disease

Authors: *I. M. SALMAN[1], C. M. HILDRETH[1], J. L. HARRISON[2], J. K. PHILLIPS[1]; [1]Australian Sch. of Advanced Med., Macquarie Univ., Sydney, Australia; [2]Sch. of Vet. and Life Sci., Murdoch Univ., Perth, Australia

Abstract: Elevated sympathetic nerve activity (SNA) is implicated in the development of hypertension in chronic kidney disease (CKD), and is associated with increased cardiovascular morbidity and mortality. Moreover, in many hypertensive models, cardiovascular responses to acute stress are exaggerated. Using a model of CKD, the Lewis Polycystic Kidney (LPK) rat, we examined the hypotheses that these animals would show increased baseline renal SNA (RSNA) under conscious conditions, and increased cardiovascular and RSNA reactivity to acute stress. Male LPK and Lewis control rats (total n = 9) were instrumented with SNA/blood pressure transmitters (TRM56SP-Telemetry Research/Millar Instruments) at 10 weeks of age. Following a one week recovery to re-establish circadian rhythms, 5-minute recordings of mean arterial pressure (MAP) and RSNA were taken every 15 minutes for 48 hours at age 12 weeks. RSNA and haemodynamic responses to acute stress (open-field exposure for 40 minutes) were tested. The quality of the nerve signal was assessed by evaluating pulse modulation of RSNA, and ganglionic blockade with hexamethonium (20 mg/kg s.c.) was used to calculate background activity. At age 12 weeks, LPK had higher RSNA (2.8 ± 1.1 vs. 0.5 ± 0.4 μV) and MAP (150 ± 13 vs. 94 ± 2 mmHg) compared with Lewis (all $P<0.05$), thus confirming our first hypothesis. Responses to open-field stress were characterised by reproducible increases in RSNA and MAP relative to baseline levels, however the LPK showed markedly blunted sympathoexcitatory and pressor responses when compared to Lewis animals over the 40-minute stress period (RSNA: 185 ± 22 vs. 269 ± 45% and MAP: 3 ± 1 vs. 12 ± 1%, all $P<0.05$). Both RSNA and MAP had returned to baseline levels in the LPK and Lewis within 40 minutes of being removed from the open field chamber. Our demonstration of attenuated RSNA and MAP responses to acute stress were not expected. A possible explanation for these findings is that the chronic elevation in

blood pressure and RSNA observed in these animals is contributed to by endogenous stress mechanisms and therefore when these pathways are activated the relative increase is less.

Title: Computational evidence for synaptic gain in human sympathetic ganglia

Authors: *J. P. HORN, M. G. SPRINGER;
Dept of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Extracellular recordings from conscious human subjects have revealed natural patterns of firing by postganglionic sympathetic neurons that project to limb muscles. Reports published by different investigators indicate that muscle vasoconstrictor neurons fire in bursts whose timing is coupled to the cardiac cycle through arterial baroreceptors. However, bursts only occur in a subset of cardiac cycles. Exercise increases sympathetic activity, increases burst size and increases the number of cycles that contain bursts. Elevations of sympathetic activity during hypertension, aging and heart failure show similar characteristics.
Single unit recordings indicate that neurons do not often fire repetitively during bursts, thus implying that bursts arise from recruitment of additional cells. In this study we used modeling to ask how synaptic integration at nicotinic synapses in sympathetic ganglia might contribute to this behavior. Using a similar approach, Macefield (Front Neurosci. 2011;5:132) recently concluded that human sympathetic firing could best be explained by convergence of two suprathreshold strong (i.e. primary) nicotinic synapses firing with intervals that were normally distributed. We report here that a single primary synapse is sufficient to replicate the experimental microneurography data, by simply assuming exponentially distributed intervals between synaptic events at average rates of 0.4 to 0.8 Hz. More importantly, a similar result is obtained by assuming convergence between 1 primary synapse and 6 subthreshold secondary nicotinic synapses firing at even lower rates (0.16 to 0.25 Hz). The difference in this case is that ganglionic integration results in synaptic amplification between 2.5 to 3.2. These results will be discussed in terms of the implications for baroreflex gain. The models also make predictions that

could be tested through future experiments and thereby advance the interpretation of clinical microneurographic assessment.

Title: Effects of G-loading and vibration on heart and breathing rate in humans

Authors: *A. GODINEZ[1], D. B. LISTON[1,2], R. AYZENBERG[3], L. S. STONE[2];
[1]San Jose State Univ., San Jose, CA; [2]NASA Ames Res. Ctr., Moffett Field, CA; [3]Santa Clara Univ., Santa Clara, CA

Abstract: Operational environments commonly expose pilots and astronauts to G-loading and vibrational stress, which modulates autonomic nervous system function. Our aim was to test the effects of vibration and G-loading, alone and in combination, on heart rate (HR) and breathing rate (BR) as metrics of stress.
Methods. Observers (n=10) began each trial by fixating a central red LED. After a randomized interval (200 - 700 ms), a target spot appeared at a random eccentric location (30 deg horizontal). The task of the subject was to look at and then point to the spot location. Each subject performed this task under two G-loading (1.0 and 3.8 Gx, along the chest-to-spine axis) and four vibration (no vibration, 8, 12 16 Hz at 0.5 g zero-to-peak) conditions while wearing a physiological monitoring device (Zephyr bioharness), which recorded heart and breathing rate. Data were collected in self-paced 315-second blocks; each subject completed three blocks per experimental session.
Results. We observed a main effect of G-loading on heart ($p<0.0001$, t-test) and breathing ($p<0.05$, t-test) rate as well as a tendency for heart rate to increase over time during the 315-second task. To assess the effect of vibration frequency while compensating for the effect of performing the task, first, we fit the time-varying effect and subtracted it out for each block. Second, we analyzed the remaining HR and BR variance across frequency (2-way ANOVA). We observed a significant main effect of vibration frequency on HR ($p<0.0001$), as well as a significant interaction between vibration frequency and G-level (p0.05, 2-way ANOVA).
Conclusion. We observed strong effects of both G-loading and vibration on heart and breathing

rate, as well as interaction between G-loading and vibration. This interaction shows that the physiological impact of G-loading and vibration are not independent and can only be assessed during combined exposure to these conditions.

Title: Effect of moderate aerobic exercise on cardiovascular autonomic function in type 2 diabetes mellitus

Authors: *R. K. GOIT, N. K. MISHRA;
Nepalgunj Med. Col., Banke, Nepal

Abstract: Aim: The aim of the study was to determine long-term cardiovascular autonomic adaptation to moderate endurance aerobic exercise in type 2 diabetes mellitus.
Methods: Heart rate variability (HRV) of 15 individuals with T2DM were assessed. Resting electrocardiogram (ECG) at spontaneous respiration was recorded for 5 min in supine position. Recording was performed before and after a nine month, supervised, progressive, aerobic training program, three times weekly. The data were expressed as median (interquartile range). The p value <0.05 was considered statistically significant.
Results: In the time domain variables, square root of the mean of the squared R-R intervals (RMSSD) [29.7 (26 - 34.5) vs. 46.4 (29.8 - 52.2) ms, p=0.02] and number of R-R intervals that differ by more than 50 ms (NN50) [35 (18 - 47) vs. 98 (20-114)] count, p=0.03) were significantly increased after exercise. In the frequency domain variables, low frequency (LF) [62.4 (59.1 - 79.2) vs. 37 (31.3-43.3) nu, p=0.03) and LF/HF [1.67 (1.44 - 3.8) vs. 0.58 (0.46 - 0.59) p=0.009] were significantly decreased while high frequency (HF) [95 (67-149) vs. 229 (98-427) power, p=0.006] and HF [37.6 (20.8-40.9) vs. 63 (56.7-68.7) nu, p=0.003) were significantly increased after exercise. In Poincare plot standard deviation (SD1) [21.3 (18.5-24.8) - 33.1 (21.5 - 37.2), p=0.027] was significantly increased after exercise.
Conclusion: These data suggest that three times weekly, nine month, moderate aerobic exercise program is associated with significant improvements in cardiovascular autonomic function in person with T2DM by increasing vagal tone and decreasing sympathetic activity.

Title: Non-invasive vagus nerve stimulation reduces sympathetic nerve activity in healthy volunteers and heart failure patients

Authors: *J. A. CLANCY[1], D. A. MARY[1], K. K. WITTE[2], J. P. GREENWOOD[2], S. A. DEUCHARS[1], J. DEUCHARS[1];
[1]Sch. of Biomed. Sci., [2]Leeds Inst. of Genetics, Hlth. and Therapeut., Univ. of Leeds, Leeds, United Kingdom

Abstract: Heart failure (HF) is a debilitating and fatal condition characterised by sympathetic activation and parasympathetic withdrawal. Tackling the underlying autonomic imbalance through parasympathetic stimulation can improve cardiac function and quality of life scores in HF patients, however, the current method of cervical vagus nerve stimulation (VNS) is invasive and associated with side effects. This study investigated the autonomic effects of a non-invasive method of VNS - transcutaneous electrical stimulation of the auricular branch of the vagus nerve (tVNS) - in healthy participants (n = 34; 18 female, 16 male; aged 19-62 years) and HF patients (n = 8; 2 female, 6 male; 51-86 years). The study was approved by the University of Leeds Ethics Committee and the National Research Ethics Service and was conducted in accordance with the Declaration of Helsinki. Heart rate (ECG), blood pressure and respiration were recorded continuously. Heart rate variability (HRV) was calculated using spectral analysis of beat-to-beat intervals derived from ECG data. Microneurography was also used to record muscle sympathetic nerve activity (MSNA; n = 10). Data were analysed at baseline, during tVNS and during recovery. Repeated measures ANOVAs were used to analyse results (data presented as mean ± S.E.M). HRV improved significantly during tVNS in healthy participants ($p = 0.026$). There was a significant reduction in single unit MSNA frequency and incidence during tVNS ($p = 0.001$ and $p = 0.002$ respectively). tVNS significantly improved HRV in HF patients ($p = 0.035$). Based on the results of this study, tVNS can improve HRV in both healthy participants and HF patients. Furthermore, microneurography revealed that the improvement in HRV during tVNS is, at least partly, due to a reduction in sympathetic activity in healthy participants. tVNS could be a

practical, non-invasive and economical therapy for heart failure patients and warrants further investigation.

Abstract: Blood pressure and heart rate are known to change in different conditions, e.g. when performing a motor or a cognitive task or when being exposed to emotional stimuli. It is unknown how the different brain areas involved in those tasks relate to the vascular response. This open issue may be of high clinical relevance since it has recently been recognized that vascular reactivity to psychological stress predicts the risk for subsequent development of cardio- and cerebrovascular disease (Matthews et al., 2004).
We investigated vascular reactions during an emotional spatial attention task while simultaneously assessing brain activity. Specifically, we hypothesized that viewing aversive compared to neutral pictures in this task would evoke greater vascular responses and greater neural activation in corticolimbic areas, including insula, amygdala and cingulate cortex which are involved in processing of stressors and which have been suggested to be involved in mediating the vascular response. Furthermore, we expected this effect to be modulated by attention: only when stimuli were attended, there would be a difference in reactivity between

aversive and neutral information.
43 healthy volunteers (22 f, 26 ± 3.77 years) participated in one 3 Tesla fMRI session during which we recorded continuous, non-invasive blood pressure and electrocardiography (ECG). As expected, modulation of attention yielded longer reaction times, more errors and greater neural activation in visual-associated areas for attended compared to unattended conditions. Contrary to our hypotheses, these effects were more pronounced for neutral compared to aversive conditions. Vascular reactivity was modulated by attention with greater reactivity into the negative direction for aversive- compared to neutral-attended conditions and no significant reactivity difference for unattended conditions. Interestingly, ROI analyses yielded delayed peak activation (at ≈7 sec) exclusively in the left and right amygdala only when aversive stimuli were attended. A shift in time and amplitude of amygdala activation has been described in voluntary emotion regulation of aversive pictures (Walter et al., 2009). We hypothesize that the instructions to ignore the stimuli's content could have provoked similar emotion regulation processes in our participants. Thus, our results indicate that the vascular response is governed by a complex interaction of emotional content, attention, and cognitive control strategies. Understanding this interaction and its neural correlates should lead to a better understanding how vascular reactivity can contribute to the pathogenesis of vascular risk factors.

Title: Sympathetic outflow in patients with obstructive sleep apnea and healthy controls correlates with grey matter thickness within the insula and cingulate cortex

Authors: *K. S. TAYLOR[1], A. J. MCREYNOLDS[1], P. J. MILLAR[1], H. MURAI[1], D. S. KIMMERLY[1], B. L. MORRIS[1], T. D. BRADLEY[1], J. S. FLORAS[1,2];
[1]Dept. of Medicine, Div. of Cardiol., Univ. Hlth. Network, Toronto, ON, Canada; [2]Dept. of Medicine, Div. of Cardiol., Mount Sinai Hosp., Toronto, ON, Canada

Abstract: Introduction: Obstructive sleep apnoea (OSA) is a pathological state characterised by exaggerated sympathetic outflow during wakefulness as well as sleep. The insula (IC) and anterior cingulate (ACC) are amongst the cortical regions considered involved in modulation of efferent sympathetic outflow but this concept has yet to be established definitively in humans. We tested the hypothesis, in patients with OSA and healthy control (HC) subjects, that grey matter (GM) thickness within the IC and ACC correlates with directly measured efferent sympathetic activity (muscle sympathetic nerve activity (MSNA)).
Methods: Seventeen OSA (3f; 58 $\pm$ 11 yrs [mean $\pm$ SD]) and 14 age-matched HC (4f; 56 $\pm$ 9 yrs) subjects underwent a 2 min resting recording of multi-unit right fibular MSNA (burst incidence (BI): bursts/100 heart beats). All subjects attended overnight polysomnography to ascertain the presence and severity of OSA. On a separate day a high-resolution FSPGR anatomical scan (FOV=24, slice thickness= 1.5mm, 120 axial slices, 256x256 matrix, flip angle=20°) was collected at 3T. A region of interest (ROI) correlation analysis between resting BI and cortical thickness within the IC and ACC was conducted using Freesurfer (ROI mask was taken from Freesurfer's built in atlas). Data was thresholded at a corrected $p \leq 0.05$ (derived from an uncorrected $p \leq 0.0075$ and 245 contiguous verticies).
Results: MSNA BI was significantly higher in OSA patients than HC (57.3$\pm$5.3 vs. 35.1$\pm$3.6 bursts/100 heartbeats respectively; $p < 0.005$). There were no significant group differences in resting heart rate, systolic, or diastolic blood pressure ($p>0.05$). The apnea-hypopnea index (average of all subjects: 19.9 $\pm$ 2.9 events/hr), a measure of OSA severity, correlated with BI ($r = 0.552$; $p \leq 0.002$). BI correlated negatively with GM in the left dorsal posterior insular cortex (LdpIC) ($r = -0.667$; $p \leq 0.001$) and correlated positively with BI in the left mid cingulate cortex (LMCC) ($r = 0.539$; $p \leq 0.002$). There were no significant correlations between BI and GM in the right hemisphere ROI.
Conclusion: The present observations are concordant with neuro-stimulatory and recent functional imaging data demonstrating insular and cingulate involvement in autonomic cardiovascular regulation, and posit contrasting roles for these ROI. They are consistent with the concepts that the left IC exerts an inhibitory and the MCC an excitatory modulator effect on MSNA. As increased sympathetic neurotransmission itself might alter regional volume, future studies should investigate the impact of long term treatment of OSA with continuous positive airway pressure, which lowers MSNA, on GM thickness within these regions.

Title: Effects of cold exposure on changes of sleep-related autonomic function and morning blood pressure surge: Human and animal studies

Authors: *C.-H. HONG[1,2], T. KUO[1,2], C. YANG[1,2];
[1]Inst. of Brain Sci., Natl. Yang-Ming Univ., Taipei City, Taiwan; [2]Sleep Res. Center, Natl. Yang-Ming Univ., Taipei City, Taiwan

Abstract: A number of studies have linked the occurrence of cardiovascular events and cold ambient temperatures as well as the morning blood pressure surge (MBPS), but findings on the effects of cold exposure on the changes of autonomic function during sleep stage transition and on the MBPS were still unclear. We hypothesized that cold exposure produce a higher sympathetic change during sleep stage transition and that this, may play an important role in cold-related cardiovascular events. In human study, all experiments were carried out on healthy male adults, who participated in two experimental conditions randomly, a warm condition (23^{o}C) and a cold condition (16 ^{o}C). Blood pressure (BP) was measured every 30 minutes for 24 hours by autonomic ambulatory BP monitoring. The electroencephalograms (EEGs), electrocardiograms (ECGs) and temperatures were recorded by miniature polysomnography over 24 hours. In animal study, polysomnographic recordings were performed on Wistar-Kyoto rats (WKYs) that were housed in thermo-regulated chambers. In humans, cold conditions led to a higher MBPS and significant sympathetic index changes during such period. The NREM-REM transition-related sympathetic elevation during the cold conditions being significantly higher in late sleep period than in early sleep period, while the vagal function index revealed contradict responses. The total power of HRV changes prior to morning awaking being significantly correlated with the changes of near body temperature and a significant higher arousal index and shorter average interval of REM periods in cold condition than in warm condition. The animal study revealed that compared with warm condition, cold conditions induced a higher BP, heart rate and sympathetic indexes and more interruptions and lower delta power. Our findings suggest that cold exposure impairs the sleep quality and elevates the amplitude of MBPS and is associated with sleep-related and late sleep stage transition sympathetic activation, which could be important implications for related cardiovascular events.

Title: Antidepressant-like effect of glucocorticoid receptor deletion in the dorsal raphé nucleus

Authors: *M. Y. VINCENT, L. JACOBSON;
Neurosci., Albany Med. Col., Albany, NY

Abstract: Glucocorticoids produced by the hypothalamic pituitary adrenal (HPA) axis can cause depression symptoms whose mechanisms remain unclear. The dorsal raphe nucleus (DRN) produces the majority of serotonin in the brain and is a target for antidepressants, which are thought to work by increasing serotonin levels in depressed patients. The DRN also expresses glucocorticoid receptors (GR). Glucocorticoids inhibit expression of the rate-limiting enzyme for serotonin synthesis in the DRN, and we have found this effect can be partially reversed by antidepressants. We therefore hypothesized that deleting GR in the DRN would have antidepressant-like effects. We used virally-transduced GR gene deletion in the DRN of floxed GR mice to test this hypothesis. We injected adeno-associated virus pseudotype AAV2/9 expressing either Cre recombinase (DRN GR KO mice) or GFP (control mice). Four weeks after injection, mice underwent tests for depression (social interaction; forced swim test; sucrose preference) in the unstressed state and again after 14d of daily social defeat stress. Before social defeat stress, deleting DRN GR increased social interactions but did not affect forced swim despair-like immobility or sucrose intake. After social defeat, deleting DRN GR had antidepressant-like effects to decrease FST despair-like behavior, increase sucrose preference and maintain higher levels of social interaction. GR DRN deletion also increased plasma corticosterone after forced swim stress. We conclude that before stress, DRN GR deletion has an antidepressant-like effect to increase social behavior, whereas during stress DRN GR may have additional roles to diminish additional depression-like behaviors and to restrain HPA activity.

Title: Chronic glucocorticoid intake alters basal Tph2 protein expression in anxiety- and resilience-related midbrain serotonergic systems

Authors: *N. C. DONNER, A. MATTI, C. A. LOWRY;
Dept. of Integrative Physiol. and Ctr. for Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Stress-related psychiatric disorders, such as anxiety and affective disorders, are often correlated with disruption of hypothalamic-pituitary-adrenal (HPA) axis function and dysfunction of brain serotonergic systems. It is, however, unclear what role glucocorticoids (GCs), the primary effector stress hormones of the HPA axis, without the experience of external stressors *per se* play in the etiology of these disorders. Previous research from our lab demonstrated that chronic GC intake via the drinking water dose-dependently induces an anxiety- and depressive-like behavioral phenotype in rats, and disrupts the diurnal expression pattern of *tph2*, the gene encoding the rate-limiting enzyme for brain serotonin synthesis (tryptophan hydroxylase 2, Tph2), by increasing *tph2* mRNA expression during the rats' inactive light-phase. Chronic GC treatment has furthermore been shown to potentiate basal and stress-induced Tph activity in anxiety-related subdivisions of the midbrain dorsal raphe nucleus (DR). Here, we used western blot technique to test the hypothesis that chronic GC treatment also increases basal Tph2 protein expression. Adrenal-intact, adult male rats were treated with 100 μg/ml corticosterone (CORT) or vehicle (0.45% 2-hydroxypropyl-β-cyclodextrin) via the drinking water for 21 days, and their emotional behavior was assessed in the elevated plus-maze (EPM) and forced swim tests (FST) after 2 weeks. In concordance with previous studies, chronically GC-treated rats displayed more anxiety-like behavior on the EPM, and in tendency less proactive stress-coping behavior in the FST. In GC-treated rats, light-phase Tph2 protein expression was significantly elevated in anxiety-related subdivisions of the DR, namely the ventral (DRV) and dorsal part (DRD). Dark-phase Tph2 expression in the DR remained unaltered by GC treatment, while dark-phase (but not light-phase) Tph2 expression in the resilience-related median raphe nucleus (MnR) was in tendency ($p=0.063$) decreased after chronic GC exposure. Our results suggest that anxiety- and resilience-related brain serotonergic systems in the DR and MnR, respectively, are particularly sensitive to GC-induced alterations of Tph2 protein expression, with anxiety-related DR subdivisions being disrupted during the inactive light-phase, while the resilience-related MnR system appears to be affected during the active dark-phase. It remains to be determined whether these region-dependent effects of chronic

GC exposure on Tph2 protein expression result in altered basal and stress-induced serotonin release in specific anxiety-and resilience-related fore- and hindbrain target regions.

Title: Peptidergic regulation of locus coeruleus output by local infusions of corticotropin releasing factor and the mu-opioid receptor agonist DAMGO: effects on sensory signal processing in noradrenergic terminal fields

Authors: *G. A. ZITNIK, III[1], B. D. CLARK[2], B. D. WATERHOUSE[2];
[2]Neurobio. & Anat., [1]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Corticotropin releasing factor (CRF), a neuropeptide that coordinates the cognitive and behavioral responses to stressors, activates the locus coeruleus-norepinephrine (LC-NE) system. Alternatively, mu-opioid receptor agonists, such as morphine or endogenous enkephalin, cause analgesia and sedation in part by inhibiting tonic release of LC-NE. Alterations in LC-NE output have been shown to modulate the transmission of sensory information along primary sensory pathways. The lateral geniculate nucleus (LGN) of the thalamus is the primary relay for visual signals from the retina to the cortex. In rat, the dorsal LGN (dLGN) receives noradrenergic projections derived exclusively from the LC. Using in vivo extracellular recording, we monitored single dLGN neuron activity before and after local infusions of CRF (1, 3, 10, 100 ng) or the mu-opioid receptor DAMGO, [D-Ala2, NMe-Phe4, Gly-ol5]-enkephalin, (10 pg) onto the ipsilateral LC of anesthetized rats during repeated presentation of light flashes at three different stimulus intensities. Intra-LC CRF administration reduced the latency and increased the magnitude of light-evoked responses to threshold level visual stimuli 15-60 min post-CRF for all doses tested (except 1 ng). This facilitation of light-evoked responses followed an inverted-U dose-response curve, with 10 ng eliciting the maximal increase in magnitude. There was also a dose-dependent increase in the number of cells responding to previously sub-threshold light stimulus intensities; i.e. recruiting new cells to the response pool. By contrast, intra-LC infusions of DAMGO at 10 pg, a dose that completely suppresses LC output, had no effect on response latency or magnitude of stimulus-evoked dLGN responses. These findings

suggest that different degrees of CRF-mediated LC activation prompt differential increases in NE release and subsequent dose-specific noradrenergic modulatory actions in the visual thalamus. Thus, activation of the CRF-LC-NE-stress circuit amplifies sensory signal processing by speeding the transmission of sensory signals through thalamic relay circuits and increasing the strength of such signals by magnifying threshold level responses of individual neurons to light stimuli and recruiting previously unresponsive neurons into the visual response pool. Opioid receptor suppression of LC output is believed to serve as a "braking" mechanism to return the output of the LC-NE system to near-baseline levels following CRF-mediated stressor activation. On the other hand, opioid mediated actions on basal LC firing may not manifest as detectable changes in terminal field function. (Supported by NIDA DA017960 to BDW)

Title: Chronic restraint stress decreases glial fibrillary acidic protein and glutamate transporter in the periaqueductal gray matter

Authors: *H. IMBE, A. KIMURA, T. DONISHI, Y. KANEOKE;
Dept. of Physiol., Wakayama Med. Univ., Wakayama City, Japan

Abstract: Stress affects brain activity and promotes long-term changes in multiple neural systems. Exposure to stressors causes substantial effects on the perception and response to pain. In several animal models, chronic stress produces lasting hyperalgesia. The periaqueductal gray matter (PAG) is involved in various important functional activities, such as fear, anxiety, defensive reaction and autonomic regulation. It also plays a crucial role in pain modulation. The PAG receives projections from the cerebral cortices, amygdala and hypothalamus and in turn controls spinal nociceptive neurons through relays in the rostral ventromedial medulla and dorsolateral pontine tegmentum. These structures constitute neural circuit of descending pain modulatory system. Postmortem studies of stress-related psychiatric disorders have demonstrated a decrease in the number of astrocytes and the level of glial fibrillary acidic protein (GFAP), a marker for astrocyte, in the cerebral cortex. Since astrocytes play vital roles in maintaining neuroplasticity via synapse maintenance and secretion of neurotrophins, impairment of

astrocytes is thought to be involved in the neuropathology. In the present study we examined GFAP and excitatory amino acid transporter 2 (EAAT2) protein levels in the PAG after subacute and chronic restraint stresses to clarify changes in descending pain modulatory system in the rat with stress-induced hyperalgesia. Chronic restraint stress (6h/day for 3weeks), but not subacute restraint stress (6h/day for 3days), caused a marked mechanical hypersensitivity and aggressive behavior. The chronic restraint stress induced a significant decrease of GFAP protein level in the PAG (32.0±8.9% vs. control group, $p<0.05$). In immunohistochemical analysis the remarkable decrease of GFAP was observed in the ventrolateral PAG. The EAAT2 protein level in the 3weeks stress group (79.6±6.8%) was significantly lower compared to that in the control group (100.0±6.1%, $p< 0.05$). In contrast there was no significant difference in the GFAP and EAAT2 protein levels between the control and 3 days stress groups These findings suggest a dysfunction of the PAG that plays pivotal roles in organization of strategies for coping with stressors and in pain modulation after chronic restraint stress.

Title: Effect of different corticosterone administration methods on corticosterone serum levels and forced swim test behavior in female rats

Authors: F. A. SHOUBAH, J. M. KOTT, *S. BRUMMELTE;
Psychology, Wayne State Univ., Detroit, MI

Abstract: High levels of chronic stress or stress hormones are associated with depressive-like behavior in animal models. However, slight elevations in corticosterone -the major stress hormone in rodents- have also been associated with improved performances, albeit in a sex-dependent manner. Some of the discrepancies in the literature regarding the effects of high corticosterone levels may be due to different administrations methods. The current study aims to compare the effects of ~ 40mg/kg given either via subcutaneous injection, through an implanted pellet, or via the drinking water for 21 days on depressive-like behavior in the forced swim test, as well as on diurnal corticosterone serum levels in adult female rats. We hypothesize that animals exposed to the daily injections will show the highest corticosterone levels by the end of the administration period and will still show diurnal differences, while the other groups may

have diminished serum concentrations as well as a flattened diurnal rhythm. In addition, we expect the injection group to show higher levels of immobility in the forced swim test. The results will contribute to the growing literature on the effects of chronic corticosterone exposure and may help to clarify some of the discrepancies among previous studies.

Title: Ketamine restores active coping behavior after stress in the rat defensive burying test - Evidence for a role of STAT3

Authors: *M. GIROTTI[1], J. J. DONEGAN[2], E. A. FUCICH[2], D. A. MORILAK[2]; [1]Pharmacol., Univ. Texas Hlth. Sci. Ctr., SAN ANTONIO, TX; [2]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: Coping style influences the psychological and physiological burden of stress and there is evidence from both clinical and preclinical studies that active coping is more adaptive than passivity. Defensive burying (DB) refers to the innate rodent behavior of displacing bedding material towards a source of threat, such as an electrified probe placed inside a test cage. Because DB is a well-validated model of defensive behavior that includes both passive (immobility) and active (burying) behaviors in response to the stressful experience of the shock, it may provide a useful context to study molecular and cellular mechanisms of shifts in coping styles. Burying behavior in the rat is dependent on circuitry from the lateral septum, prefrontal cortex, hippocampus and nucleus accumbens. We have previously shown that noradrenergic neurotransmission in the lateral septum modulates burying behavior and that a stress paradigm designed to model aspects of post-traumatic stress disorder shifts the coping style from active to passive behavior.
In this study we have examined whether other types of chronic stress paradigms influence the

choice of behavior in the defensive burying test and we have begun an investigation of the possible underlying mechanism. First, we tested whether 2 weeks of chronic intermittent cold (CIC) stress or chronic unpredictable stress (CUS) might shift the coping style from active (burying behavior) to passive (immobility) in the DB test. We found that both CIC and CUS animals displayed significantly less burying behavior than control rats. CUS also produced a significant increase in immobility, indicating that CUS shifts the rat's coping style from active to passive. We then investigated whether ketamine, a NMDA receptor antagonist previously shown to revert behavioral and cellular effects of stress, might reduce the CUS-driven increase in passive behavior. We found that ketamine (10mg/kg, i.p., 24h prior to behavioral testing) shifted the behavior of CUS animals from passive to active (decreased immobility and increased burying), indicating that ketamine-induced plasticity affects the choice of behavior in this test. We are currently searching for the molecular correlates of the behavioral shifts produced by stress and ketamine. Initial data with hippocampal sub-cellular fractions show that ketamine increases phosphorylated STAT3 in the nucleus. We have found in other studies that STAT3 is implicated in cognitive flexibility; the current results suggest it may also have a role in the ketamine-driven plasticity that underlies coping style choice.

Title: Phenotypic relationships among multiple measures of stress reactivity

Authors: *K. FITZPATRICK, P. JIANG, M. H. VITATERNA, F. W. TUREK;
Ctr. for Sleep and Circadian Biol., Northwestern Univ., EVANSTON, IL

Abstract: Resilience to stress is fundamentally required in order to maintain mental and physical health, although research into the basis of resilience has been largely restricted by the use of a limited number of stressors, response measurements, and number of subjects. We set out to identify specific molecular and genetic mechanisms underlying the stress response and resilience capacity in a comprehensive and high-throughput fashion. We utilized eight different stressors, both physical and emotional in nature, as well as a comprehensive panel of response

measurements including behavioral, cognitive, hormonal, immune, molecular, and sympathetic nervous system response systems. Here, we will present data from these multiple phenotypic measurements collected throughout a 8-week long chronic stress protocol in a genetically segregating population of 297 male (C57BL/6J x A/J) F2 mice.
We identified several correlational relationships among the phenotypic measures which revealed both expected and unexpected associations. For example, both body weight and blood glucose levels were measured at four timepoints throughout the chronic stress protocol, and we found that these two interrelated measures were significantly correlated under predominantly physical stress conditions. However, this significant relationship was not present when the stress was emotional in nature, as in the case of social defeat. Additionally, corticosterone levels at the time of necropsy correlated significantly with the naïve measure of anxiety behavior, but did not demonstrate a relationship with any of the intermediary corticosterone measurements under both physical and emotional stressors. Furthermore, we found that various behavioral measures of anxiety taken throughout the protocol were significantly correlated. Together, the relationship between and among baseline corticosterone levels and outward anxiety behaviors suggests an underlying stability of stress resistance, possibly of genetic origin. We also utilized factor analysis to uncover underlying structure among the measures, which identified four factors grouped as metabolic function, fearfulness, glucocorticoid activity, and anxiety, and which explain approximately 25% of the variance within the dataset.
We are currently analyzing how these phenotypic measures relate to genotype and gene expression levels in various brain regions in order to identify specific genetic networks for future study in stress and for the development of novel therapies to prevent stress-related decrements in the brain and cognitive performance.

Title: Anti-stress effects of electro-acupuncture (EA) on the expression of corticotropin-releasing factor (CRF) and GABA receptors in the hypothalamus and hippocampus in acute stress rats<!--EndFragment-->

Authors: *L.-T. ZHU, Y. FENG, G.-C. WU, Z.-Z. TIAN;
Fudan Univ., Shanghai, China

Abstract: CRF is a hypothalamic releasing peptide that regulates the endocrine, autonomic and behavior response to stress through interaction with typical neurotransmitters. In stress response, the CRF in the paraventricular nuclei (PVN) is signaled by the amygdala and then releases CRF to activate the HPA axis and also interacts with the hippocampus, which may suppress the hyperactivity of HPA axis through the interaction with the activation of GABA receptors. As demonstrated by many previous studies, EA treatment of acute stress is associated with the amygdaloid, hypothalamic CRF expression and regulation of the HPA axis. It is still unknown whether EA exerts central effects between hypothalamus and hippocampus in acute stress. The acute stress rats was provoked by partial hepatectomy. The righting reflex was examined after surgery immediately or 30min after anesthesia in rats without surgery. Hypothalamic and hippocampal CRF, GABA receptors levels were measured using the methods of western blot and real-time PCR. Statistically significant acceleration was observed in the recovery time over the period of that EA treatment (Fig.1). EA also decreased hypothalamic CRF mRNA and CRF1 receptor mRNA levels, while increasing GABA(A) α3 and α4 subunit mRNA levels. The hippocampal GABA(A) α5 subunit mRNA was decreased after EA treatment.(Fig.2). The hypothalamic CRF, α1 and α3 subunit of GABA(A) receptor and GABA(B) receptor were also found decreased by EA treatment. But hippocampal CRF and Ucn levels were increased. However, no statistically significant differences were observed in the hippocampal GABA receptors and GR (Fig.3). The aim of the study focuses on the suppression effect of hippocampal CRF neurons on hypothalamic CRF activation and anti-stress effects of EA. These data demonstrate that EA may attenuate the acute stress by modulating hippocampal CRF so that to activate the hypothalamic GABA receptors to inhibit the CRF neurons in the hypothalamus.

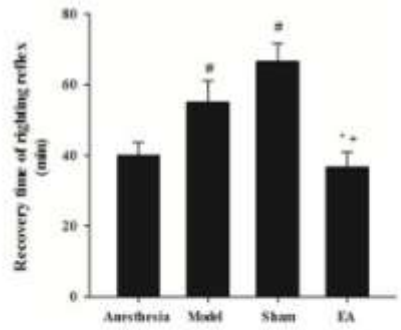

Fig 1. Effects of EA on the recovery of righting reflex after operation
The recovery time was measured every 10 min after the surgery. The operative rat with sham EA and without treatment showed long time recovery. But EA treatment promote the recovery time after the hepatectomy.
#, versus anesthesia; *, versus model; +, versus sham (acupuncture without electric)

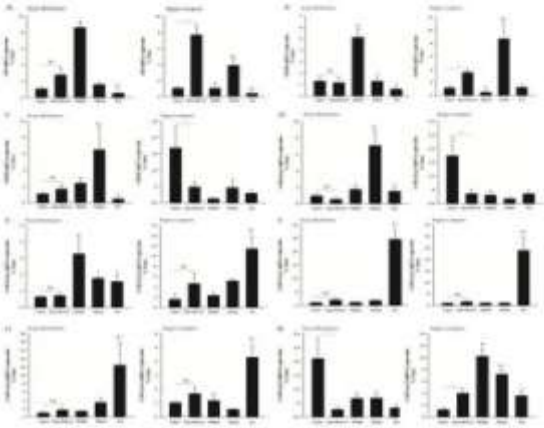

Fig 2. The mRNA level of CRF and its receptors, GABA(A) receptors expression changes after EA.
In acute stress, hypothalamic CRF, CRF1 receptor and GABA(A) α2 subunit mRNA were increased after surgery, but GABA(A) α5 was decreased, which was opposite to the changes of the hippocampus. However, despite of the down regulated CRF, CRF1 receptor and α2 subunit mRNA, EA treatment also up regulated the α3 and α4 subunit in the hypothalamus, increased the α2, α3 and α4 subunit and decreased α5 subunit in the hippocampus.
#, versus anesthesia; *, versus model; +, versus sham.

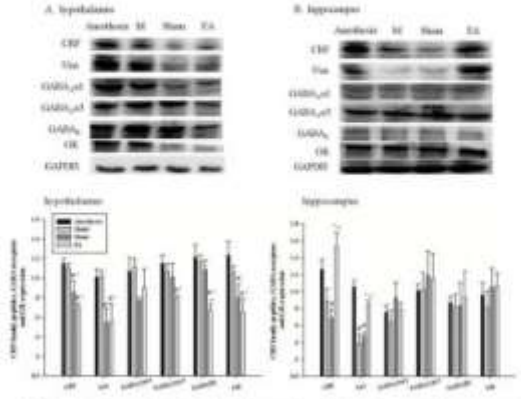

Fig 3. The anti-stress effects of EA on the expression of CRF, glucocorticoids receptor and GABA receptors.
At the protein level measured by western blot, both sham EA and true EA decreased CRF, urocortin and glucocorticoids receptor expression in the hypothalamus. But only EA treatment decreased hypothalamic α3 subunit and GABA(B) receptor level, and increased the hippocampal CRF expression.
#, versus anesthesia; *, versus model; +, versus sham.

Title: Time-dependent increase in cortisol in response to an acute stressor and the role of the dopaminergic and serotoninergic system in zebrafish (Danio rerio)

Authors: *S. TRAN[1], D. CHATTERJEE[2], R. GERLAI[2];
[1]Cell and Systems Biol., [2]Psychology, Univ. of Toronto, Mississauga, ON, Canada

Abstract: The zebrafish stress response is characterized by the release of cortisol from the interrenal gland, similar to the release of cortisol from the adrenal gland in humans. However, the use of zebrafish in behavioural neuroscience is still novel with little information on the hypothalamic-pituitary-interrenal axis. In the current experiment we exposed zebrafish to an acute net handling stressor (30 seconds) and quantified cortisol and neurochemical levels at 0, 1, 5, 10, and 15 minutes post-stressor. A separate group of zebrafish were immediately sacrificed without the stressor to serve as controls. Whole body cortisol levels were then quantified at each

time point by ELISA using a human saliva cortisol kit. In addition, the levels of dopamine, 3, 4-dihydroxyphenylacetic acid, serotonin, and 5-hydroxyindoleacetic acid from whole-brain samples were quantified by using high precision liquid chromatography (HPLC). Results demonstrated that whole body cortisol levels increased in a time-dependent manner with levels peaking at 15 minutes. Interestingly, there were no significant differences in any of the neurochemicals measured in response to stress. Previous findings showed the dopaminergic and serotoninergic system to respond to specific environmental stimuli (animated computer images) within minutes after the exposure. Our current findings together with those already published suggest that hormonal measures such as cortisol may be more sensitive to experimenter handling prior to decapitation, whereas neurochemical measures may be more resilient to this particular manipulation. The findings here provide a possible explanation for the commonly found larger variance in cortisol levels in zebrafish compared to neurochemical data.

Title: Adolescent cannabinoid treatment sex dependently alters adult stress responsivity

Authors: *T. T.-Y. LEE[1], S. R. WAINWRIGHT[2], M. N. HILL[5], L. A. M. GALEA[3], B. B. GORZALKA[4];
[1]PSYCHOLOGY, Univ. of British Columbia, VANCOUVER, BC, Canada; [2]Neurosci., [3]Psychology, Neuroscience, Brain Res. Ctr., Univ. of British Columbia, Vancouver, BC, Canada; [4]Psychology, Univ. of British Columbia, vancouver, BC, Canada; [5]Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: Cannabinoid exposure during adolescence has been shown to have a variety of adverse effects on neuroplasticity, emotional behaviour, cognition and reward sensitivity in adult rats. We investigated whether escalating doses of the cannabinoid CB1 receptor (CB1R) agonist,

HU-210, in adolescence would affect adult stress responsivity to a 30 min restraint session in male and female Sprague-Dawley rats. Escalating doses of HU-210 (25, 50, and 100 µg/kg), or vehicle were administered from postnatal day (PND) 35 to 46. Animals were left undisturbed until PND 75, in which hypothalamic-pituitary-adrenal (HPA) axis reactivity to an acute restraint stress (30 min; PND 75) was assessed. Female rats, regardless of adolescent treatment condition, had higher corticosterone levels than males at 0, 30, and 60 min following restraint stress onset. Adolescent HU-210 administration induced significantly higher peak corticosterone levels despite comparable basal levels. This effect was more pronounced in males than females when comparing the relative corticosterone response to vehicle injected groups. These findings were surprising given that females are generally known to exhibit stress sensitivity. Results of this study indicate increased CB1 receptor activation during adolescence results in long-term, sex dependent alterations to HPA axis stress responsivity in male, but not female rats. Further studies are necessary to determine the mechanisms underlying these differential effects.

Title: Orexin-1 receptor antagonism attenuates stress-induced arousal in rodents

Authors: S. YUN, J. SHELTON, P. BONAVENTURE, B. SHIREMAN, T. LOVENBERG, *C. DUGOVIC;
Janssen Res. & Develop., San Diego, CA

Abstract: Orexins are peptides produced by lateral hypothalamic neurons that exert a prominent role in arousal-related process including stress by activating orexin-1 (OX1R) and orexin-2 (OX2R) receptors located widely throughout the brain. Selective pharmacological blockade of OX2R promotes sleep by inhibiting the output of wake active neurons in the hypothalamus and brainstem regions. In contrast, pharmacological or genetic selective inhibition of OX1R does not affect sleep. Stress and corticotrophin-releasing factor activate orexin neurons, and orexin administration stimulates hyperarousal, ACTH and corticosterone release. More recently, it has been shown that in several rodent models of panic anxiety disorder activation of orexin neurons could be specifically mediated by OX1R, as OX1R antagonism can block the panic responses. In

the present study, we first evaluated the arousal effects of a psychological stress elicited by cage exchange (animal placed in a dirty cage previously occupied by another animal for one week) on EEG sleep, locomotor activity in rats, and on pituitary-adrenal activation in mice. In this model, we tested whether a selective OX1R antagonist (compound A) could attenuate these behavioral activating effects. In mice, cage exchange-induced stress produced a significant increase in ACTH plasma levels consistent with an activation of the HPA axis. In rats, cage exchange stress induced a significant delay in both non-REM and REM sleep latencies associated with an increase in wake duration and locomotor activity as compared to the control condition (brief handling). Administration of the OX1R antagonist alone did not affect any EEG sleep-wake parameters either in baseline or in control condition compared to vehicle-treated rats, but prevented the sleep onset insomnia (i.e. prolonged non-REM and REM sleep latencies) and partially attenuated the active wake induced by cage exchange. These data indicate that in a psychological stress model, behavioral arousal responses can be attenuated by a selective OX1R antagonist that could represent a new therapeutic strategy for anxiety disorder without affecting sleep per se.

Title: Toll-like receptor 4-mediated nuclear factor kappa B activation is essential for sensing exogenous oxidants to propagate and maintain oxidative/nitrosative cellular stress

Authors: *O. J. IGWE, R. KARKI;
Div. of Pharmacol. & Toxicology, Univ. Missouri- KC, KANSAS CITY, MO

Abstract: Objectives: To determine the mechanism(s) by which cells may sense exogenous oxidants to potentially initiate, propagate and/or maintain inflammation through NF-κB activation.
Methods: First, we used a human embryonic kidney (HEK-Blue) cells that stably express either mouse toll-like receptor 4 (TLR4) with the CD14/MD-2 co-receptor genes, or TLR2 with the CD14 co-receptor gene against a null background. These cells were used to examine the role of

pro-oxidants on TLR4- and TLR2- dependent NF-κB activation. Cells also express optimized secreted embryonic alkaline phosphatase (SEAP) reporter gene under the control of a promoter inducible by NF-κB transcription factor. These cells were challenged with their respective receptor-specific ligands, different pro-oxidants and /or inhibitors that act at different levels of TLR4 or TLR2 signaling pathways. We used the level of SEAP released into the culture media due to NF-κB activation as a measure of the extent of TLR4 or TLR2 stimulation. To integrate the *in vitro* system with an *in vivo* model, we used an orofacial behavioral pain model. We investigated the role of a novel prooxidant in regulating the expression of TLR4 and the levels of proinflammatory cytokines in the mouse masseter (masticatory) muscle.
Results: Pro-oxidants evoked increased release of SEAP from HEK-Blue mTLR4 cells at a much lower concentration compared with release from the HEK-Blue mTLR2 cells. Specific TLR4 signaling pathway inhibitors and oxidant scavengers (anti-oxidants) significantly attenuated oxidant-induced SEAP release by TLR4 stimulation. A neutralizing antibody directed against TLR4 inhibited responses to both TLR4-specific agonist and a prooxidant, which confirmed that both TLR4-specific and prooxidant act through TLR4. Furthermore, a novel pro-oxidant that decays to produce the same reactants as activated phagocytes induced inflammatory pain responses in the mouse orofacial region with increased TLR4 expression, and IL-1ß and TNFα tissue levels. EUK-134, a synthetic serum-stable scavenger of oxidative species decreased these effects. Pro-oxidants activate NF-κB by interacting mainly with TLR4.
Conclusions: Exogenous oxidants stimulated TLR4 at a much lower concentration than TLR2. Oxidant-induced orofacial pain increased TLR4 expression that was reduced by a scavenger for oxidative species. Our data provide *in vitro* and related *in vivo* evidence that exogenous oxidants can induce and maintain inflammation by acting mainly through a TLR4-dependent pathway.

Title: Cytisine (partial nicotinic receptor agonist) can alter epinephrine responsiveness to insulin-induced recurrent hypoglycemia

Authors: *B. B. NANKOVA[1], N. KIRTOK[2], U. AKPAN[2], O. CHAN[3], E. LAGAMMA[4]; [1]Pediatrics & Biochem & Mol Biol, New York Med. Col., Valhalla, NY; [2]Pediatrics, The Regional Neonatal Center, Maria Fareri Children's Hosp. at Westchester Med. Ctr., Valhalla, NY; [3]Intrnl. Medicine, Endocrinol., Yale Sch. of Med., New Haven, CT; [4]Pediatrics & Biochem & Mol Biol, New York Med. College, and Regional Neonatal Center, Maria Fareri Children's Hosp., Valhalla, NY

Abstract: Recently we have shown that depending on the daily frequency of stress episodes recurrent hypoglycemia can either increase adrenal TH mRNA and protein (once daily) to sustain biosynthesis and release of epinephrine or, paradoxically, suppress it's induction (twice daily) resulting in depletion of adrenal catecholamine stores and progressive loss in circulating epinephrine. Since both, the release and the synthesis of epinephrine are mediated by adrenal nicotinic acetylcholine receptors (nAchR); we hypothesized that their excessive stimulation during recurrent twice daily episodes of hypoglycemia contributes to the impaired counter-regulation.

The plant alkaloid cytisine is a nicotinic receptor partial agonist primarily studied for its effect on selected subtypes of central nAChR. Its effect on peripheral neuronal nAChRs and the attendant autonomic neurotransmission has not been addressed. Here we demonstrate that cytisine acts as a partial agonist of adrenal nAchRs *in vitro* (PC12 cells) and *in vivo* (male, non-diabetic SD rats) in regard with two main biological outputs: release of neurotransmitters and increase in catecholamine biosynthesis as compared to nicotine or endogenous neurotransmitter (acetylcholine released in response to hypoglycemia). In addition, when animals were pre-treated with cytisine, epinephrine responses to acute hypoglycemia were reduced by 30%. Interestingly, when given before each episode of twice daily recurrent hypoglycemia (an animal model of hypoglycemia associated autonomic failure, HAAF) cytisine improved the counter-regulatory responses. As hypothesized, the changes in TH mRNA levels correlated with the magnitude of the corresponding epinephrine responses. These experiments provide a proof of concept, that pharmacological manipulation of adrenal nAchR can improve the attenuated epinephrine counter-regulation *in vivo* in an animal model of HAAF and thus offer promise as a translational adjunctive therapy for insulin-dependent diabetes.

Title: Repeated restraint stress alters the corticosterone response to serotonin 1A receptor activation in males, but not females

Authors: *N. GOEL, V. VIAU;
Cell. and Physiological Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Maladaptive stress coping is associated with increased risk of affective disorders such as depression and anxiety. These disorders are more prevalent in women than in men and involve dysfunction of both the serotonin (5-hydroxytryptamine, 5-HT) system and the hypothalamic-pituitary-adrenal (HPA) stress axis. Alterations in 5-HT 1A receptor function could contribute to this sex disparity, as depression in humans and chronic stress in rodents are associated with blunted HPA axis responses to systemic administration of 5-HT 1A receptor agonists. Using a model of stress habituation, our current findings indicate that female rats do not show a reduced corticosterone (CORT) response to restraint stress after the fifth exposure, while males show robust attenuation. We propose that this sex difference in HPA axis habituation could be related to differential changes in 5-HT 1A receptor function. To investigate this possibility, we exposed adult male and female rats to 5 daily episodes of 2 hour restraint stress. We then examined HPA output responses to the selective 5-HT 1A receptor agonist, 8-OH-DPAT (0.2 mg/kg, sc), 24 h after the last restraint exposure. Again, our results showed that the CORT response to the fifth day of restraint stress compared to the first day is reduced in males, but not in females. Compared to unstressed animals, male rats exposed to repeated restraint showed an enhanced CORT response to 8-OH-DPAT. In contrast, a history of repeated stress in females had no impact on the response to 8-OH-DPAT. Previous studies show that the HPA response to acute 8-OH-DPAT administration is mediated by postsynaptic 5-HT 1A receptors. Thus, the present results provide insight into the mechanisms involved in stress adaptation and foreshadow sex-dependent changes in 5-HT 1A receptor function within forebrain afferents to the HPA axis.

Title: Partial insulin-like growth factor 1 (igf-1) deficiency promotes cerebral oxidative damage

Authors: J. E. PUCHE, U. MUÑOZ, L. GUERRA, *I. CASTILLA DE CORTAZAR;
Univ. CEU San Pablo, Madrid, Spain

Abstract: Background: Insulin-like growth factor-1 (IGF-1) is a polypeptide hormone responsible for a wide range of systemic activities (anabolic, cytoprotective and anti-inflammatory). In the central nervous system, it has been documented a relevant role for IGF-1 in normal neuron progenitor proliferation and differentiation, neuritic outgrowth, and amyloid-β clearance, among others. A model of partial IGF-1 deficiency may shed light into these underlying mechanisms.
Material and Methods: Heterozygous (*Igf1*$^{+/-}$) 5 months old mice (Hz, n=10) were compared to homozygous *Igf1*$^{+/+}$ (WT, n=10, same age) by assessing cerebral gene expression (via quantitative PCR) of IGF-1-related factors, antioxidant enzymes, inflammatory response components, heat shock proteins and cell death markers. The effect of the replacement therapy with low doses of IGF-1 (2 µg/100 g body weight/day, for 10 days, s.c.) was evaluated in parallel (group Hz+IGF, n=10, same age). Complementarily, magnetic resonance images (both ADC and MT maps) were obtained from these mice brain.
Results: We firstly confirmed that the reduced *Igf1* gene expression correlated with low circulating levels of this hormone what, in turn, induced a lower body weight of IGF-1 deficient mice. Cerebral expression of IGFBPs was found altered for isoforms 4, 6, 7 and 8. IGF-1 receptor gene expression was increased in Hz mice, thus suggesting a compensating mechanism due to the lower IGF-1 levels. An abnormal gene expression of antioxidant enzymes (*Cat* and *Gpx*), inflammatory response components (interleukins and *Ptgs2/Cox2*), heat shock proteins (*Hsp90b1, Hsp13, Hsp1* and *Hspa2*), and cell death markers (*Gadd45a, Ulk1, Grb2, Bid* and *Parp1*) was also observed in Hz mice. Substitutive IGF-1 was able to restore all of these factors. Finally, ADC and MT maps reported signs compatible with edema and inflammation, what has been previously associated with neuronal loss and gliosis.
Conclusion: This model of IGF-1 deficiency unravels protective cerebral actions of IGF-1 in adult mice, since the mere IGF-1 deficit (with no other external damage) increases parameters of oxidative damage, inflammation and cell death, that IGF-1 replacement therapy reduces to those values found in control animals.

Title: The use of designer receptors exclusively activated by designer drugs (DREADDS) to elucidate the role of orexins in adaptations to stress

Authors: *S. BHATNAGAR[1], A. SENGUPTA[2], W. HEYDENDAEL[2], J. PEARSON-LEARY[2], G. KELLY[2], D. PIEL[2], S. BECK[1];
[1]Dept Anesthesiol., Univ. Pennsylvania, Children's Hosp Philadelphia, PHILADELPHIA, PA;
[2]Dept Anesthesiol., Children's Hosp. of Philadelphia, PHILADELPHIA, PA

Abstract: Maladaptation to repeated stress is associated with psychopathology. However, our understanding of the underlying neural circuitry involved in adaptations to repeated stress is limited. Previous work from our lab has indicated an important role for the hypothalamic neuropeptides orexins in regulating the neuroendocrine and behavioral responses to repeated stress. To further elucidate how orexins regulate stress-induced behaviors, we employed a pharmacogenetic technique of evolved G protein coupled receptors (also known as DREADD) that can be activated by administration of the otherwise inert clozapine-n-oxide (CNO) to manipulate orexin neurons in vivo. We generated adenoviruses (AAV) encoding either the Gq-coupled hM3Dq or Gi-coupled hM4Di receptor fused to mCitrine under the control of the prepro-orexin promoter and injected them bilaterally to the lateral hypothalamus, the site of orexin cell bodies. Expression of these constructs was verified by co-immuno labeling with GFP and OrexinA. The functionality of the constructs was verified by bath application of CNO to hypothalamic slices using whole cell patch clamping of mCitrine-expressing cells to record baseline and CNO-evoked electrophysiological responses. Cells expressing hM3Dq exhibited increased firing whereas cells expressing hM4Di exhibited hyperpolarization after CNO application. We then examined whether repeated orexin activation or inhibition using DREADDs affected behavior during repeated defeat. We have previously shown that variations in average latency to be defeated during 7 days of defeat in the resident-intruder paradigm are associated with distinct behavioral consequences. Animals exhibiting short latencies to be defeated are passive and exhibit increased anxiety- and depression-related behaviors. In contrast, animals exhibiting long latencies to be defeated exhibit active coping strategies including increased upright boxing postures. AAV-injected rats (n=6 hM3Dq, n=4 hM4Di) were exposed to 5 days

of social defeat with no drug to establish their latency profiles followed by 3 days of social defeat with CNO application 1 hour prior to each of the three days of defeat. We found that inhibiting the orexin cells (hM4Di) significantly reduced ($p \leq .03$) their average defeat latency. In contrast, stimulating orexin cells (hM3Dq) significantly increased ($p \leq .03$) their average defeat latency compared to the 5 days of defeat without CNO application. These results suggest that orexin neurons play an important role in behavioral coping strategies exhibited during stress.

Title: Noise stress increases *In vivo* tryptophan hydroxylase activity in serotonergic systems and within anxiety and emotion related brain regions

Authors: *J. H. FOX[1], E. D. PAUL[1], B. M. SPANNUTH[1], M. W. HALE[2], C. A. LOWRY[1]; [1]Dept Integrative Physiol., Univ. of Colorado, Boulder, CO; [2]Sch. of Pyschological Sci., La Trobe Univ., Melbourne, Australia

Abstract: Studies using the acoustic startle paradigm have reported changes in serotonergic systems arising from the midbrain raphe complex. A pure tone used as a noise stressor increases in vivo tryptophan hydroxylase (TPH) activity, as measured by 5-hydroxytryptophan (5-HTP) accumulation following administration of the aromatic amino acid decarboxylase inhibitor NSD-1015 in the median raphe nucleus (MnR). More recent studies in our laboratory reported that acoustic stimuli increased in vivo TPH activity selectively within the caudal part of the dorsal raphe nucleus (DRC). Further, acoustic stimuli increase corticosterone levels which may be necessary for the increased TPH activity as adrenalectomized rats do not show the increase in TPH activity induced by acoustic stimuli. As most studies investigating the acoustic startle response use white noise as a startle stimulus, we investigated whether white noise as opposed to a pure tone would also induce an increase in TPH activity in midbrain serotonergic systems. We measured 5-hydroxytryptophan (5-HTP) accumulation in male Sprague Dawley rats as an index of TPH activity following inhibition of aromatic amino acid decarboxylase (using NSD-1015). Treatment groups included home cage control (HCC), exposure to a startle chamber with no

noise (sham-stress; AS−), exposure to a pure tone stimulus (30 tones over 30 min with a variable ITI; 3.0 kHz; 100 ms; 100 dB; AS1) and exposure to a white noise stimulus (30 tones over 30 min with a variable ITI; 3.0-32.0 kHz; 50 ms; 100 dB; AS2) group. We replicated previous findings reporting pure tones, relative to HCC, increase 5-HTP in the MnR as well as other anxiety- and emotion-related brain regions, including the cingulate cortex, area 1 (Cg1), infralimbic cortex (IL), accumbens nucleus, shell (AcbSh), dorsal hypothalamic area (DA)/posterior hypothalamic area (PH), and dorsal raphe nucleus, ventral part (DRV). In contrast, white noise had no effect on 5-HTP accumulation in the midbrain raphe complex, but increased 5-HTP within anxiety- and emotion-related brain regions like the Cg1 and IL. Importantly, we also found that sham-stress increased 5-HTP accumulation in the DRV, IL and AcbSh, relative to HCC conditions, suggesting that some of the effects of noise stress per se could be accounted for by the stress of being restrained in the chamber. These data indicate separate but related brain regions involved in specific types of noise stress. In addition, some of the effects of the noise stress paradigm can be accounted for by acute mild restraint stress-induced increases in in vivo tryptophan hydroxylase activity.

Title: Cortisol expression and related behavior change in the zebrafish (danio rerio)

Authors: *D. J. ECHEVARRIA[1], A. D. COLLIER[1], D. J. JOUANDOT[2], C. BREAZEALE[3]; [1]Dept Psychol, Univ. Southern Mississippi, HATTIESBURG, MS; [2]Brother Martin High Sch., New Orleans, LA; [3]Southern Illinois Univ., Carbondale, IL

Abstract: The zebrafish (Danio rerio) animal model is steadily gaining popularity in behavioral neuroscience research. This species' stress response has been reported to induce observable behavioral alterations within a number of paradigms adopted from the rodent literature. In this study, zebrafish were exposed to an acute stressor, consisting of isolation and confinement in 100mL of water within a 250mL beaker. Studies pharmacologically manipulating zebrafish behavior often deliver water soluble compounds via a bath solution within a beaker to be absorbed through the gills. Previous research in our lab has revealed that the beaker stress

paradigm (adapted from the bath solution method) reliably stimulates the release of cortisol, a physiological indicator of stress. We show here that this robust stress response is correlated with significant behavioral changes that have been observed within three well-utilized tasks in the literature, the novel tank dive, light-dark discrimination and open-field testing. A separate experiment sought to better understand this relationship as a function of time. Following the stressor, animals were placed in an aquatic open-field testing tank, and whole-body cortisol levels were subsequently measured over various time intervals during a 60 minute period. Mean cortisol levels were found to be highest during minutes 10 and 15 in the open field, and at minute 20, cortisol levels significantly decreased and remained relatively stable throughout minutes 25, 30, 45, and 60. All time points were also found to be significantly greater than baseline. Initial analysis revealed a strong correlation between cortisol levels and behavior change over time. Stress induced behavioral phenotypes, correlated with a measureable endocrine response, help to establish the zebrafish as a viable neurobehavioral model of stress and anxiety.

Title: Neonicotinoid pesticide disrupts circadian locomotor behavior in *Drosophila*

Authors: *M. TACKENBERG[1], K. BROADIE[2], D. G. MCMAHON[2];
[1]Neurosci., Vanderbilt Univ., Nashville, TN; [2]Biosci., Vanderbilt, Nashville, TN

Abstract: A massive decrease in honeybee populations has been observed over the past ten years. This so-called Colony Collapse Disorder (CCD) has profound global implications, as honeybees may be responsible for the pollination of up to 80% of the United States' food producing crops, with a similar role worldwide. Studies over the past decade have identified a widely-used class of pesticides, nicotinic acetylcholine receptor agonists known as neonicotinoids, as a potential culprit for CCD. Further investigation into the effects of these pesticides on honeybees has revealed decreased forager return in bees given sublethal doses. We hypothesize that this change may be brought about through disruption of the circadian system of the bee, which it uses to navigate appropriately to and from hives. We have found that in

drosophila, sublethal exposure to the neonicotinoid thiamethoxam produces a disruption of circadian locomotor activity in LD cycles, with dosed flies exhibiting an increase in dark activity and corresponding decrease in light activity. Our results indicate that the pesticide may, in fact, be causing a disruption of the clock, which may lead to navigational issues in organisms that use circadian timekeeping for orientation.

Title: Perinatal exposure to nicotine alters circadian system's response and synchronization in the juvenile mouse

Authors: *M. FUENTES-CANO[1], X. RINZA-FERNÁNDEZ[2], P. DURAN[1];
[1]Facultad De Ciencias, UNAM, Mexico City, Mexico; [2]Facultad De Ciencias, UNAM, Coyoacán, Mexico

Abstract: Tobacco and its main addictive component, nicotine have been associated to a large number of alterations in the development of the central nervous system (CNS) due to the interaction with the cholinergic system, in particular to the nicotine cholinergic receptors (nAChr). As is widely known, the cholinergic system (CS) and its nAChr are responsible for important processes during the CNS like development as neurogenesis. However, the study of the effects of nicotine during development in the circadian and system and particularly in the suprachiasmatic nuclei (SCN) remains an open question. The aim of this study was to analyze in juvenile mouse, the effects of perinatal exposure to nicotine on the circadian rhythm of locomotor activity as well as its physiological response to different photoperiods. In order to examine the SCN physiological integrity to maintain the circadian locomotor rhytms and its capacity to respond to resynchronization and constant light stress, ten 30 day-old male balb/c mouse per group, a control without treatment (Co) and a previously exposed to maternal 6mg/kg/day nicotine consumption, during gestation through lactation periods group (Pn), were submitted to a locomotor activity recording system (using infrared sensors). The recording period consisted in 65 consecutive days where the animals were exposed to: light/Dark (L:D) 12:12 by 5 days, constant darkness (CD) 0:24 by 25 days, L:D 12:12 by ten days and constant light (LC) 24:0 by 25 days. Data were analyzed using ACTIVIEW. Results showed a

consolidated circadian locomotor rhythm (CD tau=23.5 ±0.23hrs and CL tau=25.68±0.21 hrs) and resynchronization to 3±1 days in CL in the Co group. However, the Pn group increased their total locomotor activity but showed a deficient control circadian rhythm while in free running conditions (CD), since they became arrhythmic after 11 ±3 days in CD, and failed to resynchronize to LD (5±1 days). The aforementioned results suggest that the cholinergic system altered by perinatal nicotine exposure, in particular its nAChr, had a direct influence on the SCN and/or the whole circadian system, probably altering the photic response to external stimuli in the mid and long term. We conclude that the cholinergic system overstimulation (throughout the nicotinic receptors) during the critical periods of perinatal development may affect the circadian system maduration and the locomotor activity rhythm as well as the photic stimuli synchronization. Finally, it is possible that the nicotinic receptor expression and the cholinergic regulation alters the circadian system neuroanatomical substrate during those developmental critical periods.

Title: Analysis of complexity and regularity of spontaneous locomotion in group-housed mice: A novel predictive approach based on freely behaving animals

Authors: *S. SPULBER, M. CONTI, N. ONISHCHENKO, S. CECCATELLI;
Karolinska Institutet, Dept. of Neurosci., Stockholm, Sweden

Abstract: Exploration is a purposeful activity, defined as behavioural acts and postures that allow the collection of information about objects or parts of the environment. Spontaneous locomotor activity in a familiar environment displays cyclic fluctuations in relation to environmental, social stimuli and internal physiological processes. The aim of this study was (1) to investigate the complexity of spontaneous locomotion in group-housed mice; (2) to characterize the changes in response to the suppression of the circadian dark-light cycle; and (3) to identify possible correlates in behavioural disturbances assessed by classical behavioural tests. Adult male C57Bl/6 mice were implanted with subcutaneous radio frequency identification (RFID) tags. We used the TraffiCage™ system, which consists of an array of antennas placed

under the cage that detect the RFID tags, and allows the long-term monitoring of locomotor activity in group-housed mice. The raw data were exported and analysed offline using custom implementations of algorithms for assessing the underlying regularity (approximate entropy, ApEn), the fractal-like structure (analysis of scaling behaviour by means of detrended fluctuation analysis, DFA), and the coefficient of determination for spontaneous locomotion in the homecage. We found that spontaneous locomotion in group-housed adult mice displays a scale-invariant complexity (fractal-like) with a scaling exponent similar to the one measured in rats and humans, and displays a strong underlying regularity. The complexity is decreasing, while the regularity and the coefficient of determination increase when the dark-light cycle is suppressed for extended periods. To validate the interpretation of the above-mentioned alterations, we used genetically modified and pharmacologically induced models (FMR1-KO; prenatal exposure to the synthetic glucocorticoid dexamethasone; acute neuroinflammation induced by systemic administration of LPS). In each model we found specific alterations in the pattern of spontaneous locomotion in the homecage that were consistent with the findings from classical behaviour tests, including open field and hole board exploration, and social recognition. The identified set of parameters derived from the pattern of spontaneous locomotion in the homecage of group-housed mice, displayed early specific changes in the different experimental models, which appeared to be predictive of particular behavioural alterations. The possible correlation of gene expression patterns with alterations in locomotor activity is under investigation.

Title: Involvement of tPA and LRP-1 in regulating mammalian circadian clock phase

Authors: *J. COOPER, R. A. PROSSER;
Biochem. and Cell. and Mol. Biol., Univ. of Tennessee, Knoxville, TN

Abstract: The suprachiasmatic nucleus (SCN) contains the primary mammalian circadian clock. Photic entrainment of the clock depends on glutamate release from retinal ganglion cells onto SCN neurons. *In vitro* glutamate delays circadian clock phase when applied to the SCN in the early night, and advances phase in the late night. Glutamate-induced phase shifts require concurrent activation of TrkB receptors by brain-derived neurotrophic factor (BDNF). We

previously showed that tissue-type plasminogen activator (tPA) proteolytic activity regulates glutamate-induced phase shifts *in vitro*: tPA cleaves plasminogen into plasmin; plasmin cleaves pro-BDNF into its active form m(ature) BDNF; and mBDNF binds TrkB receptors allowing clock phase shifts (Mou et al 2009). In addition to its proteolytic activity, tPA elicits non-proteolytic effects (such as endocytosis and/or activation of signaling pathways) by binding various receptors, one of which is lipoprotein receptor-related protein 1 (LRP-1). In this study we investigate the effects of inhibiting LRP-1 on glutamate induced phase shifts, using either receptor associated protein (RAP) or an anti-LRP-1 polyclonal antibody as inhibitors of LRP-1 activity. SCN brain slices from adult male C57BL/J6 mice were treated with glutamate (1mM) +/- RAP (500nM) or anti-LRP-1 antibody (75µg/mL) at ZT 16 or ZT 23 (where ZT 0=lights-on in the animal colony) for 10 minutes. The following day we recorded SCN single-unit neuronal activity (SUA) to determine the time of peak activity. The results indicate that concurrent application of RAP or anti-LRP-1 with glutamate prevents the normal shifts, while RAP alone has no effect on clock phase. These results suggest that in the SCN LRP-1 activity is important for glutamate-dependent clock phase regulation. tPA and LRP-1 may represent converging pathways, or may be independent of each other. We are investigating the interrelationship of these two pathways using tPA knockout (KO) mice, B6.129S2-Plat^{tm1Mlg}/J. First we characterized the SUA rhythm in control tPA KO brain slices and after glutamate treatment. SCN slices from adult male tPA KO mice exhibit entrained neuronal activity rhythms, and 10µM glutamate at ZT16 and ZT23 induces phase delays and phase advances, respectively. Thus, tPA KO mice do not exhibit severe deficiencies in clock phase regulation, possibly reflecting redundant mBDNF-generating pathways. Finally, preliminary data suggest that RAP does not inhibit glutamate phase resetting in tPA KO slices, indicating LRP-1 may work through a tPA-dependent mechanism. Future studies will continue exploring tPA and LRP-1 regulation of SCN circadian clock phase.

Title: Matrix metalloproteinases 2/9 as potential regulators of the suprachiasmatic nucleus circadian clock

Authors: K. E. ABRAHAMSSON, *R. A. PROSSER;
Dept Biochem, Cell & Mol Biol, Univ. Tennessee, KNOXVILLE, TN

Abstract: A multitude of organisms exhibit rhythmic behavioral and metabolic processes that align with light and dark cycling of the environment. This phenomenon, called photic entrainment, is regulated in mammals by a collection of neurons in the suprachiasmatic nucleus (SCN) that comprise the master circadian clock. As abnormal entrainment of mammalian circadian rhythms is linked to sleep and behavioral disorders, clarifying the molecular mechanisms that regulate SCN clock phase is significant. It is known that during the subjective night, exposure to light or *in vitro* application of glutamate causes a delay in peak neuronal activity. In addition to the complex intracellular processes critical to photic phase resetting, a variety of extracellular proteins are known to regulate photic/glutamate phase-shifting processes within the SCN. One example is the conversion of pro-Brain Derived Neurotrophic Factor (pBDNF) to its mature form (mBDNF), allowing it to activate TrkB receptors, a necessary step for glutamate- and light-induced phase shifts. While our previous work has implicated tissue-type plasminogen activator (tPA) in this proteolytic step, in the hippocampus, the conversion of pBDNF to mBDNF is catalyzed by the matrix metalloproteinases MMP2 /MMP9. MMP2/MMP9 are classically known to serve as extracellular matrix remodelers, but our work aims to investigate MMP2/MMP9 involvement in SCN clock phase regulation. For electrophysiology experiments, we used acute SCN brain slices prepared from adult, male C57BL/6 mice. Slices were maintained for two days *in vitro* and had bath-application of drugs to the slices at Zeitgeber time (ZT) 16 (where ZT 0=lights on and ZT 12=lights-off in the animal colony) on the first day. We recorded the spontaneous activity of SCN neurons using extracellular electrodes the day following application of drug treatment. We found that *in vitro* application of the MMP2/MMP9 inhibitor ((2R)-[(4-Biphenylylsulfonyl)amino]-N-hydroxy-3-phenylpropionamide or BiPS; 100nM-10uM) alone for 50 min at ZT 16 induced 2-3 h delays, similar to the effects of glutamate. This result was contrary to our initial hypothesis and led us to think that MMP2 and/or MMP9 are acting in the SCN to regulate NMDA receptor signaling rather than through the conversion of pBDNF to mBDNF. To test this, we are currently examining whether BiPS induces phase advances when applied at ZT 23, and whether the phase shifts induced by BiPS are blocked by an NMDA receptor antagonist [(2 R)-amino-5-phosphonopentanoate; AP5]. Combining the aforementioned studies with temporal protein activity and expression assays will reveal the role of MMP2/MMP9 in the SCN.

Title: Effects of intergeniculate leaflet (IGL) lesions on behavioral and brain responses to photic stimuli in diurnal grass rats

Authors: *A. J. GALL, L. SMALE, L. YAN, A. NUNEZ;
Michigan State Univ., East Lansing, MI

Abstract: The intergeniculate leaflet (IGL), a subdivision of the lateral geniculate complex, receives direct retinal input, exhibits light-induced Fos expression, and is involved in masking in both nocturnal and diurnal species (Moore & Card, 1994; Prichard et al., 2002; Redlin et al., 1999; Gall et al., 2013). We have recently shown that IGL lesions cause diurnal grass rats to decrease their activity in response to a light pulse given at Zeitgeber time (ZT) 14; in control grass rats, a light pulse increases general activity at this time. The objective of the current study was to use Fos to shed light on pathways through which the IGL might influence this masking effect of light in grass rats. To do this, we examined the effects of IGL lesions on the photic response in two retinorecipient brain areas, the suprachiasmatic nucleus (SCN) and the olivary pretectal nucleus (OPT). The SCN and OPT are light responsive and connect reciprocally with the IGL. Because we previously found that the period of activity rhythms was unaffected by IGL lesions in both constant darkness (DD) and constant light (LL), we predicted that the Fos response to light in the SCN would be similar for both groups, whereas downstream regions from the IGL (such as the OPT) would exhibit a change in Fos expression. Here, 1-h light pulses were presented from ZT14 to ZT15 in IGL lesioned and sham operated grass rats. Animals were either sacrificed at ZT15 at the end of the light pulse, or sacrificed at the same time without receiving the light pulse. We found that following the light pulse, both shams and animals with IGL lesions exhibited a significant increase in Fos expression in the SCN. In contrast, Fos expression in the OPT was significantly increased in shams following a light pulse, whereas in animals with IGL lesions, Fos expression in the OPT was significantly decreased following the light pulse. Altogether, our results suggest that the OPT, but not the SCN, changes its responses to light following IGL lesions that reverse masking responses in diurnal grass rats. These data raise the possibility that interconnections between the IGL and OPT may play a role in determining the direction of the behavioral response to light at this time.

Title: Investigating MAPK pathway involvement in TTM- and Cu-induced phase shifts of the SCN circadian clock

Authors: *Y. YAMADA, R. A. PROSSER;
Biochemistry, Cell. and Mol. Biol., Univ. of Tennessee, Knoxville, TN

Abstract: The suprachiasmatic nucleus (SCN) is the mammalian master clock coordinating circadian rhythms under internal and environmental regulation. Light stimulates specialized retinal cells to release glutamate (Glu) onto circadian clock neurons of the SCN. During the subjective night, Glu activation of NMDA receptors (NMDAR) shifts clock phase by activating Ca^{2+}-dependent signaling pathways and downstream gene expression. One such pathway is the activation of MAPK/ ERK. Using acute brain slices containing the SCN prepared from adult, male C57Bl/J6 mice, we have shown that a copper (Cu)-specific chelator, tetrathiomolybdate (TTM), causes phase shifts in SCN neuronal activity rhythms when bath-applied for 10 min. Although TTM-induced phase shifts at Zeitgeber time (ZT) 16 and 23 (where ZT 0 = lights-on and ZT 12 = lights-off in the donor animal colony) are NMDAR-dependent, TTM also induces daytime phase shifts when applied at ZT 6 that are independent of NMDAR activation. Here we have investigated the mechanisms through which Cu modulates SCN clock phase. Previous studies show that Cu application increases MAPK/ERK signaling in various cell types, including cerebellar granule neurons. Furthermore, one study (Molecular and Cellular Biology (2012): 32, 1284-1295) demonstrated that Cu-induced ERK activation is: reduced by Cu chelators TTM or bathocuproine disulfonate; induced upon Cu binding to MEK1 (a MAPK kinase) *in vitro*; and dependent on Cu import by Copper transporter-1 (CTR1) *in vivo*. Based on these findings, we first used immunoblot procedures to show that CTR1 protein is expressed in the SCN. Next, using our SCN brain slice preparation, we determined that TTM is still able to induce *in vitro* phase delays when it is co-applied with the MEK inhibitor U0126 at ZT16, while U0126 attenuates Glu-induced phase delays *in vitro*. These results suggest that TTM-induced phase delays do not require MEK1 activity, but instead involve an alternative, intracellular mechanism downstream of NMDAR activation. On-going experiments at ZT6 and ZT23 with U0126 will help elucidate the cellular mechanisms through which TTM modulates SCN circadian clock phase at these other times. Along other lines, we have also shown that *in vitro* Cu application causes similar phase shifts during the subjective night as those induced by Cu chelators. Therefore, in future experiments we will test whether MEK inhibition blocks these Cu-induced phase shifts. Overall, the role of Cu in the SCN remains unclear, but the putative interaction between Cu homeostasis and circadian rhythms highlights the need for further investigation.

Title: Alcohol tolerance and withdrawal using the suprachiasmatic nucleus (SCN) circadian clock as a model system

Authors: *J. H. LINDSAY[1], J. D. GLASS[2], R. A. PROSSER[3];
[1]BCMB, Univ. of Tennessee Knoxville, Knoxville, TN; [2]Kent State Univ., Kent, OH; [3]Univ. of Tennessee, Knoxville, TN

Abstract: Alcohol abuse is linked to cognitive defects, depression, and sleep disturbances. The strong connection between sleep and circadian disruptions led us to investigate ethanol's effect on the circadian clock. We have shown that acute ethanol blocks photic phase shifts *in vivo* and glutamatergic phase shifts *in vitro*. Studies have shown that ethanol consumption often leads to acute, rapid and/or chronic tolerance. We have demonstrated that the SCN clock exhibits acute (developing in <30 min) tolerance to ethanol *in vitro*. We are currently investigating rapid (develops in 8-24 h) tolerance to ethanol. For these experiments C57BL/6 mice were given access to 15% ethanol during a single night. SCN brain slices were made the following morning and treated at either zeitgeber time (ZT) 16 (where ZT 0 = lights-on and ZT 12 = lights off) or ZT 23 with glutamate (1mM) +/- ethanol for 10 min. The next day spontaneous SCN neuronal activity was monitored across the 12 h subjective day period to determine the time of peak activity. 20mM ethanol blocks glutamatergic phase shifts in brain slices from ethanol-naïve mice, while 200mM ethanol is needed to induce the same effect in tissue from ethanol-exposed mice. Surprisingly, this tolerance lasts 48-96 hr after ethanol consumption. We are also investigating the effects of chronic ethanol consumption on SCN clock phase resetting, where mice are given access to free choice 15% ethanol or water *ad lib* for 10-14 days. Our data thus far indicate that chronic tolerance develops to *in vitro* glutamate-induced phase shifts, with a similar shift in the effective concentration of ethanol as seen in the rapid tolerance paradigm. Finally, we are investigating the response to ethanol withdrawal in our *in vitro* SCN brain slice preparation. For these experiments adult C57 mice have access to 15% ethanol for three consecutive weeks under a drinking in the dark paradigm. SCN brain slices are then prepared

after a 2 day ethanol withdrawal period. Preliminary results suggest that under these conditions the SCN clock exhibits an increased sensitivity to phase-resetting to glutamate. Future experiments will expand on these studies, including investigating changes in protein expression/phosphorylation in the SCN.

Title: K2P channels play a key role in defining irradiance detection and circadian photoentrainment in mice

Authors: *L. A. ATKINSON, A. A. MATHIE, G. S. LALL;
Univ. of Kent, Chatham, Kent, United Kingdom

Abstract: In mammals, the planetary day-night cycle acts as the principal signal for daily alignment of the biological circadian clock to external time. This synchronisation of behavioural and physiological rhythms is achieved through regulation of peripheral clocks in all major organ systems, choreographed by a central pacemaker within the hypothalamus known as the suprachiasmatic nucleus (SCN).
Light enters the biological system exclusively via the mammalian eye, where the retina utilises three major classes of photoreceptor, rods, cones and melanopsin-containing retinal ganglion cells to decode environmental illuminance for non-image forming (NIF) responses of circadian photoentrainment and the pupillary light reflex. Decoding of light information at the level of the retina and SCN communication to the periphery both rely on neuronal excitation mechanisms, which in the circadian system, are achieved through changes in neuronal membrane potential, from a resting potential stabilised by two-pore domain potassium leak channels (K2P channels). In the present study, using a transgenic mouse model with a deletion of a specific K2P channel, we investigate the role of K2P channels in regulating NIF responses to light from initial retinal decoding to behavioural output of the clock. Through locomotor activity studies and pupillometry we show attenuation in photoentrainment ability and alterations in pupillary light reflex in the transgenic model compared to wild-type equivalents, demonstrating the fundamental role of K2P channels in the regulation of circadian rhythms. Additionally, through the use of

specific-wavelength monochromatic light, we are able to attribute contributions of individual classes of photoreceptor to NIF responses to light.

Title: Dim light at night does not disrupt timing or quality of sleep in mice

Authors: *J. C. BORNIGER, Z. M. WEIL, N. ZHANG, R. J. NELSON;
Neurosci., The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Artificial nighttime illumination has recently become commonplace throughout the world, however, in common with other animals, humans have not evolved in the ecological context of chronic light at night. With prevailing evidence linking the circadian, endocrine, immune, and metabolic systems, understanding these relationships is important to understand the etiology and progression of several diseases. To eliminate the covariate of sleep disruption in light at night studies, researchers often use nocturnal animals. However, the assumption that light at night does not affect sleep in nocturnal animals remains unspecified. To test the effects of light at night on sleep, we maintained Swiss-Webster mice in standard light/dark (LD) or dim light at night (DLAN) conditions for 8-10 weeks and then measured EEG and EMG biopotentials via wireless telemetry over the course of two consecutive days to determine differences in sleep timing and homeostasis. Results show no statistical differences in total percent time, number of episodes, maximum or average episode durations in wake, slow-wave sleep (SWS), or rapid-eye movement (REM) sleep. No differences were evident in SWS delta power, an index of sleep drive, between groups. Mice kept in DLAN conditions showed a relative increase in REM sleep during the first few hours after the dark-light transition. Both groups displayed normal 24 h circadian rhythms as measured by voluntary running wheel activity. Groups did not differ in body mass, but a marked negative correlation of body mass with percent time spent awake and a positive correlation of body mass with time spent in SWS was evident. Elevated body mass was also associated with shorter maximum wake episode durations, indicating heavier animals had more trouble remaining in the wake vigilance state for extended periods of time. Body mass did not correlate with activity levels, nor did activity levels correlate with time spent in different sleep states. These data indicate that heavier animals tend to sleep more, potentially contributing

to further weight gain. We conclude that chronic DLAN exposure does not significantly affect sleep timing or homeostasis in mice, supporting the use of dim light with nocturnal rodents in chronobiology research to eliminate the possible covariate of sleep disruption.

Title: Rapid circadian reentrainment after simulated travel to anti-meridian time zones in Syrian hamsters

Authors: *E. M. HARRISON, M. R. GORMAN;
UCSD, La Jolla, CA

Abstract: Circadian adjustment after travel across time zones is frustratingly slow in humans and other mammals, occurring at the rate of approximately an hour a day. It has recently been established in rodent models, however, that re-entrainment can be markedly accelerated via circadian waveform manipulation induced by changes in the light/dark schedule. In particular, bifurcation of circadian waveform under permissive 24 h light:dark:light:dark (LDLD) cycles results in an unprecedented acceleration of entrainment to a new schedule. Recently, our lab has found that Syrian hamsters in a bifurcated state for 14 days adjust wheel-running activity almost immediately after transfer to any of 6 equidistant LD schedules four hours apart. To determine whether this rapid adjustment of the activity rhythm in LD is matched by a shift in the endogenous circadian pacemaker, hamsters bifurcated under a 8:4:8:4 light:dark schedule were challenged to phase-shift to one of two time-zones 12 h apart for 3 cycles and subsequently released into constant darkness (DD). Analysis of free-running rhythms indicated that the pacemaker was entrained such that night onset occurred within 1.5 h of the new scotophase, indicating entrainment to schedules 12 h in anti-phase within days. Further, to determine the minimum number of days of bifurcation required to achieve this enhanced rate of resetting, 48 hamsters were bifurcated for a period of 3, 5, 7 or 14 consecutive days (n= 8 in each condition) before being moved to one of two LD 16:8 conditions as described above. Preliminary data suggest as little as a week or less may be required for enhanced resetting. Experiments will determine whether fewer days of bifurcation are sufficient to enhance resetting.

Title: Alterations in light signalling are key contributors to the decline of circadian photoentrainment in aged mammals

Authors: S. M. BIELLO[1], D. R. BONSALL[2], L. A. ATKINSON[3], P. C. MOLYNEUX[2], M. E. HARRINGTON[2], *G. S. LALL[3];
[1]Psychology, Univ. of Glasgow, Glasgow, United Kingdom; [2]Neurosci., Smith Col., Northampton, MA; [3]Medway Sch. Pharm., Univ. of Kent, Kent, United Kingdom

Abstract: Daily changes in the environmental light-dark cycle provide the fundamental synchronising cue for physiological and behavioural circadian entrainment. The suprachiasmatic nucleus (SCN), located in the brain, integrates both the environmental irradiance and behavioural/ social stimuli to output a synchronising signal to which global physiological systems entrain, and as such, defines the SCN as the master circadian pacemaker. NMDA driven signalling pathways mediate the majority of light responses at the level of the SCN. Recently, the age related decline in circadian entrainment has been correlated to alternations in key SCN cellular mechanism, ultimately impacting output synchronisation signals.
In the current study, we investigate changes in light driven SCN resetting in aged mice (C57BL/6) at both behavioural and cellular levels. Behavioural circadian rhythms were measured using daily wheel running activity recordings. Old mice (>18 months) showed decreased phase resetting to light at both dim (30 lux) and bright (300 lux) light. In order to ascertain if this effect was attributed to a NMDA driven pathway at the level of the SCN we utilised pharmacological and molecular techniques to isolate this particular receptor class. *In vivo* microinjections of NMDA directly into the third ventricle resulted in significantly less behavioural resetting in aged mice relative to younger (6 months) counterparts. Real-time PCR analysis of the relative expression of specific NMDA receptor subunits revealed a significant reduction in the NR2B subunit. The functional impact of this finding was confirmed using a specific NR2B antagonist, *in vivo*, which resulted in attenuating light phase resetting in the young; an effect that was absent in the aged experimental group.
In conclusion, our results demonstrate that the age related decline in circadian synchronisation is, in part, attributed to the ability of the SCN in interpreting light information through the NMDA

pathway. More specifically this can be narrowed down to changes in specific NMDA subunits, in particular the NR2B subunit.

Title: Light intensity requirements for induction and maintenance of bifurcated circadian rhythms in mice under light:dark:light:dark cycles

Authors: *J. SUN[1], M. GORMAN[2];
[1]Psychology 0109, Gorman Circadian Res. Lab., La Jolla, CA; [2]Psychology 0109, Univ. of California - San Diego, La Jolla, CA

Abstract: The mammalian circadian pacemaker, which controls daily rhythms in physiology and behavior, is comprised of multiple oscillators that under a variety of natural and unnatural conditions may be temporally dissociated. In a recently described rodent model system, herein termed bifurcation, exposure to a 24 h light:dark:light:dark cycle induces the circadian pacemakers of rodents generate two subjective days and two subjective nights per 24 hour cycle. Bifurcation of the circadian pacemaker markedly increases adjustment after phase shifts, and has been proposed as a potential solution for night-shift workers due to its flexiblity, robustness, and stability. Mechanistically, bifurcation reflects a change in the coupling between multiple oscillators herein referred to as day and night oscillators. These two oscillators are maintained in a near anti-phase relationship via the interposition of bright light in between each bout of activity as suggested when bifurcated animals rejoin readily when subjected to constant darkness. Prior bifurcation has been achieved through the use of dim scotopic illumination (DSI) (<0.1 lux) in conjunction with bright (>100 lux) photophasic illumination and the introduction of a bifurcated light schedule as DSI is believed to reduce the coupling forces promoting rejoining. Except for the fact that DSI facilitates induction of bifurcation, little else is known about the properties of the environmental light cycle that induce and maintain bifurcation, especially that of photophasic light. The current study seeks to determine how timing of DSI affects bifurcation and the threshold of bright light required to keep animals entrained to a bifurcated light schedule. Prior to

manipulations, C57/Bl6J mice were bifurcated (7:5:7:5 LDLD) with DSI in both scotophases. After two weeks, mice were randomly assigned to one of two groups where DSI was subsequently dropped from either the day or night scotophase. Removal of DSI in either scotophase did not affect bifurcated entrainment. Bifurcation was maintained uniformly after gradual reduction of photophasic light intensity every 2 weeks from >100 lux to 1.0 lux regardless of the scotopic placement of DSI. Likewise, bifurcation was induced in unbifurcated mice transferred to a bifurcated 7:5:7:5 LDLD schedule with photophasic light intensities of 1.0 lux and DSI in either day or night scotophase. We show a) that timing of DSI does not affect the maintenance of bifurcated rhythms and b) that very little photophasic light is required to induce or maintain bifurcation. Thus, bifurcation may be induced and maintained in a greater variety and with lower light intensities than previously described.

Title: Changes in sleep architecture of C57BL/6J mice in response to a short photoperiod

Authors: *S. V. ROZOV[1], J. C. ZANT[2], T. H. PORKKA-HEISKANEN[2], P. PANULA[1]; [1]Anat., [2]Physiol., Inst. of Biomedicine, Helsinki, Finland

Abstract: The ways the circadian system affects the sleep-wake cycle can be assessed by several means. One of these, known as forced desynchrony, has been successfully applied in human and rat studies.It induces the uncoupling of the diurnal rhythmicity of sleep-wake behaviour, melatonin synthesis and other rhythms into an endogenously driven circadian, and the light-entrained component enabling their independent examination. We aimed to implement this protocol on mice as a model system widely used in sleep and circadian research. C57BL/6J mice were implanted with EEG/EMG electrodes and after a one week recovery period comected to a CED1401 data acquisition unit (Cambridge Electronic Design). EEG were recorder for two weeks during a normal light-dark cycle, after which the mice were to subjected to symmetric light-dark cycles of decreasing lengths: 24→22→21→20 h (170 lux light phase, <0.5 lux dark

phase; each period lasing 2 weeks). Behavioural activity of the animals showed no signs of rhythm splitting; instead it was completely entrained to all periods mentioned above. It was accompanied by a sharp progressive decrease in total locomotion although the overall % of time spent in wakefulness, NREM or REM sleep remained unchanged between different period lengths, as was shown by EEG analysis. In contrast to previous reports on rat where shortening the rhythm leads to dissociation of circadian and entrained rhythmic components, the mice in our study demonstrated a significant progressive rearrangement of the sleep-wake architecture towards an even distribution of sleep and wake amounts over the light-dark cycle. Altogether this data suggests potential differences between rats and mice in their circadian modulation of sleep and entrainment properties of the circadian oscillator.

Title: The effect of chronic photoperiod shifting on metabolism and stress in female Long-Evans rats

Authors: *S. DEIBEL, S. M. DERKSEN, N. S. HONG, R. J. MCDONALD;
Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Shift work can have detrimental effects on the brain and body. Shift workers have a higher prevalence of diseases, such as, dementia, cardiovascular disorders, cancer, metabolic syndrome, and obesity. Circadian disruption is a possible mechanism for these effects, as shift workers circadian rhythms are in a continuous state of desynchrony because they are not able to fully entrain to the aberrant light-dark cycles. While circadian disruption results in cognitive impairments, the effects on physiological processes such as metabolism and the stress response are less clear. The current set of experiments assessed the effects of chronic circadian disruption on stress and metabolism in female Long-Evans rats. A 64-day chronic photoperiod shifting paradigm was used to disrupt circadian rhythms. During photoperiod shifting the animals had access to high and low fat diets. Consumption rates of both diets were measured throughout the duration of the experiment. To determine if stress was elevated during chronic photoperiod

shifting, serum corticosterone values were quantified for each of the four cycles of phase shifting. Additionally, following photoperiod shifting serum glucose values were measured during fasting and, after a glucose challenge test. Surprisingly, the shifted animals did not gain more weight or exhibit a preference for either of the diets during photoperiod shifting. However, glucose values during fasting and, in response to a glucose challenge test were elevated in the photoperiod shifted rats. This study demonstrates that chronic photoperiod shifting has deleterious effects on metabolism, and the ability to cope with stress in the same individual.

Title: Melatonin does not improve re-entrainment after light-dark cycle shift in mice with the double knockout of Epac1 and Epac2

Authors: *Z. XIAN[1], S. CHEUNG[3], Y. WONG[3], S. CHUNG[1,2];
[2]Res. Ctr. of Heart, Brain, Hormone & Healthy Aging, [1]The Univ. of Hong Kong, Hong Kong, Hong Kong; [3]Div. of Life Sci., The Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong

Abstract: Exchange protein directly activated by cAMP (Epac), which consists of two isoforms, Epac1 and Epac2, is a downstream effector of cAMP independent of protein kinase A. Previously, a non-selective Epac analog was used to establish its involvement in the maintenance of circadian rhythm. In order to determine which isoform of Epac is involved in the regulation of circadian rhythm, mice of wild-type ($Epac^{+/+}$), homozygous knockout of Epac1 ($Epac1^{-/-}$), homozygous knockout of Epac2 ($Epac2^{-/-}$) and homozygous knockout of Epac1 and Epac2 ($Epac1^{-/-}$; $Epac2^{-/-}$) were subjected to re-entrainment experiments, which the onset of the dark cycle was advanced by 6 hours. $Epac1^{-/-}$; $Epac2^{-/-}$ mice required a longer time to re-entrain to the advance of the dark cycle than that of WT mice. No significant difference in re-entrainment was observed among $Epac^{+/+}$, $Epac1^{-/-}$ and $Epac2^{-/-}$ mice, suggesting that Epac1 and Epac2 might compensate in the absence of a single isoform of Epac. The delay in re-entrainment in $Epac1^{-/-}$; $Epac2^{-/-}$ mice might be due to altered *Clock* gene expression in hypothalamic suprachiasmatic nucleus (SCN), which is the principle pacemaker of circadian rhythm. It has been reported that

Clock mutant mice have a higher sensitivity to light stimulus with lower rhythmic expression of circadian genes *Per1* and *Per2*. Quantitative real-time PCR analysis was performed to determine the *Clock* gene expression in the SCN of the four genotypes of mice. Epac1$^{-/-}$; Epac2$^{-/-}$ mice showed a higher mRNA expression of *Clock* gene in the SCN compared that of Epac$^{+/+}$, which possibly contributed to the delayed re-entrainment in the Epac1$^{-/-}$; Epac2$^{-/-}$ mice. Interestingly, melatonin injection (4 mg/kg in 3% ethanol/saline, *s.c.*) at 30 min before the post-shift dark onset for 3 consecutive days effectively accelerated the re-entrainment in Epac$^{+/+}$ mice, whereas Epac1$^{-/-}$; Epac2$^{-/-}$ mice did not improve in re-entrainment following melatonin injection, suggesting that melatonin mediates phase shift of circadian rhythm via the cAMP-Epac pathway. Similarly, same dose of melatonin injection did not facilitate the re-entrainment in melatonin receptor MT_1 KO mice, whereas MT_2 KO mice were responsive to melatonin treatment. The similar phenotypes between Epac1$^{-/-}$; Epac2$^{-/-}$ mice and MT_1 KO mice suggest that melatonin facilitates the re-entrainment by activating MT_1 receptor and Epac.

Title: Obese mice Neotomodon alstonii present an altered phase in daily rhythms of hypothalamic leptin and ghrelin receptors

Authors: D. LUNA-MORENO[1], *M. MIRANDA-ANAYA[1], C. LUNA-ILLADES[1], A. CARMONA-CASTRO[2];
[1]Unidad Multidisciplinaria de Docencia e Investigación, Facultad De Ciencias, UNAM, Juriquilla Querétaro, Mexico; [2]Facultad De Ciencias, UNAM, México D.F., Mexico

Abstract: Obesity affects a wide and increasing population in industrialized world. For the past several years, various approaches have been used to identify the physiological and genetic bases of obesity; among the most studied are the mechanisms regulating food intake, mediated by hormones and neurotransmitters controlling the sensations of satiety and hunger in specific centers within the hypothalamus. Recent findings indicate that exist a narrow relationship

between circadian deregulation and obesity, also, obesity itself may increase circadian internal uncoupling of circadian oscillators.
The present work was aim to compare differences in hypothalamic receptors of leptin (LR) and ghrelin (GHS-R), from brains collected along the light-dark cycle in lean and obese female mice Neotomodon alstoni, a mouse that spontaneously develops overweight and obesity when fed with a regular diet for laboratory rodents, specially the females. Obese mice show altered circadian rhythmicity as well as parameters related with the metabolic syndrome.
Lean (n=20, 45± 2g) and obese (n=15, 70± 4g) mice 6-8 months old were collected during the diestrous phase, at different hours in a LD cycle (0,5,10,15,19 h). Brains were frozen and hypothalamus was separated, then the homogenate was protein extracted for Western Blot analysis. A different group of animals (7 lean and 7 obese) were used to monitor changes in locomotor activity in a freely moving cage, with infrared sensors and feeding ad libitum.
Our results indicate that obese mice display less activity during the night, but are more active than lean during the day. Also, obese mice eat more than lean. Western blot analysis of hypothalamic receptors indicates that the daily rhythms of LR and GHS-R present different acrophase in obese mice Neotomodon alstoni. The aforementioned indicates that overfeeding in Neotomodon may be related with a delayed hunger signal in hypothalamus of obese together with an insufficient feedback of the leptin system.

Title: Modeling spontaneous internal desynchrony of sleep-wake behavior and the circadian rhythm in humans

Authors: V. BOOTH[1], R. GLEIT[1], *C. DINIZ BEHN[2];
[1]Mathematics, Univ. of Michigan, Ann Arbor, MI; [2]Mathematics, Gettysburg Col., Gettysburg, PA

Abstract: When entrained to daily environmental time cues, human sleep-wake behavior cycles with an approximately 24 h period in phase with the circadian rhythm coordinated by the

suprachiasmatic nucleus (SCN). When isolated from external environmental time cues for extended periods of time, sleep-wake behavior can spontaneously desynchronize from the circadian rhythm and the two cycles no longer display the same period or a constant phase relationship. Usually, the circadian rhythm period remains close to 24 h while the sleep-wake cycle period has been reported to either increase or decrease. We used a physiologically based mathematical model of a sleep-wake regulatory network to replicate typical human sleep patterns and spontaneous internal desynchrony behavior as observed under temporal isolation conditions. The model sleep-wake regulatory network described the neurotransmitter mediated interactions among brainstem and hypothalamic neuronal populations that participate in the transitions between wake, rapid eye movement (REM) sleep and non-REM (NREM) sleep. Circadian modulation of sleep-wake behavior was provided by physiologically based interactions among these sleep-wake centers and the SCN. Model results captured stereotypical entrained human sleep-wake behavior, including typical NREM-REM cycling across the night. When effects of temporal isolation were simulated by increasing the period of the sleep-wake cycle but maintaining the ~24 h period of the circadian rhythm, model results replicated the evolution of sleep-wake patterning to internal desynchronized behavior, including transient "phase trapping." Further, varying parameters such as the strength of interactions between the SCN and sleep-wake centers allowed our model to generate a number of reported inter-individual differences in desynchronized sleep-wake behavior, including short (< 24h) sleep-wake cycles, bicircadian rhythms and irregular "phase jumping" sleep-wake behavior. Thus, this analysis predicts physiologically-plausible mechanisms to account for these inter-individual variations.

Title: Serotonergic enhancement of photic phase shifts: IGL

Authors: *R. T. JEFFERS[1,2], V. M. SMITH[1,2], M. C. ANTLE[1,2,3];
[1]Psychology, [2]Hotchkiss Brain Inst., [3]Physiol. and Pharmacol., Univ. of Calgary, Calgary, AB, Canada

Abstract: In mammals, the suprachiasmatic nucleus (SCN) functions as the master circadian clock and is responsible for regulating rhythmic aspects of an organism's physiology and behaviour. The phase of these endogenously generated rhythms can be altered by environmental stimuli such as appropriately timed light exposure. Systemic administration of serotonergic drugs such as the 5-HT1A mixed agonist/antagonist BMY7378 have been shown to greatly increase the magnitude of phase shifts resulting from light exposure in the late subjective night. Exactly how BMY7378 alters the circadian clock is unknown, and recent findings suggest that it may not exert its influence solely through the SCN. The intergeniculate leaflet (IGL), like the SCN, receives direct serotonergic and retinal innervation and is involved in regulating how the circadian clock responds to light exposure. Previous research has shown that blockade of one of the major neurotransmitters released in the SCN by neurons projecting from the IGL, neuropeptide Y (NPY), can further potentiate the effects of BMY7378. However, when the IGL was lesioned, leading to the total absence of NPY expression in the SCN, administration of BMY7378 did not result in the potentiation of photic phase shifts. To further explore the mechanism through which BMY7378 exerts its influence, the current study investigated the potentiating effects of BMY7378 on light exposure in Syrian hamsters which had received selective serotonin lesions of the IGL. Following recovery, animals were given a systemic injection of either saline or BMY7378 45 minutes prior to a 40 lux, 15 minute light pulse in the late subjective night. Phase shift analysis revealed that sham-lesioned animals showed a potentiation of photic phase shifts following administration of BMY7378 when compared to saline controls. Serotonin-lesioned animals, however, did not show a significant difference in phase shifts between the BMY7378 and saline pretreatment groups. These findings indicate that serotonergic innervation of the IGL is necessary for BMY7378 to potentiate photic phase shifts.

Title: The timing of Corticosterone peak circulation affects clock gene rhythmic expression in the rat prefrontal cortex

Authors: *L. R. WOODRUFF, L. E. CHUN, L. R. HINDS, R. L. SPENCER;
Psychology/Neuroscience, Univ. of Colorado At Boulder, Boulder, CO

Abstract: It is increasingly apparent that glucocorticoids (CORT) play a pivotal role in mediating the suprachiasmatic nucleus' (SCN) coordination of circadian rhythms in peripheral tissues. Extra-SCN tissues receive sparse direct neuronal connectivity from the SCN; however glucocorticoid receptors (GR) are ubiquitously expressed in all areas of the body except for the SCN itself. This is an important distinction and suggests that CORT may be a key element in whole-body coordination of circadian rhythms. Although disrupted CORT circulation patterns, such as those associated with chronic stress and stress-related disorders, have been shown to affect clock gene rhythmicity in certain peripheral tissues, virtually no characterization of this prospect has been examined in the brain. Studying the regulation of prefrontal cortex (PFC) circadian function in particular may be useful for understanding mechanisms of extra-SCN circadian entrainment in the brain. The PFC is a known modulator of emotional and endocrine control over the stress response. The PFC also expresses a high level of GR, but it receives no direct innervation from the SCN. It is possible that alteration of CORT secretion patterns could shift or disrupt core clock gene functioning in the PFC and result in dysregulation of its function. To examine this possibility we have conducted experiments in which the presence and daily pattern of CORT exposure was manipulated in rats by adrenalectomy (ADX) ± daily CORT injection. In an initial experiment we examined *per1* and *bmal1* mRNA expression (in situ hybridization) in sham-ADX, ADX and ADX + daily CORT at ZT1 (CORT exposure pattern antiphasic to sham-ADX rats) treated male Sprague-Dawley rats. The absence of CORT did not abolish rhythmic expression of clock gene expression in the rat PFC. Surprisingly, antiphasic CORT treatment of ADX rats largely abolished rhythmic PFC clock gene expression, perhaps reflecting a disruption of the cooperative entraining influence of endogenous CORT and the SCN. Our manipulations had no effect on *per1* and *bmal1* expression in the SCN consistent with its lack of GR. In a follow-up experiment we have directly compared the effect of daily CORT treatment of ADX rats when CORT is injected at either ZT1 or ZT11 (maintained on 12:12 h LD). ADX rats were given an i.p. vehicle (n=16) or CORT (2.5 mg/kg, n=24) daily injection at either ZT1 or ZT11 for 13 days. ZT11 is approximately the time at which endogenous CORT typically peaks. One day after the last injection rats were sacrificed at ZT0, ZT6, ZT12, and ZT18.

Title: Effect of arousal or a novel wheel on the circadian rhythm of luteinizing hormone (LH) surges and locomotor activity in estradiol-treated ovariectomized (ovx+EB) hamsters

Authors: *S. J. LEGAN[1], X. PENG[1], C. YUN[1], K. M. FRANKLIN[2], M. J. DUNCAN[2];
[1]Dept Physiol, [2]Dept Anat & Neurobiol, Univ. Kentucky, LEXINGTON, KY

Abstract: In proestrous hamsters, exposure to a novel wheel not only phase advances the activity rhythm, but completely blocks the preovulatory LH surge, which occurs 2 hours earlier the next day. Because immobilization of the wheel does not prevent these effects, they are not caused by intense locomotor activity. We hypothesized that arousal, which is associated with many nonphotic phase advancing stimuli, will block and phase advance the LH surge. Because LH surges occur daily in ovariectomized (ovx), estradiol benzoate-treated (+EB) hamsters and the effect of non-photic stimuli on such daily LH surges is not known, we examined the effect of a novel wheel and arousal in ovx+EB hamsters. Regularly cycling hamsters were housed in 14L:10D and activity rhythms were continuously monitored via infra-red detectors. After at least 7 days, the hamsters were bilaterally ovariectomized. After 2 weeks, the jugular vein was cannulated and EB or oil vehicle was injected sc. A group of intact hamsters was also cannulated on the day before proestrus. The next day (Day 1), shortly before zeitgeber time (ZT) 5 (ZT 12=lights off) the intact and ovx+oil groups were moved to the laboratory; the ovx+EB groups were moved before ZT 4 since their LH surge occurs 1 h earlier. A blood sample was obtained at ZT 5 or 4, respectively, and the hamsters were next exposed to constant darkness (DD) and either remained in their home cage or were transferred to a new cage with a running wheel, or subjected to a 2-h arousal paradigm in a new cage, i.e., exposed to 4 unique arousing stimuli for 30 minutes each. Hourly blood samples were obtained in dim red light for the next 6 h and activity was recorded hourly via an automated counter on Days 1 and 2. After the last sample, activity in DD was monitored for 1-2 weeks to analyze phase shifts. Plasma LH levels were assessed by RIA. A novel wheel had no effect on the high LH levels characteristic of ovx+oil animals. Novel wheel exposure blocked the LH surge on Day 1 in intact hamsters, and greatly attenuated this LH surge in ovx+EB hamsters. Arousal also attenuated the LH surge and delayed it 1 h ($P<0.05$). On Day 2, all LH surges were phase advanced about 2 hours. Phase advances in activity rhythms were enhanced by estradiol and arousal. In conclusion in ovx+EB hamsters, acute arousal during the normal rest phase strongly disrupts the LH surge, decreasing its magnitude and altering its timing and that of the activity rhythm, similar to novel wheel exposure. The novel wheel induced effect on LH surges is milder in ovx+EB than in intact hamsters, suggesting that either ovariectomy itself and/or the positive feedback signal elicited by exogenous estradiol treatment strengthens the neural signal for the LH surge.

Title: The activational mechanisms underlying the impact of estrogen on the formation and expression of circadian rhythms in mice

Authors: *S. E. ROYSTON[1,2], A. G. KONDILIS[3], S. V. LORD[3], N. YASUI[4], J. A. KATZENELLENBOGEN[4], M. M. MAHONEY[3,1];
[1]Neurosci. Program, [2]Med. Scholars Program, [3]Comparative Biosci., [4]Chem., Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: Estrogenic signaling shapes and modifies circadian rhythms, the disruption of which have been implicated in psychiatric, neurologic, cardiovascular, and metabolic disease, among others. While the impact of estrogen on total activity, free running period, photic phase response, activity phase angle, and the ratio of activity in the light vs. the dark (LD ratio) has been documented, the exclusively activational molecular mechanisms underlying these phenomena remain poorly characterized. To determine the activational impact of estrogen on daily behavior patterns and differentiate between the roles of ESR1 and ESR2, the primary CNS estrogen receptors, within this context, ovariectomized adult female mice were chronically administered estradiol (E), the ESR1 agonist propylpyrazole triol (PPT), the ESR2 agonist diarylpropionitrile (DPN), or cholesterol (CTL). Animals were singly housed with wheels in 12:12 LD or total darkness (DD), and wheel revolutions were recorded in 10 min bins. E administration significantly increased average daily activity compared to CTL. This effect was partially mimicked by chronic PPT, but not DPN administration, suggesting a role for ESR1, but not ESR2 in the regulation of total activity. Further, we found that E or PPT treatment consolidates activity to the dark phase, reducing the LD ratio compared to CTL. Interestingly, selective ESR2 stimulation increased the LD ratio even beyond that observed in CTL animals. Together, these data support dichotomous roles for ESR1 and ESR2 in activity consolidation across 24 hr. PPT, DPN, or E reduced the phase angle of activity onset, suggesting that ESR1 and/or ESR2

activation is sufficient for advancing the onset of activity following the transition from L to D. Similarly, the active period (alpha) was longer in animals housed in DD and treated with PPT, DPN, or E than age and litter-matched CTL animals. Conversely, the subjective day (tau) was shorter in animals administered PPT or E, but not DPN, suggesting that ESR1 activation alone is responsible for the known effect of estrogen-dependent shortening of tau. Finally, we assessed behavioral shifts in activity onset following 1 hr light pulses at various times throughout the subjective day. When pulsed in the early subjective night but no other time, activity onset was advanced in animals treated with E, PPT, or DPN compared to CTL, suggesting that ESR1 or ESR2 activation is sufficient to elicit a phase response. Importantly, we show that estrogen has strong activational effects on the temporal patterning and expression of circadian behavior, and that these effects are due to distinct mechanisms elicited by ESR1 and ESR2 activation.

Title: Nighttime light exposure impairs affective responses in a wavelength-dependent manner

Authors: *T. A. BEDROSIAN, C. A. VAUGHN, A. GALAN, G. DAYE, Z. M. WEIL, R. J. NELSON;
Dept. of Neurosci., Ohio State Univ., Columbus, OH

Abstract: Life on Earth is entrained to a 24-h solar cycle that synchronizes circadian rhythms in physiology and behavior; light is the most potent entraining cue. In mammals, light is detected by (1) rods and cones, which mediate visual function, and (2) intrinsically photosensitive retinal ganglion cells (ipRGCs), which primarily project to the suprachiasmatic nucleus (SCN) in the hypothalamus to regulate circadian rhythms. Recent evidence, however, demonstrates that ipRGCs also project to limbic brain regions, suggesting that through this pathway, light may have a role in cognition and mood. Therefore, it follows that unnatural exposure to light may have negative consequences for mood or behavior. Modern environmental lighting conditions have led to excessive exposure to light at night (LAN), and particularly to blue wavelength lights. The rate of depressive disorders has increased in parallel with nighttime light exposure. We hypothesized that nocturnal light exposure (i.e., dim LAN) induces depressive responses and

alters neuronal structure in rodents. If this effect is mediated by ipRGCs, which have reduced sensitivity to red wavelength light, then we predicted that red LAN would have limited effects on brain and behavior compared to shorter wavelengths. Additionally, red LAN would not induce c-Fos activation in the SCN. Our results demonstrate that exposure to LAN influences behavior and neuronal plasticity, and that this effect is likely mediated by ipRGCs. Modern sources of LAN that contain blue wavelengths may be particularly disruptive to the circadian system, potentially contributing to altered mood regulation.

Title: Chronic exposure to dim nighttime light provokes depressive-like responses in mice

Authors: *C. A. VAUGHN, T. A. BEDROSIAN, Z. M. WEIL, R. J. NELSON; Neurosci., The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Humans and other animals have adapted to the consistent 24-h solar cycle. The rotation of the planet on its axis and its revolution around the sun cause predictable daily light-dark cycles and seasonal patterns in day length. Modern life, however, has allowed humans to escape these naturally occurring light-dark cycles and to create schedules based on convenience. Since the invention and widespread adoption of electric lights starting ~130 years ago, humans have been increasingly exposed to artificial light at night (LAN). It seems reasonable to suggest that this unnatural light exposure may have serious effects on ecological and physiological processes that have adapted to the natural light-dark cycle. Not surprisingly, accumulating evidence suggests LAN has negative health consequences for humans, likely acting through circadian disruption. For example, shift work is associated with depressed mood and feelings of helplessness. In addition, the rate of depressive disorders in the general population has grown in parallel with increased exposure to nighttime light. LAN is a seemingly innocuous convenience, but its widespread adoption occurred prior to an understanding of circadian biology. We hypothesize that LAN is a modern source of circadian disruption leading to downstream changes in physiology and mood-related behaviors. In this study, we exposed mice for 4 weeks to either a standard 16:8 h light/dark cycle (150 lux/0 lux) or a 16:8 h light/dim light cycle (150 lux/5 lux).

Then we assessed diurnal rhythms in homecage locomotor activity and depressive-like responses in a variety of behavioral tasks. Exposure to LAN altered locomotor activity and provoked depressive-like behaviors. This study demonstrates that exposure to dim LAN has profound consequences for behavior. It is important to understand how LAN affects circadian organization and downstream physiology, particularly for urban-dwelling individuals and shift workers who are chronically exposed to disruptive LAN. Determining the types of circadian disruption provoked by LAN is critical to identifying preventative measures for these individuals.

Title: Drugs that prevent sleep also block light-induced locomotor suppression, circadian rhythm phase shifts and the drop in core temperature

Authors: *L. P. MORIN[1], P. VIVANCO[1,2], K. M. STUDHOLME[1];
[1]PSYCHIATRY, STONY BROOK UNIVERSITY MEDICAL CENTER, STONY BROOK, NY; [2]Chronobiology Lab., Dept. Physiol., Univ. of Murcia, Murcia, Spain

Abstract: When mice are briefly exposed to light during their nocturnal active phase, several simultaneous behavioral or physiological events occur. These include circadian rhythm phase shifts, a drop in core body temperature (Tc), and suppression of ongoing locomotor activity followed by sleep. The events are triggered by light, endure for a relatively fixed interval and do not require additional light for their expression. The present studies address the ability of three psychostimulant drugs to modify the light-induced responses. Methamphetamine (MA), modafinil (MOD), caffeine (CAF) or vehicle (VEH) were injected at CT11 into constant dark-housed male C57BL/j6 mice which were then exposed to a 5 min 100 uW/cm2 white light pulse or no light at CT13. Controls receiving the VEH/Light treatment showed approximately 60 min phase delays which were substantially attenuated by treatment with MA, MOD or CAF (12-15 min phase delays). Drug by itself had no effect on rhythm phase. Under a LD12:12 photoperiod, light at ZT13 induced a drop of about 1.3 oC coincident with locomotor suppression by VEH-treated mice. Both changes were generally abolished by pretreatment with any of the drugs.

Although all three drugs promoted activity increases after injection at ZT11, there was also evidence for drug-induced hypoactivity. Hyperactivity occurred during the 30 min post-injection interval for MOD, MA and CAF-treated mice, but hypoactivity was evident for CAF, but not MOD- or MA-treated, mice during 30 min of darkness (ZT12.5-ZT13) prior to the photic test stimulus. CAF acutely elevated Tc and MA acutely lowered it, but both drugs reduced Tc during the early night (ZT12.5-ZT13). The ability of the psychostimulant drugs to block the several effects of brief light exposure is not likely to be caused simply from a drug-induced locomotor activity increase. The results raise questions concerning the manner in which drugs, activity, sleep and Tc contribute to the regulation of behavioral and physiological responses to light.

Title: Role of orexin neurons in novel wheel-induced blockade of the preovulatory luteinizing hormone (LH) surge in Syrian hamsters

Authors: *M. J. DUNCAN[1], K. M. FRANKLIN[1], X. PENG[2], C. YUN[2], S. J. LEGAN[2]; [1]Dept Anat/Neurobiol, [2]Dept Physiol., Univ. Kentucky Med. Ctr., LEXINGTON, KY

Abstract: Exposure of proestrous hamsters to a novel running wheel (NW) completely blocks the LH surge until the next day in ~70% of hamsters. We hypothesized that NW exposure activates orexin neurons, which participate in alertness, and that orexinergic neurotransmission blocks the LH surge. To test this hypothesis, we investigated the effects of 1) NW exposure on Fos expression in orexin neurons, and 2) an orexin receptor 1 antagonist, SB334867 (SB), on NW blockade of the LH surge. In Expt. 1, proestrous hamsters were exposed at zeitgeber time 5 (ZT 5, i.e., 7 h before lights- off) to either a rotating or locked NW, or remained in their home cage (HC); all were exposed to constant darkness (DD). At ZT 7, the animals were anesthetized and perfused intracardially with PBS followed by 4% PFA. Brains were removed, post-fixed, infiltrated with sucrose, and sectioned. Dual immunohistochemistry for orexin and Fos was conducted. The percentage of orexin-positive neurons expressing Fos differed among the groups ($P<0.001$; HC: 14 ± 4; locked NW: 30 ± 4; rotating NW: 42 ± 3), and was greater for rotating NW than for locked NW ($P<0.05$) and for each NW group than for HC ($P<0.02$). In Expt. 2,

hamsters were fitted with jugular cannulae and on the next day, proestrus (Day 1), blood samples were obtained at ZT 5 and i.p. injections of SB (30 mg/kg) or vehicle (100% DMSO, VEH) were given. Hamsters were placed in new cages with a rotating NW or left in HC, and exposed to DD. Blood samples were taken hourly (ZT 5-11, under dim red light) on Days 1 & 2. Plasma LH levels were determined by RIA. SB decreased the proportion of animals exhibiting NW-induced blockade of the LH surge (NW+VEH vs NW+SB, 5/13 vs 0/10 blocked, $P<0.05$). However 100% DMSO appeared to interfere with the NW effect because the NW+VEH group did not differ from the HC+VEH group (5/13 vs 1/5; $P=0.44$), whereas NW exposure usually blocks the LH surge in the majority of animals (Legan et al, J. Biol. Rhythms, 2010). Therefore, Expt. 3 was conducted using the same protocol as Expt. 2 but with 25% DMSO in hydroxypropyl-beta-cyclodextrin as the VEH. Blockade of the LH surge occurred in 8 of 10 NW+VEH hamsters, as compared with 1 of 6 HC+VEH hamsters. The effect of SB was associated with the appearance of the solutions. Thus, SB tended to decrease NW blockade of the LH surge when clear solutions were injected (4 of 6 animals, $P=0.09$), but not when the solutions were turbid (3 of 4 animals, $P=0.67$). These results indicate that NW exposure activates orexin neurons whether or not the wheel is locked, suggesting that novelty alone is effective, while novelty with running is more effective. The findings also suggest that orexin neurotransmission may participate in NW blockade of the LH surge.

Title: Role of the dorsal medial habenula in the regulation of circadian rhythms

Authors: J. GILE[1], Y.-W. T. HSU[2], G. MORTON[2], S. D. WANG[2], E. E. TURNER[2], *H. O. DE LA IGLESIA[1];
[1]Biol., Univ. of Washington, Seattle, WA; [2]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA

Abstract: The epithalamic habenula has been implicated in the regulation of behaviors including motor activity and sleep. Neurons in both the medial and lateral habenula exhibit spontaneous firing that is higher during the day than night, and the lateral habenula exhibits endogenous oscillations in gene expression and neuronal activity. Here we use genetic lesions to specifically ablate neurons in the dorsomedial habenula (dMHb) in order to examine its role in the regulation of locomotor activity and circadian rhythms. Using the Cre-LoxP system, neurons in the dMHb were ablated by abolishing expression of Brn3a without affecting other regions in the habenula. dMHb-lesioned mice have reduced wheel running activity (WRA) in both a 12h:12h light-dark (LD) cycle and constant darkness (DD), but show similar levels of cage-locomotor activity compared to control animals, indicating lesions of the dMHb do not induce hyperactivity. dMHb-lesioned animals have a lengthened circadian period and re-entrain faster to a 6-hour delay jetlag. In contrast, in response to light pulses presented at CT16, they show phase shifts and increases in the expression of Per1 and cFos in the suprachiasmatic nucleus (SCN) similar to control animals. Collectively, these data suggest that the dMHb may be involved in a feedback loop that controls WRA and regulates circadian rhythms through a continuous, rather than a discrete, model of entrainment.

Title: Pavlovian fear conditioning following manipulation of circadian waveform

Authors: *C. L. BLOCK, E. HARRISON, M. GORMAN;
Dept. of Psychology, UCSD, La Jolla, CA

Abstract: Shiftwork, while common, is linked to problems in performance, safety and health which reportedly cost America over $200 billion a year and are believed to be related to the misalignment of physiological rhythms with respect to the environment. One suggestion for combating challenges faced by shift workers is a temporal reorganization of activity rhythms by entrainment of the endogenous circadian pacemaker to a 24 h light:dark:light:dark (LDLD) cycle (Harrison & Gorman, 2012). The purpose of this study is to examine in a rodent model the

effects of the resulting rhythm bifurcation on learning and memory using Pavlovian fear conditioning, a paradigm that requires sleep in a photophase immediately following training (Cai). 96 C57/Bl6 mice were first entrained to either a 6:6:6:6 LDLD light cycle or a 12:12 LD control condition. While all training took place just before light transitions, half of LD animals were trained before lights off (ScotophaseFirst), and half before lights on (PhotophaseFirst). Animals were further divided into groups of 12 to be tested for contextual and cued fear 12 or 24 hours later. Importantly, for LDLD animals, each 12 h period between training and test contained both a photophase and a scotophase. Preliminary results suggest memory is intact in bifurcated mice; subsequent findings will allow us to determine how the timing of each scotophase and photophase relates to memory consolidation.

Title: Vestibular system, a new synchronization pathway of biological rhythms?

Authors: *T. MARTIN, B. MAUVIEUX, J. BULLA, B. PHILOXENE, M.-L. MACHADO, G. QUARCK, D. DAVENNE, P. DENISE, S. BESNARD;
U1075 COMETE UCBN/INSERM, Univ. De Caen Basse Normandie, Caen, France

Abstract: All living organisms have endogenous biological timing mechanisms that regulate behavior and physiology. These biological rhythms such as body temperature (Tb) are controlled both by endogenous master clock and synchronized by external factors such as light/dark cycle (LD cycle), physical and social activities. Others parameters such as gravity has also been recently involved. Studies in dogs, monkeys and rodents exposed to hypergravity (centrifugation) show that this stimulation induces rapid fall in Tb that is mediated by the vestibular system. Fuller et al. (2002) also demonstrated that vestibular stimulation is involved by showing that centrifugation at 2G inhibits circadian rhythm of Tb in normal mice while it has no effect in mice without functional otolith system.
Instead of stimulating the vestibular system, we have studied how the loss of vestibular information via a chemical lesion influences circadian rhythm of temperature and activity in Long-Evans rats (n=18). All rats exhibited strong circadian rhythms of activity and body

temperature (τ = 24 hours) before lesion. Just after lesion, mean Tb dropped drastically by 2.5° and recovered in 4 days following an asymptotic curve but stayed lower than in sham operated rats (0.12 °). Tb circadian rhythm disappeared during 5-7 days following the lesion. The circadian period was usually recovered in all rats during the second week after the lesion. As in Tb, activity dropped during few days and its circadian rhythm was not fully recovered at day 7, probably related to a direct effect on circadian rhythm and motor symptoms of the vestibular syndrome. Sham operated rats don't present alteration of circadian rhythms of Tb and activity. Vestibular loss disrupts circadian rhythm of temperature and activity as observed after vestibular stimulation. These results confirm that the vestibular system play a role on the synchronization of circadian rhythms. Vestibular inputs might be driven by the vestibulo-latero geniculo-supra-chiasmatic neuronal pathways as hypothesized by Horowitz et al. (2005).

Title: The olfactory bulb and the piriform cortex anticipate feeding time during food anticipatory activity in the rat

Authors: *M. PABELLO[1], M. L. MORENO[1], E. MEZA[2], M. CABA[2];
[1]Doctorado En Ciencias Biomédicas CIB, Univ. Veracruzana, Xalapa, Veracruz, Mexico; [2]Ctr. de Investigaciones Biomedicas, Univ. Veracruzana, Xalapa, Veracruz, Mexico

Abstract: It is well established that the olfactory bulb (OB) has a circadian clock, independent of the suprachiasmatic nucleus, the master clock in mammals. Moreover, OB drives rhythmic oscillations in the piriform cortex (PC), which reinforce the role of the OB as a pacemaker. However, very little is known about the functional significance of OB and PC oscillations. In present experiments we explored whether OB and PC can be entrained under conditions of food restriction. To this aim we used male adult rats under a restricted feeding schedule. Subjects were maintained under a 12/12 h light/dark cycle (lights on at 07:00 h = ZT0) and divided into three groups. Group 1: Ad libitum (AL), with free access to food. Group 2: Restricted feeding (RF), with restricted food access from ZT5-ZT7 for three weeks. Group 3: Restricted feeding-

fast (RF-F), similar to Group 2, then food was removed for two days, to explore the possible persistence of oscillations. Subjects were euthanized at ZT1, ZT5, ZT7 and ZT13. OB and brains were removed and sectioned coronally in a cryostat (50 μm) and processed by immunohistochemistry for FOS protein, product of the c-fos gene, as an indicator of neural activation. In the OB we explored Glomerular, Granular and Mitral cell layers. The piriform cortex was explored at the level of the lateral olfactory tract. AL subjects expressed low levels of FOS in three OB layers and PC, at all times explored except at ZT13, i.e, around the onset of night, where FOS values were significantly higher ($P<0.01$) in comparison to previous time points. However, RF subjects showed a completely different pattern. FOS was low at ZT1 but at ZT5, at time of feeding, showed a sharp increase, which further increase at ZT7. Then values sharply decrease at ZT13. values at ZT5 and ZT7 were significantly higher ($P<0.01$) in RF, in comparison to corresponding values in AL subjects in the three OB layers and in the PC. FOS in RF-F subjects follows a similar pattern as that of RF subjects, except in PC where values do not drop at ZT13. We conclude that both OB and PC are entrained by scheduled feeding and show a similar pattern of activation. Moreover, both structures "anticipate" feeding time during food anticipatory activity when subjects show a state of high arousal in advance of mealtime.

Abstract: The blood-brain barrier (BBB) plays a crucial role in the maintenance of the chemical environment of the central nervous system by controlling the entrance and exit of substances from blood to brain and *vice versa*. A disruption of the integrity of the BBB can cause brain infection, inflammation, epilepsy, and neurodegenerative disorders. Primary cultures of

confluent brain micro-vessel endothelial cells (BMVEC) have been established as a useful model for the study of BBB physiology, biochemistry, and molecular events induced by internal and external factors. Here we report a novel approach for the labeling of toxicant-induced cell death in cultured rat BMVEC using Fluoro-Jade C (FJ-C). Fluoro-Jade stains have been extensively utilized in *in vivo* studies of neurotoxicity where they have been shown to label dead and dying neurons, but have never been applied in *in vitro* BBB model systems. Here, four different toxicants (cadmium, thimerosal, sodium nitroprusside, and silver nanoparticles) served as positive controls with the culture medium serving as a negative control in these proof-of-concept experiments. All toxicants elicited a significant, dose-dependent increase in the number of Fluoro-Jade C labeled cells. The toxicant-induced cell death, as determined by the Fluoro-Jade C labeling, was further confirmed by two conventional cytotoxicity tests, the lactate dehydrogenase (LDH) and XTT (2,3-bis-(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide) assays. Compared to these two conventional assays, the F-J C-labeling appears to have the following advantages: it is simpler, faster, has higher sensitivity, higher specificity, and a larger dynamic range. Together, these results suggest that the Fluoro-Jade C-based labeling approach can provide a simple and rapid assessment of cell death in the BMVEC-BBB model and has the potential to lead to high-throughput screening and analyses of cytotoxicity *in vitro*.

Title: The effect of chronic treatment with atypical antipsychotic drugs to P-glycoprotein in the mice brain

Authors: *T. WATANABE, K. OSADA, T. HAGA, Y. OGAWA, A. MUTO, A. TAGUCHI, T. YANAGIDA, M. NAKANO, Y. SASUGA, N. YAMAGUCHI;
St. Marianna Univ. Sch. of Med., Kawasaki/Kanagawa, Japan

Abstract: P-glycoprotein is a 130-kDa adenosine triphosphate (ATP)-dependent drug transport protein that is abundantly distributed in the apical side of brain capillary endothelial cells forming the tight junctions of the blood-brain barrier (BBB). P-glycoprotein has been demonstrated to influence the absorption, distribution, and elimination of many commonly used

drugs. It has, furthermore, been shown that P-glycoprotein influences the distribution of drugs across the BBB. The location of P-glycoprotein at the BBB is of importance for the delivery of psychotropic drugs such as antidepressant and antipsychotic medications. Among these drugs are the antidepressants nortriptyline, citalopram, sertraline, and fluvoxamine, the antipsychotic drugs olanzapine and risperidone, as well as the substrates for P-glycoprotein. But we do not know how the P-glycoprotein function after the chronic treatment with atypical antipsychotic drugs in the brain. Then we investigated which chronic treatment with the atypical antipsychotic drugs as the substrates for P-glycoprotein was changed the function of P-glycoprotein in the brain. We examined that the expression of RNA P-glycoprotein after chronic treatment with the antipsychotic drugs and compared with before treatment. C57BL/6N mice (weighing 20-25 g) were orally administrated of 10mg/kg/day aripiprazole once daily for six weeks. To quantify the amount of mRNA in mice brain, we performed real-time PCR (7500 Fast Real-Time PCR System)by using TaqMan Fast Universal PCR Master Mix (life technologies). A PCR reaction mixture of 20µl containing 10µl of TaqMan Fast Universal PCR Master Mix, 9 µl of cDNA and 1 µl TaqMan Gene Expression Assays. Aripiprazole (P-glycoprotein inhibitor) induced the increase of P-glycoprotein expression. However aripiprazole inhibited the export of digoxin (P-glycoprotein substrate) by P-glycoprotein from brain to blood, then the brain concentration of digoxin was inceased.

Title: Mechanistic insights into altered glycaemia-induced blood-brain barrier dysfunction *In vitro*

Authors: *R. K. SAJJA, S. PRASAD, P. NAIK, L. CUCULLO;
Pharmaceut. Sci., Texas Tech. Univ. Hlth. Sci. Ctr., Amarillo, TX

Abstract: Of the many microvascular complications resulting from diabetes-dependent altered glycaemia, the blood-brain barrier (BBB) dysfunction is the most critical, as it exacerbates a host of brain disorders. In this study, we assessed the impact of acute/chronic hyper or hypoglycemic conditions on brain microvascular endothelial cell (HBMEC/D3 cell line) physiology, which may compromise the function and integrity of the BBB. Parallel monocultures of D3 cells (between passages 29-35) were exposed to either hyper or hypoglycemic conditions (35 or 2.2 mM D-glucose respectively, in D3 cell/pericyte cocktail medium [1:1]). Following 24 h (acute) or 72 h exposure, the expression of various glucose transporters and tight junction proteins were analyzed by immunocytochemistry and western blot analyses and were compared to controls (normoglycemic conditions ≈ 5.5 mM D-glucose). Media samples from all cultures collected at 24 h and 72 h were further assayed for VEGF and PDGF-BB levels. Side by side comparison of immunofluorescence data at 24 h and 72 h showed a consistent up-regulation of GLUT-1 and SGLT1 under hypoglycemic condition, while hyperglycemia induced a remarkable decrease of these transporters (vs. control). Relative to control condition, hyperglycemia induced a marginal increase of insulin-β receptor expression which was instead decreased in hypoglycemic cultures. Exposure to either hyper or hypoglycemia resulted in a significant down-regulation of claudin-5 and remarkable changes in distribution patterns of P-gp. In addition, both hyper and hypoglycemia elicited a significant increase in Nrf-2 (a primary regulator of oxidative stress) expression. Moreover, a progressive elevation in VEGF levels was observed at 24 and 72 h following hyper or hypoglycemia (vs. control). Interestingly, exposure to hypoglycemic conditions (but not hyperglycemia) significantly reduced PDGF-BB levels. These data suggest that hyper and hypoglycemic conditions induce a progressive dysfunction of brain microvascular endothelial cells which could be prodromal to BBB impairment and involve oxidative stress damage. Additional studies are currently in progress (BBB integrity and corresponding functional assessments in vitro using humanized flow-based and static BBB co-culture models) to validate our results and dissect out the differential impact of acute vs. chronic altered glycemic conditions on BBB function. Title: Regulation of steroid disposition and animal aggression by Mdr1 and BCRP

Authors: *R. MUNJI[1], R. DANEMAN[1], R. BAINTON[2];
[1]Anat., [2]Anesthesia, Univ. of California - San Francisco, San Francisco, CA

Abstract: ABC efflux transporters expressed at the BBB protect the CNS from xenobiotic toxicity. However, the ability of ABC transporters, P-glycoprotein and BCRP, to efflux a myriad of endogenous compounds suggests that these transporters may function to limit the biological activity or toxicity of their endogenous substrates in the CNS. Both P-glycoprotein and BCRP have been shown to transport biologically potent substrates including steroids, neuropeptides and vitamins. Thus, we hypothesize that defects in P-glycoprotein or BCRP activity could lead to aberrant CNS signaling and potentially detrimental effects on neural function. In accord with this hypothesis, we observe abnormal aggression in male Mdr1-BCRP knockout mice. Male Mdr1-BCRP knockout mice exhibit increased responses when compared to wildtype mice in the resident-intruder inter-male aggression test. To characterize the roles of P-glycoprotein and BCRP in regulating CNS function, we are analyzing the disposition and activity of P-glycoprotein and BCRP substrates known to modulate animal behaviors. Our preliminary data suggests that sex steroid concentrations are altered in Mdr1-BCRP knockout mice. These findings implicate efflux transport as an important mechanism for regulating endobiotic disposition and CNS homeostasis. Moreover, our results reveal a potentially undesirable side effect of modulating P-glycoprotein or BCRP activity for CNS drug delivery.

Title: Arachnoid cell morphology/physiology in fibroblast co-cultures

Authors: *C. H. LAM[1], E. HANSEN[2];
[1]Neurosurg., Univ. of Minnesota, MINNEAPOLIS, MN; [2]VA Med. Ctr., Minneapolis, MN

Abstract: Introduction: Fibroblast is pervasive in the setting of injury to many organs. Its invasion into the arachnoid tissue causes scarring, adhesion of the brain, and obstruction of cerebrospinal fluid outflow. We studied the effects of fibroblast grown in close proximity to the arachnoid.
Methods: An immortalized rat cell line was used in conjunction with rat fibroblast primary cultures. Transport properties, morphology, and growth characteristics were analyzed. Semi permeable transwell membranes with monolayers of cocultured arachnoid and fibroblast cells (25%, 50%, 75%, and 100% ratio of arachnoid to fibroblast) were compared using TEER, permeability of mannitol, morphology, and mortality.
Results: The barrier function (TEER) of cell monolayers decreased with the invasion of fibroblast. Similarly the permeability of mannitol significantly increased as the ratio of arachnoid to fibroblast decreased. The morphology of arachnoid cells did not change in fibroblast co-cultures, however arachnoid cells died at a significantly higher rate when in close proximity to fibroblasts compared to arachnoid cell monocultures alone.
Conclusion: We demonstrate that fibroblast alter arachnoid cell behavior including barrier capability and viability. Fibroblasts may influence arachnoid cell's mannitol transport via soluble factors. While the arachnoid cells did not change morphologically, over time, the cells became overwhelmed, mimicking the pathologic event of scarring.

Title: Regional disparities in cerebral blood flow velocity changes induced by visual vs. executive function tasks

Authors: *T. BURNETT, P. AINSLIE, P. VAN DONKELAAR;
Univ. of British Columbia - Okanagan, Kelowna, BC, Canada

Abstract: Neurovascular coupling (NVC) is the process by which neural activity drives changes in cerebral blood flow velocity (CBFv). Visual stimulation is traditionally used to increase neural activation of the visual cortex, thus, causing an NVC response in posterior cerebral artery velocity (PCAv). How cognitive tasks increase the neural activity of the frontal cortex thereby eliciting an NVC response in the middle cerebral artery velocity (MCAv) are poorly understood. The aim of this study was to use a traditional visual stimulation paradigm to elicit an NVC response in PCAv, and compare that with NVC responses in MCAv during an executive function task. Participants were fitted with two 2MHz transcranial Doppler ultrasound probes to measure CBFv simultaneously in the right PCA and left MCA. In addition, end tidal CO_2 (PCO_2), and mean arterial pressure (MAP) were also monitored. Measurements were continuously made under three conditions: i) Passive vision in which the eyes were alternately opened and closed 5 times for 40 and 20 seconds, respectively; ii) Active vision in which the participants read a passage during the eyes open segments; and iii) Executive function in which the participants completed a task-switching task during which they alternated responding congruently and incongruently to a spatial target. Results showed that passive and active vision resulted in a larger NVC response in PCAv than the task-switching task which showed a significantly larger NVC response in MCAv. The changes induced by the task-switching task occurred despite the fact that there were robust reductions in PCO_2. Taken together, these results demonstrate regional differences in CBFv in response to neural activation across two broad categories of tasks that differentially engage frontal and posterior brain regions.

Title: Optogenetic activation of mouse cortical inhibitory interneurons is sufficient to increase local blood flow

Authors: *E. ANENBERG[1], J. LEDUE[2], T. H. MURPHY[2];
[1]Neurosci., [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Interplay between various cell types in the brain orchestrates the recruitment of blood flow in accordance with local activity. Coupling alterations in blood flow, and presumably oxygen delivery, with levels of neuronal activity is essential for normal brain function; however, the underlying mechanisms involved in this regulation are unclear. Studies suggest a role for astrocytes, pericyctes, pyramidal neurons and interneurons in controlling cerebral blood flow. Here we use optogenetic techniques, cell type selective excitation, to investigate whether direct activation of inhibitory interneurons can alter blood flow. By imaging through a polished reinforced thinned skull window, we have observed that direct photostimulation of inhibitory cells in vivo in VGAT-mhChR2-YFP BAC transgenic mice alters levels of cortical blood flow and activity. With 3.3 mW of 473nm light, 100ms of 100Hz 5ms stimulation led to a 9.15±1.08% increase in the laser speckle signal within 1.9 s (n=3). Similar increases in blood flow assessed by laser speckle (10.04±0.03%) were achieved with 4 s of sensory stimulation (n=2). Intrinsic optical signals were used to confirm that stimulation led to brain activation. The initial dip of the intrinsic signal, an indirect measure of activity composed largely of the deoxygenation of hemoglobin (Hb) (Frostig et al. 1990) , reached its minimum of -0.021±0.018 ΔR/R% within 1.2 s (n=5). Signal overshoot, which is proposed to consist largely of HbO2 increase and deoxyHb decrease (Malonek and Grinvald, 1996) reached a maximum of 0.205±0.032 ΔR/R% within 3.2 s (n=5). Sensory stimulation led to an initial dip of similar amplitude to direct optogenetic stimulation (-0.020±0.004 ΔR/R% within 1.2 s) but a smaller overshoot (0.024±0.008 ΔR/R% within 4.8 s) (n=3). These data suggest that the activation of interneurons is sufficient to mediate elevations in cortical blood flow.

Title: Effective cerebral blood volume enhancement by flexible, transparent, and non-cytotoxic graphene electric field stimulator

Authors: *C. HEO[1], S. LEE[1], A. JO[2], S. JUNG[2], M. SUH[2], Y. LEE[1];
[1]IBS Ctr. for Integrated Nanostructure Physics (CINAP), [2]Biol. science, Sung Kyun Kwan Univ., Suwon City, Kyeonggi-Do, Korea, Republic of

Abstract: The global population is aging; thus, the risk for cerebrovascular diseases and associated deaths is rapidly increasing. The enhancement of cerebral blood volume (CBV) in a targeted area without causing side effects is a primary strategy for treating cerebral hypoperfusion. Here, we report a new non-pharmaceutical, and non-vascular surgical method to increase CBV. A skin-like biocompatible graphene electrical field stimulator (GEFS) is fabricated with an ultra-thin electrode of graphene, two-dimensional honeycomb arrangement of carbon atoms which yields superb electrical conductivity, high transmittance, and excellent flexibility. GEFS was placed directly onto the cortical brain and anon-contact electric field was applied at a specific local blood vessel. Effective CBV increases in the blood vessels of mouse brains were directly observed from in vivo optical recordings of intrinsic signal (ORIS) imaging. The CBV was significantly increased in arteries of the stimulated area, but neither tissue damage nor unnecessary neuronal activation was observed. No transient hypoxia was observed. This technique provides a new method to treat cerebral blood circulation deficiencies at local vessels and can be applied to brain regeneration and rehabilitation.

Title: Capillaries dilate in brain slices and *In vivo* in response to neuronal activation, and may initiate the vascular response

Authors: *C. N. HALL[1], C. REYNELL[1], B. GESSLEIN[2], N. HAMILTON-WHITAKER[1], A. MISHRA[1], D. ATTWELL[1];
[1]Univ. Col. London, London, United Kingdom; [2]Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Neuronal activity is energetically expensive, so when different parts of the brain are active, blood flow increases to these active regions. This is thought to occur when glutamatergic signalling produces second messengers in other neurons or astrocytes, leading to dilation of arteriolar smooth muscle cells. This increases arteriole diameter and therefore blood flow to the region fed by a given vessel. Recent work, however, suggests that capillaries may also be important for controlling neuronal energy supply, as application of neurotransmitters to brain slices causes capillaries to constrict and dilate near pericyte cell bodies (Peppiatt et al., 2006, Nature 443, 700-4,). Here, we demonstrate that capillaries also dilate in brain slices when neurons are activated. This dilation, either in response to applied glutamate or neuronal stimulation, occurs via prostaglandin E2 acting on EP4 receptors. Capillaries also dilate in vivo in somatosensory cortex during whisker stimulation. This dilation often occurs before the feeding arteriole response, demonstrating that the capillary dilation is an active response due to relaxation of capillary pericytes, rather than a passive effect of altered blood pressure due to upstream arteriole dilation. Importantly, this result implies that capillary pericytes may be the vascular cells that first sense local increases in neuronal activity and initiate the signal to increase blood flow to an active region. The spatial resolution of changes in blood flow in response to local changes in neuronal activity may, therefore, be much more precise than previously thought.

Title: Intranasal targeting of antibodies to the central nervous system: A potential noninvasive strategy for chronic immunotherapy against brain disorders

Authors: *J. J. LOCHHEAD[1], N. KUMAR[1], C. VIESSELMANN[1], R. THORNE[1,2,3,4]; [1]Pharmaceut. Sci., Univ. of Wisconsin, Madison, WI; [2]Clin. Neuroengineering Training Program, [3]The Ctr. for Neurosci. and Neurosci. Training Program, [4]Cell. and Mol. Pathology Grad. Program, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Antibody therapeutics have shown efficacy in pre-clinical models of Alzheimer's disease, Parkinson's disease, and glioma. Intravenously administered anti-beta-amyloid immunoglobulin G (IgG) is currently in clinical trials as a disease-modifying therapy for Alzheimer's disease. This approach may primarily work through the sequestration of beta-amyloid by circulating antibodies (i.e. a "peripheral sink"); however, there is also evidence that antibodies can prevent beta-amyloid oligomerization, facilitate amyloid disaggregation and stimulate Fc-mediated phagocytosis by microglia within the CNS provided sufficient amounts of IgG are able to access the brain. Achieving reliable, chronic CNS delivery for macromolecules like IgG (150 kDa) has been a major unmet challenge because the blood-brain barrier severely restricts brain entry from the systemic circulation. Previously, several proteins have been shown to directly access the CNS through pathways associated with the olfactory and trigeminal nerves following intranasal (IN) administration (Lochhead & Thorne. *Adv Drug Deliv Rev*, 2012). Rapid delivery (30-60 min) of proteins to widespread areas of the CNS following IN administration has suggested a convective (bulk flow) process is involved, possibly along cerebral perivascular spaces (Thorne et al. *Neuroscience*, 2004 & 2008). Although a few studies have indicated antibodies may reach the brain after IN application, quantitative data regarding the resulting IgG distribution in the CNS has not been available. Our previous work suggested that matrix metalloproteinase-9 (MMP-9), a physiologic, nasal epithelial tight junction modulator could enhance the access of fluorescently labeled dextrans, albumin (67 kDa) and IgG to the perivascular spaces of cerebral blood vessels following IN delivery (Lochhead & Thorne. *SfN Abstracts*, 2012). We hypothesized that IN MMP-9 pretreatment would increase antibody delivery to the brain by enhancing IgG transport across the nasal epithelium and allowing it greater access to pathways connecting the nasal submucosa to the brain. In the present study, we intranasally administered MMP-9 and ^{125}I-IgG to rats and then measured ^{125}I-IgG distribution and concentration throughout the CNS using autoradiography and gamma counting. Our results demonstrate rapid delivery of ^{125}I-IgG to widespread areas of the CNS following IN administration. These findings provide evidence that passive immunization using the intranasal route may allow for noninvasive, specific targeting of pathologic antigens residing within the CNS, offering several advantages over other systemic routes for chronic immunotherapy.

Title: Novel recombinant T cell receptor ligand RTL 1000 is effective in the murine model of female stroke

Authors: J. M. PALMATEER[1], J. PAN[1], T. SCHALLERT[2], H. OFFNER[3,4,5], *P. D. HURN[6,1]; [1]Section of Neurobiology, Col. of Natural Sci., [2]Dept. of Psychology, Univ. of Texas at Austin, Austin, TX; [3]Neuroimmunology Res., Veteran's Affairs Med. Abstract:
Inflammation is an important mechanism by which the brain is damaged after ischemia but also an important element in healing and repair. Little is known about the role of T lymphocytes and adaptive immunity, but recent reports indicate that some subsets of T cells alter ischemic outcomes by a variety of mechanisms. We studied a recombinant, humanized T cell receptor ligand, RTL 1000, currently under evaluation as a clinical therapy for multiple sclerosis and which previously has been shown to reduce tissue damage after middle cerebral artery occlusion (MCAO) in male mice. We now test the hypothesis that RTL 1000 would be effective in DR2*1502 TG female mice with humanized T cell receptors, both by reducing histological damage and by improving complex behavioral recovery. Female DR2 mice (18-21g) were treated with MCAO (60 min) or sham surgery, and then recovered for 96h or 2 weeks. Ischemic cerebral perfusion was measured by laser Doppler flowmetry, and was not different between MCAO-treated groups. RTL or vehicle (VEH) was administered at 3h, 24h, 48h and 72h post-occlusion. Infarction volume (TTC staining, n=15 per group) was: Cortex: P value: 0.005; RTL1000 19.89% (+/- 6.25), Vehicle 44.24% (+/- 4.99), Striatum: P value: 0.002; RTL 1000 24.17% (SEM: +/- 6.81), Vehicle 52.4% (+/- 4.74), Infarcted hemisphere/contralateral hemisphere: P value: 0.009; RTL1000 13.94% (+/- 4.07), Vehicle 28.29% (+/- 3.03). No

differences were found for
mortality rate, intra-ischemic cerebral perfusion, body weight during recovery or post-operative general health score between groups. Reduction of infarction to near zero was observed in RTL (n=7). We conclude that RTL 1000 strongly improves ischemic outcomes in young, reproductively intact, female mice.

Title: MCT1 function in cerebral microvascular endothelial cells is decreased by cAMP through a mechanism that reduces trafficking to the cell surface

Authors: *J. P. SMITH, L. LI, N. LAVOY, M. J. VELASQUEZ, A. L. UHERNIK; Colorado State Univ.-Pueblo, PUEBLO, CO

Abstract: Monocarboxylic Acid Transporter 1 (MCT1) in cerebral microvascular endothelial cells is the main mechanism for monocarboxylic acids to cross the blood-brain barrier giving it a major role in maintaining cerebral monocarboxylic acid homeostasis in health and development. It also controls lactic acid flux from brain to blood during lactic acidosis, which is foundational to the etiology of brain damage during stroke and brain injury. Therefore, understanding the detailed mechanisms that regulate cerebrovascular MCT1 could provide important new targets for interventions that could modulate lactic acidosis to improve outcomes. Our previous studies showed cAMP-dependent regulation of Mct1 function in rat brain endothelial cells involves a mechanism that reduces the transporter's level of expression and phosphorylation on the plasma membrane. Associated with this regulation, caveolin-1 was dephosphorylated and Mct1 translocated to caveolae. However, whether caveolar dependent endocytosis or some other mechanism was responsible for reduced membrane expression of Mct1 was not determined. To investigate this, we evaluated changes in Mct1 function, total cellular phosphorylation, rates of

membrane insertion, and endocytic rates in rat brain endothelial cells that were briefly exposed to 8-Br-cAMP, and inhibitors of vesicular trafficking, methyl beta cyclodextrin (MBCD) and dynasore. Each of these agents reduced Mct1 function, reduced Mct1 trafficking to the plasma membrane, and increased the colocalization of mCherry-tagged Mct1 with GFP-tagged caveolin-1. 8-Br-cAMP increased endocytosis of 70 kD dextran, but reduced colocalization of Mct1 with the endocytosed material. In contrast, dynasore and MBCD both decreased endocytosis of 70kD dextran. Phosphorylation of total cellular Mct1 was increased by 8-Br-cAMP. Combined these results show cAMP regulates Mct1's surface expression in brain endothelial cells through a pathway in which phosphorylation of transporters causes reduced delivery to the plasma membrane, while dephosphorylated transporters remain at the surface. cAMP dependent translocation of Mct1 to caveolin-1, which becomes dephosphorylated, and the direct inhibition of Mct1 by MBCD, supports a mechanism of Mct1 inactivation in a pathway involving caveolin-1, but possibly not caveolar dependent endocytosis. Because inhibitors of endocytosis strongly inhibited Mct1 function, our overall results show a mechanism in which the dynamics of Mct1 surface trafficking not only regulate its function but are essential to it.

Title: Probing neurovascular coupling via natural and driven vasomotion in the awake mouse

Authors: *C. MATEO[1], P. S. TSAI[1], A. Y. SHIH[3], D. KLEINFELD[1,2];
[1]Physics Dept, [2]Neurobio., UCSD, La Jolla, CA; [3]Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Neuronal activation by sensory stimulation or brain microstimulation leads to a change in vascular tone that forms the basis of functional magnetic resonance imaging (fMRI) and intrinsic optical imaging. Yet, in the absence of external stimulation or a specific cognitive task, spontaneous cortical activity persists during what has been referred to as the "resting brain

state". Interestingly, infra-slow oscillations of the fMRI signal (< 0.2 Hz) in humans and monkeys correlate with spontaneous fluctuations in neuronal activity (Schölvinck, Maier, Ye, Duyn & Leopold, PNAS, 2010). We suggest that this low frequency signature may provide a means to study neurovascular coupling. Toward this goal, we combined functional two-photon imaging of cortical hemodynamics with electrophysiological recordings and optogenetics in awake, head-fixed mice. We achieve non-invasive optical access over the superficial layers of the somatosensory cortex with a thin-skull cranial window. Neuronal activity across the window was assessed using differential local field potential recordings from a pair of electrodes that spanned the window.
Consistent with a previous report (Drew, Shih & Kleinfeld, PNAS, 2011), we observe infra-low frequency dilations, at < 0.2 Hz, in surface and penetrating arterioles but not in veins. We further observe strong spectral coherence at these infra-low frequencies between the envelope of the gamma rhythm band of neuronal activity, nominally 30 to 80 Hz, and the diameter of the arterioles (n = 8). This analysis also reveals that changes in the envelope of the gamma rhythm lead the dilation of all imaged arterioles by several seconds, suggesting that the gamma rhythm serves as a predictor of slow vasodynamics in the neocortex. As one control, the observed coupling between the gamma rhythm and vasomotion was disrupted by isoflurane anesthesia, ~3 % in oxygen, which maximally dilates brain arterioles.
To probe the possibility of a causal effect of fluctuations in the local blood supply on neuronal activity, we use focused laser light to periodically dilate individual arterioles via the hyperpolarization of smooth muscle cells that genetically express halorhodopsin (n = 2). Data from these experiments will allow us to assess the potential role of changes in local perfusion on spontaneous ongoing activity.

Title: Arachnoid cell motility in fibroblast co-cultures

Authors: *E. A. HANSEN[1], C. YUAN[2], C. LAM[2];
[1]Res. Service 151, VA Med. Ctr., Minneapolis, MN; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Introduction: The barrier between the CSF and the blood is in part formed by the arachnoid cells. Models of arachnoidal tissue however are limited. We have developed an immortalized arachnoid cell line derived from the rat with barrier properties indicative of a CSF-blood barrier model and observe arachnoid cell aversive movement in fibroblast cell cultures.
Method: Rat cells were immortalized by LgTAg vector as described previously and labeled with GFP. GFP labeled arachnoid cells were plated at 1:1 ratios with fibroblast and irradiated fibroblast. Arachnoid cell motility was determined by taking a photograph using a florescent microscope with incubator every 5 minutes for up to 72 hours. Movies were created allowing single cells to be tracked and monitored for distance moved, directional movement (i.e. away from fibroblasts), and cell mortality.
Results: Arachnoid cells moved significantly longer distances when grown in fibroblast co-cultures compared to irradiated fibroblast co-cultures and arachnoid cell monocultures. Arachnoid cells died at the highest rate when grown with non-irradiated fibroblast, and had lower mortality when grown with irradiated fibroblast and arachnoid controls. Arachnoid cells appeared to move away from fibroblast cells when in close proximity (i.e. less then 5µm).
Conclusion: We demonstrate that fibroblast alter arachnoid cell behavior including movement and mortality. Development of an in vitro model for the arachnoid granulation and one that models scarring will enhance our understanding of transport in the tissue and provide the basis for the development of an arachnoid equivalent.

Title: Identification of candidate genes acting as Notch-regulators and their role under hypoxic conditions

Authors: *T. STOBDAN[1], D. ZHOU[1], G. HADDAD[1,3,2];
[1]Pediatrics, [2]Neurosci., Univ. of California San Diego, La Jolla, CA; [3]Rady Children's Hosp., San Diego, CA

Abstract: The evolutionarily conserved Notch signaling is one of the most important regulators of development. Our previous studies have found that activation of Notch signaling in the Eaat1-

positive glial cells plays a critical role in the developmental process under hypoxic conditions by showing a remarkable increase in hypoxia tolerance. To study the genetic interactions that underlie this Notch-activation that confers protection during hypoxia and development, we used UAS/Gal4 system and generated a Drosophila melanogaster line with constitutive Notch activation by specifically overexpressing Notch intracellular domain (the functional domain mediating Notch function) in the Eaat1-positive glial cells (i.e., the EN line). In the current study, we crossed this UAS-NICD/Gal4 EN line with UAS-RNAi lines targeting specific gene(s). In such cross, the targeted gene will be down-regulated on a Notch-activation background and this will serve to delineate any interaction between Notch and the targeted gene. Prioritization of candidate genes (n=66) was based on gene expression profiling of Drosophila strain that lives perpetually in an extremely low-oxygen environment. Our assay was to investigate the eclosion rates of Drosophila embryos developing under hypoxic (5% O2) and room air (21% O2) conditions. Preliminary results indicate several candidate genes, when suppressed in glial cells, showed a protective role to severe hypoxia. In contrast, down-regulating a gene encoding a ribosomal protein in glia was found to be deleterious under both room air and hypoxic conditions. Interestingly, this deleterious effect was rescued by Notch activation under both hypoxic and room air conditions. In conclusion, we have studied the interactions between Notch and other genes in Eaat1-positive glial cells and have identified interesting Notch interactive genes that play important roles in development under hypoxic conditions.

Title: Are resting state and stimulus-evoked neurovascular coupling different?

Authors: *Y. MA, A. RAYSHUBSKIY, S. H. KIM, D. TIMERMAN, M. G. KOZBERG, E. M. C. HILLMAN;
Biomed. Engin., Columbia Univ., New York, NY

Abstract: Neurovascular coupling refers to the tight link between changes in neuronal activity and changes in local cerebral blood flow and cerebral blood oxygenation. Functional neuroimaging techniques such as functional magnetic resonance imaging (fMRI) rely on the assumption that the relationship between the hemodynamic response and local neural activity is linear. Several studies have shown correlations between the stimulus-evoked hemodynamic response and both local field potential and local multi-unit activity.
More recently, resting state functional connectivity mapping has been adopted as a tool to assess the brain's innate neuronal networks by analyzing regional correlations in spontaneous fluctuations in the fMRI blood oxygen level dependent (BOLD) signal in the absence of a specific stimulus. Many studies have identified differences in resting state 'networks' between subjects with a range of neurological and psychological disorders ranging from multiple sclerosis and Alzheimer's to schizophrenia and ADHD. However, this analysis assumes that all changes in network connectivity are differences at the neuronal level. In this work, we ask two questions: 1) Can all resting state hemodynamic fluctuations be interpreted as representing underlying neuronal activity? and 2) Do alterations in resting state functional connectivity always represent neuronal differences, or could they also represent imbalance in neurovascular coupling?
To address these questions, we acquired both multi-spectral optical intrinsic signal imaging (MS-OISI) of cortical hemodynamics and multi-location electrophysiology in a bilaterally exposed cortex rat model. Electrodes were located within the bilateral hind-paw regions of the somatosensory cortex. Simultaneous electrical and hemodynamic signals were acquired both during and in the absence of sensory stimulation. Both local field potential (LFP) and multi-unit activity were compared to the observed local and distant hemodynamic responses to determine whether similar models can predict both stimulus-evoked and spontaneous hemodynamic fluctuations. A detailed analysis of stimulus-evoked and resting-state neurovascular coupling will be presented.

Title: Histochemical characterization of Wfs1 protein in mouse pituitary

Authors: *K. TEIN, A. TERASMAA, E. VASAR, S. KÕKS;
Physiol., Tartu Univ., Tartu, Estonia

Abstract: Mutations in WFS1 gene cause Wolfram syndrome, which is a rare autosomal recessive disorder, characterized by diabetes mellitus, diabetes insipidus, optic atrophy and deafness (DIDMOAD). WFS1 gene product wolframin is located in the endoplasmic reticulum and mouse lacking this gene have disturbances in peptide processing and secretion. High levels of wolframin protein are observed in the hippocampus, amygdala and limbic structures, but Wfs1 protein has not been studied in pituitary gland. It is important to know localization of Wfs1 protein in pituitary to understand better the regulation of pituitary peptides and hormones. Proopiomelanocortin (POMC) is a precursor polypeptide and is located in the anterior lobe and in the intermediate lobe of the pituitary gland.
Prohormone convertase (PC2) is located in neurons and endocrine cells and is needed for processing the precursors of neuropeptides and peptide hormones, such as vasopressin and POMC. Maturation and activity of PC2 depends on neuropeptide secretogranin V (7B2).
In this study, we used immunohistochemistry (IHC) to characterize Wfs1 protein localization in mouse pituitary. As Wfs1 takes part in protein processing, we also used IHC to detect possible co-localization of Wfs1 and POMC. Moreover, co-localization of PC2 and 7B2 with POMC was detected.
We found that Wfs1 is localized in anterior pituitary and apparently is not co- localized with POMC. In intermediate pituitary, PC2 and POMC are co-localized, while PC2 cannot be found in anterior nor posterior pituitary. 7B2 and POMC are also co- localized in intermediate pituitary. Immunohistochemistry also showed that 7B2 can be found in anterior pituitary and in posterior pituitary, though 7B2 and POMC are not co- localized in anterior pituitary.
Current results suggest that Wfs1 is expressed in anterior pituitary with POMC, notably PC2 seem to be absent in this part. Therefore, it is possible, that Wfs1 takes part in processing of POMC in absence of PC2. Further studies are needed, to characterize possible co-localization of Wfs1 with other neuropeptides in pituitary. Such study would suggest the identity of neuropeptides, which processing is regulated by Wfs1.

Title: Convection-enhanced delivery based staining method and simultaneous multi-wavelength optical imaging of calcium and intrinsic signals

Authors: *H. MA[1], S. HARRIS[2], M. ZHAO[1], J. BERWICK[2], T. H. SCHWARTZ[1];

Abstract: Neurovascular coupling is the fundamental of many functional brain imaging techniques, such as functional magnetic resonance imaging (fMRI). The clinical application of these imaging techniques relies on this coupling to infer the spatiotemporal neural dynamics. An understanding of these coupling, especially spatial coupling, remains largely unclear because a method that can simultaneously record hemodynamic can neuronal activity with same spatiotemporal resolution is missing. We used convection-enhanced delivery to stain the whole hemisphere with calcium dye and perform simultaneous multi-wavelength optical imaging to record neuronal and hemodynamic activities with same spatiotemporal resolution. The fast component of calcium imaging data can offer similar information as voltage sensitive dye imaging without occupying the popular wavelengths used in hemodynamic imaging. The slow component can reflect the activity of glia cells. We have demonstrated that this technique is useful in study neurovascular coupling during different brain activities, such as spontaneous activity, sensory processing and pathology condition like epilepsy.

Title: Longitudinal assessment of resting state functional connectivity variance in the rat brain

Authors: *S. H. KIM, V. VOLETI, Y. MA, E. RAMIREZ, M. G. KOZBERG, M. B. BOUCHARD, B. R. CHEN, A. RAYSHUBSKIY, E. M. C. HILLMAN;
Biomed. Engin., Columbia Univ. Lab. For Functional Optical Imaging, New York, NY

Abstract: Resting state functional connectivity mapping assesses correlations between spontaneous fluctuations in the functional magnetic resonance imaging (fMRI) to image blood oxygen level-dependent (BOLD) signal throughout the brain. Correlated regions are interpreted as belonging to the same functional network. fMRI BOLD signals are derived from changes in deoxyhemoglobin concentrations, and therefore represent hemodynamic and not neuronal fluctuations. As a result, although hemodynamic activity in the brain is generally well-coupled to neuronal activity, it is important to assess whether functional connectivity results truly represent a physical property of neuronal connectivity and communication in the brain. To address this, we assessed resting state hemodynamics and their bilateral correlations in a chronic rat model using multispectral optical intrinsic signal imaging (MS-OISI). After wide-field aseptic thinned-skull craniotomy, animals were imaged up to 6 times over the course of 2 weeks. In each imaging session, the animal was anesthetized with either ketamine or varying doses of isoflurane, with terminal experiments performed under urethane anesthesia. We hypothesized that if functional connectivity networks derived from all anesthesia conditions were identical, that results represented a true functional network within the brain of a given animal. Systematic, anesthesia-independent modifications to functional connectivity maps would represent adaptation of the animal and its brain to the craniotomy. Instead, our results to date demonstrate that different anesthesias invoke highly varying resting state hemodynamics, in terms of spectral frequencies and bilateral spatial coherence. Resting state functional connectivity networks were therefore most strongly correlated to anesthesia type and level, rather than to each rat's innate 'network'. In ongoing work, we are extending these studies to incorporate indwelling electrodes and imaging without anesthesia to determine whether the influence of each anesthesia on the

representation of functional mapping is the result of alterations in neuronal or hemodynamic (neurovascular) control under anesthesia. These results are important for understanding and interpreting differences in resting state networks that have been observed in different pathological states, since the condition of the brain, and the integrity of neurovascular coupling in those conditions could underlie alterations in networks otherwise assumed to be wholly neuronal.

Title: Mitochondrial Ca2+ uptake capacity impacts both intrinsic and evoked brain activities

Authors: *S. S. KANNURPATTI[1], B. G. SANGANAHALLI[2], P. HERMAN[2], F. HYDER[2]; [1]Radiology, Umdnj-New Jersey Med. Sch., Newark, NJ; [2]Diagnos. Radiology, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Despite vast knowledge on the cellular mechanisms of Ca2+ integration by mitochondria [1] its in vivo impact in the brain is not known. Mitochondrial Ca2+ uptake can regulate neural signaling [2] and oxidative energy metabolism [3], both of which are important to understand the biophysical basis of functional magnetic resonance imaging (fMRI). fMRI is increasingly used in clinical neuroscience to determine physiological and pathological brain functions in humans. Therefore we studied the in vivo mitochondrial functional impact on the intrinsic and evoked activity states of the brain by investigating cerebral blood flow (CBF), neural activity and fMRI blood oxygen level dependent (BOLD) measures in an integrated manner using both resting and task-related designs. In vivo mitochondrial function was pharmacologically modulated by altering mitochondrial Ca2+ uptake capacities by treating α-

chloralose or urethane-anesthetized rats with Ru360 or Kaempferol which inhibits or enhances the mitochondrial calcium uniporter (mCU) respectively. Inhibition of mitochondrial Ca2+ uptake by Ru360 reduced the spontaneous and evoked neural activities whereas enhancement of mitochondrial uptake by Kaempferol increased both. Furthermore the way neuronal activity coupled to CBF and BOLD responses was dependent on mitochondrial Ca2+ uptake capacity with a relatively lesser impact on the CBF hemodynamic responses compared to BOLD. The different neural-CBF and neural-BOLD relationships during the altered mitochondrial states suggested that mitochondrial Ca2+ uptake capacity impacted oxidative energy metabolism-related blood oxygen signals more intensely during both intrinsic and evoked activity conditions. Depressed mitochondrial functions occur in aging, Alzheimer's and Parkinson's disease [4,5] whereas in some other neuropathologies such as pediatric epilepsy hyperactive mitochondrial functions occur [6,7]. The results collectively suggest that mitochondrial Ca2+ handling in vivo need to be considered from relevant preclinical animal models to better interpret intrinsic and evoked brain activity differences in human neuropathologies.

Title: The brain modulatory effect of focused ultrasound-induced blood-brain barrier disruption

Authors: *H.-Y. LAI[1,2], P.-C. CHU[3], H.-C. TSAI[4], K.-Y. CHANG[5], Y.-Y. SHIH[6], H.-L. LIU[3], Y.-Y. CHEN[7], Y.-C. PEI[1,2];

Yang Ming Univ., Taoyuan, Taiwan

Abstract: The blood-brain barrier (BBB) protects neural tissues from the entry of toxins and infectious materials and also prevents most therapeutic agents passing into the brain. Focused ultrasound (FUS) co-administrated with intravenously circulating microbubbles can disrupt BBB. However, our recent study found that FUS with microbubbles affects the brain activity evidenced by a transient decrease of somatosensory evoked potential (SSEP) even using a relatively low acoustic pressure of 0.3 MPa. In the present study, we characterized the change of blood oxygen level dependent (BOLD) to investigate the correlation between FUS-induced changes of hemodynamic responses and neuronal activities. We hypothesized that the coupling between hemodynamic responses and electrical activities remains even after the administration of FUS. The present study also investigated the time course of functional recovery by observing the changes of BOLD responses and SSEPs in varying FUS acoustic pressures.
To this end, we injected SonoVue SF6-coated microbubbles (2-5 μm diameter) intravenously and transmitted FUS with acoustic pressures of 0.2, 0.3, or 0.4 MPa and recorded BOLD responses and SSEPs elicited by forepaw electrical stimulation before and after FUS to observe the time course of suppression induced by FUS. The FUS (burst duration=10 ms, pulse-repetition frequency=1 Hz) was delivered to the left S1FL cortex (1 mm posterior and 4 mm lateral to the bregma) to 40 SD rats weighing 300-350 g (n=20 for BOLD, n=20 for SSEP) under 0.1 mg/kg Domitor anesthesia. BOLD responses were obtained from a Bruker 7T system using a gradient-echo EPI sequence (BW=200 kHz, TR/TE=2000/20 ms, Matrix=80x80, FOV=2.5x2.5 cm^2, slice thickness=1 mm). The SSEP was recorded by epidural electrodes implanted on the scalp. The stimulation paradigm was a regular bipolar square-wave current of 6 mA with a pulse width of 0.2 ms and a frequency of 3 Hz.
The 0.4-MPa FUS exposure immediately suppressed both BOLD responses and SSEPs and the effect could last for 7 days ($p < 0.05$). The 0.3-MPa FUS exposure suppressed BOLD responses and SSEPs with a smaller magnitude compared to that induced by 0.4-MPa FUS exposure, and the suppression gradually weakened and disappeared 3 days following FUS. The 0.2-MPa FUS exposure did not suppress BOLD responses or SSEPs, and did not open the BBB, neither. The present study demonstrated the correlation of the change of BOLD responses and SSEP signals following FUS-induced BBB disruption, indicating the preservation of neurovascular coupling

that implies the potential utility of fMRI for assessing the brain modulatory effects induced by FUS.

Title: Conditioned place preferences in hungry and non-hungry humans

Authors: *R. S. ASTUR, A. W. CAREW, B. E. DEATON;
Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Research has shown that nonhumans can be conditioned to prefer a neutral environment by pairing that environment with a rewarding stimulus, whether it is food, water, drugs, or social interactions. In an attempt to extend this paradigm to humans, we created a virtual reality (VR) conditioned place preference task, with real-life rewards. In addition, we examined how hunger affects the strength of conditioning.
In Experiment 1, 21 undergraduates were recruited and food restricted by asking them not to eat between midnight and 9am for two consecutive days. In Experiment 2, 21 additional undergraduates were recruited and allowed to eat normally. This was a 2-day study: Day 1 was a pairing/conditioning day, and Day 2 was the place preference test day. Participants were placed into a VR environment consisting of 2 visually distinct rooms connected by a hallway. On Day 1, participants underwent 6 pairing sessions in which they were locked into one of the two rooms and were to explore the VR environment by using a joystick to move throughout the VR world. Room A was paired with real-life M&Ms for 3 sessions, and Room B was paired with no food for 3 sessions. During the M&M sessions, chocolate M&Ms were periodically dispensed into a cup and the participant was instructed to eat the M&Ms as they were dispensed; approximately 50-60 M&Ms were administered on Day 1. Room / M&M pairings and ordering were counterbalanced. Day 2 was the test day, administered the next day, and participants were given free access to the entire VR environment for 5 min.
For the hungry participants, we observe that participants spent 49% of the time in the room previously paired with M&Ms compared to 21% in the room paired with no food. Hence,

participants display a significant conditioned place preference for a VR room that was previously paired with food ($p < 0.001$). Additionally, they display a significant explicit preference for the M&M-paired room. However, for the non-hungry participants, there was no evidence of a place preference, either implicitly (e.g. dwell time) or explicitly. Hence, we show that we can reliably establish a place preference in humans, but that the preference is contingent on the participants' hunger state. Future research will examine the extent to which these preferences can be blocked or extinguished as well as whether these preferences are evident using other reinforcers.

Title: Skill acquisition in piano performance: The influence of flow on learning

Authors: *Y. MIYAKE[1], H. YANO[1], A. NAKAMURA[1], K. KATAHIRA[1], S. FURUYA[2], N. NAGATA[1];
[1]Kwansei Gakuin Univ., Sanda Hyogo, Japan; [2]Hannover Univ. of Music, Drama and Media, Hannover, Germany

Abstract: In various fields, such as the arts, sports, and design, the elucidation of the process of skilled movement acquisition is an important topic of research. We focused on the process of piano performance skill acquisition and examined the effect of intrinsic motivation as a factor in promoting the learning effect in particular. The present longitudinal study aimed to investigate the relationship between acquisition of performance skills and flow as an index of intrinsic motivation. Twenty-four right-handed adult participants participated in an hour of piano practice twenty times. Each participant selected a favorite piece from among several musical pieces and practiced it. At the end of each practice, participants answered a questionnaire about the flow state experienced during the practice. To determine the effects of training, several tests to assess fundamental hand motor functions were carried out before and after the twenty hours of practice. The tests were of three types; one consisted of playing a short tone sequence of twelve strokes as fast as possible (speed test), another consisted of playing a tone sequence synchronized with a metronome (accuracy test), and the third consisted of tapping fingers except the thumb as fast as possible (tapping test). In order to assess the result of the tests, the timing and velocity information for each keystroke was collected from an electric piano. The results of the flow

experience questionnaire were analyzed by cluster analysis and were divided three groups on the basis of tendency toward shift of flow over twenty hours; the first group maintained a high level of flow for twenty hours (A group), the second had a high level of flow at first and a declining level of flow toward the end (B group), and the third had a low level of flow constantly (C group). Among these three groups, we compared the improvement of hand motor functions through practice. Improvement of hand motor functions was observed before and after practice for the A and B groups, which had a high level of flow. A difference was observed between the results of the speed test before and after practice in these two groups; they acquired ability to play the tone sequence faster. In the tapping test, differences were observed between the results before and after practice only for the A group; they improved independence of movement across fingers. In the accuracy test, the accuracy of performance was improved only for the B group. The C group, which had a low level of flow, showed no improvement of hand motor functions in any tests. Therefore, the specific state in which flow was experienced or the flow experience itself was suggested to be effective in learning of hand motor functions.

Title: Neural basis of cognitive and motivational dynamics relevant to sustainable human-agent interaction: An fMRI study

Authors: *T. NOZAWA[1], Y. SASAKI[1], R. YOKOYAMA[1], Y. AKIMOTO[1], R. NOUCHI[1], M. SUGIURA[1], T. KONDO[2], R. KAWASHIMA[1];
[1]Japan / Tohoku Univ., Sendai, Japan; [2]Tokyo Univ. of Agr. and Technol., Tokyo, Japan

Abstract: Human-agent interaction (HAI) involves virtual or real agents and has a wide range of applications. Development and sustenance of motivation for HAI with an unknown agent is affected by various cognitive and emotional dynamics, such as prediction, adaptation and exploration, and frustration. This fMRI study investigated neural substrates of these dynamical

processes. Three runs of fMRI scan were conducted on 27 university students while they engaged in HAI with three types of agents with different predictability. A virtual agent was presented in the form of a dog-type robot. Subjects pressed one of three buttons, and the agent responded with one of three gestures. This sequential HAI continued for 16 min each session. The three types of agents were (a) a nonadaptive agent with random actions; (b) an adaptive agent with fixed input-reward mapping; and (c) an intrinsically motivated adaptive agent that pursued an intermediate level of novelty. The order of the agent types was counterbalanced. Subjects were not informed about the nature of the agents and were instructed to freely set and change their aims. Subjects were supposed to have a probabilistic internal model of their relationship with the agent, which would be updated using the HAI history. Applying information-theoretic formulation to the model, we estimated the time courses of three motivation-related internal state variables, as follows. (1) Intrinsic reward was high when the agent's reaction was highly predictable from the subject's action choice. (2) Intention to explore was high when selecting actions that were supposedly unexpected for the agent. (3) Contextual controllability expressed how the situation was controllable on average. These estimates were used as first-order parametric modulators of the input and output events in the individual-level SPM analysis over the all sessions, and the contrast images produced were subjected to group-level random effects analysis. This analysis showed that (1) activity in the thalamus was positively correlated with the intrinsic reward; (2) activities in the left frontal eye field and bilateral intraparietal sulcus were positively correlated with the intention to explore; and (3) activities in the bilateral insula cortex were negatively correlated with the contextual controllability. The results can be interpreted as the neural substrates for (1) encoding an action-specific value signal; (2) exploratory decision-making; and (3) frustration when the situation is out of control, respectively. In conclusion, the model-based analysis successfully identified the neural basis of the cognitive and motivational dynamics relevant to sustainable HAI.

Title: A computational cognitive neuroscience model of complex skill learning

Authors: *V. V. VALENTIN[1], W. T. MADDOX[2], R. MUSGRAVE[1], F. G. ASHBY[1];
[1]Univ. of California, Santa Barbara, Santa Barbara, CA; [2]Dept. of Psychology, Univ. of Texas at Austin, Austin, TX

Abstract: Procedural learning of complex skills requires dopamine mediated striatal plasticity. Most prior work investigated single stimulus-response learning followed by feedback. However, many skills are composed of several actions that must be performed in sequence before feedback is available (e.g., as when a pilot executes a banked turn). We developed a category-learning task in which highly discriminable fractal images were presented sequentially, each requiring an A or B category response, but only the third response was followed by aggregate feedback. Correct feedback was given if all three responses were correct, and error feedback was given if any of the three responses were incorrect. Learning occurred in all three positions, although the best learning was to the stimulus in position 3. We propose and test a neurobiologically detailed theory of a dopamine dependent, unstructured category-learning network using aggregate feedback. The theory assumes that the category learning is mediated by plasticity at cortical-striatal synapses, which are modified by dopamine-mediated reinforcement learning. A model-based temporal difference learning algorithm propagates the dopamine neuron response back from the reward to the three categorization stimuli. The model successfully accounts for many properties of the human behavioral data.

Title: Post traumatic stress disorder (PTSD) impairs reward learning on a probabilistic category task

Authors: *M. M. HERZALLAH[1,2], A. D. BROWN[3], D. ABU-AMARA[3], J. SCOTT[3], K. THACHER[3], C. R. MARMAR[3], M. A. GLUCK[1];
[1]Rutgers, The State Univ., Newark, NJ; [2]Al-Quds Cognitive Neurosci. Lab., Al-Quds Univ., Abu

Dis, Jerusalem, Palestinian Territory; [3]PTSD Res. Program, Dept. of Psychiatry, NYU, New York, NY

Abstract: Using a probabilistic category-learning task that allowed for dissociation between the acquisition of positive feedback (reward) and negative feedback (punishment) during learning, we tested US combat veterans who served in Iraq and Afghanistan with and without Post-Traumatic Stress Disorder (PTSD). Although individuals with and without PTSD learned equally well in response to negative feedback, individuals with PTSD exhibited minimal learning from reward stimuli. These results suggest that PTSD may be characterized, in part, by alterations in cortico-striatal pathways, and deficits in reward learning may reflect an important, but relatively unexplored mechanism underlying PTSD. Further research examining the neurobiology associated with deficits in reward learning in PTSD may serve as an important marker in assessment and treatment. Although considerable work has demonstrated the importance of alterations in the neural circuitry of fear in people with PTSD, other neural circuits, such as those for reward learning (which have received considerably less attention), may play a critical role in the pathogenesis of the disorder.

Title: Distinct neural computations mediating observational learning derived from facial expressions versus words

Authors: *D. A. STANLEY[1,2], J. STANLEY[2], R. M. PIECH[2,3], J. P. O'DOHERTY[2,1]; [1]Caltech, Pasadena, CA; [2]Trinity Col. Dublin, Dublin, Ireland; [3]Anglia Ruskin Univ., Cambridge, United Kingdom

Abstract: We often learn about the value of actions not through doing them ourselves, but through watching other people do them and observing the outcomes they experience. Much is known about the neural computations that support learning through experience, but relatively little about those that support vicarious observational learning. A major open question is how

does the source of information being observed influence observational learning: e.g. is learning through observing others' affective reactions different from gaining verbal feedback about outcomes they experienced? To address this question we investigated the neural computations of observational learning, conveying information about others' experienced outcomes using either facial expressions, words, or both.
fMRI data were collected from 25 observers. Observers learned about the likelihood that 6 lottery machines would deliver aversive (salty tea) or neutral (artificial saliva) outcomes by watching videos of 3 observees play the lotteries. Each observee was associated with a pair of lotteries and 1 of 3 interleaved conditions. The conditions were: 1) Face Only (FO), observers saw videos of observees receiving outcomes paired with a nonsense word. 2) Word Only (WO), observers saw videos of observees in which their face conveyed no expressive feedback, paired with words indicating the experienced outcome. 3) Face+Word (FW), observers saw both expressions and words depicting the experienced outcome. Lottery pairs contained one aversive (paversive=0.8, pneutral=0.2) and one neutral (paversive=0.2, pneutral=0.8) lottery. Lottery pair contingencies reversed randomly once during the experiment. To assess learning, observers completed randomly interspersed choice trials in which they chose between lottery pairs. Choice feedback was delivered between runs and without choice information.
Behavioral data were fit with a computational reinforcement learning model. Accuracy was above chance and did not differ across conditions, though learning rates were higher in the FW (0.51) than in the FO (0.37) and WO (0.38) conditions. fMRI analysis revealed signals in the amygdala and face-selective temporal/occipital cortex correlated with aversive prediction error (i.e. highest for unexpected aversive outcomes) in conditions where face expressions depicted outcomes (FO & FW). Conversely, fMRI signal in part of the caudate head correlated with appetitive prediction error in conditions in which words described outcomes (WO & FW). These data suggest that learning through observation on the basis of social and non-social observational feedback may depend on at least partly distinct neural substrates.

Title: Behavioral neurostimulation: Sustained activation of the human dopaminergic midbrain using real-time fMRI

Authors: *K. C. DICKERSON, J. J. MACINNES, R. A. ADCOCK;
Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC

Abstract: Dopamine is critically important for human motivation, learning, and memory. Nearly all prior human research of the dopaminergic midbrain has used extrinsic cues to elicit changes in midbrain activation. We reasoned that humans could learn to use internal mnemonic representations to produce sustained activation within the dopaminergic midbrain; we refer to this as 'behavioral neurostimulation.' If behavioral neurostimulation of the dopaminergic midbrain were achievable, it would have putative applications for a) enhancing motivation, learning, and memory in healthy humans and b) translating this ability to clinical populations with aberrant dopamine functioning (e.g., patients with depression). The purpose of this experiment was to investigate if healthy individuals can learn to produce sustained activation of the dopaminergic midbrain, specifically the ventral tegmental area (VTA). We hypothesized a) that individuals can learn to produce sustained activation of the VTA and b) that real-time fMRI (rt-fMRI) neurofeedback will facilitate learning to produce sustained VTA activation. Thirty-nine healthy adults participated in the experiment, and were randomly assigned to either the Experimental or Control condition. Both groups were instructed to try to increase the BOLD signal within the VTA by using motivational thoughts/imagery. Both groups completed a pre-test run, 3 training runs, and a post-test run. During both test runs, participants tried to increase VTA BOLD signal without any rt-fMRI neurofeedback indicating their success. In the training runs, the Experimental group received rt-fMRI neurofeedback indicating the magnitude of BOLD signal in the VTA via a thermometer display. This level was updated every 1 second as each new incoming data point was acquired. The Control group viewed a similar thermometer display, which showed a repeating pattern indicating the period during which they should enhance their motivation, but the pattern did not contain information about the activation of any brain region. Results revealed that the Experimental group successfully produced enhanced, sustained activation in the VTA. Furthermore, within the Experimental group, individuals who were initially not good at VTA self-activation improved significantly with training, whereas those who were already good at VTA self-activation did not change significantly over time. This is the first demonstration of enhanced, sustained VTA activation in humans, and suggests that behavioral neurostimulation is a feasible therapeutic modality.

Title: Dissociating specific and general conditioned responses in Pavlovian aversive conditioning

Authors: *S. ZHANG[1], H. MANO[1], G. GOWRISHANKAR[1], T. ROBBINS[2], B. SEYMOUR[3,1,2];

Abstract: Understanding the mechanisms of Pavlovian (Classical) conditioning is a central concern for contemporary studies of emotion, memory and decision-making. Psychological and physiological studies rely on the ability to demonstrate conditioned responses: these are elicited by the conditioned stimulus (cue) and reflect the prediction of a salient aversive or rewarding outcome. Classical psychological and ethological descriptions of conditioned responses divide them into stimulus general responses, which are common to all outcomes of the same valence (e.g. withdrawal to aversive events), and stimulus specific responses, which reflect the particular nature of the outcome (such as leg flexion to foot shock). However, it is not known to what extent these two mechanisms can be functionally dissociated, and whether specific conditioned responses can be clearly lateralized in humans. Here, we will present preliminary results from two behavioural studies of aversive conditioning, in which we try to dissociate laterality-specific limb electromyographic changes. We implemented a first order probabilistic delay conditioning design, in which visual cues were followed by thermal pain stimuli to either right or left hand. We established contingencies between different cues that 1) reciprocally and 2) independently predicted high probability pain to each hand. We recorded limb EMG, facial EMG, and autonomic responses. Preliminary results support the existence of dissociable specific and general conditioned responses: we show that limb EMG responses clear reflect the specific prediction of pain to the side being presented, with a progressive development of the responses over time, which can be modeled using a time-rich temporal difference model. These are clearly dissociable from general autonomic responses. Our results support the existence of dissociable subprocesses underlying aversive learning.

Title: The role of adaptive decision noise in exploration

Authors: *R. C. WILSON[1], J. M. WHITE[2], J. D. COHEN[1,2];
[1]Princeton Neurosci. Instititute, [2]Psychology, Princeton Univ., Princeton, NJ

Abstract: Everyone at the SfN conference faces the explore-exploit dilemma: do you go see posters from labs you know well (exploit) or wander aimlessly down row BBB in search of something new (explore)? Exploiting is the best way to get immediate reward, but if you don't explore you might miss out on the latest advances. Solving this problem optimally is intractable in all but the simplest settings, and so the question arises as to how humans balance exploration and exploitation in practice.

In machine learning, engineers have made use of noise as a tool for driving exploration. This strategy works by injecting randomness into the decision process. When little is known and learning is desired, noise is increased, promoting exploration. However, as learning occurs, and the reward structure is better understood, noise is decreased in order to exploit known sources of reward. Thus, the level of decision noise regulates the degree to which exploration or exploitation is favored.

We have previously shown that, in a very simple problem, humans adapt their decision noise in a way that is consistent with such a random-exploration strategy [1]. In the present work we tested whether this was also true in a more complicated experiment in which the potential gains for exploring were higher. In particular, we investigated the explore-exploit tradeoff in a world characterized by abrupt and unsignaled change-points. By manipulating the frequency with which change-points occurred, we were able to alter the optimal balance between exploration and exploitation and hence the optimal setting of the noise.

In our change-point task, participants made a series of choices between two options. Every time an option was chosen it paid out a reward between 0 and 100 points. The reward from each option was constant over time except at a change-point, when it was randomly reset between 0 and 100. Because the current reward value of each option was only shown when that option was

played, the longer an option remained unplayed, the more ambiguous it became, as the probability that a change-point had occurred increased.
We modeled human decisions using a simple choice rule based on the observed outcome for each option, the information available for playing it and the level of decision noise. As change-points became more frequent we found systematic increases in the decision noise. A separate analysis showed that this qualitative pattern of increasing decision noise with change-point frequency is optimal in this task.
These results suggest that humans both use and adapt their decision noise to effectively manage the explore-exploit tradeoff in complex tasks.

Title: Adjustment to variability in a reward learning task is beneficial for performance

Authors: *K. M. DIEDEREN[1], T. J. SPENCER[2], P. C. FLETCHER[2], W. SCHULTZ[1];
[1]Physiol. Develop. and Neurosci., [2]Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: An essential part of daily life is to predict which rewards will be available. We might achieve sufficient accuracy in this by adjusting our expectations to a number of factors including the variability of the environment. In addition, we frequently move between environments in which we retain our beliefs after switching to a new situation. Indeed, previous studies have shown that individuals efficiently update their predictions in noisy and volatile situations by assigning more weight to certain outcomes. Importantly, this can be determined by measuring participants' predictions and learning rates (LR). Here we investigated if individuals could adjust to variability in a reward learning task in which we alternated different levels of variability in short blocks. In addition, we tested if individuals reached similar levels of accuracy under different levels of variability and if this was predictive of overall accuracy. Finally, as variance is

often undervalued by sensation seekers we tested if subjects' level of sensation seeking was predictive of performance. We used a task in which 29 participants predicted reward magnitude on a trial by trial basis. Reward magnitudes were drawn from pseudo-Gaussian distributions with three different standard deviations (SD) which alternated in blocks of 5-8 trials. Following their prediction, participants received a reward which elicited a prediction error (PE) and enabled them to adjust their upcoming predictions. LR was derived by calculating the fraction of the PE on trial *t* that was used to update the prediction on trial *t+1*. The speed of learning (number of trials to asymptote) was faster when variability of the reward distribution was smaller. This was due to participants having higher learning rates for smaller SDs before asymptote was reached. Only the speed of learning was affected by the level of variability as participants reached similar levels of accuracy (difference from the expected value (EV)) for the different standard deviations. As a result, PEs increased monotonically with the level of variability, a difference that disappeared after normalising PEs by the SD of each distribution. Furthermore, participants reached very high accuracy (predictions close to the EV) for all SDs, indicating that switching between conditions did not impede learning. Importantly, participants that had a similar accuracy for the different SDs i.e., those that appeared to adapt best to changing variability, showed a higher level of overall accuracy. Finally, this was related to individuals' tendency towards sensation seeking with subjects' scoring higher on this trait showing superior adjustment to variability.

Title: Stress and pressure: Differential effects on physiological reactivity and cognitive performance

Authors: *S. B. HUTCHINSON[1], S. K. MCCOY[1], L. HAWTHORNE[1], S. W. ELL[1,2]; [1]Psychology, Univ. of Maine - Psychology Dept., Orono, ME; [2]Grad. Sch. of Biomed. Sci., Univ. of Maine, Orono, ME

Abstract: From family life to social life to work life, pressure and stress are so ubiquitous in modern life that it is no surprise that cognitive neuroscientists have taken great interest in the

impact of pressure and stress on cognitive performance. Recent data suggest that the impact of stress hormones on prefrontal cortical function may be a key mediator of this complex relationship. Across a series of experiments, we investigated the impact of pressure and stress on rule-based (learning is mediated by a hypothesis-testing system that is dependent upon prefrontal cortex) and information-integration (learning is mediated by a procedural-based system that is not dependent upon prefrontal cortex) category learning tasks. In Experiment 1, outcome pressure (i.e., pressure related to successful task performance) impaired accuracy on a rule-based task), had no effect on an information-integration task, but was not physiologically stressful. In Experiment 2, the addition of monitoring pressure (i.e., pressure related to social evaluation) impaired performance on both categorization tasks. Outcome + monitoring pressure was moderately physiologically stressful, but stress reactivity was unrelated to categorization performance. We compare the data from Experiments 1 and 2 to a previous study from our lab investigating the impact of a social-evaluative stressor on categorization performance. In contrast to the pressure manipulations, a social-evaluative stressor led to a robust stress response that was predictive of impaired rule-based performance and enhanced information-integration performance. In sum, in order to understand the relationship between stress, pressure, and cognition, it may be necessary to consider variability in the pressure situation, variability in the stress response, and variability in the cognitive and neural systems mediating task performance.

Title: Neural computations mediating one-shot learning in the human brain

Authors: *S. LEE, J. P. O'DOHERTY, S. SHIMOJO;
Caltech, Pasadena, CA

Abstract: In standard associative learning, an animal typically must incrementally experience a number of pairings between a stimulus and a consequence before a given stimulus pairing is fully learned. However, animals sometimes encounter outcomes that they have never experienced previously from which it is necessary to learn rapidly in order to survive. In such cases, animals can learn on the basis of only a single exposure to a stimulus pairing, a situation described in the literature as "one-shot" learning. For example, in taste aversion learning only a single exposure to a food accompanied with delayed sickness or nausea is sufficient for learning to occur. While the neural computations underlying incremental learning are gradually being elucidated, very little is known about how, at the computational level, one-shot learning might be implemented in the brain.

One-shot learning imposes a substantial challenge to standard learning algorithms including Bayesian models and power PC theory, as such models are not optimized to facilitate learning from a single experience. Here, we propose a novel computational mechanism for one-shot learning in which a Bayesian learner attempts to establish the casual relationship between stimuli and outcomes. Critically, this learner uses knowledge about the uncertainty with which a particular stimulus has caused a given outcome to drive the extent to which learning occurs about that stimulus. Stimuli paired with outcomes about which there is large causal uncertainty can result in very rapid learning, such that even within a single-trial substantial learning has occurred. We applied this model to fMRI and behavioral data from human participants while they engaged in a task designed to assess one-shot causal learning. Our fMRI data suggests that parts of the prefrontal cortex including the ventrolateral prefrontal cortex (vlPFC) were found to be involved in encoding causal uncertainty that was postulated by the model to drive changes in the learning rate needed for one-short learning. Crucially, functional coupling between the vlPFC and areas involved in episodic memory encoding were significantly increased during the period in which the model predicts one-shot learning compared to situations where incremental learning was taking place. These findings suggest that vlPFC may act as a switch: engaging episodic memory systems when learning needs to proceed from a single episode (one-shot) as opposed to incrementally. Taken together these findings form the basis of a new understanding of the neural computations underlying the ability to learn from a single exposure to an event and its consequences.

Title: Brain activity by selfish partner dynamically modulates the reward-related cortical network

Authors: *M. SHIKAUCHI[1], H. MIZUHARA[2];
[1]Dep. of Dynamic Brain Imaging, Advanced Telecommunications Res. Inst. Intl. (ATR), Kansai Science City, Japan; [2]Kyoto Univ., Kyoto City, Japan

Abstract: An abstract item (e.g., money) activates the same reward-related regions in the human brain as do primitive rewards (e.g., food). These regions can also be activated by various stimuli, such as social stimulus/condition (e.g., admiration). The reward system needs to be dynamically modulated in order to adapt to fluid environments in the social environment because humans obtain their rewards during interactions with both cooperative and selfish partners.
Assuming that a partners' cooperative/selfish behavior would be a crucial factor in the modulation of the reward system and that this phenomenon would be produced by the interaction of social- and reward-related brain activity, we hypothesized that a partner's cooperativeness would modulate the reward-related activity and network. Recording brain activity by fMRI, we investigated this using as an experimental task a modified version of the centipede game. In this task, which is a dynamic version of the prisoner's dilemma, participants were required to decide their strategy according to their partner's cooperativeness.
Results showed that the caudate correlated significantly with the reward value using a general linear model analysis, and that the middle cingulate cortex (MCC) and putamen activated significantly in the case of a selfish partner. To investigate the relationship of these regions, we estimated effective connectivity by Dynamic Causal Modeling (DCM). This DCM analysis showed there to be an effective connectivity from the caudate to the putamen, and that this was modulated by the effect of the MCC activity so that the putamen activity was increased when the partner was selfish.
These results suggest that caudate-putamen connectivity as the reward system can be modulated by social-related activity. Our view would be also that the network modulation system recreates the variety of reward and flexibility found in the social environment.

Title: Moving from model-free to model-based RL in a probabilistic learning environment: A generalized hierarchical reinforcement learning model

Authors: *M. BALCARRAS[1], S. ARDID[1], T. WOMELSDORF[2];
[2]Biol., [1]York Univ., Toronto, ON, Canada

Abstract: In real-world environments, learning optimal responses to stimuli faces a problem of scale: there is always a very large number of possible state to action-outcome mappings and many rewarding outcomes rely on correct complex action sequences. Structuring decision-making hierarchically is one of the solutions to the problem of scale because it facilitates the abstraction of state-action-outcome mappings from one situation to another (Botvinick, Cur Opin Neurob 2012). Here, we set out to test whether Hierarchical Reinforcement Learning (HRL) frameworks can be adapted to explain the shift between exploratory and exploitative behaviours in reinforcement learning during a probabilistic choice task.
We devised a probabilistic decision-making task with hidden reward structure where subjects were required to choose between two stimuli (each composed of two features: color and shape), with discrete trials grouped into blocks by stimulus sets and reward schedules. In half the blocks, different reward probability was associated with a particular stimulus feature (i.e. just shape or colour is predictive of reward), whereas in the other half of blocks, the likelihood of rewards were associated with combinations of features, i.e. colors and shapes, that formed an object. We observed that although a feature-reward block increases the scale of learning difficulty (3 shape and 3 colour combinations to consider as possibly predictive of reward), subjects deploy a policy of making choices in one domain of feature space, speeding learning of optimal responses. We also observed that subjects moved from periods of exploration into exploitation more rapidly during feature-reward blocks suggesting the deployment of a behavioural policy is rapid.
We compared several types of RL models to explain these behaviours. Model-free RL employs no learned information to structure state-action-outcome mappings, and was the best model for explaining behaviour in fixed-feature blocks. Model-based RL considers only a subset of possible choice options, employing previous experience to speed learning, and it was the best model for non-combined blocks. Neither model-free or model-based RL performs well overall and neither employs a mechanism to switch strategies. A generalized HRL model that employs

model-free learning to select a feature-based policy in only a single feature domain (model-based RL) captured subject behaviour best overall, suggesting that subjects initially explore the total space of stimulus-outcome mappings but when they detect feature related structure in a history of reward they deploy a behavioural policy that isolates one stimulus feature domain.

Title: What should you do when you don't know what to do: Balancing the tradeoff between reward exploitation and information extraction

Authors: *J. COCKBURN, M. J. FRANK;
Cognitive, Linguistic and Psychological Sci., Brown Univ., Providence, RI

Abstract: Learning and action selection are significantly complicated by the fact that observed events (e.g your flight departing on time) are often determined in part by unobserved processes (e.g weather conditions at your destination). The advantage of considering latent processes comes when events are predictable if considered in concert with their latent influences, but appear random otherwise. Knowing the hidden state is helpful not only for conditionalizing action selection, but also for conditionalizing learning to prevent interference about action-outcome associations across separable states (e.g it's the airline's fault and you should avoid them next time, or did bad weather impact everyone).
Considering latent processes imports additional levels of uncertainty about the true state of the latent process. Recent studies have reexamined choice behaviour through the lense of uncertainty, and have suggested that 'exploratory' behaviour can be conceptualized as targeting the reduction of various forms of uncertainty about action-outcome contingencies. However, very little work has examined whether agents actively select actions that would reduce uncertainty about the state of latent processes that determine those contingencies.
We propose a model that defines action selection in terms of both expected value and mutual information shared between action outcome and latent state. Critically, the tradeoff between reward exploitation and information extraction is a function of unexpected uncertainty (UC). In short, our model predicts that the probability of selecting informative actions increases as expected outcome violations mount.

We investigate this hypothesis using a latent structure reinforcement learning task. Participants were asked to repeatedly pick amongst a set of cards that could be drawn from one of two decks. Participants were never told which deck was in play, but were told that the deck in play would switch on occasion. They were also told that cards in both decks look alike, but could have different payoffs. Each deck included a card with high expected value (but low mutual information), and a card with high mutual information (but low expected value). Behavioural results reveal an exploitive strategy when UC is low, and an increased probability of foregoing possible reward to gather information when UC is high. This pattern was observed across a broad range of task parameters. It was even observed when the optimal exploitive strategy would be to pick the same card regardless of the current deck in play. These results suggest that UC predicts the prioritization of information relative to reward, and that the reduction of UC is valued in its own right.

Title: The reward neural network mediates optimistic belief updates

Authors: *B. KUZMANOVIC[1,2], K. VOGELEY[2,3];
[1]Res. Ctr. Juelich, INM-8, Juelich, Germany; [2]Dept. of Psychiatry and Psychotherapy, Univ. Hosp. Cologne, Cologne, Germany; [3]Res. Ctr. Juelich, INM-3, Juelich, Germany

Abstract: People tend to learn more from disconfirming information when it leads to favorable outcomes. The present study investigates the neural correlates of such optimistic belief updating in order to provide empirical evidence for a specific involvement of the reward neural network. 24 subjects estimated their likelihood of experiencing a total of 88 adverse life events while undergoing fMRI. After a first estimation, the official average probability of the respective event was presented, followed by a second estimation with the opportunity for an update. Based on a tendency to adopt the most rewarding future outlook, updates were expected to be higher when the average probability was desirable (lower than the first estimation), than undesirable (higher than the first estimation). Estimations were done either for oneself or for a similar other, resulting in a two-by-two design, with factors target (self vs. other) and valence (desirable vs. undesirable). Unbeknownst to participants, the average probability was experimentally

manipulated in order to systematically create the valence conditions.
Behavioral results confirmed that mean updates were higher for desirable than undesirable trials, and that this effect was stronger for self than other. FMRI analyses focused on neural activity that tracked increasing amounts of updates on a trial-by-trial basis (pFWE-corr<.05). During the second estimation, the activity in the medial orbitofrontal cortex (OFC) increased with increasing updates more strongly in desirable than undesirable trials, and within desirable trials more strongly for self than other. During the presentation of the average probability, the activity in an extended neural network including the insula, the ventral striatum and the anterior cingulate cortex predicted the subsequent amount of update to a greater extent in undesirable than desirable trials, and this effect was stronger for self than other.
While behavioral results show asymmetric updates that promote optimistic beliefs, fMRI results provide evidence for a motivational explanation of this bias, which is stronger for self-related judgments. The activity in the OFC associated with reward experience was higher, the greater the amount of desirable updates. However, in the moment of the confrontation with the disconfirming information, a greater 'learning signal' due to the prediction error should be necessary in order to learn from undesirable relative to desirable information. Exactly this was mirrored by a greater correlation of activity with the amount of subsequent updates in undesirable than desirable trials in regions known to encode for aversive prediction errors.

Title: Conditioned responses to a drug cue in healthy, non-dependent humans

Authors: *L. M. MAYO, H. DE WIT;
Psychiatry & Behavioral Neurosci., Univ. of Chicago, Chicago, IL

Abstract: In the treatment of drug addiction, one of the greatest challenges is propensity to relapse,even after long periods of drug abstinence. It is widely believed that conditioned responses, established between environmental stimuli and drugs, contribute to relapse. Studies with laboratory animals suggest that these associations develop through classical conditioning mechanisms, but studies with humans typically assess responses to cues that are assumed to have

been associated with drug, making it difficult to determine whether they reflect classical conditioning or other learning processes. Here, we used classical conditioning procedures in a controlled environment to study the process of acquisition of drug-conditioning in humans. Healthy, non-dependent human volunteers (N=30) completed a pre-test session in which we measured responses to two neutral stimuli (preference, subjective liking, attention, and emotional reactivity). Subjects then underwent 4 conditioning sessions; 2 with placebo and 2 with 20mg methamphetamine (MA; oral), in which one stimulus was always present when they received the drug and the other was present during placebo sessions. Then we re-assessed responses to the stimuli after conditioning. After conditioning, subjects exhibited an increase in preference for the drug-paired stimulus, as measured with a forced choice task, and an increase in subjective liking of the drug-paired stimulus. In addition, emotional reactivity to the drug-paired stimulus increased, as measured by facial electromyography recordings of zygomatic and corrugator muscles. Finally, subjects also demonstrated a bias in attention towards the drug-associated stimulus. These studies indicate that healthy volunteers develop conditioned motivational responses to drug-paired cues, under carefully controlled conditions, which are detectable with subjective and objective measures of emotional reactivity and attention. Future research will focus on individual variation in the acquisition and expression of the responses, neurobiological underpinnings, and pharmacological and behavioral methods to manipulate such responses.

Title: Intrinsic connectivity within and between large-scale functional brain networks supports learning

Authors: *R. T. GERRATY[1], J. Y. DAVIDOW[1], I. KAHN[2], D. SHOHAMY[1];
[1]Psychology, Columbia Univ., New York, NY; [2]Technion- Israel Inst. of Technol., Haifa, Israel

Abstract: Learning is essential for adapting behavior to a changing environment. Research on the neural bases of learning and memory has indicated that there are multiple specialized learning systems that differ in both their cognitive functions and their neural substrates. Emerging data suggest that these systems operate not as separate modules but as interactive

networks, raising questions about the nature of these interactions and their behavioral implications. In this study, we focused on two central questions: First, to what extent does baseline connectivity between the striatum and the hippocampus relate to habitual vs. flexible learning at the behavioral level? Second, what role do interactions between these systems and broader large-scale functional networks play in learning? To address these questions, we characterized resting-state functional connectivity (rsFC) both within and between the striatum, hippocampus, and large-scale networks, and examined how these circuit-level interactions relate to behavior. We specifically focused on feedback-based learning and learning-guided decision making. Healthy participants were scanned with fMRI during rest, after having previously completed behavioral paradigms that involved feedback-driven learning as well as generalization of learned information to new decisions. Spatial Independent Component Analysis (sICA) was used as a model-free means of defining regions and networks of interest. Results revealed intrinsic connectivity within a robust network including the hippocampus, the ventral striatum, and the ventral medial prefrontal cortex during rest. Across participants, the strength of connectivity both within this network, as well as between these regions and other resting state networks, was related to behavioral measures of flexible learning and decision making, tested separately. These findings shed light on the nature of the interaction between the striatum and the hippocampus and their participation in a broader circuit that supports learning and decision making.

Title: The neural correlates of aberrant emotional learning and flexibility in OCD

Authors: *A. M. APERGIS-SCHOUTE[1,2], C. M. GILLAN[2,3], J. A. BLAY[1], E. FERNANDEZ-EGEA[1,2], N. A. FINEBERG[4], T. W. ROBBINS[2,3], B. J. SAHAKIAN[1,2];
[1]Psychiatry, [2]Behavioural and Clin. Neurosci. Inst., [3]Psychology, Univ. of Cambridge, Cambridge, United Kingdom; [4]Natl. Obsessive Compulsive Disorders Specialist Service, Hertfordshire Partnership NHS Fndn. Trust, Welwyn Garden City, United Kingdom

Abstract: Obsessive-compulsive disorder (OCD) is characterized by the dysfunction of the fronto-striatal network. Fear reversal learning involves flexibly readjusting behaviour when circumstances change which means adapting from one predictive stimulus to another, largely depending on a fronto-striatal and fronto-amygdala network. The process of fear learning and extinction are thought to be related to the pathophysiology of anxiety disorders including OCD. Our study used functional magnetic resonance imaging (fMRI) concurrent with Galvanic Skin Responses (GSRs) to compare a sample of 18 OCD patients to 18 age matched healthy controls on a fear reversal paradigm. The results showed a clear bimodal distribution in the OCD patient group only. Compared to controls, half of the patients exhibited normal conditioning (significantly higher GSRs to the CS+ than the CS-), while the other half of OCD patients showed the opposite effect (significantly higher GSRs to the CS- than the CS+). Interestingly, during reversal learning, while the GSRs of healthy controls reflect flexible learning with significant higher responses to the new CS+ (previous CS-) compared to the new CS- (previous CS+), our OCD patient group shows an absence of differentiation between the reversed CS+ and CS-. In line with our hypothesis, we find inflexibility in fear learning in OCD patients, however the the presence of a bimodal distriubtion in the OCD patient group during conditioning suggest differences in emotional learning within OCD patients. Following these results we will investigate possible interactions with anxiety as well as with fronto-striatal and fronto-amygdala activations, which are currently being analyzed.

Title: A Bayesian approach to model-based reinforcement learning

Authors: *E. M. MILLER[1], S. PIANTADOSI[2], N. GOODMAN[1], S. M. MCCLURE[1]; [1]Stanford Univ., Stanford, CA; [2]Univ. of Rochester, Rochester, NY

Abstract: Ever since it was discovered that dopamine neurons encode reward prediction errors in their firing rates, interest has focused on understanding the mechanism by which this signal facilitates learning (Schultz et al., 1998). One particular open question concerns the distinction

between model-based and model-free learning in the brain (Daw et al., 2005). Whereas in model-free learning, the actor is limited to encoding stimulus-response relationships between environmental cues and rewards, model-based learning allows one to benefit from higher level knowledge regarding the structure of the environment. The current study investigates the neural correlates of model-based learning in a category learning task. Optimal performance on the task required participants to learn to categorize stimuli based on three binary perceptual dimensions (shape, color, pattern). To model this type of learning, we employed a grammar-based Bayesian model of category learning that infers category membership based on previous evidence and prior beliefs about the structure of the task. Using this model, we generated a prediction error signal (surprisal) for each trial, representing the extent to which the evidence received deviated from participants' expectations. We found that this surprisal signal scaled with activation in the dorsal caudate and dorsolateral prefrontal cortex. Additionally, we found that Kullback-Leibler divergence, a measure of the extent to which the model's estimates of rule likelihoods changed after the receipt of new evidence, predicted activation in the dorsolateral prefrontal cortex after the receipt of surprising feedback, as well as during the implementation of this new information on the subsequent trial. These findings indicate that hypothesis updating during model-based reinforcement learning involves communication between the dorsal striatum and lateral prefrontal cortex.

Title: Neural correlates of model-based and model-free reinforcement learning strategies

Authors: *B. B. DOLL[1,2], K. D. DUNCAN[2], D. A. SIMON[1], D. SHOHAMY[2], N. D. DAW[1]; [1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Psychology, Columbia Univ., New York, NY

Abstract: Incremental learning across species is well described by reinforcement learning (RL) algorithms. The bulk of such demonstrations correlate behavioral and biological signals with signatures of model-free RL algorithms. This class of models is retrospective in nature, choosing

options based solely on outcomes previously obtained by selecting them. More recently, interest has grown in correlates of model-based RL which, by prospectively planning over a world representation, can exhibit more cognitive flexibility than model-free RL, though with greater computational cost.
Using fMRI, we investigated the neural correlates of learning in a task that dissociates model-based from model-free RL. Participants repeatedly navigated to terminal task states from different starting states in search of monetary reward. The states in this sequential task were represented by different classes of stimuli that activate unique regions of visual cortex. This task feature permitted us to search for neural correlates of RL strategies by searching for brain activations of different states in the sequential task.
Across the population, choice behavior showed evidence of both model-based and model-free learning. Preliminary fMRI results permitted closer investigation of the mechanisms by which these classes of learning algorithms are implemented. For each subject, we identified ROIs that showed preferential responses to the stimulus categories used to represent the different task states in an independent functional localizer. We then assessed the activity in these ROIs during the reward learning task start states. We looked for prospective activation of states to be navigated to, as well as retrospective reactivation of previous states visited. We observed significant reactivation of states visited in the previous trial. This reactivation was observed when these previous visitations terminated in a monetary gain, but not when they terminated in a loss. These results speak to the particular series of states subjects consider when engaging in model-based valuation, and suggest that this process may rely on replaying previous experiences rather than directly iterating a model of future state transitions.

Title: Cue-approach training influences choice behavior via modulation of reward-related circuitry

Authors: *T. SCHONBERG[1], A. BAKKOUR[2], A. M. HOVER[3], J. PEREZ[3], L. NAGAR[3], J. A. MUMFORD[3,4], R. A. POLDRACK[3,4,5];
[1]Imaging Res. Ctr., The Univ. of Texas At Austin, Austin, TX; [2]The Univ. of Texas at Austin, Imaging Research Center, TX; [3]Imaging Res. Ctr., [4]Dept. of Psychology, [5]Dept. of Neurosci., The Univ. of Texas at Austin, Austin, TX

Abstract: Deliberate exertion of effortful self-control often fails when trying to make life style changes, highlighting the importance of targeting automatic processes for behavioral change. We present a novel cue-approach task designed to influence subsequent choices of snack food items. Twenty five participants (16 females, ages 18-29, mean 20.7 ± 3.3) completed the task inside the MRI scanner (3T Siemens Skyra).
Participants were asked to fast for 4 hours prior to the experiment and participated in an auction that allowed us to obtain an individual measure of willingness to pay (WTP). We split the items based on the WTP's and defined 8 items as higher valued (HV) and 8 items as lower valued (LV).
The go-signal task is functionally the opposite of the stop-signal task. Images of 60 junk food items were presented on the screen for 1 sec. Participants were instructed to press a button as fast as they could only when they heard a tone. Sixteen (8 HV and 8 LV) out of the 60 items were consistently associated with the tone. The items were presented 12 times each during training. In the probe phase, participants were presented with pairs of items from the same value category (32 choices per type) that had similar values in the initial auction, but only one of the items in each pair was associated with the signal in the training phase (e.g. GoHV vs. NoGoHV). Participants were asked to choose one item per trial for a chance to consume that item at the end of the session. To measure the success of training we compared the ratio of choices of the Go vs. NoGo items (within HV or LV pairs).
We found that items associated with the go-signal during training were chosen significantly more during probe: for HV items (60% of trials p=0.008, LV items in 57% of trials, p=0.04).
In the imaging analysis we tested the modulation of the Go trials during training by the number of times each item was later chosen at probe and compared this modulation between the first and last runs of training. Data analysis and preprocessing were conducted using FSL5.
We found a modulation in value-related regions (precuneus and ventro-and medial prefrontal cortex) for the Go response of the HV items but only for the last training run but not the first. Thus, a cue-approach signal for individual items influenced subsequent choice via modulation of activity of value-related brain regions during training. Development of novel real-world behavioral change paradigms could benefit from this cue-approach technique to target automatic behavioral processes to bolster results and minimize relapse.

Title: Neural circuitry underlying extinction learning with appetitive and aversive conditioned stimuli

Authors: *A. H. LEWIS, H. MANGLANI, M. R. DELGADO;
Psychology, Rutgers Univ., Newark, NJ

Abstract: On a daily basis, appetitive and aversive events are experienced in proximity to neutral stimuli; subsequently, these stimuli acquire affective properties. This type of conditioning is known to depend on the integrity of various subcortical regions involved in affective learning, such as the striatum and the amygdala. More recently, studies across species have begun to examine the neural circuitry underlying changes in conditioned responses once conditioned stimuli (CS) are presented in the absence of appetitive or aversive outcomes. This process, known as extinction, involves new learning or adapting of previously formed associations, and is essential in cases where CS elicit excessive, maladaptive emotional responses (e.g., fear in PTSD). However, it is unclear whether the extinction of appetitive and aversive CS depends on similar or distinct neural circuitry. In this study, we used fMRI to investigate the behavioral and neural processes underlying extinction learning with both appetitive and aversive CS. The experiment was framed as a game, using gain and loss of desirable items as appetitive and aversive outcomes, respectively. The use of instructed reinforcement in the context of the game ensured that appetitive and aversive outcomes were equated to one another. Participants underwent two blocks of a partial reinforcement Pavlovian conditioning procedure wherein four neutral fractals (CS) were each reinforced with a specific outcome that varied with respect to valence (gain, loss) and magnitude (high, low). In the extinction training that followed, all CS were presented in the absence of reinforcement. Preliminary analysis (n=10) suggests that both appetitive and aversive CS gained affective properties over the course of acquisition. These results were coupled with valence-specific differences in BOLD signals in the striatum during the initial acquisition phase. Behavioral results from the extinction phase suggest extinction of the affective properties gained by both appetitive and aversive CS during acquisition. During this phase, a valence by magnitude interaction was observed in cingulate cortex and bilateral insula, highlighted by increased activation in response to the less favorable outcome within each valence (e.g. low gain, high loss). Additionally, medial prefrontal cortex exhibited sensitivity to

magnitude, but not valence, during extinction. Further analyses will probe potential differences in connectivity between appetitive and aversive extinction circuits as well as changes over time in brain regions involved in affective learning.

Title: Single-cell responses in human OFC, amygdala and ACC during two different neuroeconomic tasks

Authors: *M. R. HILL[1], E. D. BOORMAN[2], C. KOCH[1], I. FRIED[3];
[1]Behavioral Biol., [2]Div. of the Humanities and Social Sci., Caltech, Pasadena, CA; [3]Dept. of Neurosurg., UCLA, Los Angeles, CA

Abstract: In the current study we simultaneously recorded the spiking activity of multiple individual neurons in three different areas in the awake human brain known to be involved in neuroeconomic decision making; the orbitofrontal cortex (OFC), the amygdala and the anterior cingulate cortex (ACC). We conducted these recordings in patients with pharmacologically intractable epilepsy who were routinely implanted with depth electrodes for clinical diagnostics. We recorded data whilst subjects performed a classic slot machine task with random winning and losing outcomes. This task allowed us to find general neural correlates of winning and losing devoid of choice or learning. In a second experiment subjects had to pick a card from one of two decks. One deck had a 70% chance of winning, the other deck had a 30% chance of winning. Through trial and error the subjects could optimize their winnings by finding out which was the higher winning deck. Subjects played this game in turn with two virtual players. By watching the choices and outcomes of these two additional players the subjects could also acquire information about which of the two decks was the winning one.
We recorded from 116 units in the OFC, 148 units in the amygdala and 201 units in the ACC. In the slot machine task we found 4 units in the OFC, 9 in the amygdala and 12 in the ACC that responded to winning or losing. In the card game 7 OFC units responded to winning or losing

whilst in both the amygdala and the ACC we found 21 such responsive units respectively. From these responsive units only 1 OFC unit showed a significantly different response to winning vs. losing, whilst in the amygdala we found 9 such differentiating units and in the ACC 11. Amongst the responsive units, we found individual cells that significantly encoded in their firing rate the amount that was either won or lost ($10 or $100), the reward prediction error of the outcome or the outcomes and amounts won or lost by the two other players. We are collecting additional units to discover regional specialization of different neuroeconomic parameters.

Title: Memory recall for high value items correlates with individual differences in white matter pathways associated with reward processing and fronto-temporal communication

Authors: N. REGGENTE, M. S. COHEN, Z. ZHENG, N. G. DE SHETLER, A. D. CASTEL, B. J. KNOWLTON, *J. RISSMAN;
Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: How people manipulate their mnemonic abilities in a strategic manner (prioritizing the recall of material that would more likely produce a reward) is a complex phenomenon that integrates executive control and memory processes. Models of selective, reward driven behavior elucidate the diverse and complex interactions between prefrontal cortex, temporal lobe, and the mesolimbic dopaminergic reward circuitry. This study aimed to investigate the contributions of and communications between these systems to the recall of high value words.
With the adaptation of a value-directed memory paradigm, fMRI results showed that participants whose recall performance exhibited the greatest sensitivity to item value preferentially recruited left ventrolateral prefrontal cortex (VLPFC) and left lateral temporal cortex during the encoding of high value items. While this effect may partially be driven by individual differences in the strategic use of deep semantic encoding for high value words, it is also possible that structural differences in the connectivity between VLPFC and temporal lobe regions is a contributing factor. The Left Uncinate Fasciculus, a white matter tract that links the anterior parts of the temporal lobe with the ventral surfaces of the frontal lobe and a key pathway for semantic control (Harvey et al., 2013), is a likely candidate for an information highway between our two

fMRI result regions. As a measure of inferable integrity and efficiency of the white matter along the Left Uncinate, the Fraction Anisotropy (FA) was a strong correlate of subject's recall for high value words. This shows that not only were both regions from our fMRI results preferentially recruited for the encoding of high value items, but also the structural integrity of the white matter between them was a predictor of individual differences in recall performance. Given the strong role that item point values plays in determining subsequent recall performance, it is also of interest to examine the relationship between white matter pathways that connect core components of the brain's mesolimbic dopaminergic reward circuitry such as the nucleus accumbens (NAcc) and ventral tegmental area (VTA). Speaking to the richness of this circuitry's connections, the number of fibers that projected from the Left Nacc to the VTA was also a predictor for subject's recall for high value words. This study provides novel insights into the brain-behavior correlations between white matter connectivity between recruited functional regions and subsequent performance. Additionally, it speaks to the structural abundance of reward circuitry and its modulation of behavior.

Title: Resting-state functional connectivity of automatically segmented nucleus accumbens in a large sample

Authors: *J. F. HUCKINS[1], T. F. HEATHERTON[2], W. M. KELLEY[2];
[1]Psychology and Brain Sci., [2]Dartmouth Col., Hanover, NH

Abstract: Introduction: The nucleus accumbens(NAcc) is an integral part of the mesolimbic-dopamine system, a substrate that is integral to a wide-range of functions including reward based learning. The NAcc is irregularly shaped and previous studies have used spherical, atlas based or

hand-drawn regions. The current study employs automated subcortical segmentation of the NAcc across a large sample and compares those results provides similar results to previous results with other methods for ROI identification.
Methods: Resting-state (10 minutes) and high-resolution T1 anatomical scans were obtained from 554 individuals. Standard preprocessing was performed in subject space with Data Processing Assistant for Resting-State fMRI (DPARSF), Resting-State fMRI Data Analysis Toolkit and custom scripts for scrubbing (Power et al., 2012) with spline interpolation to replace offending frames. FSL's FIRST automatically segmented NAcc ROIs from the T1, which were resliced to EPI resolution and functional connectivity maps were created per subject. Functional connectivity maps were normalized and smoothed. Group connectivity maps were created using SPM8.
Results: Visual inspection of ROIs created by FSL's FIRST showed corrected segmentation of the NAcc. Positively correlated resting-state functional connectivity results from the NAcc are similar to results seen from hand-drawn regions of interest in smaller sample sizes, prominently including contralateral NAcc, dorsal striatum, orbitofrontal cortex, medial prefrontal cortex, dorsal anterior cingulate cortex and medial cingulate cortex. Negatively correlated resting-state functional connectivity results from the NAcc were of smaller effect sizes and showed less overlap with previously published literature, prominently including visual cortex, precuneus, pons and temporal pole.
Discussion: Previous investigation of NAcc resting-state connectivity has relied upon hand-drawn, spherical or atlas based regions of interest. Automated segmentation of the NAcc using FSL's FIRST provides refined maps on an individual basis that can be applied to resting-state functional connectivity in a reliable manner with less manual intervention or possibility of human error. In summary, this study provides a method to interrogate resting-state functional connectivity of the nucleus accumbens in a reliable and automated way.

Title: Episodic memory interferes with reward learning and decreases striatal prediction errors

Authors: *G. WIMMER[1,2], E. K. BRAUN[2], N. D. DAW[3], D. SHOHAMY[2];
[1]Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Columbia Univ., New York, NY; [3]New York Univ., New York, NY

Abstract: Learning from experience is central to adaptive decision making. Research on memory systems has demonstrated distinct cognitive and neural systems for learning stimulus-reward associations and for encoding episodes. In even simple experiences, however, these two types of learning often co-occur and may interact. Currently, it is unknown whether and how learning of stimulus-reward associations is influenced by memory for learning-related events. Here we sought to address this by examining how incremental reinforcement learning and reward-guided choices are influenced by episodic memory formation for the experience. During the experiment, participants made choices between two options (colored squares), each associated with a drifting probability of reward, with the goal to earn as much money as possible. Incidental, trial-unique object pictures, which were unrelated to the reward learning task, were overlaid on each option. The next day, participants were given a surprise memory test for these pictures.
We found that choices were significantly influenced by recent reward experience. Participants also exhibited significant memory for the pictures that were presented during learning, although they were unrelated to the reward learning task. This memory formation interacted with how reward guided choices: both across and within-participants, successful memory formation was associated with a decreased influence of recent reward experience on choice. Neurally, the canonical reward prediction error signal in the ventral striatum was decreased by successful memory formation and this decrease was preceded by enhanced functional connectivity between the hippocampus and striatum. These results demonstrate a mechanism by which reward-guided choices can be influenced by multiple memory systems. Further, they provide insight into the interactions between neural systems for reward learning and episodic memory.

Title: Why do we structure our knowledge? Two levels of rule generalization in reinforcement learning

Authors: *A. G. COLLINS, M. J. FRANK;
Brown University, CLPS, Providence, RI

Abstract: Even without supervision or incentives, people are able to acquire the complex rules that govern their environment. When learning stimulus-action mappings through reinforcement, they can structure their policy into abstract rules, and our prior behavioral and modeling work suggests that they seem have a naturally strong prior to do so, even when this does not afford any immediate advantage. Here we further investigate how and why individuals build such rules, outside of immediate usefulness, using our structured reinforcement learning model to derive and test behavioral predictions.
In a new reinforcement learning paradigm, subjects learned to select correct actions in response to stimuli presented in three different contexts. There were two stimulus-action rules, where one of them was valid in two contexts and the other only in a third context (but where each rule was equally frequent across trials). To test acquisition of structure, two subsequent phases introduced (i) new stimuli in old contexts, and then (ii) new contexts with old stimuli.
Consistent with model predictions, subjects transferred their self-constructed rule structure to new situations, at different processing levels. First, they were able to abstract away sensory context in favor of gathering rule-specific, rather than context-specific, knowledge, thus learning faster by clustering contexts cueing the same rule. Second, they learned faster in new contexts by generalizing known rules across stimuli. They thus transferred knowledge of self-built structure in two distinct ways. For a new stimulus, identification of the correct action in one context carried over to all contexts known to be associated with the same rule. Conversely, while in a new context, identification of the valid rule allowed transfer of a known rule to all stimuli in that new context. Moreover, when faced with a new context, subjects were more likely to reapply rules that were valid across multiple contexts than those that applied to only one, controlling for rule frequency. These results confirm our model's predictions, and show that the seemingly suboptimal strategy of building complex structure affords long term advantages given the opportunity to generalize across contexts in various sorts of new situations.

Title: Slow and fast-spiking neurons in the human substantia nigra are functionally distinct during reinforcement learning

Authors: *A. G. RAMAYYA[1], K. ZAGHLOUL[3], C. T. WEIDEMANN[4], B. LEGA[2], M. KAHANA[2], G. BALTUCH[2];
[1]Psychology, [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Surgical Neurol. Br., NINDS, Natl. Inst. of Hlth., Bethesda, MD; [4]Swansea Univ., Swansea, United Kingdom

Abstract: Animal studies of reinforcement learning (RL) have demonstrated that inhibitory interactions between slow-spiking, dopaminergic neurons and fast-spiking, GABA-ergic neurons in the midbrain are important during outcome evaluation. However, because animal studies typically study RL from primary rewards (e.g., juice), it is challenging to generalize these findings to human behavior, which is often motivated by secondary and tertiary rewards (i.e, higher-order rational, emotional and social goals). Here, recording from the substantia nigra (SN) of 41 Parkinson's patients performing a probability learning task with abstract feedback, we show that slow and fast-spiking neurons were anti-correlated in their temporal dynamics during the post-feedback interval. This functional distinction was absent when participants did not perform well during the task, suggesting that it may be related to RL. Our findings suggest that inhibitory interactions between dopaminergic and GABA-ergic neurons in the human midbrain may be important even when learning from higher-order, abstract outcomes.

Title: Intracranial spectral activity comparison between recognition and recall

Authors: *M. B. MERKOW[1], J. F. BURKE[2], M. J. KAHANA[3];
[1]Neurosurg., [2]Grad. Neurosciences Group, [3]Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: This study contributes to the longstanding debate of whether recall and recognition represent unique or overlapping memory processes. We sought to determine if the neural activity at encoding differentially predicts the success of retrieval between recall and recognition. Seven patients who underwent intracranial electrographic recordings for treatment of medically refractory epilepsy participated in a delayed free recall task. Following free recall, we tested subjects' ability to recognize the same words as the ones they had seen in the free recall task. This paradigm allowed us to compare spectral activity for words that were both recognized and recalled compared to those that were recognized but not recalled. Given the documented importance of the hippocampus for verbal memory function, we collected recordings from this anatomic region and surrounding structures. In the hippocampus, we found that low frequency activity decreased in recognized and recalled words relative to words that were recognized but not previously recalled. These results suggest that distinct neural activity in the medial temporal lobe occurs during successful encoding in the compared retrieval tasks.

Title: The influence of selective attention at encoding on post-retrieval monitoring

Authors: J. ARNDT[1], *A. L. DUARTE[2];
[1]Psychology, Middlebury Col., Middlebury, VT; [2]Georgia Inst. Technol., ATLANTA, GA

Abstract: We conducted an experiment examining how selective attention during encoding influenced the execution of post-retrieval monitoring processes. During encoding, pictures of objects were shown along with a scene source (a city scene, an outdoors scene, or an indoors scene) and a color source (red, green, or brown). Participants were asked to attend to one of the two sources on each encoding trial by deciding if the object was appropriate for the scene or

color that accompanied it. At retrieval, participants made old-new recognition judgments for each object, as well as source judgments for the scene and color that accompanied each object. Behavioral performance indicated that attention enhanced source memory, such that source memory performance was greater for attended than unattended sources. Event-related potentials (ERPs) were formed during retrieval for trials where participants correctly remembered an object was presented (hits) and 1) accurately remembered both sources (2 source correct), 2) accurately remembered the source to which they selectively attended during encoding only (1 source correct), and 3) remembered neither source presented during encoding (item only). Results demonstrated that a neural correlate of recollection the "parietal-old new effect" was modulated by the amount of source details retrieved with 2 source correct trials producing larger old-new effects than 1 source correct trials. Importantly, source retrieval accuracy modulated late right-frontal old-new effects often linked to post-retrieval monitoring, such that item only trials produced larger effects than 1 source correct and 2 source correct trials. These results suggest that when selective attention that is directed to an association between an object and a source fails to produce accurate source retrieval, as occurs for item only trials, people engage post-retrieval monitoring processes in an effort to recover the associations linking objects to their sources. In contrast, when attention during encoding successfully forms an association between an object and the sources encountered with it, as occurs for 2 source correct and 1 source correct trials, there is less of a need to engage post-retrieval monitoring processes compared to item only trials.

Title: Physiological relevance of estrogen effects on memory across the menstrual cycle of young women

Authors: A. POMPILI, M. D'AMICO, B. ARNONE, P. FEDERICO, *A. GASBARRI; Applied Clin. and Biotechnologic Sci., Univ. of L'Aquila, Dept. of Applied Clin. and Biotechnologic Scien, 67100 L'Aquila, Italy

Abstract: It is well known that brain encodes memories according to their emotional content and that emotional arousal influences the consolidation of long-term memory.

The aim of the present study was to verify the effects of estrogens on memory during the processing of affective pictures in young women, since the natural fluctuation of female hormone levels affect both physiological and psychological processes. Images from the International Affective System, based on valence (pleasant, unpleasant and neutral), were viewed passively by two groups of young women, one in a periovulatory phase (PO), characterized by high level of estrogens and low level of progesterone, and the other in early follicular phase (EF), characterized by low levels both of estrogens and progesterone. The electrophysiological responses to images were measured, data of visual evoked potentials were collected, and P300 peak was considered. One week after the presentation of emotional stimuli, long-term memory were tested by means of free recall.
As we expected, overall arousal images were better remembered compared to neutral pictures. However, the comparison between groups showed an interesting difference related to positive and negative stimuli: the PO women showed a significant better memory for positive images, while EF women showed a significant better memory for negative images. This could be explained as an effect of the levels of circulating estrogen, high in PO, and low in EF: memory is somehow modulated according to the phases of menstrual cycle. Moreover, results showed that women in the PO had better memory performance than women in the EF, and remembered a number of pictures significantly higher. The subjects in the PO phase showed greater P300 amplitude in parietal and frontal areas compared to women in EF, confirming that larger amplitudes correspond to a better ability to recall; therefore, amplitude of the P300 can be a predictive value of a better long-term memory consolidation.

Title: Multivariate algorithm for trial-by-trial estimate of goodness of encoding using human intracranial EEG

Authors: *J. BURKE[1], R. HAQUE[2], M. J. KAHANA[3];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Univ. of Pennsylvania, Phiadelphia, PA;
[3]Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: The hallmark of episodic memory is mental time travel, or the ability to retrieve and re-experience past events. Episodic memory consists of the encoding, storage and retrieval of perceptual information. Behavioral studies indicate that the overlap between perceptual information at the time of encoding and retrieval is critical in the process of episodic re-experiencing. However, it is unclear where in the brain such overlap occurs. Here, we used intracranial electroencephalography (iEEG) from 98 neurosurgical patients participating in a delayed free recall task to investigate the spatial and spectral features that activated during both encoding and retrieval. We found that high-frequency activity increased during encoding and retrieval in a left hemispheric network consisting of the left ventrolateral temporal cortex, prefrontal cortex, and posterior parietal cortex. In addition, we found that theta oscillations in the right temporal cortex were specific to item retrieval and were not reliably observed during encoding. These data suggest that a spatiotemporally distinct subset of the neural activity that occurs during episodic encoding is recapitulated at the time of episodic retrieval.

Title: Boosting recall of childhood memories with a child-size body illusion

Authors: *L. BERGOUIGNAN, B. VAN DER HOORT, H. H. EHRSSON;
Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: The default mode of encoding life-experiences is from the perspective of one's own body. However, because our body grows throughout development, the body-size context of the child during encoding is in discrepancy with the body-size context of the adult during recall. This could explain why adults have difficulties remembering their childhood memories. To test this hypothesis we introduce a novel experimental approach where healthy adult participants recalled childhood memories while they simultaneously experienced a multisensory illusion[1] of owning a child-size or adult-size artificial body in otherwise equivalent conditions. First, employing a within-subject design (n = 26), we showed that participants recalled significantly older negative memories when they experienced the child-size body illusion (t = -2.199; p = 0.037; see Figure, panel A). Next, constraining the age of the memories and using a between-subjects design (n =40), the child-size body illusion group showed a significantly increased episodic recall (t = 2.26; p = 0.029; see Figure, panel B). This study demonstrates that a child-size body illusion improves access to episodic childhood memory in adults. This suggests that the body-size context discrepancy between encoding and recall, which can be reduced by the child-size body illusion, contributes to the so-called childhood-amnesia phenomenon[2]. 1. Title: Alternating study and retrieval practice leads to neural and behavioral differentiation of competing memory representations

Authors: *J. C. HULBERT, K. A. NORMAN;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Practicing retrieval of an item from memory can lead to impaired recall of related but unpracticed items (retrieval-induced forgetting; Anderson, Bjork, & Bjork, 1994). Retrieval-induced forgetting is commonly thought to arise as the result of inhibition, incited by the need to resolve competition between memories during selective retrieval. However, subsequent investigation has shown that the weakened competitors benefit disproportionately when retrieval practice is interleaved with opportunities to restudy the unpracticed materials. In some cases, this benefit can even lead to a reversed retrieval-induced forgetting effect (i.e., better recall of unpracticed competitors, relative to control items; Storm, Bjork, & Bjork, 2008). To explain this benefit, we hypothesized that the interleaving of competitive retrieval practice and restudy opportunities leads to differentiation of the neural representations of competing memories, thereby making memories of the items from the practiced category less confusable with one another and, through this, improving subsequent recall of both practiced and unpracticed items from this category. To evaluate this hypothesis, we measured the effects of interleaved rounds of retrieval practice and restudy using an fMRI sequence optimized to recover BOLD signal from the memory-related regions of the medial temporal lobe. Representational similarity analysis (Kriegeskorte, Mur, & Bandettini, 2008) was employed to measure the degree of neural overlap between competing memories. Using a combination of searchlight and region-of-interest analyses, we found that interleaved cycles of retrieval practice and restudy led to a decrease in neural overlap between competing memories (i.e., differentiation) in the hippocampus. Furthermore, this decrease in representational similarity predicted behavioral performance on the final test: participants showing greater levels of neural differentiation as a result of interleaved retrieval practice and restudy also showed the greatest behavioral benefit of this procedure on the recall of unpracticed competitors.

Title: Time perception and contextual drift with a naturalistic stimulus

Authors: *O. LOSITSKY, D. TOKER, J. CHEN, C. J. HONEY, J. L. POPPENK, U. HASSON, K. A. NORMAN;
Princeton Univ., Princeton, NJ

Abstract: The question of how our experiences influence our perception of time has occupied experimental psychology for decades. In particular, what gives rise to our sense of duration on the order of minutes? Sahakyan and Smith (2013, in press) recently provided evidence that paradigms that induce changes in internal context can lead to greater retrospective duration estimates. In the present study, we further investigated how the evolution of mental context influences retrospective time estimates for episodes occurring on the order of minutes. As a proxy for mental context change, we used fMRI to track how distributed patterns of activity in the brain evolve gradually over time. Subjects were scanned while they listened to a 25-minute science fiction radio drama. Outside the scanner, subjects listened to pairs of audio clips from the story and were asked to estimate how much time had elapsed during the original story presentation between the first and second clips. Unbeknownst to participants, the actual time between clips varied between only two values: two and six minutes. As a result, the difference in time estimates within a condition could only arise from subjective factors. Subjects were reliably above chance at estimating the temporal distance between events, assigning longer durations to the six-minute intervals than to the two-minute ones. In addition, time estimates within a condition (two or six minutes) were consistent across subjects; that is, subjects tended to overestimate and underestimate the same intervals, despite them all being the same length. For our fMRI analysis, we approximated the "contextual similarity" between two clips as the correlation between brain patterns corresponding to those clips when they were originally played in the scanner. For each predefined region of interest, we correlated the similarity between brain patterns in that region with the subject's temporal proximity judgments. Preliminary results from these analyses show that greater pattern change was positively correlated with duration estimates in a right-lateralized set of brain regions, including the hippocampus, parahippocampal gyrus, basal ganglia and prefrontal cortex.

Title: EEG and behavioral evidence for auditory directed forgetting in older adults

Authors: *M. E. CANO[1], R. T. KNIGHT[2,1];
[1]Helen Wills Neurosci. Inst., [2]Psychology, UC Berkeley, Berkeley, CA

Abstract: The neural basis of directed forgetting has received increased attention in the memory literature, with a focus on prefrontal cortex as the source of memory inhibition. The purposes of this study are twofold: 1) While the majority of directed forgetting studies have used visual stimuli, we seek to determine whether intentional forgetting extends to other sensory modalities 2) We aim to examine the behavioral and neuroelectric effects of auditory directed forgetting in older adults. To address these issues, we recorded electroencephalography (EEG) during a modified auditory version of Anderson and Green's Think/No-Think paradigm with healthy older adult participants. Participants were instructed to first learn auditorily presented word pairs. Successful initial learning was followed by a recall test to confirm sufficient learning. In the next phase of the experiment, participants were again presented with the first word of each pair, accompanied by a visual instruction cue consisting of a red or green box, which indicated either to silently retrieve the second word of the pair (green box) or to inhibit recollection of the second word of the pair (red box). Subsequent memory was later tested with same-probe and independent-probe memory tests to determine the effect of instruction and active control of memory on later memory. Here, we examine task- related EEG activity during covert intentional memory retrieval and inhibition. Behaviorally, older adults showed a directed forgetting effect similar to that seen in previous studies using young adults, such that No-Think words were forgotten at a higher rate than baseline and Think words ($p<.05$ and $p<.01$, respectively), demonstrating successful active memory suppression for No-Think items. ERPs were examined during two periods of the Think/No-Think phase of the experiment and were time-locked to instruction cue onset and word onset. Cue-related activity produced a fronto-central ERP negativity for No-Think compared to Think trials (200-300 ms, $p<.05$), which may reflect the process of general preparatory inhibition. Word-related activity produced a sustained and widespread ERP negativity for No-Think compared to Think trials ($p<.05$), potentially reflecting the active inhibition of the particular item in memory. The behavioral and ERP data suggest that auditory directed forgetting elicits similar effects to those seen in the visual directed forgetting literature, and that those effects can also be elicited in older adults.

Title: Reinstatement of content-specific intracranial EEG activity during retrieval in a spatial navigation task

Authors: *H. ZHANG[1], J. FELL[1], B. STARESINA[1,2], N. AXMACHER[1,3];
[1]Dept. of Epileptology, Univ. of Bonn, Bonn, Germany; [2]Med. Res. Council Cognition and Brain Sci. Unit, Cambridge, United Kingdom; [3]German Ctr. for Neurodegenerative Dis., Bonn, Germany

Abstract: Retrieval of episodic memories depends on the reinstatement of encoding-related activity. Representational similarity analysis (RSA) is a straightforward method to analyze the similarity between neural activity patterns based on correlations. Indeed, previous RSA studies have shown that stimulus-specific neural activity patterns re-occur during subsequent retrieval of the same information, however, the exact time-frequency signature of this process still remains to be investigated. Here, we explored the reinstatement of content-specific activity patterns in ten pre-surgical epilepsy patients. Depending on their clinical background, patients were implanted either with medial temporal depth electrodes or subdural grid and strip electrodes or both (average number of electrode contacts: 19.5; range: 9~32). In a first-person virtual navigation experiment, patients first encoded and then retrieved their route through a virtual furnished house. We extracted time-frequency activity patterns across all electrodes in each patient. Then, for each time-frequency bin, we calculated correlations across electrodes between encoding and retrieval of the same room in a house as compared to encoding of one room and retrieval of a different room. We found that encoding-related activity was reinstated in a content-specific manner during retrieval. Specifically, reinstatement occurred mainly in the high (gamma) frequency range between 30-80 Hz, and only before the decision point in each virtual room. This suggests that encoding-related activity is only recalled when subjects need to remember their virtual route. Taken together, these data are the first to delineate the specific time-frequency pattern of content-specific memory reinstatement.

Title: Neural correlates of memory encoding as a function of practice

Authors: *N. M. LONG[1], M. J. KAHANA[2];
[2]Psychology, [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The neural correlates of successful memory formation, although well characterized, are typically the result of single session data. In contrast, memory formation outside of the confines of the laboratory is the result of a lifetime of practice, leaving open the question of whether the same mechanisms that support initial one-shot learning support memory formation across multiple study episodes. To address this issue, we collected scalp EEG as subjects studied and freely recalled lists of words across 7 sessions on separate days. Recall accuracy increased across sessions, as did subjects' tendency to exhibit a contiguity effect. Analysis of the spectral correlates during encoding showed that the contrast of successfully encoded to forgotten items was characterized by significant power decreases across low frequencies, an effect which increased significantly across sessions. Temporal clustering, the tendency to consecutively recall study neighbors, was characterized by an increase in gamma power across sessions. Taken together, these results suggest that mechanisms underlying successful memory encoding and subsequent temporal clustering become more pronounced with practice.

Title: Interacting signals of memory during competitive encoding

Authors: *J. HUTCHINSON, N. B. TURK-BROWNE;
Dept Psychology, Princeton Univ., Princeton, NJ

Abstract: Although memory encoding and retrieval are often studied as separate entities, old and new items are often encountered at the same time. The deployment of attention in such competitive situations is varied, including being biased to repeated information in some settings and to novel information in others, depending on the memory system(s) involved. Using fMRI of the human brain, the current study sought to isolate the contributions of novel and repeated information to attention and memory systems during competitive processing. Specifically, competition was induced by presenting participants with a face image at central fixation, which was surrounded in the periphery by a scene image. The face image had either been encountered recently or was novel, and participants were given a subsequent memory test for the competing scene stimuli. This design allowed us to examine: (1) behavioral memory for novel scenes as a function of whether they were presented in competition with novel or repeated faces, (2) neural evidence of priming for the novel vs. repeated faces, as reflected in attenuated evoked responses in face-selective visual cortex, (3) neural evidence of encoding for the novel scenes, as reflected in the activity of scene-selective visual cortex, and (4) the interaction of these measures both within visual cortex and more broadly in attention networks. Preliminary results suggest that neural activity in ventral temporal regions and beyond is differentially related to memory outcome for the scenes, depending on whether there is competition from repeated or novel faces. Such findings indicate that the encoding of novel information can be influenced by signals from multiple memory systems about the mnemonic status of other currently presented items.

Title: Brain structural differences associated with mnemonic control

Authors: *G. LERMA-USABIAGA[1], L. GARCIA-PENTON[1], M. CARREIRAS[1,2,3], P. PAZ-ALONSO[1];
[1]BCBL, Basque Ctr. on Cognition, Brain and Language, San Sebastian, Spain; [2]IKERBASQUE, Basque Fndn. for Sci., Bilbao, Spain; [3]Dept. de Lengua Vasca y Comunicación, UPV/EHU, Bilbao, Spain

Abstract: A component of goaldirected behavior is the ability to focus on memories that are relevant to our current goals. The Think/No-Think (TNT) paradigm is a useful tool to examine mnemonic control as it is designed to study the effects of intentional attempts to bring or to not bring to mind information from long-term memory. Behavioral research suggests that efforts to suppress memory retrieval are associated with a reduction in memory for these associations in a subsequent test. Recent neuroimaging evidence has showed that compared to individuals who were not able to suppress memory retrieval, participants who did so exhibit tighter coupling between key nodes in a dorsolateral prefrontal cortex-cingulate-parietal-hippocampal network which cortical inputs may be mediated by the cingulum bundle (Paz-Alonso et al., 2013). Also, a recent study has shown that suppression of memory retrieval is associated with overall reduction of hippocampal volume (Depue et al., 2011). Based on prior evidence suggesting the involvement of the cingulum bundle in mnemonic control and longaxis specialization within the hippocampus (Poppenk et al., 2013), the present study was aimed at investigating if volume differences in anterior versus posterior hippocampus and the integrity of the main white-matter pathways connecting the hippocampus and the prefrontal cortex are associated with memory suppression. A total of 27 healthy young adults participated in the study. Our procedure involved three phases. First, participants learned a series of word-pairs (Vacation-Palm). Second, they were presented with the first word of the pair (Vacation), and asked to either remember (Think condition) or suppress (No-Think condition) the second word (Palm). Finally, participants were encouraged to recall all of the studied item-pairs. fMRI data was acquired between the learning and the testing phases. As expected, behaviorally, participants exhibited a lower percent recall for No-Think items compared to Baseline items (items that were learned but were not included in Think/No-Think phase. Our neuroimaging results revealed that reduced anterior, but not posterior, hippocampal volume was associated with memory suppression. These results support prior evidence of a longaxis specialization in the hippocampus and qualify prior findings (Depue et al., 2011). Furthermore, probabilistic tractography analysis revealed that white-matter integrity of the bilateral cingulum bundle, but not of the uncinate fasiculus, was associated with memory

suppression. These results constitute the strongest and most detailed evidence so far for the relation between brain structure and mnemonic control.

Title: fMRI examination of motivated learning and memory of scenes in adults and adolescents

Authors: *A. MATTFELD[1], M. SHERMOHAMMED[2], J. D. E. GABRIELI[2];
[2]Dept. of Brain and Cognitive Sci., [1]MIT, Cambridge, MA

Abstract: We used fMRI to investigate the neurobiology of reward-motivated learning and memory in adults and adolescents during encoding and retrieval. Systems neuroscience has identified a network of regions including midbrain dopaminergic neurons, ventral striatum and orbito- and medio-frontal cortices that are important for reward processing. Similarly, a network of regions has been identified as important for the acquisition and subsequent expression of declarative memory including the medial temporal lobe (MTL), parietal, and prefrontal cortices. The interaction between these two networks and their changes across development have been unexplored. Here, we used the monetary incentive encoding (MIE) paradigm to examine motivated learning and memory in adults and adolescents. During the MIE task, participants were required to learn scenes for a subsequent memory test, with a cue preceding each scene indicating whether a large reward ($5) or a small reward (10¢) would be received for later remembering that scene,
Behaviorally both adults and adolescents showed greater memory, as measured by d-prime, for scenes paired with large relative to small rewards. Adults during the reward cue period showed activation across the reward network including the medial prefrontal cortex, dopaminergic midbrain, and bilateral caudate. There was also activation in bilateral hippocampus and right parahippocampal cortex for successfully remembered compared to forgotten scenes during the target scene period. These findings suggest that during encoding, motivated learning and memory recruit distinct reward and memory networks. Evaluation of their interactions and how these interactions change across development will provide useful insight into the motivated learning and memory circuitry.

Title: The oscillatory signature of voluntary forgetting: Intracranial EEG data from prefrontal cortex and hippocampus

Authors: *C. OEHRN[1], J. FELL[1], C. BAUMANN[1], S. HANSLMAYR[2], M. LESZCZYNSKI[1], A. JAHANBEKAM[1], A. T. DO LAM[1], C. E. ELGER[1], N. AXMACHER[1];

Abstract: Forgetting is commonly regarded as a limiting rather than as a valuable feature of our memory system. However, forgetting can help us to eliminate unwanted, irrelevant or emotionally straining information,
and thus enables a flexible and goal-directed use of memory resources. A powerful way to keep our memory clean is to prevent the formation of unwanted memories in the first stage, during encoding. This process can be driven intentionally, as shown in the item-method directed forgetting paradigm, where participants are cued to forget individual items briefly after presentation. We investigated the time-frequency pattern underlying this form of voluntary forgetting by recording intracranial EEG from the dorsolateral prefrontal cortex (DLPFC) and the hippocampus in 22 epilepsy patients undergoing pre-surgical evaluation. We found that the "forget" instruction triggered an increase in gamma-band activity (30-150 Hz) in the DLPFC and in the hippocampus. Furthermore, we observed that voluntary forgetting was associated with increased activity in the beta (13-18 Hz) frequency range, specifically in the anterior hippocampus. These results are the first to draw a detailed picture on the oscillatory signature underlying voluntary forgetting and suggest that forgetting is reflected by an increase in prefrontal gamma band activity and increased gamma and beta band activity in the hippocampus.

Title: Recall order is predicted by category-specific neural activity of preceding items at study

Authors: *S. C. Y. CHAN[1], M. C. APPLEGATE[1], J. R. MANNING[1], N. W. MORTON[2], S. M. POLYN[2], K. A. NORMAN[1];
[1]Princeton Univ., Princeton, NJ; [2]Vanderbilt Univ., Nashville, TN

Abstract: Context-based models of episodic memory posit that memories of items are linked to a "mental context" representation that drifts over time; at test, we can retrieve recently-studied items by cuing with the current state of mental context. These models have successfully explained a wide range of memory effects (e.g., temporal clustering in free recall), but there is still considerable debate over the factors that shape mental context. Early context models (e.g., Estes, 1955) posited that mental context drifted randomly over time, whereas modern implementations (e.g., Howard & Kahana, 2002) posit that mental context reflects a running average of recently-experienced thoughts. A key prediction arising from the latter set of models is that, if two items are preceded by similar thoughts, they will be linked to similar mental contexts, which in turn will bias participants to recall the items sequentially at test. To test this prediction, we scanned participants in an fMRI scanner while they studied, one item at a time, lists of the form AACBBCAACBBCAACBBC, where A, B, and C denote different categories. For each list, participants were asked to recall as many C-items as possible, in any order. We used an fMRI pattern classifier to track category-specific neural activity, and examined pairs of C-items that were preceded by the same category during study (e.g. A). For a given pair, if the classifier showed an elevated level of the preceding category when the two C-items were studied, the participants showed an elevated probability of recalling the two items sequentially, as predicted.

Title: Periodic interplay between inhibition and maintenance in the human hippocampus during working memory task

Authors: *M. LESZCZYNSKI[1], J. FELL[1], C. OEHRN[1], A. DO LAM[1], C. E. ELGER[1], N. AXMACHER[1,2];
[1]Dept. of Epileptology, Univ. of Bonn, Bonn, Germany; [2]German Ctr. for Neurodegenerative Dis., Bonn, Germany

Abstract: Recent evidence suggests that the hippocampus does not only contribute to long-term memory encoding and retrieval, but also supports working memory (WM) processes. Here, we used intracranial EEG recordings in epilepsy patients to describe properties of the hippocampal contribution to WM. We observed a load-dependent increase of activity in the gamma frequency range (30-150Hz), possibly indicating enhanced recruitment. Furthermore, we found that activity in the alpha/beta frequency range (8-20Hz) decreased with load, putatively reflecting release from inhibition. Interestingly, the latter effect was not sustained across the entire maintenance period, but occurred during four clusters that were interrupted by periods of similar length during which no alpha/beta load effect was observed, but which, in contrast, showed a load-independent increase of alpha/beta power as compared to baseline.
We further tested several mechanistic predictions derived from the multiplexing buffer model of WM (Lisman & Idiart, 1995; Lisman & Jensen, 2013). First, we found that the amplitude of high-frequency activity depends on the phase of simultaneous low-frequency oscillations (cross-frequency coupling, CFC), as previously observed during maintenance of faces. We observed a pronounced phase-to-power coupling between the phase of theta oscillations (4-6Hz) and the power of alpha/beta oscillations (8-20Hz), as well as between theta phases and gamma power (30-50Hz) and between alpha/beta phase and gamma power. Across all clusters, the average CFC ratio was at around 7 and thus significantly higher than the CFC ratio during maintenance of faces, which was at 4. Most importantly, we found that CFC was not constant across the maintenance period but fluctuated between states of high and low CFC strength. This fluctuating pattern was complementary to the previous alpha/beta load-dependent effect: Periods showing load-dependent release from inhibition displayed lower CFC values, whereas periods with load-independent alpha/beta enhancement were characterized by higher CFC values. This difference cannot be explained by a change in overall (load-independent) power, which was identical for both intervals. These results suggest a refined model for WM maintenance depending on a

periodic interplay between periods of pronounced cross-frequency coupling and periods of load-dependent release from inhibition.

Title: Memory for shape reactivates the lateral occipital complex

Authors: *J. M. KARANIAN, S. D. SLOTNICK;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Memory is thought to be a constructive process in which the cortical regions associated with processing the features of the preceding event are reactivated during retrieval. Although there is evidence for non-detailed cortical reactivation during retrieval (e.g., memory for visual or auditory information reactivates the visual or auditory processing regions, respectively), there is limited evidence that memory can reactivate cortical regions associated with processing detailed feature-specific information. Such evidence is critical to our understanding of the mechanisms of episodic retrieval. The present functional magnetic resonance imaging (fMRI) study assessed whether the lateral occipital complex (LOC), a region that preferentially processes object shape, is associated with the accurate recall of shape information. At encoding, participants were presented with colored abstract shapes that were either intact or scrambled. At retrieval, colored disks were presented and participants indicated whether the corresponding shape was previously “intact” or “scrambled”. A random-effect general linear model analysis was conducted. Activity associated with the recall of intact shapes was isolated by contrasting “intact”/intact > “scrambled”/intact, and activity associated with the recall of scrambled shapes was isolated by contrasting “scrambled”/scrambled > “intact”/scrambled (i.e., hits > misses). Preliminary analysis revealed that the recall of intact shapes, but not scrambled shapes, activated the LOC. Furthermore, LOC activity was significantly greater during the recall of intact than scrambled shapes. The present results suggest that the LOC is preferentially associated with retrieval of shape information. This feature-specific evidence supports the view that retrieval is constructive in nature.

Title: Oscillating auditory stimulation during sleep promotes sleep spindles

Authors: *J. W. ANTONY[1], J. BAE[2], K. A. PALLER[1,2];
[1]Interdepartmental Neurosci., Northwestern Univ., Chicago, IL; [2]Dept. of Psychology, Northwestern Univ., Evanston, IL

Abstract: Two types of oscillations play particularly important roles in memory processing during sleep. Slow oscillations (>75 μV, 0.5-2.0 Hz) occur most prominently during slow-wave sleep (SWS). Spindles are bursts of oscillatory activity between 11-16 Hz lasting 0.5-2 seconds occurring during stage-2 and SWS. Spindles occur non-uniformly across the scalp, with slow spindles (11-13.5 Hz) more prominent at frontal regions and fast spindles (13.5-16 Hz) more prominent at centroparietal regions. Several methods have been used to show that facilitating slow waves can enhance memory, perhaps due to indirect effects on spindle activity. Here we attempted to manipulate spindles directly by presenting oscillating white-noise bursts at spindle frequencies during sleep. Two groups of 11 young, healthy subjects napped in the afternoon for up to 90 minutes with an auditory background of white noise. Following EEG signs of stage-2 or SWS, we presented 2-second bursts wherein the amplitude of white noise oscillated sinusoidally between 20-100% of the background amplitude at 15 Hz in one group and 12 Hz in the other (corresponding roughly to fast and slow spindles, respectively). Each burst was followed by 8 seconds of white noise at the background amplitude. Spindles were detected using an established automated algorithm. During 15-Hz stimulation, there was an increase in fast spindles relative to subsequent non-stimulation periods. Slow spindles did not differ between the stimulation and non-stimulation periods. During 12-Hz stimulation, there was only a trend for an increase in slow spindles. Between-group comparisons confirmed that spindle frequency varied reliably as a function of stimulation frequency. Further analyses compared spindles during stimulation to spindles following stimulation. No differences were found in EEG power spectral density, duration, or topography, suggesting that induced spindles were physiologically similar to spontaneous spindles. Prior findings have linked spindles with memory consolidation, general

intelligence, and sleep stability. This successful demonstration of a method to facilitate spindles selectively and non-invasively opens the door to new research into the physiological functions of spindles and to practical applications of spindle induction methods.

Title: Evolution of hippocampal involvement in tactile-kinesthetic memory encoding and retrieval

Authors: *L. T. LIKOVA;
Smith-Kettlewell Eye Res., SAN FRANCISCO, CA

Abstract: Introduction. Recently, we developed a memory-training paradigm based on non-visual drawing and found dramatic improvements in memory-guided spatiomotor performance in both congenitally blind and blindfolded (sighted) subjects (Likova 2012, 2013) with a one-week training protocol. To assess the evolution of hippocampal involvement, we ran a pre/post-training analysis of the memory-related activation. Methods. The tasks were: encoding through tactile exploration and memorization (EM) of the complex spatial images to be drawn, memory-retrieval through drawing guided solely by tactile memory (MD), and control scribbling (S), each of 20s duration, separated by 20s rest-intervals. FMRI (Siemens 3T scanner) was run before and after a week of drawing training in the congenitally blind, and also following a prolonged consolidation period. A fiber-optic motion-capture system recorded the drawing movements. Results and Conclusions. The hippocampal region, which was activated in encoding (EM) but strongly deactivated in memory retrieval (MD) before training, reversed its sign to become strongly activated in retrieval after training and consolidation, but non-responsive in encoding. Interestingly, this dramatic reversal was highly correlated with the changes of the response pattern in the primary visual area V1, which we have previously implicated as the (amodal) spatial-sketchpad for working memory. As expected, no response was observed in these regions for the control (S) condition either pre- or post-training. The progression of the hippocampal/V1 response reorganization was well coordinated with a differentiation into non-overlapping encoding and subsequent retrieval networks throughout the inferotemporal cortex (IT). The

observed training-driven evolution of this rapid functional reorganization carries important implications for theories of the role of the hippocampus, as well as of V1 and IT, in human learning and memory encoding and retrieval, with particular reference to cross-modal brain plasticity under tactile-kinesthetic guidance, and to potential strategies for blindness rehabilitation.

Abstract: We have demonstrated that individual differences in cognitive performance, such as attention, procedural learning and working memory are associated to genetic polymorphisms of the CNR1 gene, which codes for Cannabinoid receptor 1 (CB1R). However, association of polymorphisms of CNR1 and encoding and retrieval performance of episodic memory remains unknown, and seems plausible because CB1R are highly distributed in hippocampus, which is involved in episodic memory. Studies in animals and human subjects have revealed a functional role of endocannabinoid system in episodic memory. Here, we studied the association of the genotypes of the rs2180619 of the CNR1, a polymorphism located in a regulatory region of the

CNR1, and the performance on an encoding-recognition episodic memory task. The alleles of the rs2180619 are A>G; the G allele has been associated to addiction and high levels of anxiety (when G allele interacts with the SS genotype of the 5-HTTLPR gene). One-hundred and sixty four participants were genotyped (AA, n=41; AG, n=90; GG, n=33), and solved an encoding and a recognition episodic-memory task. During encoding phase, subjects had to categorize 60 words between concrete and abstract meaning (50% of each category). Immediately after and surprisingly for subjects, a recognition task was administered; subjects had to discriminate between old (presented during encoding phase) and new words. Only during encoding phase, a differential performance was associated to genotypes of the rs2180619: GG subjects did not show difference in speed processing of concrete vs. abstract words, whereas AA and AG subjects responded faster to concrete than to abstract words, as previously has been reported. Despite this differential performance in speed during encoding, no differences among genotypes were found in performance during recognition. Our results suggest that performance of genotypes of the rs2180619 is more related to a semantic processing than to an episodic one.

Title: The effects of perceptual distortion, age and proficiency on functional activation for sentence comprehension

Authors: *S. KRISHNAN[1], R. LEECH[2], E. MERCURE[3], S. LLOYD-FOX[1], F. DICK[1]; [1]Birkbeck, Univ. of London, London, United Kingdom; [2]Imperial Col., London, United Kingdom; [3]UCL, London, United Kingdom

Abstract: In the school years, children become proficient language users. They acquire a larger vocabulary, and start to comprehend and use more complex syntactic constructions. During the same developmental period, perceptual, attentional and cognitive abilities are changing. These changes influence children's language comprehension ability. A gradual refinement of syntactic comprehension occurs in tandem with refinements of perceptual and attentional ability. In adverse listening conditions, this trajectory for sentence processing is extended even further (Leech et al., 2007). The functional neural bases of these protracted behavioural changes in language comprehension are not well understood. In adults, syntactic comprehension is associated with activation in a well defined set of regions. Nonetheless, this activation can vary with relation to sentence complexity & task demands. Only a handful of studies focus on developmental differences in syntactic comprehension (Yeatman et al., 2010; Nunez et al., 2011). These studies focus on neural effects related to syntactic complexity alone. However, despite children's everyday exposure to noisy & distracting environments (such as classrooms/ playgrounds), the effects of perceptual/attentional factors on neural activation for language remain largely unexplored.
We compared school-age children (7-13 year olds, N = 38) and adults (N = 18) to characterise developmental differences in the neural activation for sentence comprehension.In our fMRI task, participants had to identify the agent of a sentence. Sentence complexity as well as perceptual/attentional demands were modulated. Complexity was modulated by using simple (active/ subject clefts) & more complex sentences (passives/ object clefts). Perceptual/attentional demands were increased by introducing speech compression plus low-pass filters (Dick et al., 2001). To identify potential interactions, we explored the relationships between neural activation, age, & performance on a range of auditory-motor behavioural tasks. All conditions elicited activation in the superior temporal and inferior frontal regions in both groups. Perceptual distortion was associated with decreased activation in the superior temporal regions. Although overall patterns of activation were similar, group differences were observed when comparing children/adults. These indicate that the functional organisation of language comprehension in schoolchildren is still undergoing significant change. We also discuss the complex interplay between individual differences in auditory/ syntactic proficiency on children's neural activation for sentence processing.

Title: Recognition of novel words learnt with levodopa modulates striatal and temporal cortical activity

Authors: *A. RAWLINGS[1], K. MCMAHON[2], A. MACDONALD[1], E. FINCH[3], P. SILBURN[1], P. NATHAN[4], D. A. COPLAND[1];
[1]Ctr. for Clin. Res., Univ. of Queensland, Herston, Australia; [2]Ctr. for Advanced Imaging, [3]Sch. of Hlth. and Rehabil. Sci., Univ. of Queensland, St Lucia, Australia; [4]Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Background: Levodopa, a dopamine precursor, has been shown to improve new word learning in healthy adults. However the neural and cognitive mechanisms underlying this effect remain unclear. This study aimed to investigate this effect using a double-blind, placebo-controlled drug study in young healthy adults. Participants learnt new names for familiar objects over a four-day period, followed by a functional magnetic resonance imaging (fMRI) task examining recognition of newly learnt words.
Methods: 33 (17 female) healthy young adults were randomly assigned to one of two drug arms. Participants received a tablet (Madopar 125mg or placebo) prior to daily training sessions in a novel explicit word learning paradigm over four consecutive days. Participants learnt new auditory names (legal nonwords) for 50 commonly-known familiar objects. After completion of the four training sessions, recall and recognition of the newly-learnt words was tested while event-related fMRI data was acquired with blood oxygen level-dependent (BOLD) contrast at 4 Tesla. All image processing and analysis was conducted in SPM8.
Results: Region-of-interest analysis (using $p < .05$ corrected) showed that while performing the new word recognition task, participants who had taken levodopa exhibited increased activity in the left striatum and left hippocampus as compared to participants who had taken a placebo. Additionally, participants in the levodopa group exhibited less activity in left superior and middle temporal gyri compared to participants in the placebo group.
Conclusions: The results suggest that levodopa may modify learning of new words through increased recruitment of the left striatum and hippocampus, two primary targets of dopaminergic signalling that are strongly implicated in learning and memory. The decreased temporal cortex activity observed for the levodopa group suggests more efficient retrieval of recently acquired word representations. This research contributes to our understanding of the role of dopamine in language learning and could assist with the development of novel pharmacological treatments for language disorders such as post-stroke aphasia.

Title: Involvement of left inferior frontal cortex in processing compound words for lexical decision

Authors: *W.-J. KUO;
Inst. of Neurosci., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: During the course of learning to read, the readers need to develop a mechanism to regulate computation of various representations and the way to get access to their mental lexicon. Studies have shown that the
mechanism is often complicated by the trade-off between storage and computation for the representation and processing, as for the processing of compound words (Taft and Forster, 1976; Butterworth, 1983; Marslen-Wilson et al., 1994). In Chinese, over 80% of Chinese words are two-character compounds (Tsai et al., 2011). For content words, the meaning of a two-character compound can be either semantically transparent or opaque to its constituent characters. As recognized by research in this regard, semantic transparency is an important factor to affect dynamics of compounding process (Andrews, 1986; Zwitserlood, 1994; Libben, 1998; Libben et al., 2003; Fiorentino and Poeppel, 2007). In this study we specifically designed an fMRI experiment to explore neural bases of this lexical control mechanism for word compounding by using Chinese two-character compounds. The results indicated that processing the opaque words needs more time than the transparent words, and it interacts with their neighborhood size. For opaque words, the larger their neighborhood size the more time it takes for their processing. For the transparent words, the opposite response pattern was observed. Interestingly, the left inferior frontal cortex (BA 44, the Broca's area) was involved in this type of morphological computation by mirroring its activity pattern in the same way.

Title: Cortical organization of semantic representations for natural speech revealed by fMRI

Authors: *A. G. HUTH[1], W. A. DE HEER[2], F. E. THEUNISSEN[2], T. L. GRIFFITHS[2], J. L. GALLANT[2];
[2]Psychology, [1]UC Berkeley, Berkeley, CA

Abstract: The human brain is adept at extracting meaning, or semantic content, from natural speech. Low-level speech features such as phonemes are known to be processed in specialized areas of auditory and motor cortex. In contrast, previous research suggests that semantic processing is widely distributed across the brain, involving much of the temporal, parietal, and frontal lobes. However little is known about how different aspects of semantic information are mapped systematically across the cortical surface.

To address this issue we collected BOLD fMRI responses from five subjects while they listened to over two hours of natural speech (stories from "The Moth Radio Hour"). Each word in the stimulus was projected into a 1000-dimensional semantic feature space constructed using word co-occurrence statistics from a large corpus of text. We used this feature representation to build a separate L2-regularized linearized finite impulse response (FIR) regression model for each voxel in each subject's brain. These models predict the response of each voxel as a linear combination of the 1000 semantic features.

To find a compact, meaningful representation of these models we applied principal components analysis (PCA) to model weights from individual subjects and to combined data. This procedure produces a low-dimensional semantic space in which concepts that are represented similarly in the brain are close together but concepts that are represented differently in the brain are far apart. The resulting semantic spaces are similar across subjects, suggesting that different individuals share a common representational space for the meaning of speech. We then used the common semantic space to visualize the cortical organization of semantic processing in each subject. To show how the representation of each semantic dimension is distributed across cortex, we projected the model weights for each voxel onto each dimension of the semantic space, and then plotted voxel projections on the cortical surface of each subject. This process reveals highly complex semantic maps in temporal, parietal, and prefrontal cortices that are similar across subjects. In sum, our data suggest that different individuals share a common semantic space that is organized similarly across cortex.

Title: Language lateralization in 297 healthy volunteers: Association with manual preference strength exists only in left-handers

Authors: *N. TZOURIO-MAZOYER, D. MARIE, L. ZAGO, G. JOBARD, E. MELLET, L. PETIT, F. CRIVELLO, M. JOLIOT, B. MAZOYER;
GIN UMR 5296 CNRS CEA Univ. Bordeaux, Bordeaux Cedex, France

Abstract: 297 healthy volunteers (aged 25.3 years, [18, 57]), balanced for sex, and including 153 left-handers (LH), completed a sentence and word list covert production task (PROD) during BOLD fMRI. For each individual a left - right Hemispheric Functional Lateralization Index (HFLI) was computed using the LI toolbox for the contrast sentence minus word list production. Manual preference (MP) was quantified with the Edinburgh Score (right-handers (RH): 93.1 ± 11.0, LH: 60.0 ± 41.0). PROD HFLI distribution was optimally fitted by a mixture of 4 Gaussian functions mixture (figure) allowing the definition of 3 language Lateralization Types (LLatT): "Typical" HFLI > 18 (N=250), "Atypical" -50 > HFLI < 18 (N = 37), Strong-Atypical" HFLI < -50 (N = 10). Proportion of LH was lowest for Typical (48%), increased in Atypical (62%) and reached 100% for Strong-Atypical. Concordance between LLaT and hand lateralization (defined on a 3-level scale, Strong LH, weak MP, Strong RH) was not better than expected by chance alone (Kappa-statistic = 0.025, p = 0.17). In addition, while a logistic regression revealed a significant association between ES and the proportion of atypical subjects during PROD (p = 0.0001, atypicality occurrence increasing as ES decreases), such association was significant only in LH (RH: p = 0.56, LH: p = 0.011). Moreover HFLI did not differ between LH and RH in either the Typical (p = 0.31) or Atypical (p = 0.26) subgroups. Comparison of the functional anatomy of PROD between LatT groups revealed that Strong-Atypical and Atypical activated right hemisphere areas mirroring those more activated by Typical in the left hemisphere (figure). Between groups differences corresponded to differences in the left-right balance of frontal and temporo-parietal language areas. In conclusion, hand/language lateralization strength correlation exists in LH only. Right hemisphere lateralization for language is a rare (0.08% of the general

population), but normal, variant of language lateralization in healthy subjects.

Title: The perception of speech in noise and other maskers by musicians and non-musicians

Authors: *D. BOEBINGER[1], S. EVANS[1], C. LIMA[1], N. LAVAN[1], S. ROSEN[2], S. K. SCOTT[1];
[1]Inst. of Cognitive Neuroscience, Univ. Col. London, London, United Kingdom; [2]Speech, Hearing & Phonetic Sciences, Univ. Col. London, London, United Kingdom

Abstract: Extensive musical training is associated with better speech-in-noise perception. However, here are multiple ways to mask speech with noise, and these various maskers show different behavioural and neural effects. Given that musical experience also seems to offset the age-related decline in speech-in-noise perception, understanding the relationship between musical experience and speech-in-noise perception is of great importance. This experiment uses fMRI and multiple types of speech maskers to determine whether there are differences in speech-in-noise perception between trained musicians and non-musicians, and whether that difference varies across masker types.
During the behavioural task, musicians (n=16) and non-musicians (n=16) passively listen to stimuli that consist of simple sentences masked with continuous noise, speech-modulated noise,

rotated speech, or another speaker. After hearing each sentence, the subject repeats as much as possible of the sentence. Subjects will be scored based on how many key words they get correct. All subjects will also fill out a questionnaire detailing their musical experience and complete tasks measuring their pitch discrimination, executive control, working memory, and nonverbal IQ. In the fMRI task, subjects listen to stimuli consisting of short narratives taken from a British newspaper and masked with either continuous speech, discontinuous speech, rotated speech, speech modulated noise, and continuous noise. Subjects are instructed to report as much as possible from the last phrase of the target speaker. Scoring is based on how many key words subjects correctly report. To determine whether performance differs between the musician and non-musician groups and between conditions, a musician x condition repeated-measures ANOVA will be performed for both the behavioural and fMRI phases of the experiment.
A behavioural advantage shown by musicians, relative to non-musicians, will replicate previous studies and extend these findings to include several types of maskers. A difference between the groups only with certain maskers could help determine the mechanism by which musicians are better able to perceive the target stimuli. Although the direction of causality cannot be inferred from this experiment, results could provide further evidence that musical training improves performance on certain linguistic and attentional tasks, as well as help clarify the underpinning neural systems.

Title: Neural correlates of contextual variability in second language learning

Authors: *L. VERGA[1], S. A. KOTZ[1,2];
[1]Max Planck Inst., Leipzig, Germany; [2]Manchester Univ., Manchester, United Kingdom

Abstract: Introduction
Learning new words firstly requires the understanding of word meaning. To accomplish this task, adult learners rely on cues provided by the context, in which a new word is encountered (1, 2). However, when a new word is repeated several times, different contextual cues can be used to

identify its meaning (3). The aim of the current study is to clarify the extent to which contextual variability influences the brain mechanisms underlying word learning in adults. We expect to observe both behavioural and neural differences during the learning phase as a function of contextual variability.

Methods

41 participants (20 F, mean age: 26 years, sd: 3.35 years) learned 20 new pseudowords during a scanning session (3T Siemens Trio scanner). In a given context, participants had to identify a matching object to which a pseudoword was assigned. Each object was repeated 9 times either i) in the same sentence context, or ii) in a different sentence context. A behavioural testing phase was subsequently conducted. Participants were presented with a novel context sentence. Their task was to select from 3 possible pseudowords the correct missing word learnt during the learning phase.

Results

Behaviourally, we observed an advantage for new words when embedded in the same sentence context as compared to a different context in terms of faster response times ($p<.001$) and greater accuracy ($p<.001$) during the learning phase. No differences were observed between the two conditions in the subsequent testing phase. At the neural level, the two conditions led to different activations in the left inferior frontal gyrus (BA 44) and middle occipital gyrus/inferior parietal cortex as well as the right cerebellum (all $p<.05$, FWE corrected for multiple comparisons, $k>20$ voxels).

Conclusions

Our results suggest that context variability influences the encoding of new words in adult learners. Further studies are required to evaluate the potentially differential impact of different contextual factors (such as a social context) on word learning.

Title: Does early exposure to a visual signed language "hurt" auditory language tissue development: Evidence from fNIRS neuroimaging of language processing in deaf individuals cochlear implants

Authors: *K. K. JASINSKA[1,2], C. LANGDON[2], L.-A. PETITTO[2,3];
[1]Psychology, Univ. of Toronto Scarborough, Toronto, ON, Canada; [2]Gallaudet Univ., Washington, DC; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: Controversy abounds regarding the specific impact of differences in language experience on the neural systems underlying auditory spoken language processing in deaf individuals with cochlear implants (CI). Does early exposure to a visual signed language impact classic spoken language tissue development, including left Inferior Frontal Gyrus (LIFG) and Superior Temporal Gyrus (STG), in the CI individual? We further investigate how language processing in the deaf CI individual is impacted by variation in early-life language experience. To address this question, two hypotheses are tested: (1) Early language experience, signed or spoken, facilitates normal neural development supporting language processing in the CI individual. (2) Only early spoken language experience facilitates normal neural development supporting language processing. Early signed language experience disrupts classic language tissue recruitment in the CI individual.

METHODS CI individuals (mean age of cochlear implantation: 13 y) with early (birth-5y) or late (5y+) exposure to a visual signed language read aloud single English words while undergoing functional near infrared spectroscopy neuroimaging (Hitachi ETG 4000). Like fMRI, fNIRS measures hemodynamics, but has key advantages for studying language: tolerates movement, nearly silent, has good spatial and greater temporal resolution (10Hz), and crucially, is safe for CI individuals (Shalinsky et al., 2009).

RESULTS The age of exposure to a visual signed language yielded differences in patterns of neural activation during auditory language processing. CI individuals with early signed language exposure showed greater activation in the LIFG during reading, whereas individuals with later signed language exposure showed greater activation in the right IFG.

The results provide a new view on how early life language exposure, irrespective of modality (signed, spoken), can facilitate language processing in the CI individual. The finding that late

exposed CI individuals showed greater activation in the right hemisphere, not in primary left hemisphere language tissue supports the hypothesis that early speech or sign exposure facilitates normal language processing. In contrast to the late exposed individuals, early signed language exposure facilitates typical LIFG activation. We found no evidence of a negative impact on language processing in CI individuals as a result of early visual signed language exposure. The findings have vital implications regarding the optimal developmental timing of signed language exposure: Early language exposure, be it signed or spoken, supports healthy, typical language development.

Title: Differential activation patterns in visual and motor areas after enriched foreign language learning

Authors: *K. M. MAYER[1], I. B. YILDIZ[1,2], M. MACEDONIA[1,3], K. VON KRIEGSTEIN[1]; [1]MPRG Neural correlates of human communication, Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany; [2]Dept. d'Etudes Cognitives, Col. de France, Paris, France; [3]Johannes Kepler Univ. Linz, Linz, Austria

Abstract: Learning foreign languages in adulthood is time consuming and effortful. In education settings, learning is often based on verbal input such as hearing the language and reading text. Previous studies showed that enriching foreign language learning material with additional visual or motor information (e.g. viewing pictures or conducting pantomimic gestures) leads to significantly better learning outcome than exclusively verbal learning. It is unclear how enrichment can improve learning performance. At present, there are two theories explaining the enrichment benefits at the brain level. One attributes the enrichment benefits to increased activation in brain areas specialized for semantic processing. The other one attributes the enrichment benefits to recruitment of brain areas that are specialized in processing the provided enrichment. We conducted two behavioral and two fMRI studies to adjudicate between the two theories. We taught adults vocabulary in an artificial language with exclusively verbal and enriched learning material. We monitored learning progress with vocabulary tests. Furthermore, we conducted a vocabulary test during fMRI after vocabulary learning was completed.

Behaviorally, we found beneficial effects of both motor and visual enrichment. Two and six months after learning participants recalled significantly more words learned with self-performed gestures and pictures than words learned verbally or with other types of enrichment. At the brain level, multivariate pattern classifiers revealed that visual and motor areas carry information about the enrichment conditions during learning. Our findings support the theory that attributes enrichment effects to enhanced activation in areas specialized in processing enrichment.

Title: Identifying hub structures of emotional speech in the human brain

Authors: *S. A. KOTZ[1], S. K. SCOTT[2], S. ROSEN[3], J. OBLESER[4];
[1]Neuropsychology, Max-Planck Inst. Cog & Brain Sci., Leipzig, Germany; [2]Insitute of Cognitive Neurosci., [3]Speech, Hearing & Phonetic Sci., UCL, London, United Kingdom; [4]Auditory Cognition, MPI for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Two distinct dimensions convey emotional content of speech: A verbal (segmental) “what” dimension and a non-verbal (prosodic) “how” dimension. As these two dimensions occur in tandem, it necessitates core structures in the brain to fuse them. By now, an extended brain network subserving emotional speech has been suggested1,2,3. However, controversy persists as to (i) which of these brain areas are driven by the “what“ and “how” aspects of emotional speech, and (ii) which candidate areas support their integration. Relevant hub structures of emotional speech should therefore not only be sensitive to the respective dimensions, but should also exhibit joint sensitivity to both. We applied acoustic manipulations previously employed in speech intelligibility research4 to dissociate segmental from prosodic information. These manipulations entailed rotated speech5 and vocoded speech6 next to intelligible speech. This allows identifying brain areas that dissociate and or fuse the “what” and “how” dimensions of emotional speech, with specific emphasis on the anterior superior temporal gyrus/sulcus (STG/STS) featuring prominently as a hub of emotional speech integrating the “what” and “how” information.

Methods
In 3-T (Bruker) functional magnetic resonance imaging (fMRI) using temporally sparse sampling, normal hearing participants (N=16, 8 female) passively listened to German sentences spoken with emotional and neutral prosody in a pseudo-randomized order of acoustic degradation formats (intelligible, rotated, noise-vocoded, and rotated+noise-vocoded).
Results
Contrasting emotional > neutral speech for (1) intelligible-vocoded speech and (2) intelligible-rotated speech, a conjunction analysis revealed hub structures in the bilateral anterior STS , the right ventrolateral orbitofrontal cortex (OFC), the cerebellum, and the left parahippocampal gyrus. We confirm a clear distinction of "how" (STG) and "what" (STS) dimensions of emotional speech bilaterally.
Conclusions
The application of acoustic manipulations allowed identifying hub areas of emotional speech. Next to these core areas, distinct fingerprints of "what" and "how" information were identified. The current results confirm recent evidence on emotional speech2 and emphasize the importance of the anterior temporal cortex, an area of recent controversy2,7 in emotional speech.

Title: Selective grammatical comprehension deficits in non-fluent/agrammatic primary progressive aphasia

Authors: D. CHARLES, C. OLM, J. POWERS, S. ASH, D. J. IRWIN, C. T. MCMILLAN, K. RASCOVSKY, *M. GROSSMAN;
Dept Neurol., Univ. Pennsylvania Sch. Med., PHILADELPHIA, PA

Abstract: Grammatical comprehension difficulty is a necessary characteristic of the non-fluent/agrammatic variant of primary progressive aphasia (naPPA), also known as progressive non-fluent aphasia. However, clinical measures of grammatical comprehension are few, and those available are controversial. We developed a novel, two-alternative, forced-choice sentence-picture matching task sensitive and specific for grammatical comprehension, and examined this comparatively in 39 PPA patients (naPPA=12, logopenic variant PPA (lvPPA)=15, and semantic variant PPA (svPPA)=12) 27 non-aphasic patients with behavioral-variant frontotemporal degeneration (bvFTD), and 12 healthy controls. We also assessed the neuroanatomic basis for grammatical comprehension deficits in a subset of these patients with volumetric grey matter (GM) atrophy and whole-brain fractional anisotropy (FA) in white matter (WM) tracts. We found that patients with naPPA have selective difficulty understanding cleft sentence structures (e.g. “It was girls that boys chased”), while all PPA variants and bvFTD patients were impaired with more complex, center-embedded sentences (e.g. “Girls that boys chased were tall”). All patients had more difficulty with object-relative than subject-relative sentences. We also found that bvFTD patients are selectively impaired understanding sentences involving a strategically-placed adjectival phrase stressing short-term memory. Regression analyses related grammatical comprehension difficulty in naPPA to left anterior-superior temporal GM atrophy and reduced WM FA in anterior corpus callosum and inferior frontal-occipital fasciculus. Difficulty with center-embedded sentences in other PPA variants was related to other brain regions implicated in a large-scale sentence processing network. These findings emphasize a distinct grammatical comprehension deficit in naPPA, and associate this with interruption of a frontal-temporal neural network involved in sentence processing.

Title: Modulation of phonological selection on interhemispheric connectivity

Authors: *C.-Y. WU[1], M.-H. R. HO[1], K. MATSUO[2], W.-Y. I. TSENG[2], C.-W. HUE[3], S.-H. A. CHEN[1];

Abstract: Although language is known as a lateralized function, much research has reported bilateral recruitment of the frontal, parietal, and ventral occipito-temporal regions during Chinese phonological processing. We used functional magnetic resonance imaging with dynamic causal modeling (DCM) to examine interhemispheric connectivity within the bilateral language network. Thirty right-handed Chinese speakers (15 males; age M = 22.5, SD = 2.76) performed an event-related homophone judgment task on pairs of characters - many-to-one pairs (MO: characters with more than one sound) or one-to-one pairs (OO: characters with one sound) - in a 3T scanner. Image analyses were performed using SPM8 and DCM10. Only homophonic pairs (i.e., MO_H and OO_H) were considered in the current analyses. Volumes-of-interest were selected from 8 regions: inferior frontal gyrus (IFG), middle frontal gyrus (MFG), inferior parietal lobule (IPL), and fusiform gyrus (FG) bilaterally. The optimal model was determined from 16 models using the random-effects family-level Bayesian model selection method in a hierarchical structure with 4 levels. At each level, 4 models with different interhemispheric modulatory connections between each pair of bilateral FG, IFG, MFG, and IPL were compared sequentially. MO_H was found to recruit more activation than OO_H in the right MFG, and bilateral IFG and IPL (Fig. 1A), which could be attributed to higher loadings of orthography-to-phonology transformation, phonological selection and verbal working memory taxed by MO pairs. Within the selected model, however, only OO_H but not MO_H had significant modulations on the intra- and interhemispheric connections among IFG, MFG, and IPL (as illustrated in Fig. 1B). The results showed that reading MO_H pairs was associated with increased regional activity but reduced intrinsic couplings between activated regions. This may suggest that while the distributed network of activity may serve as the baseline for phonological processing, regional activity is enhanced and tends to work more independently as task demands increase.

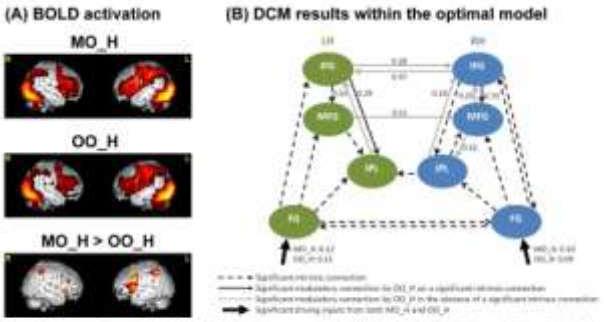

Figure 1. Summary of results. N = 30. (A) Group activation maps of the MO_H and OO_H conditions and the contrast of MO_H > OO_H, p < .005 (uncorrected). MO_H: many-to-one homophonic pairs, R and L: view at the right and left hemispheres, respectively. (B) The significant intrinsic connections, modulatory effects, and driving inputs within the optimal model selected using the family-level Bayesian model selection method in a hierarchical structure (p < .05). Significant intrinsic connections were all positive. Values represent the average parameter estimates (in Hertz) of the significant modulations and driving inputs. IFG: inferior frontal gyrus; MFG: middle frontal gyrus; IPL: inferior parietal lobule; FG: fusiform gyrus. Green regions are in the left hemisphere (LH) and blue in the right hemisphere (RH).

Title: Onomatopoeias and mimetic words represent mirror system but generate different mental images: An fMRI study

Authors: *K. YAOI[1], T. MINAMOTO[2], M. OSAKA[2], N. OSAKA[1];
[1]Grad. Sch. of Letters, Kyoto Univ., Kyoto, Japan; [2]Grad. Sch. of Human Sci., Osaka Univ., Osaka, Japan

Abstract: In our daily lives, we often use a variety of onomatopoeias (hearing-based) and mimetic (visual movement-based) words. By using these words, we can enrich our expression during conversation and tell others easier our conscious quality by mirroring external world. Recently, some neuroimaging studies have investigated neural basis of onomatopoeias and mimetic words (Osaka et al. 2003), but there have been a few studies observing brain activation during image generation evoked by the words while keeping their eyes closed. Onomatopoeia and mimetic words are the unique exception to a rule of language theory that indicates no direct

link between word's sound and meaning as Saussure (1916) argued. Here we show that they have a direct link between sound and meaning by providing mirror neuron-based brain imaging evidences. Furthermore, we hypothesized that onomatopoeia and mimetic word could be dissociated by showing an independent brain activation areas evoked by onomatopoeia and mimetic words each other. In MRI scanner, 15 participants were instructed to listen Japanese onomatopoeias ("sawa-sawa" (sound of leaves flowing together), "kata-kata" (rattling sound), "hyu-hyu" (sound of wind blowing), "byu-byu" (sound of strong wind blowing), "wan-wan" (barking of a dog) and "nya-nya" (cat mewing)), mimetic words ("yochi-yochi" (baby toddle), "yota-yota" (walk awkwardly), "yobo-yobo" (elderly's infirm walk), "noso-noso" (walk sluggishly), "sui-sui" (move unrestricted) and "suta-suta" (walk briskly)) or no-meaning words ("heyu-heyu", "mepe-mepe", and so on). Then, they were asked to imagine visual or auditory image for each word. fMRI results indicated that onomatopoeias showed greater activation in left inferior frontal gyrus (IFG), left middle temporal gyrus, left premotor cortex and left parahippocampal gyrus than no-meaning words. Mimetic words also indicated greater activation in bilateral IFG, bilateral temporo-parietal junction, premotor cortex, supplementary motor area and some other regions than no-meaning words. These greater activations of IFG and premotor cortex were probably indicated that both onomatopoeias and mimetic words evoked mirror neuron systems. Then, from the direct comparison between onomatopoeias and mimetic words, mimetic words evoked greater activation in mid-cingulate cortex and medial prefrontal cortex than onomatopoeias, whereas onomatopoeias showed no greater activation. These results may indicate that onomatopoeias and mimetic words generate different types of mental image, and there are some neural dissociation between onomatopoeias and mimetic words.

Title: Reading abilities in different languages are linked to variations in the same white matter microstructure

Authors: *M. ZHANG[1], C. CHEN[2], G. XUE[3], L. MEI[2], H. XUE[3], Q. DONG[3];
[1]Researching Backup Solutions, Beijing, China; [2]Univ. of California, Irvine, Irvine, CA; [3]Beijing Normal Univ., Beijing, China

Abstract: Recently, several studies discovered that white matter properties could be the efficient neural markers for reading abilities (Ben-Shachar et al., 2007; Friederici, 2009; Vandermosten et al., 2012). However, no study has evaluated the relationship between white matter connectivity and reading abilities across different languages. Using DTI, current study investigated the common and divergent relationship between white matter integrity indexed by fractional anisotropy (FA) and native language reading abilities.
95 students (age range: 18-30 years, mean age=20.8, SD=2.3, 56 female and 39 male) in U.S and 89 students (age range: 19-25 years, mean age=21.7, SD=1.7, 45 female and 44 male) in China were scanned. Their native language reading abilities were tested. Image processing was carried out by FSL (version 4.1.8) and TBSS (v1.2).
In both samples, white matter integrity in several fiber bundles correlated with their native reading abilities (Table1). Further conjunction analysis revealed the FA of two white matter fiber bundles in the left hemisphere was positively associated with native language reading abilities of both English and Chinese speakers: the inferior fronto-occipital fasciculus/superior longitudinal fasciculus (IFO/SLF) which is part of the dorsal phonological processing stream of reading, and the uncinate fasciculus (UF)/IFO which is part of the ventral semantic processing stream (fig1). The comparison between English and Chinese readers showed that no white matter integrity contributed only to either English or Chinese reading but not the other. These results support a common white matter microstructural basis for reading across language systems.

Title: Silences in speech in primary progressive aphasia

Authors: *S. ASH, D. WEINBERG, J. HALEY, A. BOLLER, J. POWERS, C. MCMILLAN, M. GROSSMAN;
Neurol, Univ. Pennsylvania Sch. Med., PHILADELPHIA, PA

Abstract: Efforts to characterize variants of primary progressive aphasia (PPA) on the basis of language-based clinical characteristics have met with difficulty. Nonfluent/agrammatic PPA (naPPA) has been described as “effortful,” although the nature of effortfulness is not well defined. These patients also have grammatical difficulty. Semantic variant PPA (svPPA) is distinguished by impairments of semantic memory and object knowledge, and they have difficulty with confrontation naming.
The present study quantifies the pattern of pauses in the speech of patients with PPA to determine how these pauses contribute to the apparent effortfulness of speech and how they relate to grammatical impairments and word-finding difficulty.
We studied 31 patients, including 18 with naPPA and 13 with svPPA, and 19 healthy seniors. A semi-structured speech sample was analyzed for pauses longer than 2.0 sec within utterances. We assessed the occurrence of these pauses in environments preceding or within a noun phrase (NP) and preceding or within a verb phrase (VP). Voxel-based morphometry was used to relate

gray matter atrophy to measures of performance.
naPPA patients produced long pauses more than other patient groups and paused in all environments indiscriminately, contributing to their slowed speech. Only naPPA had significant pauses related to verb phrases. svPPA patients paused more frequently in NPs compared to VPs. Pausing in the patient groups was related to differing cortical regions of the left hemisphere: to prefrontal and inferior temporal regions in naPPA and to temporal regions in svPPA.
The frequent occurrence of long pauses within utterances contributes to the effortfulness of speech in naPPA patients. Unlike the other groups, naPPA patients pause in the production of verb phrases as much as in the production of noun phrases, and this is linked to their grammatical difficulty. svPPA patients pause more in noun phrases than in verb phrases, which may be related to their semantic impairments. svPPA is relatively spared in verb phrase production as measured by long pauses.

Title: Language context modulates reading route selection: An electrical neuroimaging study

Authors: *K. BUETLER[1], D. DE LEÓN RODRÍGUEZ[1], M. LAGANARO[2], R. MÜRI[3], L. SPIERER[1], J.-M. ANNONI[1];
[1]Dept. of Med., Univ. of Fribourg, Fribourg, Switzerland; [2]Fac. of Psychology and Educational Sci., Univ. of Geneva, Geneva, Switzerland; [3]Dept. of Neurol., Univ. of Bern, Bern, Switzerland

Abstract: Introduction: The Orthographic Depth Hypothesis (Katz & Feldman, 1983) posits that different reading routes are engaged depending on the type of grapheme/phoneme correspondence of the language being read. Shallow orthographies (e.g. German and Italian) with consistent grapheme/phoneme correspondences favor encoding via non-lexical pathways, where each phoneme is sequentially mapped to its corresponding grapheme. In contrast, deep orthographies (e.g. French and English) with inconsistent grapheme/phoneme correspondences favor lexical pathways, where phonemes are retrieved from specialized memory structures. This hypothesis, however, lacks compelling empirical support. The aim of the present study was to

investigate the impact of orthographic depth on reading route selection using a within-subject design.
Method: We presented the same pseudowords (PWs) to highly proficient bilinguals and manipulated the orthographic depth of PW reading by embedding them among two separated German or French language contexts, implicating respectively shallow or deep orthography. High density electroencephalography was recorded during the task.
Results: The topography of the event-related potentials to identical PWs differed 300-360 ms post-stimulus onset when the PWs were read in different orthographic depth context, indicating distinct brain networks engaged in reading during this time window. The brain sources underlying these topographic effects were located within left inferior frontal (German >French), left superior parietal (French > German) and left anterior cingular areas (German > French).
Conclusion: Reading in a shallow context favors non-lexical pathways, reflected in a stronger engagement of frontal phonological areas in the shallow versus the deep orthographic context. In contrast, reading PW in a deep orthographic context recruits "unnatural" non-lexical pathways, reflected in a stronger engagement of visuo-attentional parietal areas in the deep versus shallow orthographic context. These collective results support a modulation of reading route selection by orthographic depth.

Title: Phonemic versus allophonic status modulates early brain responses to language sounds: An MEG/ERF study

Authors: *A. H. NIELSEN[1,2], L. GEBAUER[1], W. B. MCGREGOR[2], M. WALLENTIN[1,3]; [1]Ctr. of Functionally Integrative Neurosci. (CFIN), [2]Dept. of Aesthetics and Communication - Linguistics, [3]Ctr. for Semiotics, Aarhus Univ., Aarhus C, Denmark

Abstract: Objective: An early component of the auditory event-related potential (ERP), the mismatch negativity (MMN/MMNm), has been shown to be sensitive to native versus non-native language sounds (Brandmeyer et al., 2012; Kazanina et al., 2006; Näätänen et al., 1997); i.e. sensitive to phonemic versus allophonic sound contrasts. So far this has only been attested between languages. In the present study we wished to investigate this effect within the same language: Does the same sound contrast that is phonemic in one environment, but allophonic in another, elicit different MMNm responses in native listeners?
For this purpose we employed the /t/-/d/-contrast in Danish (heavily aspirated versus unvoiced; only realized syllable-initially, not in syllable coda (Grønnum 2005)). Thus, [tæ] and [dæ] are separate words in Danish ('take' and 'then', respectively), whereas [æt] and [æd] are not (both meaning 'that').
This allowed us to manipulate the phonemic/allophonic status of exactly the same sound contrast (/t/-/d/) by presenting it in different immediate phonetic contexts (preceding a vowel (CV) versus following a vowel (VC)), in order to investigate the auditory event-related fields of native Danish listeners to a sound contrast that is both phonemic and allophonic within Danish.
Methods: Relevant syllables were recorded by a male native Danish speaker. The stimuli were then created by cross-splicing the sounds so that the same vowel [æ] was used for all syllables, and the same [t] and [d] were used for the relevant syllables. The final stimuli were validated by two native Danish listeners, ignorant to the design of the experiment. MEG was recorded from 17 native Danish listeners (5 females) while watching a silent movie and listening to the auditory stimuli. [tæ] and [æt] acted as standards, and [dæ] and [æd] thus as deviants, respectively. Data were preprocessed using Elekta's MaxFilter software and SPM8, all statistical analyses were conducted in sensor-space using SPM8.
Results: Focusing on the 150-300 ms time period after stimulus onset (typical MMNm time range for language sound contrasts), only the phonemic [tæ]-[dæ]-contrast showed significant effects (FWE-corrected at the cluster-level). Comparing the differences of the two contrasts, the phonemic [tæ]-[dæ]-contrast showed a significantly larger difference around 250 ms after stimulus onset than the allophonic [æt]-[æd]-contrast (FWE-corrected at the cluster-level).
Conclusion: By manipulating the immediate phonetic context, we demonstrate that native Danish listeners' early brain responses to exactly the same language sound contrast are modulated by its phonemic versus allophonic status.

Title: Role of posterior temporal lobe for language production revealed by transcranial magnetic stimulation study

Authors: *Y.-H. CHOI, H. PARK, N.-J. PAIK;
Rehabil. medicine, Seoul Natl. Univ. Bundang Hosp., Seongnam, Korea, Republic of

Abstract: Despite studies based on functional brain imaging suggest that superior temporal gyrus (STG) related pathway is engaged in phonological process, whereas middle temporal gyrus (MTG) related pathway in lexical-semantic one, the precise role of posterior temporal lobe is not sufficiently elucidated.
Neuro-navigation guided repetitive transcranial magnetic stimulation (rTMS) was used to identify the role of posterior temporal lobe during auditory language processing in the intact human brain and to clarify the functional relevance of the left posterior STG and MTG during auditory repetition and lexical decision tasks.
Twelve healthy volunteers were tested with lexical decision task (on word or pseudoword) and auditory repetition task (on word and sentence) prior to and during 3 sessions of rTMS or sham stimulation. We applied low-frequency rTMS to posterior STG and posterior MTG for 10 minutes in a random order. Reaction time and error rates for each task measured prior to and during stimulation were compared.
Stimulation of left posterior MTG significantly slowed response time of lexical decision task from 478.9±56.5 to 583.1±80.0 ms (p=0.008) (figure). However, stimulation over left posterior STG or MTG did not affect response time or error rates of auditory repetition task.
The present results suggest that left posterior MTG is engaged in lexical decision process. Neuro-navigation guided rTMS could be used to identify the functional role during language process.

Title: Reading without speech sounds: VWFA and its connectivity in the congenitally deaf

Authors: X.-S. WANG[1], A. CARAMAZZA[2,3], M. V. PEELEN[3], Z. HAN[1], Y. BI[1];
[1]Natl. Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China; [2]Dept. of Psychology, Harvard Univ., Cambridge, MA; [3]Ctr. for Mind/Brain Sci., Univ. of Trento, Rovereto, Italy

Abstract: The connections with language regions have been commonly assumed to contribute to the placement and development of the visual word form area (VWFA). In this study, we specifically examined the effects of connections with auditory speech regions in shaping VWFA by investigating the VWFA location distribution, activation strength, and its functional connectivity pattern in congenitally deaf participants. We found that the locations and activation strength of the VWFA in congenitally deaf participants were highly comparable to those of hearing controls. Furthermore, while the congenitally deaf group showed reduced resting-state functional connectivity between the VWFA and the auditory speech area in left anterior superior temporal gyrus, a similar intrinsic functional connectivity pattern between the VWFA and a fronto-parietal network was observed in the two groups. Together, these results suggest that auditory speech experience has consequences for aspects of the word form-speech sound correspondence network, but that such experience did not modulate VWFA's placement or response strength. Instead, the role of the VWFA might be to provide a representation that is suitable for mapping visual word forms onto language-specific gestures, be they speech or manual signs, without the need to construct an aural representation.

Title: The role of high gamma power and theta- and alpha-phase coherence in brain network dynamics during language production

Authors: *J. C. CASE[1], E. CHANG[2], N. E. CRONE[3], J. PARVIZI[4,5], R. T. KNIGHT[1,6], A. Y. SHESTYUK[1];
[1]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [2]Dept. of Neurology, Surgery, and Physiol., San Francisco, CA; [3]Dept. of Neurology, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Dept. of Neurol. and Neurolog. Sci., Palo Alto, CA; [5]Stanford Human Intracranial Cogntive Electrophysiology Program, Stanford Sch. of Med., Palo Alto, CA; [6]Dept. of Psychology, Univ. of California, Berkeley, CA

Abstract: Growing evidence suggests that the interaction between high- and low-frequency brain rhythms and within-frequency phase coherence among brain areas are essential mechanisms for network communication and information transfer among brain regions. Specifically, whereas neuronal activity within the high gamma range (70-150 Hz) has been shown to index local cortical activation, theta- (4-7 Hz) and alpha- (8-12 Hz) phase coherence across areas has been shown to reflect larger network dynamics. However, the interplay between these proposed mechanisms of neuronal information coding during cognitive tasks remains largely unexplored in humans. We examined the role of high gamma activation, as well as theta- and alpha-phase coherence during performance of two linguistic tasks with and without lexical

search (i.e., word repetition vs. word generation). We employed intracranial electrocorticography (ECoG), a unique technique that provides superior temporal resolution and reduced volume conduction. ECoG signals were recorded in 4 subjects with intractable epilepsy (3 left and 1 right fronto-temporal grids). Participants performed two tasks: in the word repetition task, patients were asked to repeat aurally presented words of varying lengths, and in the word generation task, patients had to generate a semantic antonym to each aurally presented word. The generation task was more cognitively demanding, as evidenced by more errors and non-completions as well as longer reaction times ($p < 0.01$). The generation task elicited greater increases in high gamma over the middle frontal and inferior frontal gyri, duration of which predicted reaction times ($p < 0.01$). Similarly, greater theta- and alpha-coherence between prefrontal and other brain regions, including temporal, motor, and parietal cortex, was evident in the generation relative to repetition task. Theta- and alpha-phase coherence was restricted to temporal and parietal areas in the repetition task. These findings suggest that high gamma activity and phase coherence support network communications among prefrontal, temporal, motor, and parietal areas during performance of complex linguistic tasks.

Title: The μ-opioid system optimizes human reward behavior, a drift diffusion model account

Authors: *M. EIKEMO[1], G. BIELE[2], F. WILLOCH[3], S. LEKNES[2];
[2]Psychology, [3]Med., [1]Univ. of Oslo, Oslo, Norway

Abstract: Balancing speed and accuracy of decisions, identifying the ‘best’ option when several rewards are available, and expending effort through enhancing attention to options, are all strategies for improving value based decisions. Computational models, like the drift diffusion model (DDM, Ratcliff & McKoon, 2008, Neural Comput), allow us to parse decision making into these constituents based on reaction time and accuracy data. The model permits us to estimate speed-accuracy trade-off (decision boundary, a), overall task performance (drift rate, v), and behavioral preference for one alternative (bias, b). This information can improve

understanding of reward processing in the human brain, and how reward behavior is optimized. While rodent studies show that the μ-opioid system is essential for several aspects of reward behavior, less is known about the role of the μ-opioid system for reward processing in the healthy human brain. Combining psychopharmacology and computational modeling, we investigated μ-opioid effects on reward behavior in 30 healthy, opioid naïve males. We predicted that μ-opioid receptor (MOR) agonism would enhance, and MOR antagonism would impair, reward behavior in humans. A two-alternative decision making task in which correct responses for one response alternative were more frequently rewarded (skewed reward schedule) was used. Three versions of the reward task were implemented using a randomized, placebo-controlled, double-blind cross-over design. Participants received a MOR agonist (morphine, 10mg), a non-selective opioid receptor antagonist with high MOR affinity (naltrexone, 50mg) or placebo on three separate days. Response data were analyzed using Bayesian estimation of DDM parameters (Wiecki et al., 2012, SfN abstract). Both the overall task performance (v) and preference for accuracy over speed (a) were higher in the agonist and lower in the antagonist condition compared to placebo. The overall preference for the most frequently rewarded response option (b) was higher in the agonist condition than in the placebo and antagonist conditions. These results suggest that the endogenous μ-opioid system guides reward behavior in humans by increasing motivation and attentiveness when rewards are available. The μ-opioid system may also influence the selection of the most valuable response option. Overall, our results confirm the hypothesis that the endogenous μ-opioid system optimizes human reward behavior.

Title: A drift-diffusion model of decision-making in dynamic environments

Authors: *C. M. GLAZE[1], J. I. GOLD[2];
[2]Neurosci., [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Many kinds of decisions are based on evidence that is sampled sequentially over time to reduce uncertainty about the identity of the source of the evidence. Models of this kind of decision-making typically make the simplifying assumption that the source does not change

during the sampling process, making all sampled evidence relevant to determining the source. However, this assumption does not hold in real-world settings in which abrupt changes in the environment render past evidence irrelevant to future decisions. The goal of this study is to take well-established, sequential-sampling frameworks that have been applied to static, two-alternative forced-choice (2AFC) decision problems and extend them to account for dynamic environments that undergo such abrupt changes.

Our starting point is the drift-diffusion model (DDM), in which noisy evidence is accumulated over time to identify which of two possible sources generated the evidence. Here, we extend the model to account for abrupt change-points in the identity of the source that can occur during the decision process. The model is derived from the Bayes optimal solution and is related to estimation in a hidden Markov process. As in certain forms of DDM, the decision variable is the logarithm of the ratio of the conditional probabilities of the two options, given the accumulated evidence. The model forms sequential updates of this decision variable as a stochastic difference equation with a nonlinear term that accounts for a possibly time-varying generative process; i.e. a probability>0 that the "correct" decision will change at any given time (hazard rate). When the probability is zero, the nonlinear term drops out and the model reduces to classical DDM.

We support the model with pilot data from a 2AFC task in which human subjects decide which of two sources on a computer screen generated a given spatial data point on the current trial. After ~200-300 trials, subjects begin biasing their decisions by an amount that is proportional to the generative hazard rate, combining the trial-dependent prior probability of each source with the current likelihood in a nearly optimal manner. After correctly identifying change-points, subjects demonstrate immediate "flips" in the decision bias, the magnitude of which reflects the amount of certainty that a change-point occurred. This framework represents a new way to investigate how we form binary decisions in noisy, dynamic environments.

Title: Neural activity build-up during decision-making is not caused by evidence accumulation but by a growing urge to act

Authors: *P. E. CISEK, D. THURA;
Univ. of Montreal, Montreal, QC, Canada

Abstract: Many studies, including extracellular recordings in monkeys and neuroimaging in humans, have reported that during decision-making tasks, neural activity builds-up at a rate related to the strength of sensory evidence. This is usually interpreted as the gradual accumulation of evidence to a decision threshold, often called the "bounded accumulation" or "drift diffusion" model. However, an alternative explanation exists: that sensory evidence is computed quickly and the neural activity build-up is instead due to a growing signal that reflects the urge to commit to an action. In most conditions previously tested, sensory information is constant over time, which renders these models mathematically identical and therefore indistinguishable. However, recent studies aimed at distinguishing these models (by presenting information that changes over time) strongly support the latter, "urgency-gating" model. Here, we present the mathematical foundation for why the urgency-gating model may be better suited to explain decision-making behavior in general. First, it implements a dropping criterion of accuracy, which achieves a higher reward rate than any setting of a constant criterion (as usually assumed by bounded accumulation). Second, it takes account of the fact that sequential samples are often partially redundant, and that estimates of evidence should primarily emphasize novel information. In simple tasks, an approximation of this optimal policy may be achieved by low-pass-filtering sensory input and then combining it with a growing urgency signal. We summarize behavioral and neural results of three studies which strongly suggest that sensory information is not integrated over time, but simply low-pass-filtered and combined with urgency. In summary, we suggest that despite the widespread acceptance of the bounded accumulation model, urgency-gating may offer a better explanation of decision-making mechanisms in a wide variety of tasks.

Title: Tracking the integration of time-varying sensory evidence with human EEG

Authors: *K. E. KAYE, E. F. ESTER, J. T. SERENCES;
UCSD, La Jolla, CA

Abstract: Theoretical and experimental work suggests that perceptual decision making is an integrative process: information about a noisy stimulus is continuously sampled and integrated until an internal criterion is reached. In a recent paper, O'Connell and colleagues (Nat Neurosci 15:1729-35) described a human ERP component - termed the centro-parietal-positivity, or CPP - that appears to track the temporal evolution of a decision variable in a gradual target detection task. However, it is unclear whether momentary changes in CPP amplitude track temporal fluctuations in the "strength" of sensory evidence, as would be expected of a decision variable. To examine this possibility, we recorded EEG while subjects viewed arrays of randomly oriented and spatially overlapping light and dark bars. During each trial, we gradually increased the percentage of light or dark bars that shared a common orientation (specifically, -45 or 45° with respect to vertical) up to an asymptotic limit (16-64% in increments of 16%), and subjects were instructed to report which set of bars (i.e., light or dark) shared a common orientation as quickly and accurately as possible. Critically, the percentage of iso-oriented bars in the target varied over the course of a trial. We reasoned that if the CPP reflects the temporal evolution of a decision variable, then momentary changes in the amplitude of this component should covary with changes in the strength of sensory evidence. Our data accord with this view. Specifically, we observed a large CPP component that reached a peak amplitude near the mean response latency for a given task difficulty level (i.e., 16-64%). Peak CPP amplitudes were substantially larger during correct relative to incorrect trials, but did not vary as a function of task difficulty. Critically, CPP slope increased monotonically with gradual increases in stimulus strength, consistent with the view that momentary fluctuations in the amplitude of this component reflect real-time changes in sensory evidence. These findings provide additional evidence suggesting that the CPP tracks the temporal evolution of a decision variable.

Title: The role of the subthalamic nucleus in multiple alternative perceptual decision-making revealed by 7T structural and functional MRI

Authors: *M. C. KEUKEN[1,2], L. VAN MAANEN[1], R. BOGACZ[3], A. SCHAEFER[2], J. NEUMANN[2], R. TURNER[2], B. U. FORSTMANN[1,2];
[1]UvA, Amsterdam, Netherlands; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [3]Univ. of Bristol, Bristol, United Kingdom

Abstract: In our everyday life we constantly have to make decisions between many different choice options. Recently, quantitative mathematical and neurocomputational models have been developed that make predictions about brain structures involved in decision-making with multiple alternatives. One such model is the Multiple Sequential Probability Ratio Test (MSPRT), which predicts that activity in the subthalamic nucleus (STh), a small structure in the basal ganglia, becomes more active with an increasing number of choice alternatives1,2. However, Frank et al. suggest that such an increase in STh activity might be caused by the amount of conflict between choice alternatives rather than the number of choices3.
The present study set out to test these two hypotheses using ultra-high 7T structural and functional magnetic resonance imaging in healthy human subjects. By simulating the MSPRT model, we generated specific predictions that allowed us to disentangle the influence of the number of alternatives and/or the amount of conflict between choice alternatives. These model predictions were then compared to the observed behavior as well as the activation pattern in the STh. Preliminary results are in line with the first hypothesis in that the activity in the STh is increased with more choice alternatives independent of the level of conflict.

Title: Perceptual decisions in the presence of relevant and irrelevant sensory evidence

Authors: *J. DITTERICH;
Ctr. for Neurosci. & Dept. of Neurobiology, Physiol. & Behavior, Univ. of California, DAVIS, CA

Abstract: In everyday life, perceptual decisions have to be made in the presence of both relevant as well as irrelevant sensory information. Thus, successful decisions require a separation of decision-relevant from irrelevant sensory evidence. To characterize how perceptual decisions are made in the presence of irrelevant sensory evidence, we asked human observers to make decisions about two-component random dot motion stimuli. On every trial, a fraction of the dots moved coherently along a horizontal axis, either leftward or rightward, while another fraction of the dots moved coherently along a vertical axis, either upward or downward. Only one of these two motion components was decision-relevant on any given trial, randomly selected and indicated by a cue at the beginning of the trial. Two choice targets were presented along a diagonal axis, and the subjects were instructed to make an eye movement to the target that was closest to the relevant direction of motion, while ignoring the irrelevant motion component. While our subjects were able to ignore the irrelevant information to a large degree, their choices and response times were still influenced by it, which allowed us to test computational models of perceptual decision making in the presence of irrelevant sensory evidence. The data pattern, including choices, mean response times, and the shape of response time distributions, is surprisingly well described by an integration-to-threshold mechanism for perceptual decisions between two alternatives, which is driven by a linear combination of the decision-relevant and irrelevant net sensory evidence signals. This suggests that the separation of decision-relevant from irrelevant sensory evidence can be characterized as a strong linear gain modulation.

Title: Dynamic calibration of the influence of priors and sensory input for perceptual estimation

Authors: K. KRISHNAMURTHY, M. NASSAR, S. SARODE, J. CHEN, *J. I. GOLD;
Dept Neurosci, Univ. Pennsylvania, PHILADELPHIA, PA

Abstract: Perception of an ambiguous sensory stimulus often depends on both sensory information and prior expectations about the presence or identity of the stimulus. Numerous studies support the idea that the brain follows Bayesian inference for a broad range of perceptual problems by combining each source of information in proportion to its reliability. However, this idea has typically been tested under conditions in which the reliability of prior expectations is relatively stable, which is often not the case in dynamic, real-world environments. More realistically, the underlying statistics of the environment can undergo changes that alter the reliability of prior expectations. Here we tested how abrupt, unexpected changes in the reliability of expectations about a stimulus affected the extent to which those expectations influence perception.

We used a novel sound-localization task to measure the influence of dynamically adjusted prior expectations on perceptual localization reports by human subjects. The location of a virtual sound source was varied randomly from trial-to-trial about a mean value, and on certain, randomly chosen trials, the location of the mean itself changed abruptly. On each trial, the subjects indicated both their prior expectation about the location of the sound before listening to the sound and the perceived location of the sound location afterwards.

We found that: 1) following a change-point in the virtual location of the sound source, when the prior reflected irrelevant data, the prior had the weakest influence on perceived location, and 2) on subsequent trials, both the reliability of the prior and its influence on perceived location increased steadily. These effects are consistent with an ideal-observer model describing the relative influence of priors and sensory evidence on perception in this environment. The results indicate that the brain is capable of rapidly adjusting the influence of bottom-up and top-down information on perception in a dynamic environment. Ongoing work is testing whether these effects are encoded by the pupil-linked arousal system, which we have shown can contribute to the updating of prior beliefs in a changing environment

Title: A rational analysis of sequential effects in perceptual decision-making: Fluctuations in RT and accuracy driven by prior bias due to recent trial history

Authors: *S. ZHANG[1], A. J. YU[2];
[1]Dept. of Cognitive Sci. MC 0515, UCSD, La Jolla, CA; [2]Dept. of Cognitive Sci., Univ. of California San Diego, La Jolla, CA

Abstract: Human subjects exhibit a sequential effect in many behavioral tasks: they respond more rapidly and accurately to stimuli that reinforce, rather than violate, a local pattern in stimulus history. For example, in 2-alternative forced choice (2AFC) tasks, despite a randomized design that deliberately de-correlate stimuli from trial to trial, subjects pick up transient sequences of repetitions and alternations; their responses are facilitated when a stimulus retains the pattern (e.g. AAAAA followed by A, ABABA followed by B), and are impeded when the stimulus violates the pattern (e.g. AAAAA followed by B, ABABA followed by A). Yu and Cohen (2009) used a normative Bayesian model, known as the dynamic belief model (DBM), to demonstrate that sequential effects may reflect adaptive learning in a changing environment. They showed that non-stationary prior belief can induce observed sequential effects in experiments, while using an otherwise Bayes-optimal algorithm. In this study, we examine the explicit consequence of a non-stationary beliefs on discrimination reaction time and accuracy in a 2AFC task. We model the relationship between a biased prior about stimulus type, generated by DBM, and speed/accuracy using a well-studied perceptual decision model, the drift-diffusion model (DDM). We jointly estimate the parameters for DBM and DDM in order to account for subjects' behavioral data, and show that the joint model accounts for trial-by-trial fluctuations in reaction time and accuracy due to recent trial history. Our result provide an explanation for the prevalence and persistence of sequential effects: the large behavioral benefit of being able to extract patterns when they exist versus the relatively small cost of finding them in error when the world is unpredictable.

Title: Brain activity during perceptual decision-making in the visual domain

Authors: *B. LAMICHHANE[1], B. ADHIKARI[1], M. DHALAMA[1,2];
[1]Physics and Astronomy, Georgia State Univ., Atlanta, GA; [2]Neurosci. Institute, Georgia State Univ., Atlanta, GA

Abstract: The brain makes many moment-to-moment perceptual decisions, ranging from the identity of single objects to the relative timing of multiple external events, based on incoming sensory signals. How exactly does the brain integrate sensory information to arrive at these decisions? What are the brain mechanisms for making decisions when incoming sensory signals are weak or ambiguous? Using various perceptual categorization tasks at different difficulty levels in behavioral and fMRI experiments, we investigated the brain activity under the influence of ambiguity in object identity and motion directions from visual stimuli to answer these questions. In behavioral and fMRI experiments, thirty-three human volunteers performed visual categorization tasks, face-house and left -right motion discrimination. We found that the behavioral performance degraded and the reaction time increased with ambiguity or with task difficulty. A network of brain regions in the prefrontal and insular cortices showed elevated activity during difficult tasks and a network of early sensory visual regions showed elevated activity during easier tasks. We also evaluated how these regions and networks interact with each other. The differential brain activity in lower order sensory and higher-order decision-making brain regions and network activity between these networks provide us important clues about the functional organization of brain signals during perceptual decision-making processes.

Title: Distortion of perceptual beliefs by categorical decisions in the human brain

Authors: *V. WYART, P. DOMENECH, J. DRUGOWITSCH, E. KOECHLIN;
Ecole Normale Superieure, Paris, France

Abstract: Real-life decisions need to be made and revised iteratively in face of an ever-changing environment. In the lab, however, perceptual decisions are usually studied independently from one another using paradigms in which the state of the environment changes abruptly following each decision. In such situations, perceptual decision-making has been described by near-optimal Bayesian inference, where individual decisions arise from probabilistic beliefs formed through gradual accumulation of sensory evidence. Past studies in primates have identified the neural substrate of this inference process in parietal and frontal cortices. Here we designed a categorization paradigm in which successive decisions were prompted at different points of a single, gradual inference process. Computational modeling of human behavior in this task revealed that, although decisions considered in isolation were indeed near-optimal, each of them triggered a specific distortion of the underlying perceptual belief: an inflated likelihood of the chosen category, and a reduced difference in perceived likelihood among unchosen categories. We analyzed magnetoencephalographic (MEG) and functional magnetic resonance imaging (fMRI) signals obtained from healthy human subjects engaged in this task, and isolated in space and time a functionally connected network of frontal and parietal regions responsible for this decision-triggered distortion of perceptual beliefs. We propose that this interaction between executive and perceptual systems allows for the compression of parametric, multi-dimensional representations of sensory information into their two first moments: a discrete, categorical percept, and a confidence level associated with it. By simplifying perceptual beliefs, this compression may also enable abstract, task-dependent rules to be applied to these beliefs, which is a hallmark of human reasoning and intelligent behavior.

Title: Decision-making is influenced by a context-dependent urgency signal

Authors: *M. CARLAND[1], E. MARCOS[2], D. THURA[1], P. VERSCHURE[2], P. CISEK[1];
[1]Physiologie, Univ. De Montréal, Montreal, QC, Canada; [2]Catalan Inst. of Advanced Studies (ICREA), Univ. Pompeu Fabra, Barcelona, Spain

Abstract: Many models of decision-making propose that neural activity builds up to a threshold due to a gradual accumulation of sensory information. However, an alternative explanation is that sensory information is computed quickly, and the build-up in decision-related neural activity is due to a signal that grows over time, reflecting the urgency to make a choice. Distinguishing these models experimentally is difficult because they behave identically in most of the conditions previously tested. Here, we aim at distinguishing between them by presenting subjects with a Constant Motion Discrimination (CMD) task, in which subjects must decide on the direction of motion in a noisy random-dot motion display. Consistent with previous studies, we observed that brief motion pulses added to the stimulus have an effect on the subject's reaction times if presented early in the trial (<400ms) but not if they occur later. According to the bounded accumulation model, the reason late pulses do not have an effect is because the decision threshold has already been reached, and the decision has already been made. Following this reasoning, one would predict that if subjects adopt a slower decision policy by increasing the threshold, the effective window of pulses will expand to include both early and increasingly later pulses. In contrast, the urgency model predicts that as subjects adopt a slower decision policy the effective window for pulses will shift, rendering early pulses ineffective as later pulses become more effective.
We compared subjects' responses to motion pulses under two conditions; one in which CMD trials were blocked, and another in which identical CMD trials were interleaved among trials of a Variable Motion Discrimination (VMD) task in which the motion changes over time, leading subjects to wait longer before responding. We report three main results: First, analyses of the VMD trials showed that subjects' behavior was not consistent with bounded accumulation of the changing motion stimulus, but could be explained with the urgency gating model. Second, we found that average RTs in identical CMD trials were significantly slower when they were interleaved among VMD trials than when they were blocked together. Third, results to date suggest that the effective window for pulses in CMD trials shifts when they are interleaved among VMD trials, such that early pulses are no longer effective. These results can be accounted for by the urgency gating model, implemented as an attractor network whose dynamics are modulated by a growing urgency signal that is sensitive to broad task context.

Title: Human learning and decision-making in a bandit setting exhibits forgetful Bayes and myopic planning

Authors: *A. J. YU, S. ZHANG;
Cognitive Sci., Univeresity of California San Diego, La Jolla, CA

Abstract: We examine how humans actively explore a novel environment through repeated trials and noisy outcomes. We use a multi-armed bandit paradigm, where subjects choose one of four "arms" to pull on each trial and receive a binary outcome (win/lose). We compare human behavior to a variety of models that vary in their representational and computational complexity. Our result shows that subjects' choices, on a trial-to-trial basis, are best captured by a "forgetful" Bayesian iterative learning model (Yu & Cohen, 2009) in combination with a partially myopic decision policy known as Knowledge Gradient (Frazier, Powell, & Dayanik, 2008). This model accounts for subjects' trial-by-trial choice better than a number of other previously proposed models, including optimal Bayesian learning and risk minimization, epsilon-greedy, information maximization, and win-stay-lose-shift. It has the added benefit of being closest in performance to the optimal Bayesian model than all the other heuristic models that have the same computational complexity (all are significantly less complex than the optimal model). These results constitute an advancement in the theoretical understanding of how humans negotiate the tension between exploration and exploitation in a noisy, imperfectly known environment.

Title: Pre-stimulus alpha power biases perceptual decisions and confidences

Authors: *J. LANGE, T. BAUMGARTEN, A. SCHNITZLER;
Med. Faculty, Heinrich Heine Univ., Inst. of Clin. Neurosci. & Med. Psychology, Düsseldorf, Germany

Abstract: Previous studies have shown that perceptual decisions are based on the accumulation of sensory evidence, beginning at a starting point until a perceptual decision bound is reached. Less is known about decision making when sensory evidence is incomplete or ambiguous. Here, we studied decision making in a two-alternative forced-choice tactile discrimination task with ambiguous stimuli. We presented two brief electrical stimuli to 16 human subjects' left index finger with varying stimulus onset asynchrony (SOA) and subjects had to decide whether they perceived one or two stimuli. Additionally, they reported the subjective confidence of their decision. Individual SOAs were determined for which subjects reported to perceive one stimulus in ~50% of the trials (mean SOA: 25.9 ± 1.9). We used Magnetencephalography to study how inter-trial variability of subjective decisions is explained by fluctuations in ongoing and evoked brain activity.

Subjects made negligible errors for short SOA (0 ms, i.e. one stimulus) and long SOA (100 ms, i.e. two stimuli). For intermediate SOA (~25 ms), subjects perceived two stimuli in ~41% of all trials. Perception of two stimuli in trials with intermediate SOAs was predicted by significantly reduced alpha-band (8-12 Hz) power in contralateral somatosensory and posterior parietal regions -900 to -200 ms prior to stimulation. In addition, pre-stimulus alpha-band power predicted subjective confidence of the decision.

Trials with intermediate SOA and low pre-stimulus alpha-power showed significantly increased post-stimulus evoked fields (EF) relative to high power trials between 120-160 ms. Within this this time window , however, EF were highest when subjects unambiguously perceived two stimuli (SOA 100 ms) and lowest for unambiguously perceived one stimulus (SOA 0 ms).

We propose that the reported post-stimulus EF reflect a decision bound and pre-stimulus alpha-power reflects the (fluctuating) starting point of a decision process. Since the stimulation was short, sensory evidence could not be accumulated until the decision bound, reflected in variable decisions and lower confidence ratings. We suggest that this incomplete accumulation is influenced by pre-stimulus alpha-band power. Fluctuating alpha power shifts the decision variable towards either decision bound and thus spontaneously biases decisions.

Title: Practice in perceptual decision making produces structural changes in white and grey matter

Authors: *W. BOEKEL[1], E.-J. WAGENMAKERS[1], D. VAN RAVENZWAAIJ[2], B. U. FORSTMANN[1];
[1]Dept. of Psychology, Univ. of Amsterdam, Amsterdam, Netherlands; [2]Cognitive Psychology, Univ. of New South Wales, Sydney, Australia

Abstract: Recent studies have shown that practice on cognitive tasks is accompanied by structural changes in the brain. However, it is still unclear which latent cognitive processes are involved in practice on cognitive tasks, and its underlying structural changes. In the current study, human participants were trained on a random-dot-motion task. Practice effects on performance were decomposed in latent cognitive processes by estimating parameters from the drift diffusion model (DDM). The grey and white matter structural changes associated with these parameter changes were examined using voxel-based morphometry (VBM) and tract-based spatial statistics (TBSS). The results showed that practice increases the rate with which participants extract information from the stimulus. This increase was associated both with increases in grey matter density and with an increase of white matter fractional anisotropy in a visuomotor network.

Title: The impact of motion stimulus variability on the temporal dynamics of a target selection task

Authors: *E. LAM, J. F. KALASKA;
Univ. De Montreal, Montreal, QC, Canada

Abstract: Random-dot kinetogram (RDK) stimuli with different degrees of coherent motion in one of two opposite directions (Britten et al 1996) have been widely used in behavioral and neural studies of decision-making about action choices. Data suggest that this decision process is driven by the net motion coherence and is highly stochastic, with possible sources of variability in both the RDK stimuli and central processing mechanisms.

We used two types of modified RDK stimuli that paired different amounts of coherent motion signals in both opposite directions. In the "narrow-coherence" (NC) set, the vector component in the coherent direction replaced the background Brownian motion of these dots for that frame. In the "Brownian-drift" (BD) set, the coherent vector component was added to their Brownian motion, rather than replacing it. For each set, different amounts of net unidirectional coherent motion (0 - 32%) were superimposed on different amounts of base coherence signal (0 - 32%) moving simultaneously in both directions, resulting in combinations of coherences ranging from (0%/0%) to (64%/32%).

We previously showed that subjects' performance (RTs and target choices) was influenced primarily by the net motion coherence across the range of tested base coherences (Lam & Kalaska SfN 2012). However, at low net coherences (0-8%), subjects' RTs tended to decrease as base coherence increased (cf., Niwa & Ditterich 2008). Total stimulus variance also increased with base coherence level. The present study examined to what degree the trial-to-trial variability of the observed visual RDK stimuli could explain the trial-to-trial variability in subjects' performance. Signal variability was measured both by counting the number of dots moving in each direction in each stimulus frame, and by using a motion energy filter analysis (Kiani et al. 2008).

For each stimulus combination, trials with shorter RTs had a greater variance of mean motion signal in the stimulus than trials with longer RTs. However, mean instantaneous stimulus variance was constant between short- and long-RT trials, indicating that shorter RTs did not result from inherently more variable stimuli. Similarly, there was no significant relation between the net directional deviation of the stimulus from the intended mean net coherence and either RTs or target choices. This evidence suggests that the stochastic variability in the RDK stimuli cannot account for the variability of subject performance. This in turn suggests that a central source of neural variability is a more important contributor to the stochastic nature of decision making process.

Title: Modeling of subject independent and dependent cognitive biases in a resource allocation task

Authors: S. E. GOLDFARB[1], S. E. CHELIAN[1], J. D. COHEN[2], *R. BHATTACHARYYA[1]; [1]Information and Syst. Sci. Lab., HRL Laboratories, LLC, MALIBU, CA; [2]Dept. of Psychology and Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Cognitive biases such as loss aversion, risk aversion, and overreliance on exploration or exploitation cause suboptimal behavior in a variety of domains. For example, extreme loss sensitivity, in which subjects make overly conservative assessments after high loss decisions, has been offered as an explanation for probability matching, a suboptimal preference to match base rates to outcome probabilities as opposed to the Bayesian optimal strategy of binary assignments. Here we study cognitive biases in a variant of the n-armed bandit task in a military setting: given attack probability estimates for four groups, agents allocate troops to defend against a potential attack. An attack then occurs by one of the four groups and all troops not allocated against the actual attacker are said to be lost. In addition to finding subject independent probability matching, we further divide subjects into cognitive phenotypes that relate to dimensions of the Behavioral Inhibition System/Behavioral Activation System (BIS/BAS) scales. Using a recent neural network model that simulates interactions between neuromodulatory and prefrontal areas, we simulate these cognitive phenotypes by varying model parameters. Results suggest that we can account for subject independent and dependent cognitive biases by varying dimensions that can be derived from BIS/BAS questionnaires. Directions for future work include the addition of a control loop that may more closely approximate internal adaptive responses of decision makers who exhibit near-optimal performance, and/or may prove useful as an external (e.g., tutoring) mechanism for adaptively instructing those who exhibit suboptimal performance.

Title: Optimal repeated change detection and value-based approximation

Authors: *T. TSUCHIDA[1], A. J. YU[2];
[1]Dept. of Computer Sci. and Engin., [2]Dept. of Cognitive Sci., UC San Diego, La Jolla, CA

Abstract: Sensory systems are often tasked with detecting discrete changes in the environment based on a noisy stream of inputs. Previously, we showed that the Bayes-optimal control policy for detecting the first change event in a single stream of noisy inputs requires accumulating Bayesian evidence up to a fixed threshold, and that the optimal procedure naturally gives rise to integrate-and-fire neuronal dynamics (Yu, NIPS, 2007). Here, we extend the framework to show that when the task is to detect repeated changes between signal-off and signal-on states, the optimal policy exhibits more complex dynamics than those of the LIF neuron models. In particular, penalizing duplicate detection signals induces refractory period profiles similar to what are observed in temporal receptive properties of early visual processing (Cai et al., J. Neurophysiol 78:1045-1061, 1997). The optimal change-detector requires maintaining and continually updating two state variables: the belief that world is in a signal-on state, and the onset of this state has not been previously detected. We explore whether this two-state solution can be efficiently and accurately approximated by a one-state representation that could be accomplished by a single neuron. We describe one such approximation, by representing the belief state jointly with the differential Q-values of the two possible actions (similar to q-factors in the Q-learning algorithm), the “detect” and “silent” actions, along with the time since the last output spike (detection event). The dynamics of this approximation is qualitatively similar to those of spike response models. We characterize how the properties of the optimal and

approximate change-detectors are altered by the behavioral task parameters, and we predict how the decision unit ought to adapt to these changes.

Title: High gamma duration in human prefrontal cortex predicts categorical decision time

Authors: *M. HALLER[1], J. DEVRIES[2], N. J. HANSON[2], N. E. CRONE[3], E. F. CHANG[4], J. PARVIZI[5], R. T. KNIGHT[2,1], A. Y. SHESTYUK[1];

Abstract: Categorization is a fundamental principal of cognition, allowing for the grouping of perceptually distinct objects and concepts. Categorical effects are observed across perceptual domains and involve decreased discrimination between members of the same category than between members of different categories. Converging evidence from human and animal studies indicates that the prefrontal cortex (PFC) plays a fundamental role in decision-making. In the current study we examined the spatio-temporal dynamics of categorical decision-making using electrocorticography (ECoG), which involves recording of neural signals directly from subdurally implanted electrode arrays in patients with intractable epilepsy (n= 14). Local field potential power in the high gamma band (70-150 Hz) has been linked to single unit activity and was used as an index of local cortical neuronal activity. Subjects performed several

categorization tasks, which used facial stimuli (emotion and gender categorization), adjectives (self-referential categorization), or morphed images or sounds (implicit and explicit perceptual categorization). Stimuli were presented either in the auditory or visual modality in each task. Local high gamma cortical activity in the middle and inferior frontal gyri (MFG, IFG) was evident in all categorization tasks, independent of sensory modality, and increased with task difficulty. Critically, the duration of the high gamma signal in PFC electrodes, but not in sensory regions, predicted the subjects' reaction time in all tasks (R range 0.44-0.74 across PFC electrodes, $p < 0.001$). The similarity of the high gamma duration effect across a diverse set of tasks demonstrates the central role of the PFC in categorical decision-making, spanning the spectrum from simple perceptual categorization to abstract categorical judgments. The results provide evidence that temporally integrated neural activity in the PFC supports decision-making.

Title: The encoding of higher-order reward prediction errors during decision making

Authors: *R. GUO[1,2], M. HEBART[3], K. OBERMAYER[1,2];
[1]Dept. of Software Engin. and Theoretical Computer Sci., TU Berlin, Berlin, Germany; [2]Bernstein Ctr. for Computat. Neurosci. Berlin, Berlin, Germany; [3]Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Humans are able to identify patterns in temporal sequences in order to predict future events. This kind of sequence learning requires not only to track the frequency of encountered stimuli, but also the higher-order statistical relationships between stimuli. In contrast, standard reinforcement learning models cannot accommodate this behavior, because they learn the mean expected future reward and bias action selection toward the most rewarding event. To explain how humans use the temporal structure of stimuli, we developed an adjusted Rescorla-Wagner (RW) model that learns the conditional probabilities of stimuli given the sequence of previous

stimuli. The validity of this model was tested in two experiments employing a two-armed bandit task, where a visual stimulus alternates between the left and right sides on the screen with varying statistical dependencies across blocks of trials. We utilized the Markovian steady state property to construct the stimulus sequences. In Experiment 1, we manipulated only the first-order conditional probabilities (e.g. the probability of the stimulus appearing twice in a row on the left) while in Experiment 2, second-order conditional probabilities were manipulated (e.g. the probability of the stimulus appearing on the left after a sequence of left and right). Importantly, all other lower-order conditional probabilities were fixed at 0.5 and the mean reward of each option was the same. 20 naïve subjects had to correctly predict the forthcoming stimulus location to gain a monetary reward. In both experiments, subjects' performance reached 80 percent correct when the stimulus alternated in a highly predictive manner. As expected, the RW model performed at chance when these conditional probabilities were smaller than 0.5, because the model could not capture the temporal dependencies of the task. In contrast, our adapted RW model was able to learn the conditional probabilities in the same manner as a standard RW model updates reward prediction. The model fitted the behavioral data significantly better than a random agent and closely simulated subjects' behavior. This indicates that conditional probabilities are estimated by higher-order reward prediction errors. We will investigate this hypothesis in detail by model-based fMRI to reveal the neural encoding of higher-order prediction error.

Title: Distinguishing conceptual from motor decisions

Authors: *J. V. SCHWARZBACH[1], A. CARAMAZZA[1,2];
[1]Ctr. For Mind/Brain Sci., Rovereto, Italy; [2]Dept. of Psychology, Harvard Univerity, Cambridge, MA

Abstract: We make decisions by giving more importance to one set of influences than to another set and deriving a choice from it. The predominant idea postulates that the brain accumulates evidence in a decision variable leading to some ramping activity, until the accumulated evidence

reaches a critical threshold to make a decision (1). Finally, the resulting choice can be expressed in many ways, by a motor act or by a mental activity, e.g. planning the upcoming holidays rather than tonight's dinner.
The fact that in several neurophysiological studies the same areas that show activity during motor planning also are activated in decision making has led to the view that decisions are made within the same sensorimotor circuits that are responsible for planning and executing the associated actions (2, 3). Such an intentional framework rejects the notion of conceptual decisions that are qualitatively distinct and separated from sensory and motor information.
We argue that decision making experiments that require overt reports, in particular with known SR mappings are confounding conceptual and motor decisions and may wrongly attribute functions to sensorimotor networks. We have attempted to disentangle perceptual decisions from motor decisions by successively presenting two stimuli (S1: face or house, S2: colored rectangle) and having participants perform a two step task in which a non-motor perceptual decision on S1 (face or house?) determined what participants had to overtly report about S2 (color or orientation). We monitored the blood oxygen level dependent (BOLD) response in 23 healthy participants with a 4T MR-scanner.
We found that the BOLD signal increased bilaterally in the ventral portion of precentral sulcus, and in the precuneus (areas 7 and 31) irrespective of whether participants were categorizing pictures, shapes or colors. Motor areas showed an increase in BOLD only when participants made overt responses.
Our results show that activity in motor areas reflects the motor decision (preparation and execution) but not the perceptual decision, while other areas reflect perceptual decisions abstracted from the input domain and the behavioral output. We argue for the notion that the brain represents conceptual decisions distinct from sensory and motor information.

Title: Dissecting different types of decision-making: An ERP study of reasoned vs. unreasoned voluntary decisions

Authors: *L. MUDRIK[1], U. MAOZ[1], D. XU[1], C. DUNCAN[1], Q. ZHANG[2], C. KOCH[1,3]; [1]Caltech, Pasadena, CA; [2]Natl. Univ. of Singapore, Singapore, Singapore; [3]Allan Inst. for Brain Sci., Seattle, WA

Abstract: The neuroscientific study of voluntary action suggests that consciousness may follow rather than initiate the decision to act. However, these experiments examined meaningless, arbitrary actions that bear no future consequences - as opposed to meaningful decisions that involve reasoning. Here, we used EEG to directly compare consequential, reasoned decisions (i.e., "choosing") with consequential, unreasoned decisions ("significant picking") and inconsequential, unreasoned decisions ("insignificant picking"). In Experiment 1, subjects pressed a button with their right or their left hand to either play against the computer in a matching-pennies game, where they could win or lose a fixed amount of money (choosing); guess whether that amount of money is associated with the left or right button (significant picking); or perform an arbitrary movement that always led to a gain of that amount (insignificant picking). Subjects were informed of the type of task at the beginning of each trial (stimulus onset). Choosing trials elicited a stronger centrofrontal positivity than both types of picking, starting as early as 300ms after stimulus onset, accompanied by a left posterior negativity. Further analysis revealed that these effects stem from differences in spatial distributions of brain potentials and not only in amplitudes. Interestingly, choosing trials also elicited a stronger central negativity that overlapped - yet not preceded - subjects' report of consciously deciding. In Experiment 2, we obtained similar results using a very different paradigm, based on food preference decisions. In each trial, two food brands were presented. Subjects again pressed right or left button to select one item (choosing), to guess a random association of the buttons either with both items or with two of their least favorite items (significant picking), or to perform an arbitrary movement that always resulted in receiving both items (insignificant picking). This paradigm required no tracking of choice history, nor involved competition against another player. Yet, choosing trials again gave rise to frontal positivity accompanied by posterior negativity that started at ~300ms. Taken together, our results suggest that decision type affects the very early stages of decision making, rather than the later ones that presumably lead to the conscious experience of deciding. Then, post-decision processes (e.g., result monitoring) are again modulated by decision type.

Title: A distributed functional network underlying strategic decision-making

Authors: *A. C. PARR[1], B. C. COE[1], D. P. MUNOZ[1], M. C. DORRIS[2,1];
[1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Inst. of Neurosci., Shanghai Inst. for Biol. Sciences, Chinese Acad. of Sci., Shanghai, China

Abstract: During competitive social interactions, one's chosen actions and their associated outcomes change dynamically based on the actions of other agents. This often requires that one avoid exploitation from opponents by employing the use of mixed-strategies; choosing among available actions unpredictably and stochastically. During strategic interactions, an individual's history of choices and reward outcomes, as well as those of their opponent, are used to predict future outcomes of each action by estimating the value of available actions. The neural mechanisms that calculate abstract value representations and transform these into specific actions during human decision-making are not well understood. Although game theory outlines mathematical frameworks to predict optimal strategies in social situations, discrepancies exist between these optimal strategies and how people actually behave.
The current study used functional MRI to investigate the neural processes related to mixed-strategy decision-making. A colour-based version of Matching Pennies was played against a dynamic computer opponent that exploited biases in players' response patterns. Participants selected one of two different coloured visual targets, and were rewarded if their selection matched that of the opponent. Results were contrasted with an instructed control task that matched the strategic task in terms of sensory input, choice direction, and reward rate. Therefore, any differences in brain response patterns should highlight strategic-related processes. Individuals behaved strategically, choosing each option in equal proportions, and unpredictably from trial-to-trial. More importantly, strategic decision-making was associated with activation of a highly distributed network, including bilateral dorsolateral prefrontal cortex, parietal cortex,

anterior cingulate gyrus, and the insular cortex. We propose that the observed pattern of brain activation represents the core elements of a distributed functional network underlying strategic forms of decision-making.

Title: Hierarchical decision-making in humans: An fmri study

Authors: *W. YOSHIDA;
ATR, Kyoto, Japan

Abstract: Making optimal decisions requires the ability to select mappings between states and actions based on internally maintained representations of the environment. When the environment is large, hierarchical representation of state-space is effective, and computational models with a hierarchical extension are commonly used in engineering problems such as speech recognition and robot-navigation. Hierarchical organization can also be seen as a function of the structure of human behaviour, and humans build a hierarchical cognitive map that contains multiple levels representing the same large environment at different resolutions. Recent studies suggest that the prefrontal cortex represents an environmental model and has functionally hierarchical organization, with more anterior regions having increasingly abstract representations. However, the computational and brain mechanisms of decision-making in a hierarchical environment are still not fully understood.
To address this question, we designed a hierarchical maze navigation task in which two levels of state representation are required. First, the subjects are trained to learn the structures and the goal positions of three different types of maze. The mazes are partially-observable; the subjects infer their current positions from the observation of circum-spaces which are frequently ambiguous. After the training, they performed an experimental task in which they navigated in the learned maze to reach the goal but the type of maze (higher-level hidden state) and the current position in the maze (lower-level hidden state) were both unknown. Thus, to achieve this task efficiently required inference of two different levels of hidden states concurrently.

Nineteen healthy subjects performed the experiment in an fMRI scanner and we examined their brain (BOLD) activities related to their behaviours. We found strong reward-related brain activities in basal ganglia when the subjects reach the goal, and the activities of distinct regions in the parietal cortex with different spatial situations and navigation behaviours. We then use a computational technique based on probabilistic model inference: we statistically estimated the individual subjects' on-going state estimate and its associated uncertainty, based on their behavioural sequence, and then used this model to generate regression functions to predict brain activities. We compare models with and without a hierarchical environmental model and show the brain regions which are involved in hierarchical state inference in navigation.

Title: Comparing restoration of novel object recognition (NOR) in mice sub-chronically (sc) treated with NMDA receptor non-competitive antagonists phencyclidine (PCP), dizocilpine (MK-801), or ketamine, with rats treated with PCP: Effect of 5-HT_{1A} partial (PA) agonism and $GABA_A$ receptor stimulation

Authors: *L. RAJAGOPAL[1], Y. OYAMADA[1,2], M. HUANG[1], H. Y. MELTZER[1];

[2]Dainippon Sumitomo Pharma Co., Ltd.,, Osaka, Japan

Abstract: Introduction: Sub-chronic (sc) administration of NMDA receptor antagonists to rodents produce deficits in cognitive function, including novel object recognition (NOR), an analog of human declarative memory (DM). The hypoglutamatergic current produced by sc phencyclidine (PCP) has been considered to model the deficits in glutamate function in schizophrenia (Yuen et al.,2011). We and others have previously reported that atypical, but not typical antipsychotic drugs (APDs), can restore the deficit in NOR produced by sc PCP in female rats (Horiguchi et al., 2011) and that 5-HT_{1A} receptor partial agonism (PA), 5-HT_7 antagonism, and $GABA_A$ receptor stimulation can also reverse these deficits in female rats. We sought to determine if similar effects occurred in mice, as background for studies in transgenic mice, and whether the mechanisms effective in rats might also restore NOR following sc treatment with

two other NMDAR non-competitive antagonists, ketamine and dizocilpine (MK-801), in C57BL/6 mice. The novel APD, lurasidone (a D_2 antagonist/5-HT_{1A} PA,/5-HT_7 and 5-HT_{2A} antagonist properties) and a 5-HT_{1A} PA, tandospirone were tested in PCP, ketamine, and MK-801-treated mice. **Materials and methods:** PCP (10 mg/kg), MK-801 (0.1 mg/kg), and ketamine (30 mg/kg) were administered for 7 days followed by 7 days washout to male C57BL/6 mice. On the test day, day 15 or thereafter, acquisition trial was conducted for 10 min, in habituated mice, followed by a retention trial 24 hr later. Vehicle, lurasidone (0.3 mg/kg) or tandospirone (0.1 mg/kg) were administered 30 min before the acquisition trial. **Results:** Sc PCP, MK-801, or ketamine all induced deficits in NOR ($P<0.05$-0.01) compared to control mice. Lurasidone ($P<0.05$-0.001) or tandospirone ($P<0.05$-0.001 significantly reversed the NOR deficit in each group. The $GABA_A$ positive allosteric modulator, TPA023, and the 5-HT_7 antagonist SB269970 also reversed the NOR deficit in PCP-treated mice. **Discussion:** This study confirms that sc NMDAR antagonist treatment in mice produce a NOR deficit in mice, comparable to rats. The reversal of the NOR deficits produced by all three NMDAR treatments by lurasidone and tandosprione indicates a shared mechanism as a basis for the deficit and no obvious need to study more than one NMDAR antagonist. Thus, reversal of the scPCP-induced deficit with TPA023 and SB69970 is likely to also occur in the sc ketamine and sc MK-801-treated mice. However, in light of the development of intravenous ketamine for the treatment of severe depression, the cognitive deficit produced by sc ketamine may have special clinical relevance.

Title: Scopolamine alters encoding but not retrieval on the E-maze version of the what/where/which task

Authors: *A. JOHNSON[1], C. STANCHFIELD[2];
[1]Psychology, Bethel Univ., MINNEAPOLIS, MN; [2]Biol., Bethel Univ., St. Paul, MN

Abstract: Novelty preference in the E-maze version of the what/where/which task is dependent on the hippocampus (Easton et al., 2009). We examined the development of novelty preference, vicarious trial and error behaviors, and pausing behavior at the choice point. Although a slight

novelty preference develops across training, the behavior that underlies novelty preference undergoes significant reorganization. Early in training, longer pausing at the choice point is associated with heightened novelty preference. Late in training, longer pausing at the choice point is associated with a preference for the familiar object.
We then used systemic scopolamine injections delivered immediately prior to an encoding session in order to assess the contribution of acetylcholine-based encoding processes to recollective memory and injections delivered immediately after an encoding session in order to assess the contributions of acetylcholine-based retrieval processes to recollective memory within the E-maze. Novelty preference was compromised by scopolamine during encoding and caused a shift to a preference for the familiar object in a subset of animals. Scopolamine treatment also induced a reversal in the relationship between novelty and time spent at the choice point in a trial-by-trial analysis. In contrast, scopolamine treatment rescued novelty preference in the retrieval condition - most likely as a result of reduced interference.
These results suggest that acetylcholine-based encoding contribute to recollection on the E-maze version of the what/where/which task while recollection-based retrieval is not acetylcholine dependent. These findings are consistent with a memory model in which familiarity and recollective memory processes share an encoding mechanism and only diverge during memory retrieval.

Title: Hippocampal activation of estradiol receptors α and β restores memory deficit caused by chronic estrogen deprivation

Authors: *C. P. BASTOS, L. M. PEREIRA, G. S. PEREIRA;
Physiol. and Biophysics, Federal Univ. of Minas Gerais, Belo Horizonte, Brazil

Abstract: We showed previously that object recognition memory is compromised by chronic estrogen deprivation in mice. Here we decided to test the hypothesis that the memory is impaired due the lack of estradiol modulation on hippocampal plasticity. To address this question, we used female C57BL6 mice that went to ovariectomy (OVX) at 8 weeks age. Eleven weeks latter, mice were submitted to stereotaxic surgery to implantation of bilateral cannulae in the dorsal

hippocampus (AP-1.7 mm from bregma; LL± 1.9 mm from midline; DV-1.0mm from the skull surface). After one week of recovery, mice were submitted to the object recognition task that consists of three phases: habituation, sample and choice phases. In the habituation, mice were placed in an empty plastic box and allowed to freely explore it for 5 min. Twenty-four hours later, in the sample phase, mice were first re-habituated to the empty box for 1 min. Next, two identical objects were placed on the right and left side of the box and the mice explored the objects for 30s in total. The choice phase was similar the sample phase except that a new object replaced a familiar one. Immediately and 3hs after the sample phase the animals received intra-hippocampal 0.5 µL/side of one the following drugs: vehicle (ciclodextrine or 50% DMSO), 17β-estradiol (E2, 5.0µg/µl), the ERα agonist propyl pyrazole triol (PPT, 1.0µg/µl) and the ERβ agonist diarylpropionitrile (DPN, 2.0µg/µl). Mice were tested in the choice phase 24 h after sample phase to evaluate the long-term memory (LTM). The preference for one object over another was assessed using one-sample t-test to determine whether the preference of the novel object differed significantly from hypothetical value 15. First, we demonstrated that intra-hippocampal infusion of E2 immediately after the sample phase but not 3hs after, increases the time exploring the novel object (15.38s ± 2.50s vs. 18.33s ± 3.01s, p = 0.04) and compared to vehicle group (15.62s ± 1.75s vs. 18.33s ± 3.01s, p = 0.04). Next, we showed that animals that received intra-hippocampal administration of either PPT (15.88s ± 2.58s vs. 18.80s ± 2.58s, p= 0.03) or DPN (15.62s ± 1.75s vs. 20.33s ± 3.83s, p= 0.01) spend more time with the novel object compared to vehicle group. Thus, our results showed that the reestablishment of E2 action on the hippocampus, right after learning, allows object memory to persists in chronic OVX mice. Furthermore, we showed that the activation of both ERα and ERβ improve the memory deficits related to chronic hormonal deprivation. Sources of research funding: Fapemig, CNPq, Capes.

Title: Methylphenidate acts within the prefrontal cortex to enhance memory storage

Authors: *S. LIU[1], F. YI[1], B. LI[1,2], X. ZHANG[1];
[1]Inst. of Neurobio., Fudan Univ., Shanghai, China; [2]Ctr. for Neuropsychiatric Dis., Nanchang Univ., Nanchang, China

Abstract: Methylphenidate is one of major treatments ameliorating cognitive dysfunction in attention deficit hyperactivity disorder (ADHD) and can improvement learning and memory. However, such improvements have previously been thought to result from increased attention. Here, we showed that methylphenidate directly alters mechanisms underlying learning and memory. In the present study, we investigate the effect of methylphenidate on synaptic potentiation and behavioural memory in the prefrontal cortex of young rats. Our results show that methylphenidate enhances long-term memory storage and facilitates long-term synaptic potentiation via dopaminergic D1 receptors and noradrenergic β1 receptors in the prefrontal cortex.

Title: Role of cannabinoid receptors and endocannabinoids in an animal model of Post-Traumatic Stress Disorder

Authors: W. D. JOHNSTON, *C. SEXTON, D. FETTERHOFF, A. J. SWEATT, S. A. DEADWYLER, R. E. HAMPSON;
Physiology/Pharmacology, Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Post-traumatic stress disorder (PTSD) is a growing problem in psychological health, especially among veterans, with patients exhibiting flashbacks, heightened anxiety, and impairment of memory and impulse control. PTSD is often associated with alcohol and drug abuse suggesting that neural systems affected by drugs also interact with stress mechanisms. An animal model of intense stress, the Single Prolonged Stress (SPS) procedure (Liberzon and

Young, Psychoneuroendocrinology, 1997; 22:443-453), has been demonstrated to cause physiological and behavioral changes seen in human patients, as well as increased glucocorticoid receptor expression in the hippocampus (Knox et al., Neuroscience 2012; 223:163-173). Moreover, deficiencies in cannabinoid receptor (CB1R) and endogenous cannabinoid signaling mimic the effects of chronic stress (Hill et al., Cerebral Cortex 2011; 21:2056-2064), suggesting an interaction of CB1R signaling in the hippocampus and PTSD-like effects on memory. Previous studies have successfully blocked some of the effects of SPS by administration of the CB1 agonist WIN 55,212-2 one day after the procedure (Ganon-Elazar and Akirav, Neuropsychopharmacology 2012; 37:456-466); therefore we hypothesize that effects of stress on hippocampal function may be modulated by cannabinoid receptor agonists or antagonists. We used performance on a short-term memory task, Delayed Nonmatch to Sample (DNMS), as a measure of hippocampal function. Adult male Long-Evans rats were exposed to SPS: (1) prior to training in the DNMS task; (2) after training, but prior to DNMS testing; and (3) prior to reversal to the Delayed-Match-to-Sample (DMS) contingency. SPS-treated rats exhibited delayed progression through the stages of DNMS training, and were impaired during DNMS-to-DMS reversal , but short term memory performance was unaffected at any length of delay. Comparison of post-SPS performance on DNMS training and reversal showed similarities to the effects of a cannabinoid agonist on these processes, suggesting that CB1Rs may mediate aspects of the effects of PTSD on learning and memory. Administration of a CB1R agonist shortly after an intense stressor may interfere with the development of changes in the endocannabinoid system which facilitates these effects. These results will be discussed with respect to potential therapeutic intervention for both PTSD and concomitant drug use

Title: Relationship of cortical dopamine, acetylcholine, serotonin, glutamate, and GABA to restoration of novel object recognition by antipsychotic and specific receptor agonists or antagonists

Authors: *M. HUANG[1], J. J. PANOS[1], S. KWON[1], Y. OYAMADA[1,2], L. RAJAGOPAL[1], H. Y. MELTZER[1];
[1]Psychiatry and Behavior Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL;
[2]Dainippon Sumitomo Pharma Co., Ltd, Osaka, Japan

Abstract: Background: The ability of atypical antipsychotic drugs (APDs) to improve some domains of cognitive impairment of schizophrenia may be due, in part, to increased release of dopamine (DA) and acetylcholine (ACh) in various cortical and temporal lobe regions. It has been reported that the cortical or hippocampal DA, ACh, and glutamate (Glu) were increased during the cognitive processes related to attention and working memory. Sub-chronic(sc) phencyclidine (PCP), an NMDA receptor non-competitive antagonist, which induces impairment in glutamatergic neurotransmission impairs novel object recognition (NOR) in rodents and primates. Our previous studies have shown this deficit can be acutely reversed by administration of atypical, but not typical APDs, by 5-HT_{1A} partial agonists (PA), but not 5-HT_{2A} inverse agonists (IA). **Method:** In the present study, using microdialysis and UPLC-MS/MS to assay neurotransmitter efflux in awake freely moving rats, we compared the effect of the atypical APDs blonanserin (D_2/5-HT_{2A} receptor antagonist, 3 mg/kg, ip), lurasidone (5-HT_7/5-HT_{2A}/D_2 receptor antagonist, 5-HT_{1A} PA, 0.5 mg/kg), and olanzapine (5-HT_{2A}/D_2/5-HT_6 receptor antagonist, 1 mg/kg), as well as the typical APD, D_2 receptor antagonist, haloperidol (0.1 mg/kg), the 5-HT_{1A} PA tandospirone (5 mg/kg), and pimavanserin (3 mg/kg), a 5-HT_{2A} IA, on the efflux of cortical DA, ACh, Glu, GABA, serine, glycine, 5-HT, and the metabolites, dihydroxyphenylacetic acid (DOPAC), homovanillac acid (HVA), and 5-hydroxyindoleacetic acid (5-HIAA). **Results:** All compounds, with the exception of haloperidol and pimavanserin, increased the efflux of cortical DA and its metabolites, DOPAC and HVA. Only olanzapine and lurasidone increased cortical ACh efflux. Only lurasidone slightly, but significantly, increased cortical Glu efflux. None of the compounds, at the doses tested, significantly altered the efflux of cortical 5-HT or its metabolite, or glycine or GABA. **Conclusion and Discussion:** The present data suggests that atypical APDs, probably due to 5-HT_{2A} receptor blockade, combined with lesser D_2 receptor blockade, and direct or indirect5-HT_{1A} receptor activation, but not D_2 or 5-HT_{2A} receptor blockade alone, increases cortical DA and, in some cases, ACh efflux. The Glu efflux induced by lurasidone could possibly be related to its potent 5-HT_7 receptor blockade. The ability to increase cortical DA, ACh as well as Glu efflux might contribute to amelioration of the deficit in NOR following scPCP treatment. Additional data testing this conclusion and its relation to NOR in scPCP treated rodents will be reported at the SFN meeting.

Title: Estradiol enhances object memory through estrogen receptor α, but not β, activation in the hippocampus of female mice

Authors: *L. M. PEREIRA, C. P. BASTOS, G. S. PEREIRA;
Federal Univ. of Minas Gerais, Belo Horizonte, Brazil

Abstract: 17β-Estradiol (E2) enhances hippocampal function and improves performance in several memory tasks. However, the molecular mechanisms underlying estrogenic-induced promnesic effects remain unclear. In the present study, we asked whether E2 exert its mnemonics effects through the estrogen receptors alfa (ERα) and beta (ERβ). To assess the object recognition memory we used the Novel Object Recognition task. First, we demonstrate that in Swiss ovariectomized mice post-training intraperitoneal (i.p.) injection of E2 (0,2mgKg) enhances the retention of object recognition memory. Second, we show that this effect is reproduced by intrahippocampal administration of PPT (1μg/μl), a selective ERα agonist, but not of DPN (0,4 and 2μg/μl), a selective ERβ agonist. We confirm this result blocking the mnemonic effect of i.p. E2 by dorsal hippocampal inhibition of ERα activation. Animals received i.p. injection of E2 followed by intrahippocampal administration of TPBM (10, 50 and 250ng/μl), a selective ERα antagonist. We also demonstrate that DPN, but not PPT, intrahippocampal administration has anxiolytic-like effect, in the elevated plus-maze, in Swiss mice and that none of these drugs has effects in the locomotor activity. Taken together, these data suggest that E2 acts as a cognitive enhancer through activation of dorsal hippocampal ERα.

Title: Role of cannabinoid system in hippocampal memory

Authors: D. FETTERHOFF, *A. J. SWEATT, W. D. JOHNSTON, C. A. SEXTON, R. E. HAMPSON, S. A. DEADWYLER;
Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Activation of the brain cannabinoid (CB1) receptor produces a clear modulation of memory in rats performing a Delayed-Nonmatch-to-Sample (DNMS) task. Exogenously applied CB1R agonists reduced behavioral performance and suppressed the hippocampal neural response which encodes task-critical information [Hampson & Deadwyler, J. Neurosci. 2000; 20(23):8932-42]. On the other hand, CB1R antagonists enhance behavioral performance and hippocampal neural activity in some but not all behavioral contexts [Deadwyler et al. Behav. Pharmacol. 2007; 18(5-6):571-80]. The reciprocal nature of CB1R activation/inactivation suggests that endocannabinoid modulate memory processes as part of the normal function of the hippocampus; however, demonstrating such a role via direct manipulation of endocannabinoids has proven to be much more difficult.

This study examined the role of cannabinoid signaling in memory by manipulating endocannabinoid signaling with CB1R activation/inactivation and direct electrical stimulation of hippocampal neural ensembles. Inhibition of endocannabinoid degradation by inhibition of fatty-acid-amide-hydrolase via URB597, or by inhibition of MAG-lipase via URB602, produced mnemonic impairment in two ways: a) DNMS performance was impaired at long delays by both URB597 and URB602, and b) hippocampal neuronal encoding of Sample phase information in the DNMS task was suppressed by both URB597 and URB602. The CB1R antagonist rimonabant blocked behavioral impairment produced by exogenous or endogenous cannabinoids, and also strengthened hippocampal neural encoding of task-relevant information in the DNMS task. Patterned electrical stimulation of hippocampal neurons reversed CB1R agonist-induced behavioral impairments, implying that CB1Rs specifically modulate the encoding of mnemonic information critical to task performance. To further understand the neural correlates associated with manipulating the endocannabinoid system, the neural recordings were used to estimate the multifractal singularity spectrum using the Wavelet Leaders method (Serrano and Figliola, Physica A, 2009; 388:2793-2805; Wendt et al., IEEE Signal Processing, 2007; 24:38-48). Preliminary results show that changes in the multifractal spectrum due to CB1R activation or inactivation are directly related to the functional role of the neuron during the DNMS task. Together these results suggest that the differential modulation of CB1Rs via the action of endocannabinoids may play a normal role in memory processing, and may enhance future understanding of cannabinoid signaling with respect to information processing by the brain.

Title: Improved neuritogenesis and mitochondrial dynamics by levetiracetam might explain cognitive improvement in brain aging and animal models of Alzheimer's disease

Authors: *W. E. MUELLER[1], D. VIANO[2], C. SCHILLER[2], K. LEUNER[3];
[1]Dept Pharmacol, Univ. Frankfurt, D-60438 Frankfurt, Germany; [2]pharmacology, goethe university frankfurt., frankfurt, Germany; [3]clinical and molecular pharmacy, university erlangen, erlangen, Germany

Abstract: The antiepileptic levetiracetam (Lev) has been shown to improve hippocampal hyperactivity associated with Mild Cognitive Impairment (MCI) in patients and cognitive deficits in an animal model of Alzheimer's disease (AD). These effects have been explained by improvement of synaptic function but the mechanism has not yet been clarified, also effects on mitochondrial function seem to be involved. Since loss of synapses and neurites associated with impaired mitochondrial function and dynamics (fission and fusion) are typical for brain aging and early AD, we assessed the effects of Lev on neurite outgrowth and mitochondrial parameters. Human neuroblastoma cells (SY5Y) and PC12 cells were used under conditions imitating aging and SY5Y cells expressing slightly higher beta-amyloid levels typical for very early stages of AD. These cells exhibit impaired neuritogenesis and mitochondrial dynamics already under baseline conditions and/or after treatment with rotenone. Lev at a concentration as low as 20 micromolar improves neuritogenesis and mitochondrial dynamics in both cell lines following oxidative stress either induced by rotenone treatment (complex I inhibition) or by sodium nitroprusside (SNP). At similar concentrations levetiracetam also had beneficial effects on both parameters in SY5Y cells overexpressing beta-amyloid. Improved neuroplasticity followed by improved neuronal communication might be associated with the beneficial effects of Lev on cognitive functions in patients and Alzheimer mice independent of its anticonvulsant properties.

Title: TPA023, a GABA($_A$) α2,3 subtype-selective partial agonist, enhances the efficacy of lurasidone to reverse the sub-chronic phencyclidine (PCP)-induced impairment in novel object recognition (NOR)

Authors: *Y. OYAMADA[1,2], L. RAJAGOPAL[1], M. HUANG[1], H. Y. MELTZER[1];
[1]Dept. of Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL; [2]Dainippon Sumitomo Pharma Co., Ltd.,, Osaka, Japan

Abstract: Background: Cognitive impairment in schizophrenia (CIS), reflects deficits of multiple cognitive domains, among them being declarative memory (DM), primarily a hippocampal-based function. CIS is believed to result from hypoglutamate, deficient $GABA_A$ receptor function, and diminished dopamine D_1 receptor stimulation. Typical and atypical antipsychotic drugs (APDs) ameliorate deficits in DM in some patients beyond a practice effect (Meltzer et al., 1989; Keefe et al., 2007). We have previously reported the effectiveness of the novel antipsychotic drug, lurasidone (a D_2 antagonist, 5-HT_{1A} partial agonist, and 5-HT_{2A} and 5-HT_7 antagonist) and the selective 5-HT_{1A} receptor agonist, tandospirone, in reversing the deficit in novel object recognition (NOR), an analog of DM, following sub-chronic (sc) treatment with the NMDA receptor non-competitive antagonist, PCP, in rats (Horiguchi et al., 2011). The use of add-on pharmacological agents for CIS might enhance the efficacy of atypical APDs such as lurasidone. In this light, TPA023, a GABA type A receptor subunit α2/α3 positive allosteric

modulator, was studied as adjunctive for lurasidone and tandospirone in rat NOR. We also studied the effect of the $GABA_A$ antagonist, bicuculline alone or in combination with TPA023 on NOR. **Materials and Methods:** Female Long-Evans rats received vehicle or PCP (2 mg/kg, b.i.d.) for 7 days, followed by a 7-day washout. PCP-treated rats were given TPA023 (0.01 or 0.05 mg/kg) or bicuculline (0.1 or 0.5 mg/kg), alone, or along with a sub-effective dose (SED) of lurasidone (0.03 mg/kg), or tandospirone (0.2 mg/kg), 30 min prior to NOR testing. The NOR procedure has been described elsewhere (Snigdha et al., 2010). **Results:** Acute treatment with TPA023 (0.05 mg/kg), but not 0.01 mg/kg, significantly reversed the scPCP-induced NOR deficit. Acute treatment with, the $GABA_A$ antagonist, bicuculline (0.5 mg/kg), but not 0.1 mg/kg, also significantly reversed the scPCP-induced NOR deficit. Co-administration of SED of TPA023 (0.01 mg/kg) with SED of lurasidone (0.03 mg/kg), but not tandospirone (0.2 mg/kg), enhanced the ability of lurasidone to reverse this deficit. Additional data with bicuculline pretreatment of lurasidone and tandospirone will be reported.
Conclusion and Discussion: These findings demonstrate the significance of the $GABA_A$ mechanism for the cognitive deficits induced by scPCP, a putative model for CIS, alone and as adjunctive treatment with lurasidone and possible other APDs. The amelioration of NOR deficit by both agonist and antagonist could be attributed to their effect on the number of $GABA_A$ receptors.

Title: Involvement of GSK3β/β-catenin signaling in the impairment effect of ketamine on memory

Authors: *X. LIU[1], H. LIU[1], K. WANG[2], G. XU[1], J. CAO[3], Y. LI[1];
[1]Dept. of Anesthesiol., [2]Dept. of Neurol., The First Affiliated Hosp. of Anhui Med. Univ., Anhui, China; [3]Jiangsu Province Key Lab. of Anesthesiol., Xuzhou Med. Col., Jiangsu, China

Abstract: Background: Ketamine produces acceptable analgesia, it is accompanied by amnesia. The cellular mechanisms underlying ketamine induced amnesia are not clear. The current

experiments were designed to examine the effects of ketamine on memory consolidation in rats, and, more precisely, whether the glycogen synthase kinase (GSK)3β/β-catenin signaling pathway was involved in mediating the effects of posttraining ketamine administration on Morris water maze retention.

Methods: Adult male Sprague-Dawley rats were injected with ketamine (25, 50,100 mg/kg) immediately after a water maze training session consisting of eight trials. A probe trial was carried out 24 h later to examine the effects of ketamine on memory. The rats' hippocampi were obtained for measurement of levels of different forms of GSK3β and β-catenin protein expression.

Results: Memory performance was significantly impaired in rats injected with ketamine (100 mg/kg) after training. This dose altered activation of GSK3β/β-catenin signaling pathway in the hippocampus. Acute injection of the GSK3β specific inhibitor SB216763 (1 ng/0.5 μl/side) into area CA1 of the hippocampus after water maze training prevented ketamine-induced impairment of memory consolidation and blocked ketamine-induced effects on the GSK3β/β-catenin signaling pathway in the hippocampus.

Conclusion: An anesthetic dose of ketamine injected immediately after Morris water maze training impaired memory consolidation. Pharmacological inhibition GSK3β/β-catenin signaling blocked the memory impairing effect of ketamine, suggesting that GSK3β/β-catenin signaling may play a role in ketamine-induced amnesia.

*Fig.6. Administration of SB216763 immediately after water maze training blocks the effects of 100 mg/kg ketamine on the phosphorylation state of GSK-3β (A) and β-catenin (B) in the hippocampus. Data are shown as mean percentage levels (±SEM) with respect to the DMSO vehicle control group.*p < 0.05, Tukey's test after one-way ANOVA, n = 5 each group.*

Title: Oleanolic acid attenuates scopolamine-induced memory impairment in mice

Authors: Y. LEE[1], S. PARK[1], H. LEE[1], Y. AHN[1], G. KWON[1], H. WOO[1], Q. GAO[1], *J. RYU[2,1];

Abstract: Oleanolic acid and ursolic acid are pentacyclic triterpenoids that are found in medicinal herbs as well as foods. In the present study, we investigated the memory-ameliorating effect of these two triterpenoids on cholinergic blockade-induced memory impairment in mice. The behavioral tests were conducted to evaluate the memory-ameliorating effect of both oleanolic acid and ursolic acid. Cognitive impairment was induced by scopolamine (1 mg/kg), a muscarinic receptor blocker, in prior to 30 min before the behavioral tests. Oleanolic acid (2.5 or 5 mg/kg, p.o.) significantly ameliorated the scopolamine-induced cognitive impairment, whereas ursolic acid did not exert any memory-ameliorating effect in our present behavioral tasks. To clarify the mechanism underlying memory-ameliorating effect of oleanolic acid, the receptor antagonism study and Western blot analysis were conducted. We will discuss on the structural differences between oleanolic acid and ursolic acid which are responsible for cognitive function.

Title: Distinct cortical connectivity pattern of the anterior and posterior mediodorsal thalamic nucleus in mice

Authors: *J. LEE[1], F. MÁTYÁS[2], L. ACSÁDY[2], H.-S. SHIN[1];
[1]Ctr. for Cognition and Sociality, Inst. For Basic Sci., Seoul, Korea, Republic of; [2]Inst. of Exptl. Med. of the Hungarian Acad. of Sci., Budapest, Hungary

Abstract: The mediodorsal thalamic nuclei (MD) provide one of the most significant thalamic inputs to the frontal cortices and plays pivotal role in frontal cortical function including attention, planning and decision-making. Indeed, MD lesions results in similar behavioral symptoms than the lesion of the cortical region they are connected with, which underlies the importance to understand the precise connectivity between the two regions. Earlier investigators described the topographic connection between the medial thalamus and frontal cortex as serial, parallel loops via the basal ganglia in rats. In this study we used anterograde and rertrograde tracing to study the connectivity of MD in various antero-posterior levels in mice. The study was motivated by our recent study which that the MD also has a vital role in fear extinction, a classical prefrontal function.
Injection of the retrograde tracers to the caudal MD labeled cortical layer 6 and layer 5 cells as described previously. The vast majority of the labeled cell was in the primary motor cortex. In addition, significant amount of labeled cell was found in the secondary motor, dorsal cingulate, primary somatosensory, agranular insular and perirhinal cortices but not in the pre- or infralimbic cortices. More anterior injections, however, resulted in dense labeling of the deep layers of pre-, infralimbic and agranular insular cortices but not in the somato-motor cortices. A moderate number of contralateral corticothalamic cells were also observed in both cases. Double-labeling experiments suggested an abrupt rather than a gradual change in the cortical innervation pattern of rostral vs. caudal MD. Distinct cortical inputs were paralleled by distinct thalamic reticular nucleus (TRN) inputs arising from different sectors of the nucleus. Indeed, only few TRN cells were found which projected to both the anterior and posterior MD. Interestingly retrogradely labeled cells were not found in the amygdala following either anterior or posterior MD injections, which was confirmed by the lack of fibers in the MD after anterograde tracing from both the basolateral and the central amygdalar nuclei.
Based on the cortical innervation pattern, our results suggest a functional heterogeneity in the MD. The data suggest the caudal MD is involved in motor execution and planning, whereas rostral MD is responsible for emotional behavior, like fear and anxiety.

Title: Naringin ameliorates okadaic acid induced cognitive dysfunction and apoptotic neurodegeneration in the rat brain

Authors: *A. K. SACHDEVA, K. CHOPRA;
Pharm., UIPS, PANJAB UNIVERSITY, CHANDIGARH, India

Abstract: Tau hyperphosphorylation and memory deficit are characteristic alterations of Alzheimer's disease (AD). Protein phosphatases (PP) 2A plays a crucial role in AD-like lesions. Inhibition of PP2A through intracerebroventricular injection of okadaic acid (ICV-OKA) induces tau hyperphosphorylation and memory impairment. In the present study, we investigated the effect of naringin on ICV-OKA-induced cognitive impairment in rats. ICV-OKA administration produced significant cognitive deficits as assessed by both Morris water maze and elevated plus maze task which is accompanied with significantly enhanced oxidative-nitrosative stress, acetylcholinesterase, and mitochondrial enzyme (I, II,III and IV) activities and surge in serum inflammatory cytokines (TNF-α, TGF-β and IL-1β. Chronic treatment with naringin, (50, 100 and 200 mg/kg; oral gavage) for 14 days significantly and dose dependently improved cognitive deficits in ICV-OKA rats along with mitigation of oxido-nitrosative stress mediated alterations in mitochondrial enzyme activities and serum inflammatory cytokines. Naringin produced comparable effects to rivastigmine (2mg/kg; po). Thus the study demonstrates the effectiveness of naringin in preventing cognitive deficits caused by ICV-OKA in rats and it may provide a novel and effective strategy to treat neurodegenerative diseases such as Alzheimer's disease.

Title: The precision of contextual familiarity memory is attenuated in remote retrieval

Authors: *J. PARK, H. SHIN;
Ctr. for Cognition and Sociality, IBS, Seoul, Korea, Republic of

Abstract: The research to elucidate the neural basis of remote memory has been mostly studied only within the small fields, such as fear conditioning. Our daily life is, however, usually in neutral contexts without severely fearful incidents. It has been known that a decrease of locomotive behavior is frequently observed in rodents when exposed to a familiar circumstance. Thus, the memory level for a given context can be measured at this moment. This methodology was employed to investigate the characteristics of remote memory in neutral circumstance. We recruited 2 kinds of sensory modalities, box shape and odor, which of two are useful to distinguish open filed contexts. The context "A" consists of square shape and cineole odor while the context "B" is composed of circular shape and heptanole odor. These two types of conditions were used either for a novel or a familiar contextual environment. In order to induce distinct types of contextual familiarity memory, one group of mice was exposed to the context A, and the other, the context B. The retrieval of remote memory was tested 6 weeks following each initial exposure. To evaluate whether locomotive behavior was actually reduced in the only experienced context, mice were exposed to novel context again 1 day after the remote memory test. Interestingly, exposures to both contexts were resulted in decreased locomotive behavior in the mouse. It was confirmed that mice could distinguish two different contexts in recent retrieval, and even 3 consecutive days of training could not prevent the attenuation of memory precision in remote retrieval. Here I report that contextual familiarity memory is generalized in remote, but not recent retrieval.

Abstract: Impaired cognitive control, an inability to use relevant information and ignore salient but irrelevant information, is perhaps the most debilitating deficit in schizophrenia but this and other cognitive symptoms are not treated by antipsychotic medications. The development of procognitive antipsychotics is stymied by the lack of mechanistic hypotheses both for the cognitive deficits and model systems for evaluating them. We examined the "discoordination hypothesis" that discoordination of electrical neural activity underlies cognitive dysfunction. We show, in the most widely used animal model for developing antipsychotics, that the psychotomimetic phencyclidine (PCP) impaired cognitive control in rodents performing a two-frame active place avoidance task that requires using relevant cues and ignoring irrelevant cues to avoid a shock zone. PCP also discoordinated the electrical activity in networks of hippocampal CA1 place cells at the levels of both ensemble action potential discharge and field potential oscillations, without disrupting the spatial firing of individual place cells.
We then sought the molecular mechanism of this PCP-induced neural and cognitive discoordination. Multiple findings indicate that PCP rapidly induces aberrant group 1 mGluR stimulated protein synthesis. We injected mice with PCP or vehicle, and hippocampal slices were obtained to assess the protein synthesis dependent mGluR-stimulated LTD at the Schaffer collaterals to CA1 synapses by bath application of the group I mGluR agonist DHPG. Anisomycin, a protein synthesis inhibitor, given prior to the PCP injection, blocked the PCP-induced increase of mGluR-LTD, prevented the PCP-induced impairment of cognitive control as well as discoordination of neural spike trains. The PCP-induced cognitive control impairment was also prevented by pretreating mice with MPEP, the group I mGluR antagonist.
These findings indicate that PCP causes rapid group 1 mGluR-stimulated protein synthesis that leads to neural discoordination and cognitive control failures. These data i) strongly support the hypothesis that neural discoordination is a central pathophysiology underlying cognitive dysfunction in schizophrenia, ii) identify a novel biochemical cause of the pathophysiology, and iii) provide both a rationale and experimental platform for developing procognitive antipsychotic medications.

Title: Activity of extrasynaptic gabaa receptors in mediodorsal nucleus of thalamus modulates fear extinction learning

Authors: *A. PAYDAR, S. LEE, B. LEE, G. GANGADHARAN, H.-S. SHIN;
Ctr. for Cognition and Sociality, Inst. For Basic Sci., Seoul, Korea, Republic of

Abstract: In fear extinction repetitive exposure of a conditioned animal to conditional stimulus (CS) alone will result in decrease of conditional response (CR). This approach can be used for treating patients with anxiety disorders, e.g. phobias and post-traumatic stress disorder (PTSD). Prefrontal cortex (PFC), amygdala and hippocampus are essential for fear extinction. Mediodorsal nucleus (MD) of thalamus has been implicated in fear extinction learning. GABA, the main inhibitory neurotransmitter in the brain, has an essential role in the fear extinction. GABAA receptors provide phasic (through synaptic GABAA receptors) and tonic (via extrasynaptic GABAA receptors) inhibition.
In this study we investigated the role of GABAergic activity in MD in fear extinction learning. Injection of Gabazine, a GABAA receptor antagonist, into MD region of mice brain before fear extinction decreased freezing behavior in response to tone (CS), i.e. facilitated fear extinction learning. Also, injection of Gaboxadol (THIP), an extrasynaptic GABAA receptor agonist, into the MD region before extinction, attenuated fear extinction.
In addition to confirming the role of MD in fear extinction learning, our results show the GABAergic activity in MD nucleus of Thalamus, especially the “tonic GABA inhibition” resulted from the extrasynaptic GABAA receptors, modulates the fear extinction learning.

Abstract: Hippocampal theta oscillations are implicated in diverse brain functions including novelty behavior. Although T-type calcium channels are crucial for the genesis of many neuronal oscillations and different behaviors, it remains unexamined whether these channels control theta oscillations and associated behaviors. Here we show that mice with a knockout or medial septal-specific knockdown of Cav3.1 T- type channels exhibited increased cholinergic theta oscillations and enhanced novelty behavior. Cav3.1 channels are strongly expressed in GABAergic neurons in the medial septum. Interestingly, in the mutant mice the septo-hippocampal projecting GABAergic neurons lacked low threshold spikes and markedly increased spontaneous discharge activities. Moreover, optogenetic stimulation of septo-hippocampal GABAergic neurons reproduced the increased novelty behavior shown by the Cav3.1 knockout or knockdown mice. These results highlight the new role of Cav3.1 T-type calcium channels in the control of hippocampal cholinergic theta oscillations and novelty behavior.

(POSTECH), Pohang, Korea, Republic of

Abstract: Microelectrodes are widely used for monitoring neural activities in various neurobiological studies, but these devices either can damage cells during penetration or are incapable of drug injection. Here, we report carbon-nanotube-based nanoelectrodes with a diameter of ~300nm for interrogating cells, transporting fluids at the single cell level. The carbon-nanotube wire was fabricated using dielectrophoresis and surface tension which is much more easy-to-make and shape-controllable technique than previously a carbon-nanotube pipette (CNP). For neural electrodes, the nanoelectrodes have excellent electrochemical properties such as low impedance, large electrochemical surface area and ohmic contact characteristic. In addition, the nanoelectrode, which is made by placing a single-walled nanotube at the tip of a glass pipette, can probe the intracellular environment and deliver specific drug to the target cell without disrupting the cell. Because they are combined on conventional micropipettes, the nanoelectrodes are readily applied to traditional instruments, creating various opportunities for minimally invasive intracellular recording, and drug delivery.

Title: CE-245677-induced cognitive deficits: A translational story implicating inhibition of trkb-mediated pathways

Authors: *A. N. FOOTE[1], C. HSU[1], A. MEAD[1], R. NEWMAN[2], K. CANNON[1];
[1]Pfizer, Inc, Groton, CT; [2]Pfizer, Inc, Sandwich, United Kingdom

Abstract: CE-245677 is an antagonist at Tie2 (IC_{50} = 0.28 nM), a member of the receptor tyrosine kinase family, and was in Phase 1 clinical trials for the treatment of solid tumor growth. Administration of 100 mg CE-245677 q.i.d. resulted in a spectrum of cognitive dysfunction that ranged from mental fogginess appearing as early as day 2 to memory loss that appeared by day 15 in 3 out of 4 patients (IND Annual Report, CE-245677). Total plasma exposure of CE-245677 from the patient presenting with mental fogginess on day 2 was approximately 814 ng/mL. Nonclinically, the contextual renewal (CR) assay was used to assess alterations in cognitive performance after acute oral administration of CE-245677 to male Wistar Han rats. The CR model assesses the ability of a rat to learn simple associations between environmental cues and rewarding stimuli (i.e., food). When administered as a positive control, 1 mg/kg s.c. scopolamine decreased memory recall and cue-induced renewal responding in the CR assay. Oral administration of 0.3 mg/kg CE-245677 failed to produce changes in memory recall or cue-induced renewal responding in this assay. However, oral administration of 10 or 100 mg/kg CE-245677 decreased memory recall and cue-induced renewal responding when compared to the renewal vehicle, thus suggesting that these doses of CE-245677 alter aspects of cognitive performance in rats. The total plasma exposure levels of CE-245677 were 46.5, 802, and 7458 ng/mL following administration of 0.3, 10, and 100 mg/kg, respectively. Calculated from total brain exposures levels (ppb = 0.99), the estimated free brain exposure levels of CE-245677 were 0.5, 9, and 73 nM following administration of 0.3, 10, and 100 mg/kg.
In addition to activity at Tie2, CE-245677 also possess inhibitory secondary pharmacology at TrkB receptors (TrkB K_i = 4.8 nM). TrkB receptors have been hypothesized to play a role in learning and memory processes (Yamada & Nabeshima, 2003). Thus, inhibition of these receptors may lead to cognitive impairment. Given the putative role of TrkB receptors in cognitive processes, it is possible that CE-245677-induced alterations in cognitive performance observed both clinically and nonclinically may be a result of off-target activity at TrkB receptors. In support of this, estimated free brain concentrations of 10 and 100 mg/kg CE-245677 in rats were approximately 1.9x and 15.1x, respectively, over CE-245677's K_i for TrkB. From the clinical data, the estimated free brain concentration was approximately 2x over the compound's K_i for TrkB. These findings suggest that CE-245677-induced alterations in cognitive performance may be a result of TrkB inhibition in the brain.

Title: The role of striatal cholinergic transmission in cognition: Assessment of mice deficient for the vesicular acetylcholine transporter (VAChT) in the striatum

Authors: *D. R. PALMER[1], K. GAHNSMITH[2], R. COURTNEY[2], I. PLUMB[2], B. BULOSAN[2], E. BINSELL[2], A. VAN MAANEN[2], S. CREIGHTON[2], V. F. PRADO[3], M. M. PRADO[3], E. CHOLERIS[1], B. D. WINTERS[1];
[1]Psychology: Neurosci. and Applied Cognitive Sci., [2]Univ. of Guelph, Guelph, ON, Canada; [3]Dept. of Physiol. & Pharmacol., Western Univ., London, ON, Canada

Abstract: The neurotransmitter Acetylcholine (ACh) has been implicated in numerous aspects of cognition including learning, memory, and attention. Previous research has indicated important roles for the cholinergic neurons of the basal forebrain in many of these functions. In addition to the basal forebrain, however, there are other cholinergic networks in the brain that may influence cognition. For example, the striatum contains a population of cholinergic interneurons that help to regulate basal ganglia activity. At present, it is not clear whether these cholinergic interneurons play a role in cognition. Recently, a strain of genetically modified mice have been developed which are deficient for the Vesicular Acetylcholine Transporter (VAChT) within the striatum (Guzman et al, 2011). We tested these Striatal VAChT mice on a battery of learning, memory, attention, and cognitive flexibility tasks. Striatal VAChT mice were impaired on a spontaneous object recognition task when the delay between initial learning and memory testing was 15-minutes, but not when the delay was extended to 3 hours. Impairment was also observed in male VAChT mice tested on a social recognition paradigm with the short delay, but not the long delay. Similar impairment was not seen on a spontaneous object location task assessing spatial memory. On a mouse touchscreen 5-choice serial reaction time task it was found that striatal VAChT mice showed impairments in attention, as accuracy was reduced and omission rates were increased. To assess associative learning and cognitive flexibility, mice were also trained on a visual pairwise discrimination task using touchscreens. Striatal VAChT mice acquired the visual discrimination normally; interestingly, however, they were impaired on subsequent trials where the reward contingency was reversed, suggesting a deficit in cognitive flexibility. In all, these results indicate that striatal cholinergic transmission is involved in short-term social and object recognition processing, attentional processing, and the reversal of highly

trained associations. These effects may be related to striatal cholinergic influences on interactions between the dorsal striatum and prefrontal cortex.

Title: Genetic analysis of the roles of NMDA receptors in the parafascicular nucleus in sensory processing

Authors: *K. YASUDA[1,2], Y. HAYASHI[1], M. TANAKA[1], S. ITOHARA[1];
[1]RIKEN Brain Sci. Inst., Wako-Shi, Saitama, Japan; [2]Grad. Sch. of Agr. and Life Sci., 1-1-1, Yayoi, Bunkyo-ku, Tokyo, Japan

Abstract: Distinct brain regions perform different types of computations for processing sensory information to support various behaviors. Little is known, however, about how sensory information processed in individual brain areas is integrated.
The parafascicular nucleus (Pfn), an intralaminar thalamic nucleus, might have a special role in integrating sensory information. The Pfn has abundant mutual connections with two specific brain systems: the anterior cingulate cortex and the striatum. The anterior cingulate cortex and striatum are involved in the selection of sensory stimuli and behavioral output, respectively. Therefore, the Pfn might serve an important role in selecting sensory inputs that are relevant to behavioral decision. Neurons of the Pf are activated by unfamiliar or unexpected stimuli, and these firing responses often habituate rapidly when the same stimuli are presented repeatedly. We postulate that the habituation serves as a mechanism for selecting salient or task-relevant stimuli, and that the rapid habituation of Pf neurons is modulated by NMDA receptors.
To test this hypothesis, we generated Pfn-selective conditional knockout (cKO) mice of NR1,

which encodes an essential NMDA receptor subunit. We developed a transgenic mouse line expressing Cre selectively in this brain area and crossed these mice with mice in which NR1 is flanked by loxP. These cKO mice exhibited hyperactivity in their home cages, although there was no evidence of hyperactivity in a novel environment. Furthermore, they displayed motor coordination deficits on the accelerating rotarod. These preliminary results support the notion that the rapid habituation of Pfn neurons via NMDA receptors is crucial for the selection of task-relevant sensory information.

Title: Microinfusions of estradiol to the medial prefrontal cortex bias adult female rats towards use of a place learning memory system

Authors: *A. ALMEY, K. BERTRAM, E. CANNELL, W. G. BRAKE;
Concordia Univ., Montreal, QC, Canada

Abstract: There are at least two memory systems that rats use to learn spatial tasks such as a maze: a place memory system, where spatial cues are used to arrive at the desired location, and a response memory system, where the same physical response (i.e. turning left) is used to arrive at the desired location. Estrogens affect which of these memory systems is employed, with higher levels of estrogens biasing rats towards use of a place memory system. The hippocampus and dorsal striatum have been implicated in these memory systems but it is still not fully established where in the brain estrogen acts to bias memory system use. There is evidence that the prefrontal cortex plays an important role in solving maze tasks and the development of habitual behaviour. Therefore, this study examined whether increasing estradiol (E2) in the medial prefrontal cortex (mPFC) biases rats towards use of a place memory system. For this experiment 29 female rats were ovariectomized and implanted with bilateral cannulae; 14 had cannulae implanted in the mPFC and 15 had cannulae implanted in a control brain region, the anterior cingulate cortex (AC). The rats were trained, via 10 daily trials, to go to the same arm of a t-maze to receive a food reward. Once a rat had learned to go to the correct arm they were tested to determine what memory system they were using to navigate the maze by rotating the maze 180 degrees for testing. For the test, if the rat arrived at the arm containing the food reward this indicated that the

a place memory system was used, but if the rat arrived at the arm without the food reward this indicated a response memory system was used. Following the first test all rats were retrained, and retested following a microinfusion of either E2 or cyclodextrin, whichever they had not received prior to the first test. The results show that following an infusion of E2 to the mPFC 85% of the rats used a place memory system to navigate the maze. In contrast, 28% of rats that received cyclodextrin in the mPFC, and less than 20% of rats that received either E2 or cyclodextrin in the AC, used a place memory system to navigate the maze. This demonstrates that increasing levels of E2 in the mPFC biases female rats towards use of a place learning memory system.

Title: Role of Dopamine in observational learning in rats

Authors: *M. A. MAHMOUD[1], A. GHESTEM[1], P. CARLIER[1], M. MOFTAH[2], D. BOUSSAOUD[1];
[1]Inst. De Neurosciences Des Systèmes UMR INSERM 1106, Marseille, France; [2]Zoology Department, faculty of science, Alexandria univeristy, Alexandria, Egypt

Abstract: Learning new sensorimotor skills relies heavily on practice, also termed trial-and-error learning (TE). In social species, TE learning may gain in speed if the learner had a chance to observe a conspecific perform the task to be learned. At the behavioral level, this gain from observation has been well demonstrated in various species, including rodents and human and non human primates. By contrast, the neural mechanisms of observational learning (LeO) remain unknown. Recent brain imaging studies in humans (Monfardini et al. unpulished) suggest that LeO and TE activate overlapping neuronal networks, including frontal cortex and basal ganglia. In monkeys, neuronal recordings have shown that prefrontal cortex neurons process feedback signals in both conditions (Isbaine et al., 2012). As dopamine plays a key role during TE learning (Puig & Miller, 2012), we hypothsized that it may also be involved in LeO. To test this hypothesis, we blocked dopamine D1 receptors (D1R) in prefrontal cortex of rats, and measured their gain from observation as compared to controls. The testing apparatus is composed of two

compartments separated by a partition, which allows visual/tactile communication between animals. One compartment (actor) contained a vertical lever which can be pushed in two directions (right or left), and a food well located at one of the corners. The correct lever push triggers the delivery of food pellets in the food well (reward), synchronized with a low frequency tone, whereas the incorrect push triggered a high frequency tone, and no reward. A group of rats were first exposed to an expert rat pushing the lever in the correct direction before they were placed in the actor compartment. In another group, rats learned through TE, and the results show that LeO rats learn much faster compared to TE rats, confirming the idea that rats can learn by observation. We then injected 2 key areas, orbitofrontal cortex (OFC) and anterior cingulate cortex (ACC) with a D1R antagonist (SCH 23390) in naïve rats before each session. Their learning rate was compared to rats injected with saline. Preliminary data show that blockade of D1R in OFC and ACC impairs severely observational learning. They suggest that dopamine plays a key role in OFC and ACC neural processes involved in observational learning.

Neurosciences, UCSD, San Diego, CA; [6]NorthShore Univ. Hlth. System, Ctr. for Basic MR Research, Evanston, Il, Univ. of Chicago, Chicago, IL

Abstract: We reported earlier that we induce mild Traumatic Brain Injury (TBI) by blasting anesthetized male 8 week old C57BL/6N mice (Harlan) with a Helium pressure wave delivered from a 6 foot-long and 2 inch-wide shock tube to the back of the mouse head. Other parts of the body are protected by a firm ballistic Nylon coat. The pressure wave resembles a characteristic free field blast wave with an almost instantaneous rise to an overpressure (16 psi) lasting 1.4 msec. The blasted mice are subjected to auditory trace or delay fear conditioning as models for declarative and non-declarative memory, respectively. After a 24 hour delay, the blasted mice show increased freezing during re-exposure to the original and to a novel context which we ascribe to effects associated with Post-Traumatic Stress Disorder (PTSD). We also find decreased freezing to the auditory cue in a novel context. Behavioral changes are significantly correlated with fractional anisotropy values determined with *ex vivo* Diffusion Tensor Imaging (DTI) of the corpus callosum.

This mouse model of mild TBI has now been further analyzed for its relationship to CTE, a pathological condition that has been observed in Iraqi and Afghanistan war veterans suffering from PTSD. It has been speculated that CTE is involved in the recently increased suicide rate among veterans of the Iraqi and Afghanistan wars as well as among NFL football players. CTE is immunohistologically identified by typical cortical foci of hyperphosphorylated tau protein (phospho-tau), a CTE biomarker.

We report here that we found increased phospho-tau staining with the mouse monoclonal antibody PHF1 (Peter Davies) in slices of frontal cortex and the dentate gyrus of the hippocampus from mice that were blasted at 16 psi. The phospho-tau staining was significantly reduced when NitroMemantine, an uncompetitive dual-site NMDA-type glutamate receptor antagonist, developed in our laboratory (by SAL), was administered i.p. 30 minutes before the blast at a dose of 28 mg/kg.

We conclude on the basis of these preliminary data that NitroMemantine may qualify as a drug to ameliorate CTE and possibly mild TBI.

Title: Effects of nicotine exposure termination and subsequent nicotine administration on responding for delayed rewards

Authors: *K. YONEZAKI[1], J. R. FADEL[2], J. A. BURK[3];
[1]Hokkaido Univ., Yokohama, Japan; [2]Pharmacology, Physiol. and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC; [3]Psychology, Col. of William & Mary, Williamsburg, VA

Abstract: Changes in delay discounting performance are known to be associated with subsequent drug use. However, the effects of abstinence and re-exposure to nicotine on sensitivity to reward contingencies are not well-characterized. In the present experiment, rats were trained in a delay discounting task and then exposed to nicotine (0.4 mg/kg, twice per day) or saline for four days. All rats then received nicotine (0.1 mg/kg) on Days 5, 8 and 12 and saline on all intervening days prior to task performance. Nicotine exposure elevated omission rates during the initial administration period. There were no differences on Day 5 between nicotine- and saline-pre-exposed rats following 0.1 mg/kg nicotine or upon termination of nicotine exposure (Days 6 & 7). Following 0.1 mg/kg nicotine on Day 8, nicotine pre-exposed rats were more likely to enter the delayed, larger reward compared with the immediately accessible smaller reward. Following saline exposure on Days 9-11, nicotine pre-exposed animals were less likely to enter the delayed, larger reward and omitted more trials than saline pre-exposed rats. Following 0.1 mg/kg nicotine on Day 12, the group differences in choice preference and omissions were no longer present. Water consumption from the home cage measured after completion of delay discounting testing was not affected by prior repeated nicotine exposure. Termination of nicotine exposure and subsequent nicotine re-exposure may decrease sensitivity to reward contingencies which could increase risk of future drug use.

Title: Loss of medial prefrontal cortical cholinergic projections increases preference for an immediately available reward in a delay discounting task

Authors: *J. A. BURK[1], K. YONEZAKI[2];
[1]Psychology, Col. of William & Mary, Williamsburg, VA; [2]Hokkaido Univ., Yokohama, Japan

Abstract: Attentional control is thought to regulate numerous processes, including impulsive choices. The cholinergic projections to the medial prefrontal cortex are thought to be part of a distributed neural circuit that maintains attentional control. In the present experiment, male FBNF1 hybrid rats were trained in a delay discounting task that involved a choice between a small, immediately available reward and a larger reward. The larger reward was also immediately available at the beginning of the test session and then the delay to receive this reward was progressively increased within a session (0-40 s). After reaching stable performance levels, rats then either received infusions of the cholinergic immunotoxin, 192IgG-saporin, or vehicle into the medial prefrontal cortex. After recovering from surgery, rats were tested in the same delay discounting task that had been trained prior to surgery. Relative to sham-lesioned animals, rats with a loss of the cholinergic projections to the medial prefrontal cortex exhibited an increased preference for selecting the smaller, immediate reward. Subsequent administration of nicotine (0.0, 0.1, 0.2, 0.4 mg/kg, ip) did not substantially alter the effects of the lesion on delay discounting performance. The present results suggest that medial prefrontal cortical cholinergic projections contribute to choice behavior based upon delay to reward access and reward magnitude. Moreover, these results are consistent with the idea that disruption of attentional control can increase impulsive choices.

Title: Analysis of the use of positive and negative feedback after methamphetamine

Authors: *A. STOLYAROVA, D. RODRIGUEZ, A. IZQUIERDO;
California State Univ, Los Angeles, Los Angeles, CA

Abstract: Convergent evidence from rat, monkey, and human studies suggests maladaptive decision making in methamphetamine (METH) addiction. Actor-Critic architecture is currently a widely accepted model of striatal function, in which ventral striatum is assigned the role of critic, which stores state-dependent values and signals reward prediction error (δ), and dorsal striatum represents an actor, which assigns state-action-dependent preferences (Sutton & Barto, 1998; Takahashi et al. 2008). Reversal learning is a behavioral task measuring flexibility of response to changes in reward contingency and is well-suited to examine animals' ability to integrate positive and negative outcomes into decision making within the framework of the actor-critic model. In the present experiment we compared the long-term effects of METH and saline (SAL) on pairwise visual discrimination reversal learning. Specifically, we analyzed how animals use positive and negative trial-by-trial feedback (Izquierdo et al. 2013), domains not previously explored in rat drug studies. No significant treatment group differences were observed in overall trial-by-trial responses to positive or negative feedback in reversal learning. However, based on previous suggestions that task demand and interference strength change across stages of reversal learning, we performed analyses of 3 distinct stages: zero to 50% correct (Stage 1), at 50% (Stage 2) and 50% to criterion (Stage 3). Trial-by-trial analysis showed that METH-treated animals benefited more from correctly-performed (C) trials Δ(C+1)/C total during Stage 1 and required more experience switching from incorrectly-performed (E) to C trials Δp(E+1)/ΔpC to update behavioral responses compared to SAL. Differences in learning from C feedback persisted into Stage 2. SAL-treated animals' progression to Stage 3 was accompanied by a reduction in the proportion of C trials resulting from negative feedback Δ(E+1)/C total, whereas METH-treated animals failed to demonstrate the same pattern. Prolonged escalating METH exposure, not binge exposure, yielded the most aberrant responses. Binge-treated rats, however, showed less reduction in C trials followed by E trials Δ(C+E)/C total. No differences were observed in response to either C or E feedback across groups at Stage 3. Overall, results indicate enhanced learning from positive feedback and increased interference in METH treated rats. This suggests both increased positive δ and decreased rate of state value update in the Actor-Critic after METH. Additional experiments are aimed at uncovering the neural correlates of these maladaptive learning patterns.

Title: Discrimination reversal learning and self-administration in adulthood following adolescent methamphetamine exposure

Authors: *T. YE[1], H. POZOS[1], T. J. PHILLIPS[2], A. IZQUIERDO[1];
[1]California State University, Los Angeles, Los Angeles, CA; [2]Veterans Affairs Med. Ctr. and the Methamphetamine Abuse Res. Ctr., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Adolescence is a period of profound neurobiological change. As the frontal cortex continues to develop through adolescence into adulthood, the ongoing refinement of frontocortical processes (i.e., cognitive control) precipitates heightened impulsivity and poor decision-making. Poor cognitive control in adolescence may contribute to an accelerated progression from recreational use to compulsive substance use in adulthood. Previous research found increased vulnerability for learning and memory impairments when rats were exposed to methamphetamine (METH) in late adolescence, specifically Post Natal Days (PND) 41-50 (Vorhees et al., 2005) and PND 50-51 (White et al., 2009). The purpose of the present study was to investigate the long-term effects of escalating, adolescent METH exposure on cognitive flexibility as measured by visual discrimination and reversal learning in adulthood (Experiment 1) and the likelihood of later self-administration of the drug (Experiment 2), also in adulthood. In Experiment 1, male Long-Evans rats were treated with either saline (n=8 SAL) or escalating doses of 0.3 mg/kg to 3.0 mg/kg METH during PND 41-50 (n=10 METH). Following treatment, rats were trained to nosepoke stimuli associated with reward (S+) and withhold response to stimuli associated with no reward (S-) on a touchscreen, i.e. visual discrimination learning. Upon reaching criterion, reward contingencies were reversed, i.e. reversal learning. Results showed there was a significant effect of METH treatment on both visual discrimination and reversal learning, with most pronounced attenuations in the reversal learning phase. Impairments in this phase are consistent with previous research in the adult, however, discrimination learning impairments have not been previously reported. In Experiment 2, rats exposed in adolescence to either METH or SAL underwent voluntary self-administration of low (10 mg/l) and high dose (20 mg/l) METH or quinine in a two-bottle choice design: a bottle of pure water vs. a bottle mixed with METH or quinine. We found that rats pre-exposed to METH during adolescence self-administered significantly more drug in adulthood. Additionally, results showed there was a significant positive correlation between sessions to criterion on discrimination learning and consumption of the low METH dose. Taken together, these findings show that even modest exposure to METH during late adolescence may induce long-term general learning impairments and an increased likelihood to self-administer METH in adulthood. Ongoing experiments are aimed at uncovering the neural correlates of these behaviors.

Title: Effects of a D2R antagonist on changes in cross-frequency power coupling related to the trade-off between attention demanding and automatic processes in frontal-striatal circuits

Authors: *E. LEE[1], M. SEO[1,2], O. DAL MONTE[1], B. B. AVERBECK[1];
[1]Unit on Learning and Decision Making, Lab. of Neuropsychology, NIMH, NIH, Bethesda, MD;
[2]UCL, Inst. of Neurobio., London, United Kingdom

Abstract: In daily life, we often shift between automatic and attention demanding processes without effort. Emerging research suggests that frontal-striatal circuits are involved in the trade-off between attention demanding and automatic processes. However, the role of dopamine in frontal-striatal circuits in this trade-off has not been examined directly. To investigate this, we trained monkeys on an oculomotor sequential decision making task with random and fixed conditions. In the random condition (attention demanding) the correct spatial sequence of eye movements varied from trial to trial and the animal had to carry out a difficult perceptual decision to determine where to saccade. In the fixed condition (automatic), the sequence was fixed for blocks of eight correct trials. Thus once the animal learned the sequence it could automatically execute it from memory. While the monkeys performed the task, we injected locally a dopamine D2R antagonist (Eticlopride, 1.2ug/1ul) or saline into the dStr (2ul/site at 3nl/sec, 8 ul/side) bilaterally. Moreover, we recorded local field potentials from lateral prefrontal cortex (lPFC) and dorsal striatum (dStr) simultaneously with the injections.
We examined changes in cross-frequency power coupling between pre- and post-drug (saline) injections within each session. DStr-dStr cross frequency power coupling showed significant changes in the 8-30 hz (alpha and beta) range during the task in the fixed condition in drug sessions. LPFC-dStr power coupling showed significant changes in the 13-30hz (beta) range during the stimulus presentation period and the 8-12hz (alpha) range during the movement period in the fixed condition in the drug sessions. In saline sessions, no changes were found between the pre and post injection periods. Overall, our results suggest that the indirect pathway through the basal ganglia, which contains primarily D2Rs, modulates the transition between attention demanding and automatic processes. Furthermore, the effects of antagonist injections on the interaction within the dStr and between dLPFC-dStr in the 8-30 hz (alpha and beta) range

suggests an important role for dopamine in the trade-off between attention demanding and automatic processes.

Title: Increased impulsive action after a history of chronic alcohol intake and abstinence

Authors: *C. IRIMIA, I. Y. POLIS, L. H. PARSONS;
Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., La Jolla, CA

Abstract: Impaired cognitive processing is a hallmark of addiction. In particular, deficits in inhibitory control (impulsive action) can propel continued drug use despite adverse consequences. Clinical studies have provided substantial evidence that detoxified alcoholics exhibit poor inhibitory control in the Continuous Performance Task (CPT) and related tests of motor impulsivity. Premorbid impulse control disorders also contribute to the initiation of problem drinking, for example adolescents that score higher on the Baratt Impulsivity Scale are also more likely to use alcohol and other drugs and to start drinking at an earlier age. A persistent question in alcohol research regards the relative influence of pre- existing cognitive disruptions that confer susceptibility to problem alcohol use versus the induction of cognitive impairment related to cortical damage induced by repeated cycles of intoxication and withdrawal. In this regard animal models can provide important insight into the etiology of alcohol-induced cognitive impairment and can provide a platform for mechanistic studies and rapid pharmacotherapy screening. Using behavioral paradigms analogous to clinically employed tasks we have gathered evidence of significant increases in impulsive action that emerge during protracted withdrawal in alcohol-dependent rats. In the 5 Choice Serial Reaction Time Task (5CSRTT) we observe an emergence of significant impulsive action behavior over the course of 34d of abstinence. This form of impulsivity is ameliorated following a return to alcohol consumption, but re-emerges during subsequent periods of abstinence. Using a novel animal model of CPT we find that alcohol-dependent rats also exhibit an inability to suppress prepotent responses (e.g. high levels of false alarms) during early stages of withdrawal along with excessive premature responding under task conditions with enhanced cognitive load, and these

disruptions persist during at least 7 weeks of abstinence. These forms of impulsive behavior are reliant on proper function of the medial prefrontal cortex, and as such our findings point to dependence-induced impairment of frontal cortical function. Collectively, these findings demonstrate the emergence of increased impulsive action in alcohol-dependent rats during protracted withdrawal and this may provide a viable animal model for characterizing the neurobiological substrates underlying dependence-related impulsivity.

Title: Adolescent behavior and nac neuronal recording following methylphenidate (0.6, 2.5, 5.0, 10.0 mg/kg i.p.)

Authors: A. FROLOV[1], *C. REYES-VAZQUEZ[2], N. DAFNY[1];
[1]Neurobio. and Anat., Univ. of Texas at Houston, Houston, TX; [2]Depto. de Fisiología, Depto. De Fisiología, Mexico DF, Mexico

Abstract: Methylphenidate (MPD) has become one of the most commonly prescribed drugs for the treatment of ADHD. The broadening of its use both as a standard treatment and, more controversially, as a method of cognitive enhancement and recreation has led to a need to evaluate its effects more closely, especially when used chronically in adolescents. Studies have demonstrated that after chronic administration of the same dose of MPD, some animals will exhibit behavior indicative of tolerance to the drug, while others will exhibit behavior indicative of sensitization. Furthermore, the nucleus accumbens (NAc) has been shown to play a key role in the brain's reward response to MPD, and thus is the target of this study. The present study postulates that the same dose of MPD will elicit in some animals behavioral sensitization and in others tolerance, and that NAc neuronal activity from animals expressing behavioral tolerance will be significantly different from NAc neuronal activity recorded from animals expressing behavioral sensitization. To test this hypothesis, behavioral and neuronal activity was recorded from the NAc of freely behaving adolescent rats before and after acute and chronic administration of 4 different MPD doses. Five groups of rats were used: all received saline injections, followed by either saline or 0.6, 2.5, 5.0, or 10.0 mg/kg MPD i.p. on experimental day

1 (ED1). On ED2 to ED6, the control group received saline, while the others received the same dose of MPD as they did on ED1. On ED7 to ED9, the rats received no injections, representing a washout period. Finally, on ED10, neuronal activity was recorded after saline or MPD rechallenge in the same manner as on ED1. Statistical analysis of the data reveals that at all doses of MPD (but not in saline controls), some animals demonstrate behavioral tolerance and others behavioral sensitization, and that neuronal firing rates in animals exhibiting sensitization show a significantly different response to MPD from neuronal firing rates in animals exhibiting behavioral tolerance. This indicates that when studying the effects of chronic MPD on adolescents, it is critical to simultaneously record both neuronal activity and behavioral data, and to evaluate all data based on the animals' behavioral response to chronic MPD exposure.

Title: Etanol,exposure in binge episodes during adolescence change the bdnf levels, attention and aggressive behavior in adults wistar rats

Authors: *R. M. DE ALMEIDA[1], L. BIZARRO[1], L. SCHEIDT[1], A. PIRES[1], J. PASSOS[1], L. STERTZ[2], G. FRIES[2], F. KAPCZINSKI[2], K. MICZEK[3];
[1]Psychology, UFRGS, Porto Alegre, Brazil; [2]Psychiatry, HCPA, Porto Alegre, Brazil; [3]Psychology, TUFTS Univ., Boston, MA

Abstract: Animal models provide a useful alternative for studying the mechanisms of dependence and cognitive-behavioral deficits caused by repeated by alcohol intake during adolescence. Morphological and molecular changes in the limbic system such as hippocampus have been documented after many types of stress including alcohol administration. We investigated the effects of ethanol exposure in adolescent rats during adulthood and assesss the attention, impulsivity, aggression, anxiety-like behaviors and the check the levels of inflammatory markers. Three groups of male Wistar rats (mean weight 81.4 g, N=120 were housed in groups of four until post-natal day 60 (P60). From days P30-P46 rats received one of three by ">treatments: 3 g/kg of ethanol (15% v/v, PO, n = 48), 1.5 g / kg of ethanol (12.5% v/v, PO, n = 36), or water (n = 36) every 48 hours. Groups of 40 animals were studied for aggression

and anxiety-like behaviors; attention and impulsivity. And also some animals were assessed to investigated the levels of BDNF on the pre-frontal cortex and hippocampus. After P60, attentional
performance was assessed in the 5-choice serial reaction time task (5CSRTT) and impulsivity was assessed on an operant delay discounting task. Results: In the 5-CSRTT, animals achieved stable base line responding in 89 sessions, with no differences among treatment groups. In test sessions, when the ITI was 15s the group that received 3 g/kg showed lower accuracy (72.5%) than the others (81.9% accuracy in the 1.5 g/kg group and 83.4% in the water group). The latency of correct
responses was longer in 1.5 g/kg group than the latency of 3 g/kg group ($p < 0.05$). There was no group effect or group x session type interaction in the other measures. With respect to delay discounting, the animals treated with alcohol (1.5 g/kg and 3.0 g/kg) did not show any difference when compared to control group. Animals treated with the lower concentration of alcohol were more aggressive (i.e. showed shorter attack latency to attack the intruder) when compared to the control group and had no effects on anxiety-like behaviors on the EPM as compared to control group. The animals wich receive a low concentartion of alcohol had low levels of BDNF in the hippocampus but not prefrontal cortex when compared to the control group.Binge-like, intermittent exposure to alcohol during adolescence led to impaired performance on an attention task in adulthood and may have compromised the readiness to respond. Adult animals were more promp to attack the intruder, showing more aggressive behaviors.
These behavioral aberrations were accompained by decreased level of BDNF in the hippocampus.

Title: The contribution of nicotinic acetylcholine receptors to learned inhibition

Authors: R. B. PUTNEY, *D. J. BUCCI;
Dartmouth Col., HANOVER, NH

Abstract: Learning to withhold a behavioral response when signaled by a cue in the environment (i.e., a 'stop signal') is an essential aspect of cognitive control and inhibition. Compared to adults, adolescent humans and laboratory animals often exhibit difficulty in using stop signals to guide behavior and successfully withhold a response and these deficits are exacerbated in ADHD and schizophrenia. Adolescents are also particularly vulnerable to taking up cigarette smoking, and nicotine use in persons with ADHD or schizophrenia is disproportionately high compared to the general population. Recent studies have shown that nicotine administration in juveniles and young adults with ADHD normalizes deficits in behavioral inhibition as measured in the Stop Signal Reaction Time Task. We have previously modeled this finding in rats by showing that treatment with nicotine enhances negative occasion setting, a form of learned inhibition. In this procedure, a tone is presented and followed immediately by food reward on a subset of trials. On other trials, a light precedes the tone and no food is delivered. Normal adult rats learn to discriminate between these two trial types after ~7 training sessions, indicated by approaching the food cup in anticipation of receiving a reward when the tone is presented by itself, but inhibiting that response when the light precedes the tone. Nicotine (0.35mg/kg free base equivalent) reduces the number of sessions needed to learn the discrimination and also enhances the magnitude of discrimination between trial types specifically by reducing responding during the non-reinforced trials. Here we tested additional doses of nicotine to derive a dose response curve and also tested the effects of mecamylamine (nicotinic acetylcholine receptor antagonist) to determine whether cholinergic activity is necessary for negative occasion setting. Adult male Long-Evans rats were maintained at 85% free feeding body weight and treated with either mecamylamine (0.125-2.0 mg/kg) or nicotine (0.2-0.5 mg/kg, free base equivalent) 20 minutes before each daily training session. Compared to vehicle-treated control rats, those treated with mecamylamine needed more sessions to learn the discrimination and also did not exhibit as robust discrimination between the trail types. Rats treated with nicotine learned the task in fewer sessions in a dose-dependent fashion. Together with the finding that rats with lesions of the prefrontal cortex are impaired in negative occasion setting, these data indicate that acetylcholine, perhaps acting through cortical nicotinic receptors, may be necessary for learning to inhibit behavioral responses.

Title: Nicotinic α4β2 receptor stimulation strengthens working memory-related neuronal activity in prefrontal cortex

Authors: Y. YANG[1], L. E. JIN[1], A. F. T. ARNSTEN[1], *M. WANG[2];
[1]Yale university, New Haven, CT; [2]Yale Univ. Sch. of Med., New Haven, CT

Abstract: Acetylcholine acts through a variety of nicotinic and muscarinic receptors to modulate wakefulness, and is essential for the working memory (WM) functions of the primate dorsolateral prefrontal cortex (dlPFC). Our previous study showed that nicotinic α7 acetylcholine receptors (α7-nAChRs) are localized in dlPFC synapses on spines, and are essential for the persistent neuronal firing of dlPFC circuits, permitting the NMDAR actions needed for communication between dlPFC neurons. Nicotinic α4β2 receptors are another important nicotinic receptor subtype in PFC. There is behavioral evidence that α4β2 stimulation can improve the working memory and attention functions of the PFC in rodents, monkeys and humans. The current study examined the effects of α4β2 receptor stimulation on the persistent neuronal firing of neurons in the dorsolateral PFC in monkeys performing a spatial working memory task. α4β2 receptor agonists were applied directly onto the neurons using iontophoresis. Preliminary data show that iontophoresis of the α4β2 receptor agonist, ABT-418, produces a dose-related enhancement of delay-related persistent activity and improvement in spatial tuning. These results indicate that an α4β2 receptor agonist, similar to an α7 receptor agonist, can enhance the memory-related firing of the dlPFC, encouraging the development of α4β2 receptor agonists as potential treatments for cognitive disorders.

Title: Investigating the role of striatal dopamine signalling during performance of a visual discrimination reversal task

Authors: *N. K. HORST[1,2], T. W. ROBBINS[1,2], A. C. ROBERTS[2,3];
[1]Dept. of Psychology, [2]Behavioural and Clin. Neurosci. Inst., [3]Dept. of Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Behavioural flexibility is impaired in numerous neuropsychiatric conditions, including Obsessive Compulsive Disorder (OCD; Dalley et al., Neuron, 2011). Reversal learning is a test of behavioural flexibility in which the stimulus-outcome contingencies switch, such that subjects must inhibit responding to previously rewarded stimuli and direct actions toward stimuli with no immediate history of reward. Previous studies in marmoset monkeys have demonstrated an important role for orbitofrontal cortex (OFC; Dias et al., J Neurosci, 1997) and medial striatum (Clarke et al., J Neurosci, 2008) in reversal performance. Notably, these regions have also been shown to be hypoactive during reversal learning in OCD patients (Remijnse et al., Arch Gen Psychiatry, 2006). Dopamine (DA) is a prominent neuromodulator in the striatum and is thought to be involved in facilitating learning about new or changing contingencies between behavioural events and outcomes (Schultz & Dickinson, Ann Rev Neurosci, 2000). Indeed, depletion of DA in marmoset caudate has been shown to produce deficits when stimulus-outcome contingencies are reversed (Clarke et al., J Neurosci, 2011). Recent studies have revealed a specific role for DA D2 receptors (D2Rs) in these effects. Relatively lower levels of D2Rs in the caudate have been linked to reversal deficits in human subjects (Jocham et al., J Neurosci, 2009) and vervet monkeys (Groman et al., J Neurosci, 2011) and are evident in OCD patients (Denys et al., Biol Psychiatry, 2009). To further examine the role of striatal D2Rs in flexible behaviour, we trained marmosets in a serial reversal task in which stimulus-outcome contingencies were switched within-session. Cannulae were implanted bilaterally in ventromedial caudate, which receives dense projections from OFC (Roberts et al., J Comp Neurol, 2007). Reversible inactivation of this region by co-infusion of the GABA-A agonist muscimol (2.2 nmol / side) and the GABA-B agonist baclofen (2.2 nmol / side) disrupted reversal learning in two animals, measured as an increase in trials to criterion greater than the 95% confidence interval of baseline responding. Local infusions of quinpirole (0.3-10.0 µg / side), a D2R agonist, improved reversal at moderate doses and impaired reversal at high doses. These manipulations did not affect retention. Saline infusions had no effect. These data confirm that the ventromedial caudate is required for optimal reversal performance in marmosets. The data also indicate that there is an inverted U-shaped

relationship between D2R stimulation and performance, which will be discussed in terms of pre- vs. post-synaptic D2R function (Cools et al., J Neurosci, 2009).

Title: Regional differences in amphetamine-induced dopamine release in non-human primates

Authors: *H. P. JEDEMA[1], R. NARENDRAN[2], C. W. BRADBERRY[3,4];
[1]Psychiatry, Univ. Pittsburgh, Pittsburgh, PA; [2]Radiology, Univ. Pittsburgh Med. Ctr., Pittsburgh, PA; [3]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [4]VA Pittsburgh Hlth. Services, Pittsburgh, PA

Abstract: Amphetamine (AMPH) is frequently used to increase catecholamine levels in attention disorders and PET imaging studies. Although the effect of AMPH varies across regions in rodents, data on regional differences in the primate are very limited, despite their frequent use to characterize PET ligands, including novel ligands whose displacement can be measured in the cortex (Narendran et al., 2013). The present study examined the impact of AMPH on the extracellular levels of dopamine (DA) in the prefrontal cortex and the caudate of non-human primates (n=5).
Average baseline levels in the anterior cingulate cortex were 0.31±0.03 nM (n=31 observations). Upon AMPH injection (0.15, 0.3, 0.5, or 1.0 mg/kg) cortical DA levels increased to 593±36, 965±130, 1385±213, or 2067±393 % of baseline levels, respectively. Peak DA levels in the cortex varied linearly with dose and were achieved on average 53±4 min after AMPH. Average

baseline DA levels in the caudate were 12.9±2.9 nM (n=12 observations). AMPH injection (0.3, 0.5, or 1.0 mg/kg) increased DA levels in the caudate to a greater extent, 1834±282, 2670±809, or 5807±235 % of baseline values, respectively. Peak DA levels in the caudate were achieved significantly faster, on average 32±3 min after AMPH. DA levels in the caudate appeared to decline in a biphasic manner, with an initial phase of rapid decline followed by a phase of slower decline similar to the steady decline observed in the cortex. Extrapolation of the data using first order kinetics over the final 70 min of the experiment (50-110min post AMPH) yielded a half-life of approximately 2.5±0.5 and 1.6±0.5 hrs in the cortex and caudate, respectively. These regional differences in amplitude and temporal profile of AMPH-induced DA levels can likely be attributed to differences in the regulation of DA uptake and biosynthesis. Furthermore, these regional differences in DA response may provide insight into the therapeutic use of stimulants in attention disorders and may have implications for the interpretation of PET and pharmacological MRI studies.

Title: Neural control of feeding: Optogenetic and pharmacological studies on the medial frontal cortex and ventral striatum

Authors: *M. A. PARENT[1], M. LAUBACH[2];
[1]Neurobio., The John B. Pierce Lab., New Haven, CT; [2]Neurobio., John B. Pierce Labs., New Haven, CT

Abstract: Previous work from our lab demonstrated a role of the medial frontal cortex (MFC) in control of feeding (Parent et al., SFN 2012, 604.03). Rats were trained to perform a consummatory incentive contrast task and received alternating 30 seconds access to high value (20% sucrose) or low value (4% sucrose) solutions. Animals learned to inhibit their drinking during low value epochs and augment their drinking during high value epochs to maximize reward. We originally hypothesized that inactivation of MFC would disrupt the ability to inhibit

consumption of low-value solutions. However, using muscimol-based inactivations, we found that MFC was instead crucial for the maintenance of bouts of licking and did not lead to overconsumption of the low-value solution. Here, we report further studies on this issue using targeted pharmacological and optogenetic inhibition of MFC. We found that intake is differentially influenced by inactivation across the rostral-caudal axis of MFC, with consumption of high value sucrose affected to a greater degree with inactivation of the rostral part of MFC. Previous recordings of unit activity and local field potentials in MFC show that spike activity is modulated, and field potentials show phase locking, around bouts of feeding (Horst and Laubach, 2013). Classic studies on cortical oscillations have implicated the cholinergic system in the control of cortical rhythms. Therefore, we examined how cholinergic neuromodution of MFC influences intake behavior, especially the microstructure of licking. Infusions of the muscarinic antagonist, scopolamine, into MFC dramatically decreased consumption of the high value option, paralleling the effects of MFC inactivation. Oppositely, XE991, an M-current blocker whose underlying channel is controlled by muscarinic receptors, increased the consumption of high value solution. Due to the heavy efferent projections of MFC to ventral striatum (VS), and in line with previously published work (Baldo et al., 2005), we explored the role of VS in consummatory contrast and found that inhibition of VS increased consumption in the contrast task. This suggests that interactions between MFC and VS have opposing roles in the control of feeding. We propose that cholinergic-sensitive oscillatory neuronal activity in the MFC is crucial for the maintenance of goal-directed action sequences (e.g. measured by the duration of bouts of feeding) and that inhibitory control over intake is based subcortically, in the ventral striatum.

Title: Concomitant apomorphine and cholecystokinin supress apomorphine tolerance induction

Authors: *C. A. TIEPPO[1], H. R. SILVA[2], C. LOPES[3];
[1]Physiological Sci., Santa Casa Med. Sci. Sch. of São Paulo, São Paulo, Brazil; [2]Santa Casa of Sao Paulo Med. Sci. School, Sao Paulo - Brazil, Physiological Sci. Dept., Sao Paulo, Brazil;

[3]Physiological Sci. Dept., Santa Casa of Sao Paulo Med. Sci. School, Sao Paulo - Brazil, Sao Paulo, Brazil

Abstract: Objective: Chronic apomorphine (APO) treatment, a non-specific dopaminergic agonist, induces a classical behavioral tolerance to APO. Cholecystokinin (CCK) treatment modifies behavioral responses related to dopaminergic stimulation. Our previous results showed that CCK was able to decrease APO-induced stereotyped behavior scores in rats. Our goal was to test if CCK associated with APO chronic treatment can modulate stereotyped behavior responses to APO.
Methods: Eighty young male Wistar rats with approximately 280 g were divided in eight groups and submitted to a seven-days APO treatment (n=40; 0.6 mg/kg; s.c., once a day) or saline (n=40). Fifteen min before APO, animals received CCK4 (12 nmol/kg; i.p.), CCK8S (12 nmol/kg; i.p.) or saline (SAL). On the 8th day, all animals received APO (0.6 mg/kg; s.c.) and the stereotypy was immediately evaluated by Setler's score scale (10 s were observed in every 10 min, during 60 min) as follows: 0 - asleep or still; 1 - active; 2 - predominantly active but with bursts of stereotyped sniffing and rearing; 3 - constant stereotyped activity, but with locomotor activity still present; 4 - constant stereotyped activity maintained at one location; 5 - constant stereotyped activity with bursts of licking and/or gnawing and biting; 6 - continual licking of cage grids. Setler scores were analyzed by Mann Whitney U test. Animal Experimentation Ethics Committee protocol number: CEUA 011/09.
Results: The seven-days APO treatment induced dopaminergic tolerance, as rats treated with SAL and APO displayed less intense stereotyped behavior expression (SAL-APO: 16 {14;17}) when compared to SAL-SAL group (21 {19;25}), $p<0.0001$ on the 8th day of treatment. CCK-4 and CCK-8 treatments suppressed APO-induced dopaminergic tolerance, as animals treated with CCK8S-APO and CCK4-APO showed stereotyped behaviors higher than with the treatment with APO alone (CCK4-APO: 20 {19;22} and CCK8S-APO: 20 {19;24} vs SAL-APO 16 {14;17}) $p<0.006$ and compatible with those who received only SAL.
Conclusions: The APO treatment protocol used was able to induce APO tolerance. The long-term treatment with the CCK agonists prevents expression of tolerance, revealing a potential role of the CCK system in the genesis of this phenomenon. In previous results, we showed a remarkable APO tolerance after chronic cocaine treatment. It reveals the importance of a broader understanding of CCK modulation of the dopaminergic plasticity for enhance our understanding of drug addiction mechanisms.

Title: 5-HT2AR antagonism and 5-HT2CR stimulation attenuates hyperlocomotion produced by intra-striatal cocaine infusions

Authors: *T. DER-GHAZARIAN, L. POCKROS, R. MIRANDO, S. BRUNWASSER, N. PENTKOWSKI, J. NEISEWANDER;
Sch. of Life Sci., Arizona State Univ., Tempe, AZ

Abstract: We have previously shown that 5-HT_{2A} receptor (R) blockade and 5-HT_{2C}R activation interact to attenuate cocaine-induced hyperlocomotion and Fos expression in the dorsal caudate-putamen (dCPu). This study examined whether the 5-HT_{2A}R antagonist M100907 and the selective 5-HT_{2C}R agonist CP809101 attenuate hyperlocomotion produced by cocaine infusions into dCPu. We first examined the dose-dependent effects of CP809101 (0.25, 0.5, 1.0 mg/kg, SC) on spontaneous locomotion to find a subthreshold dose (i.e., the highest dose that failed to alter spontaneous locomotion). Subsequently, a dose of M100907 (0.025 mg/kg, SC) previously found to be subthreshold for altering locomotion and the subthreshold dose of CP809101 (0.25 mg/kg, SC) were used in a combined cocktail in order to examine receptor interactions locomotion produced by intra-CPu cocaine infusions (100 μg/side at a volume of 0.05 μl/side). Male rats were tested repeatedly with a minimum of 3 days between each test day under each of the following drug conditions: 1) vehicle; 2) 0.025 mg/kg M100907; 3) 0.25 mg/kg CP809101; and 4) a cocktail of the same doses of M100907 and CP809101 combined (n=15). On each test day, rats were placed into the test cage for a 1-h habituation phase. They then received the drug treatment and were returned to their home cage for 30 min. Next, rats received cocaine infusions (100 μg/side) into the dCPu and were immediately placed back into the test cage for 1 h. As expected, M100907 given alone had no effect on cocaine-induced locomotion, whereas, CP809101 given alone produced a mild attenuation. In contrast, the cocktail attenuated cocaine-induced locomotion to a greater extent than CP809101 alone (i.e., the cocktail group significantly differed from all other groups). These findings suggest that 5-HT_{2A}Rs and 5-HT_{2C}Rs do in fact interact to attenuate hyperlocomotion produced by intra-dCPu cocaine infusions. These findings provide further support for the idea that concurrent 5-HT_{2A}R antagonism and 5-HT_{2C}R agonism may offer a novel approach to treating cocaine dependence. This research was supported by National Institute on Drug Abuse (DA11064).

Title: Receptor and frontostriatal circuit mechanisms underlying the cognition-enhancing actions of psychostimulants

Authors: *R. C. SPENCER, C. W. BERRIDGE;
Univ. of Wisconsin, Madison, WI, WI

Abstract: Psychostimulants, including Methylphenidate (MPH, Ritalin), enhance a variety of cognitive/behavioral functions dependent on the prefrontal cortex (PFC) and extended frontostriatal circuitry. These actions are seen in individuals with and without Attention Deficit Hyperactivity Disorder (ADHD) as well as normal animal subjects. Despite widespread use of these drugs, the brain regions/receptor mechanisms involved in their cognition-enhancing and therapeutic effects remain poorly understood. The current studies examined the degree to which MPH acts within distinct frontostriatal subfields to improve PFC-dependent cognition and the receptor mechanisms involved in these actions. We observed that MPH elicited an inverted-U shaped facilitation of PFC-dependent cognition when infused into the dorsomedial PFC (dorsal prelimbic and anterior cingulate; maximum improvement at 0.125 μg/500 nl), but not ventromedial PFC (infralimbic), dorsomedial striatum, or ventromedial striatum (Nucleus Accumbens). The ability of MPH to improve working memory when infused into the dorsomedial PFC was blocked with the concurrent infusion of either a NE α2 (Atipamezole; 1.25 μg/500 nl) or DA D1 (SCH23390; 0.5 μg/500nl), but not NE α1 receptor antagonist (benoxathian; 2nMol/500 nl), at doses that did not alter performance when given alone. These observations provide the first definitive evidence that psychostimulants act at NE a2 and DA D1 receptors directly within the PFC to enhance delay related cognition.
Recent evidence from our lab demonstrates that in contrast to spatial working memory tasks, performance in a sustained attention task shows a broader and right-shifted dose response curve to MPH. Furthermore, this improvement in sustained attention requires action at α1 receptors. Ongoing studies are identifying the frontostriatal circuitry and receptor mechanisms involved in attention-enhancing effects of MPH and the degree to which these mechanisms differ from the working memory-enhancing effects of this drug.

Title: Dopamine depletion in the dorsolateral striatum impairs the acquisition of an egocentric task but not spatial reversal or strategy switch

Authors: *J. J. YOUNG, K. SEIP-CAMMACK, M. L. SHAPIRO;
Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Damage to the dorsolateral striatum (DLS) in rodents and primates impairs egocentric (body-turn) and stimulus-response (S-R) learning. While dopamine is required for S-R learning, the specific mechanism supporting this type of learning remains unclear. We hypothesized that dopamine in the DLSmay help consolidate S-R reward associations and helps to transmit that information to extended memory systems (e.g., prefrontal, hippocampal) for higher-order processing. Rats receivedbilateral microinjections of6-hydroxydopamine (6-OHDA) into the DLS to selectively destroy dopaminergic (DA) input from thesubstantianigra pars compacta (SNc). Lesions eliminated approximately 50-70% of the total DA input to the DLS. After recovery from surgery, the rats were trained on an egocentric or a spatial task on a plusmaze. After reaching a criterion of six consecutive correct trials, ratswere given 24 additional trials to establish stable performance.The ratswere then trained to the same criterion on alternating spatial and egocentric tasks, which required them to switch strategies between tasks, over the subsequent 6-10 days. A separate group of rats was trained in a series of spatial reversals that did not include strategy switches.The effect of DA depletion on egocentric tasks varied with training history. Rats with DA depletion learned the egocentric taskmore slowly than intact rats only if they learned this task first. In contrast,rats with DA depletion trained first in the spatial task learned the egocentric task normally. After learning to criterion,both groupsperformed equivalently on each task. DA depletion did not impair rats' ability to switch between egocentric and spatial strategies. The transient and selective impairment in egocentric learning, together with intact strategy switching suggests that dopamine in the DLSmay contribute toinitial S-R

reward learning when extended memory systems have not already been involved in the acquisition of similar tasks.

Abstract: Humans and non-human primates are vulnerable to age- and menopause-related decline in working memory, a cognitive function reliant on the energy-demanding recurrent excitation of layer III neurons within Area 46 of the dorsolateral prefrontal cortex (dlPFC). Here, we tested the hypothesis that the number and morphology (straight, curved, or donut) of mitochondria in dlPFC presynaptic boutons are altered with aging and menopause in the rhesus monkeys and that these metrics correlate with delayed response (DR) accuracy, a well-characterized measure of working memory. While bouton size was not significantly different across groups, aged postmenopausal monkeys had a higher percentage of boutons with mitochondria and a higher number of total and straight mitochondria per bouton compared to young and aged premenopausal monkeys. We next examined possible relationships between dlPFC mitochondria and the integrity of working memory, and found that the number of total and straight mitochondria per bouton showed significant positive correlations with DR accuracy.

In contrast, the frequency of boutons containing donut-shaped mitochondria, a morphological correlate of oxidative stress, exhibited a strong inverse correlation with DR accuracy. Lastly, we used a treatment known to enhance working memory to test whether mitochondrial morphology is regulated in relation to the treatment. Cyclic estradiol administration in aged ovariectomized monkeys, which significantly improved working memory, decreased the frequency of donut-shaped mitochondria. Together, our data suggest that hormone replacement therapy may enhance working memory, in part, by promoting mitochondrial health in the dlPFC.

Title: Regional-, laminar-, and target-specificity of prefrontal cortical pyramidal cell dendritic spine loss in response to dopamine denervation

Authors: H.-D. WANG[1], *A. Y. DEUTCH[2];
[1]Psychiatry, [2]Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: A number of post-mortem studies have reported decreased dendritic spine densities in the prefrontal cortex (PFC) in schizophrenia. Dopamine (DA) plays a key role in PFC function, and has been linked to certain cognitive deficits in schizophrenia. However, cognitive performance in schizophrenia is not globally affected, but restricted to certain domains, such as working memory. We examined dendritic spine loss in the cortex in response to DA loss. Disruption of the cortical DA innervation resulted in a decreased dendritic spine density in neurons of the medial PFC (areas 32) but not in the forepaw representation of the primary motor cortex. Subsequent analysis revealed that the loss of dendritic spines on PFC pyramidal cells (PCs) was restricted to layer V, and was not seen in layers II/III. We then examined dendritic spine loss in layer V PCs that project to a number of different target regions by retrogradely-labeling the PCs and then performing intracellular fills in these PFC PCs. We found that a very small minority (<10%) of layer V cells collateralized to innervate multiple subcortical targets such as the nucleus accumbens and ventral tegmental area. Dopamine depletion of the PFC resulted in a significant loss of dendritic spine density on layer V cortico-accumbens neurons. In

contrast, we did not observe a change in spine density in layer V cells projecting to the ventral tegmental area. Similarly, we did not uncover a loss of dendritic spines in PFC neurons innervating the amygdala, either from Layer V or Layers II/III. We also examined PFC PCs retrogradely labeled from the mediodorsal thalamus (MD). The projection from the PFC to the MD primarily originates in layer VI, with a smaller input from Layer V. Although no changes in dendritic spine density was seen in layer VI PFC cells projecting the MD, basilar and apical spine density was decreased by ~25% in layer V cortico-thalamic PCs. We are currently quantifying dopamine, serotonin, and glutamate receptor transcripts in the PFC neurons that innervate the various targets to determine the dopamine receptor subtype(s) involved in the dendritic remodeling seen after dopamine depletion of the PFC. These data suggest that specific circuits emanating from layer V of the PFC are dysfunctional in schizophrenia, and it may be possible to differentially relate dysfunction in one circuit (e.g., the circuit that emanates from the PFC to the MD and thalamofugal sites) may subserve specific symptoms (e.g., working memory deficits) in schizophrenia.

Title: Claustrum projections to the prefrontal cortex of the common marmoset: New insights regarding claustrum function?

Authors: *D. H. RESER[1], J. CHAN[1], K. BURMAN[1], K. WORTHY[1], X. PHAM[2], T. CHAPLIN[1], M. G. P. ROSA[1];
[1]Dept. of Physiol., [2]Fac. of Medicine, Nursing, and Hlth. Sci., Monash Univ., Clayton, Australia

Abstract: The function of the claustrum remains highly debated. Factors that complicate progress in addressing this question include the diffuse cortical connectivity, complex geometry, and relative surgical inaccessibility of this structure. Several hypotheses have been advanced suggesting a role for the claustrum in binding of polysensory information, and imaging studies suggest claustrum involvement in Alzheimer's disease, schizophrenia, and autism, but relatively

little detailed information about this structure is available. Here, using retrograde neuronal tracers, we mapped the claustrum projections to multiple histologically defined areas of the primate prefrontal cortex. Fluorescent tracers were injected into 18 sites in prefrontal cortex of 12 adult marmosets (Callithrix jacchus) under Alfaxan anaesthesia (8 mg/kg). After 1-3 weeks survival time, brains were extracted, postfixed, and cryoprotected, then sectioned (40 micron thickness) for histology and microscopy. All procedures were approved by the Monash University Animal Ethics Committee. Labelled cells were mapped and digitized using fluorescence microscopy and visualized using the CARET software package.
The distribution of labelled cells showed a marked rostral-caudal inhomogeneity, with projections to prefrontal areas involved in monitoring of internal states and executive functions (e.g. BA10, BA9, BA8B) located in the rostral claustrum, while areas involved in higher order and polymodal sensory processing (e.g. BA8aV) restricted to the caudal portion of the claustrum. Claustrum projections to the ventromedial prefrontal cortex and subgenual anterior cingulate cortex (BA32 and BA24) were tightly clustered in the rostro-medial claustrum. The pattern of claustrum projections to prefrontal cortex of the marmoset strongly suggests involvement of the rostral claustrum in the primate default mode network (DMN), which includes the prefrontal areas 8B, 10, 9, and 32, as well as the anterior cingulate region 24. Although the DMN has been widely studied in the context of normal function, as well as its role in the clinical conditions described above, we are not aware of previous reports of claustrum involvement in this network. Our data point to a need for more detailed study of the interaction between the claustrum and DMN, as well as other resting state networks.

Title: Enhanced c-fos immunoreactivity in the prefrontal cortex of male rats following pre- and postnatal stress exposure

Authors: *E. ULUPINAR[1,3], E. SOZTUTAR[1], E. COLAK[2];
[1]Dept Anat., [2]Dept. of Biostatistics and Med. Informatics, Eskisehir Osmangazi Univ., Eskisehir, Turkey; [3]Interdisciplinary Neurosci., ESOGU Hlth. Sci. Inst., Eskisehir, Turkey

Abstract:
Prefrontal cortex has critical centers related to the cognitive functions, memory and emotional behaviors. Development of this region continues from prenatal period to late adolescent ages. In this study, we exposed male Sprague-Dawley rats to early-life stress by keeping the dam immobile for 3 hours per day in the last week of gestation and separating the pups from their mothers for 3 hours daily, until weaning. According to anxiety levels, pups from different litters were categorized into two groups, as high and low anxious, at postnatal day 30. Elevated plus-maze test was repeated at postnatal day 60 to evaluate the emotional condition of the animals. Then, rats were subjected to the forced swim test immediately before their perfusion. The level of neuronal activation was analyzed by c-Fos immunohistochemistry and the total number of c-Fos expressing neurons in the medial prefrontal cortex (mPFC) was estimated by the optical fractionator method using Stereo-investigator software. Elevated plus maze test results indicated that early-life stress exposure increased anxiety-like behavior in stressed animals compared to the control group. Histological analysis showed that total number of c-Fos expressing neurons was significantly higher ($p<0.001$) in the mPFC of high anxious group than those of low anxious and control groups.These results showed that c-Fos activation in the mPFC display a positive correlation with the anxiety level of animals exposed to early-life stress.

Title: Anatomical characterization of long-range thalamic projections in mouse

Authors: *B. J. HUNNICUTT[1,2], B. LONG[1,2], D. KUSEFOGLU[1,2], H. ZHONG[2,1], K. SVOBODA[3], T. MAO[2,1,3];

Abstract: The thalamus is a central relay and integration site for sensory, cortical, and subcortical information as it transmitted into and within the brain. While thalamic projections have been studied for decades, several questions remain about the details of connectivity between the thalamus' roughly 40 cytoarchitecturally distinct subdivisions and their cortical targets. First, it is poorly understood whether thalamic axons are guided to their precise cortical targets via intrinsic molecular cues or if they arrive at their approximate topographic location and refine their positions based on activity. In addition, the layer specific axon distributions of thalamic projections is incompletely understood, primarily due to a lack of comprehensive, yet detailed, mapping techniques. Finally, there is virtually no anatomical data obtained from the widely used genetic model system, mouse. Here, we employed a systematic, dual-color, focal viral injection strategy to fluorescently visualize thalamic axons at high resolution as they project to multiple mouse cortical regions. Using this data set, we generated the first comprehensive map of thalamic projections to every subdivision of the frontal cortex. In addition, we demonstrate the power of our technique to uncover layer-specific thalamocortical projections, and to reliably localize the origins of previously unidentified projections. Understanding the detailed projection patterns of thalamic inputs to the cortex is crucial for deciphering the dynamic roles that the thalamus plays in cognition. Our results serve as a necessary resource for future studies investigating the functional roles of thalamocortical circuits.

Title: Enhanced D2-type receptor activity in the nucleus accumbens shell facilitates conditioned same-sex socio-sexual motivation in male rats: Behavioral and cellular evidence

Authors: *R. TRIANA-DEL RIO[1,2], J. MORIN[3], C. LOZANO-FLORES[3], V. RAMÍREZ-AMAYA[3], G. CORIA-AVILA[2], R. PAREDES-GUERRERO[3];

Abstract: Dopamine activity in the nucleus accumbens (NAcc) plays a funamentel role in motivated behavior and instrumental learning. Additionally, activation of D2R is required for the establishment of partner preference. In the present longitudinal study we tested incentive sexual motivation and partner preference of male Wistar rats to sexual stimuli (femenine and masculine) in three different experimental stages: 1) before cannula implantation, 2) after cannula implantation in the nucleus accumbens shell, 3) after a conditioning period which consisted in infusion of 1 uL (.25 ug/uL) of quinpirole (a specific D2R agonist) in the NAcc and cohabitation in individual cages with another sexually experienced male which bore peppermint scent as a conditioned stimulus (conditioning occurred every 4 days, for a total of three trials). In these 3 stages males were tested for incentive sexual motivation and partner preference in a two-goal compartment chamber (peppermint scented male vs. sexually receptive female). The behavioral results revealed that in the first 2 stages, the experimental males visited more frequently the receptive female, but after the pharmacological treatment with quinpirole, the males displayed more time in close contact with the other male, increasing genital exploration and play solicitations towards him. Additionally, quinpirole treated males displayed less mounts, intromissions and ejaculations towards females. Four days after the preference test the subjects were exposed to the conditioned stimulus alone (peppermint odor) during 5 min, then were left undisturbed for 20 min in their home cages and finally exposed 5 min to a known but neutral stimulus (mango odor). Brains were immediately collected and quickly-frozen. Coronal brain sections were process for fluorescent in-situ hybridization for Arc mRNA, in order to identify the anatomical location of neurons that respond to the different odors. We are currently evaluating how same sex conditioning enhanced by dopamine D2R induces Arc transcription in several brain regions involved in information-processing of the relevant stimuli. Preliminary results support the idea that same-sex partner preference can result from associative conditioning and may depend, in part, on dopamine activity in the NAcc shell

Title: Long-withdrawal from repeated nicotine did not change NPY and CRH-R1 gene expression in the amigdala

Authors: *C. S. PLANETA[1,2], T. F. GOTTSFRITZ[1], P. BIANCHI[2];
[1]Unesp - Sch. Pharmaceut. Sci., Araraquara, Brazil; [2]Joint Grad. Program in Physiological Sciences, UFSCar/UNESP,, Araraquara, Brazil

Abstract: Dysregulations in the NPY-CRF systems have been associated to behavioral changes observed during nicotine abstinence in rats. The goal of the present study was to investigate whether repeated treatment with nicotine during adolescence could modify the expression of neuropeptide Y (NPY) and corticotropin-releasing factor receptor type 1 (CRF-R1) gene expression in the amygdale following long-term withdrawal. Male adolescent (postnatal day 28) Wistar rats received three daily injections of nicotine (1.0 mg/kg; s.c.) or saline for 10 days. Ten days (postnatal day 27) after the last nicotine (NIC) or saline (SAL) administration, animals were killed by rapid decapitation and the amigdala was isolated, frozen in liquid nitrogen and stored in -80 º C freezer for posterior analyses. The (NPY) and (CRF-R1) gene expression were measured by the reverse transcription-polymerase chain reaction (RT-PCR). The results showed that repeated treatment with nicotine during adolescence did not change NPY or CRF-R1 mRNA levels ten days after the withdrawal from nicotine, these data does not exclude the possibility that changes in NPY-CRF systems occurred in the early abstinence period and are no longer present 10 days after the interruption of nicotine treatment. We can also consider that nicotine - induced changes during early adolescence are transient and may not be detected in the late adolescence phase.

Title: The weight-loss drug diethylpropion increases LFP's delta power and inhibits neuronal activity of the nucleus accumbens

Authors: *K. BALASUBRAMANIAN, JR[1], J. SOLORIO[1], A. VARGAS[2], A. LUNA[3], M. MORENO[1], I. PEREZ[1], R. GUTIERREZ[1];
[1]Lab. 36,LABORATORY OF NEUROBIOLOGY OF APPETITE, PHARMACOLOGY, CINVESTAV-IPN, DEPARTMENT OF PHARMACOLOGY, MEXICO CITY, Mexico;

[3]DEPARTMENT OF BIOELECTRONICS, CINVESTAV-IPN, MEXICO CITY, Mexico

Abstract: Despite the wide use of diethypropion (DEP) as an appetite suppressant and as a short term weight-loss therapy for more than 50 years, there is a paucity of information about the neuronal mechanisms by which DEP produces its anorectic effect. The nucleus accumbens shell (NAcS) is a brain region associated with the regulation of reward, motivation and locomotor behaviors, and it is a part of the neuronal circuit that controls appetite. However, it is unknown if DEP can modulate NAcS activity. To address this issue, we first evaluated the effect of DEP on body weight-loss and locomotor activity and then we performed multielectrode recordings of local field potentials (LFPs) and single unit activity in the NAcS while behaving rats received an intragastric DEP administration. Our behavioral results found that both doses of DEP 20 and 40 mg/kg significantly decreased food intake and induced body weight-loss and hyperarousal state that may last up to 9 hours. We also observed a dose dependent impairment on locomotor activity and a prominent head weaving behavior (a stereotypic movement of the head) and this effect was stronger at high doses. Finally our electrophysiological results shown that intragastric DEP administration (20 mg/kg) evoked a significant increase in power at delta (1-4 Hz) and decrease in power at theta (5-11 Hz) bands in the NAc's LFPs. Regarding single spike activity; we found that DEP strongly inhibits NAcS single neuron activity and changed the spiking pattern of neurons from irregular single spike mode to rhythmic bursting pattern. Taking all together, we conclude that DEP produces a synchronous activity state (at delta - theta frequencies) in the NAcS, and we posit that this rhythmic activity plays a potential role on the anorectic and weight-loss effects of DEP. Our results also indicate that DEP can partially act by modulating this brain reward region.

Title: The peripheral satiety signal induced by cholecystokinin modulates the activity of single neurons of the nucleus accumbens shell

Authors: *C. PEREZ DIAZ, JR, M. MORENO, R. GUTIERREZ;
PHARMACOLOGY, CINVESTAV, MEXICO CITY, Mexico

Abstract: Cholecystokinin (CCK) is a gut hormone that decreases food intake and delays gastric emptying. CCK is secreted postprandially from the I cells of the small intestine after intake of protein and fat rich foods and its anorectic action appears to be mediated through cholecystokinin receptor subtype 1 (CCK1R) located on peripheral vagal afferents. Despite that CCK do not cross the blood brain barrier, vagal activation of CCK1R can modulate the activity of several brain regions involve on feeding behavior. In the other hand, it has been shown that pharmacological inactivation of the nucleus accumbens shell (NAcS) promotes overeating, whereas its electrical stimulation stops feeding behavior, suggesting that the NAcS is a key brain region involved on the regulation of food intake. Moreover, in rodents, exogenous administration of CCK globally modulates neuronal activity of the NAcS measured by mediated manganese-enhanced magnetic resonance imaging. However, it is unknown if exogenous CCK can modulate NAcS activity at a single neuronal level, in freely moving animals. To answer this question, we performed multichannel recordings of the NAcS in freely moving rats while they received i.p. CCK injections (2 µg/kg) either alone or accompanied by devazepide, an antagonist with high affinity to CCK1R. In our preliminary electrophysiological results we found that peripheral CCK can modulate (either increase or decrease) the firing rate of NAcS single neurons and this modulation may last up to 10 to 15 min. Next, we behaviorally determined that 50 µg/kg of devazepide completely blocks both the decrease of food intake (Ensure -chocolate flavored drink) and the delay of gastric emptiness -induced by CCK. We conclude that single neurons

located in the NAcS are sensitive to the peripheral CCK satiety signal and we are currently testing whether devazepide can block the modulation of NAc activity induced by exogenous administration of CCK. These data suggest that the NAcS is part of the gut-brain axis of some peripheral satiety signals.

Title: In the Thy1-ChR2 mice, optogenetic activation of nucleus accumbens' inputs is sufficient to stops feeding behavior

Authors: *L. E. PRADO RODRÍGUEZ, R. GUTIERREZ;
Pharmacol., CINVESTAV I.P.N., Distrito Federal, Mexico

Abstract: The nucleus accumbens shell (NAc) is a brain region part of the reward system that is involved in many brain functions such as coding reward, motivation and feeding behavior. In this regard, pharmacological inhibition of the NAc promotes overfeeding, whereas electrical stimulation inhibits feeding behavior, suggesting that a pause on the activity of this region can "gate" and thus allow the overconsumption of palatable foods. This hypothesis then proposes that opposite global activity of the NAc has a bidirectional control over feeding. Herein, we tested that hypothesis by using optogenetic global stimulation NAc's input stimulation in the B6.Cg-Tg(Thy1-COP4/EYFP)18Gfng/J mice. Thy1-ChR2 mice express the microbial opsin ChR2 mainly on glutamatergic principal cells of layer V of cortex, and in many other brain regions that also project to the NAc, but it barely expresses ChR2 on NAc's neurons itself. We implanted a unilateral fiber optic on the NAc, in order to optogenetically activate all axons of the NAc that express ChR2 in this mice. Animals were trained on a lick task in which they had to lick three times a sipper fill with 10% sucrose solution. In the fourth lick cycle a blue LED was

turn on, during 1 sec duration, the sucrose solution was always available. In each trial, mice could receive either no-stimulation or a pulse of 4, 7, 14 or 21 Hz. We found that lower frequency stimulation (4 and 7 Hz), in 5 out of 6 mice, there was no effect on licking, but at high pulse frequencies (14 and 21) mice immediately stop licking the sucrose solution and this effect last during several seconds (>12 s). In fact, after LED stimulation at high frequencies animals were not able to emit the next lick. Further experiments showed that optogenetic NAcS' input activation stops sucrose intake at any moment during the licking cluster that is either in the very first lick or during the 4 or 16 lick cycle. We found that even a very short stimulation (80 ms; two pulses at 21 Hz) was enough to stop sucrose intake in this mice. We also tested if NAcS' input stimulation was self-rewarding; we found that 2 out of 6 mice were willing to lick four times an empty spout in order to receive self-stimulation demonstrating that global activation of the NAc is sometimes rewarding. We conclude that optogenetic NAcS' input stimulation is sufficient to stop feeding behavior.

Title: Different populations of nucleus accumbens neurons are associated with approach behavior and reward

Authors: *C. J. BROKER, D. WANG, S. IKEMOTO;
The Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Previous studies have shown that the dopaminergic system in the nucleus accumbens plays an essential role in invigorating approach behavior and inducing reward(s) associated with abused drugs. However, little is known about how individual accumbens neurons are responsible for encoding this reward and its goal-directed signals.
We examined unit activities of the nucleus accumbens in mice trained to self-stimulate with photo-stimulation that excited dopamine neurons in the ventral tegmental area (VTA). We injected a Cre-dependent adeno-associated virus encoding channelrhodopsin-2 into the VTA and implanted an optical fiber in the VTA and a bundle of 8 tetrodes (32 wires) in the accumbens shell of TH::Cre mice.
Mice quickly learned to vigorously lever-press for VTA optical stimulation. We found that many

accumbens neurons exhibited increased or decreased activities immediately after lever presses, triggered by optical stimulation of dopamine neurons. Moreover, these accumbens neurons also responded to non-contingent VTA optical stimulation in a similar manner. Thus, these neurons may be important for encoding dopamine neuron-mediated reward. We also recorded other accumbens neurons that exhibited firing changes before (~1 sec) lever presses, and these neurons were typically not responsive to VTA optical stimulation. Thus, these neurons may be involved in approach behaviors.
Together, our results suggest that different populations of nucleus accumbens neurons are associated with approach behaviors and reward.

Title: Neural activity of nucleus accumbens induced by rewarding optogenetic stimulation of VTA dopamine neurons

Authors: *D. V. WANG, C. BROKER, S. IKEMOTO;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Scientific questions on brain reward systems were prompted by the discovery that animals learn to lever-press for electrical stimulation of certain brain areas, a phenomenon known as intracranial self-stimulation. Since then, numerous studies using anatomy, pharmacology and electrophysiology methods have established dopamine neurons in the ventral tegmental area (VTA) projecting to the nucleus accumbens (NAc) as a key reward substrate. Recent studies using optogenetics confirmed that animals learn to self-stimulate VTA dopamine neurons, suggesting that excitation of dopamine neurons is sufficient in inducing reward. The question remains is how excitation of VTA dopamine neurons influences downstream brain areas. We sought to identify firing patterns that encode ‘dopamine neuron-mediated reward’ in the NAc. We injected the AAV-ChR2 viruses and implanted optical fibers in the VTA area of TH::Cre mice, a procedure that allowed us to specifically activate dopamine neurons through optical stimulation; a bundle of 8 tetrodes (32 wires) was implanted in the NAc shell for neural activity recording. We found that VTA optical stimulation in freely-behaving mice evoked fast

excitatory local field potential (LFP) responses in the NAc, and the amplitudes of this LFP correlated well with the animal's self-stimulation rates. Consistent with the LFP activity, 35% of the recorded NAc neurons showed fast phasic excitations, suggesting an excitatory input to the NAc from VTA dopamine neurons. We also recorded neurons that showed phasic inhibitions (17%). To determine whether these firing pattern changes were mediated by dopamine, mice were systemically injected with the dopamine D1 receptor antagonist SCH 23390. Although the antagonist decreased majority basal firing in the NAc, it did not abolish optical stimulation-evoked neural responses, suggesting that transmitters other than dopamine were released by VTA dopamine neurons. In light of recent in vitro studies showing that dopamine neurons can also release glutamate and GABA to depolarize or hyperpolarize post-synaptic neurons, our above results could be explained by the co-realease of glutamate or GABA from dopamine neurons. Together, our results suggest that VTA dopamine neurons may employ multiple neural transmitters for inducing reward in vivo.

Title: Rapid fluctuations in nucleus accumbens glutamate levels during motivated glucose drinking behavior

Authors: *S. E. MYAL, K. T. WAKABAYASHI, E. A. KIYATKIN;
BNRB, NIDA IRP, NIH, Baltimore, MD

Abstract: Glutamate (GLU) is the brain's major excitatory neurotransmitter. Though it is thought to be critically involved in the development and regulation of motivated behavior, the measurement of rapid fluctuations in extracellular GLU during behavior has been inaccessible until recently. To clarify this issue, we used enzyme-based GLU biosensors coupled with high-speed, fixed-potential amperometry to examine changes in extracellular GLU levels in the shell region of nucleus accumbens (NAc) during a simple task of motivated glucose drinking. For four days, non-food or -water-deprived male Long-Evans rats were moved to the test chamber and pre-trained to drink 5-ml of 10% glucose solution presented in a cup; two cup presentations were performed per day at 2h intervals. After pretraining, rats were implanted with a unilateral

cannula in the NAc for future insertion of GLU sensors. After a 5-day recovery period, rats were re-trained in an additional drinking session one day prior to GLU measurement. Electrochemical recordings using GLU sensors were conducted in 8-hour sessions, which included two drinking episodes at 2h intervals. Parallel recordings with GLU-null (enzyme-free) sensors were used to exclude contributions of non-specific electrochemical interferents. Our preliminary data suggest that NAc GLU levels slightly increase during cup presentation and movement toward the cup, followed by a rapid decrease during glucose consumption. After glucose is fully consumed, GLU levels increase again, correlating with searching behavior and grooming before falling to baseline when the rat returns to a resting state. When a water-filled cup is presented instead of glucose, the rat drinks much less and GLU levels are variably increased. Our data suggest that NAc GLU levels fluctuate biphasically during motivated behavior, with increases associated with seeking behavior and decreases during consumption of a palatable substance. Title: The rewarding and aversive effects of nicotine are encoded by differential neuronal population activity dynamics in the nucleus accumbens shell

Authors: *S. R. LAVIOLETTE, N. SUN;
Univ. of Western Ontario, London, ON, Canada

Abstract: The mammalian mesolimbic pathway comprising the ventral tegmental area (VTA) and nucleus accumbens (NAc) has been identified as a critical neural system involved in processing both the rewarding and aversive stimulus properties of nicotine. Within the VTA, nicotine dose-dependently produces either rewarding or highly aversive behavioural effects, both of which are strongly modulated by mesolimbic DAergic transmission (Laviolette & van der Kooy, 2003; Tan et al., 2009). Indeed, transmission through dopamine (DA) receptor populations has been shown to functionally modulate these effects directly within the NAc. Nevertheless, the neuronal mechanisms within the NAc responsible for the bivalent motivational effects of nicotine are presently not known. Using an unbiased place conditioning procedure combined with in vivo neuronal electrophysiological array recordings, we examined the effects of intra-

VTA nicotine reward and aversion behaviours on specific neuronal sub-population activity patterns during nicotine conditioning, including acquisition, recall and extinction phases of nicotine-related associative memories. We report that sub-populations of fast-spiking interneurons (FSI) or medium spiny neurons (MSN) within the shell region of the NAc (NAshell) display differential activity patterns during the acquisition and extinction of rewarding vs. aversive conditioning doses of nicotine, directly within the VTA. Thus, while the rewarding effects of nicotine were associated with inhibition of FSI and activation of MSN neurons, the aversive effects of nicotine were associated with the opposite pattern of neuronal population activity. Similar to previous reports, pharmacological blockade of DA transmission with the broad-spectrum DA receptor antagonist alpha-flupenthixol, reversed the motivational properties of intra-VTA nicotine, switching nicotine aversion behaviours into rewarding conditioned effects. Remarkably, DA receptor blockade concomitantly switched differential intra-NAshell FSI and MSN neuronal population activity from an aversion pattern to a reward pattern, concomitant with the observed behavioural nicotine motivational switch. Furthermore, we report that alpha-flupenthixol, similar to other neuroleptic drugs, dramatically decreased striatal gamma band activity within the 50-80 Hz range. Rewarding doses of intra-VTA nicotine were associated with decreased striatal FSI-associated Gamma band 80 activity whereas aversive doses increased Gamma band 80 levels. Again, this effect was reversed following DA receptor blockade, concomitant with a switch from behavioural aversion, to reward.

Title: Chronic testosterone treatment can cause neuroplasticities in the nucleus accumbens of adolescent rats

Authors: *S. A. ENGI[1], C. C. CRESTANI*[2], C. S. PLANETA[2];
[2]PANT, [1]UNESP ARARAQUARA, ARARAQUARA, Brazil

Abstract: Studies suggest that testosterone interacts with the brain reward system by affecting the endogenous opioid peptide and dopaminergic system. However, few studies investigated testosterone-induced changes in gene expression in the mesolimbic system. The aim of this study

was to investigate the central effects of the chronic testosterone treatment in adolescent rats. We used adolescent male Wistar rats (PND 28) that received a single daily injection of testosterone (10 mg/kg, s.c.) or vehicle during 10 days. Three days after the last testosterone administration animals were decapitated and had their brains removed to measure endogenous opioid peptide dynorphin and the dopaminergic receptor D1 in the nucleus accumbens. This study showed that 10-day testosterone treatment caused a significant increase in the prodynorphin mRNA expression and a significant decrease in the D1 receptor mRNA expression in the nucleus accumbens. Our results suggest that the chronic testosterone treatment can cause central neuroplasticies in the reward system.

Title: Blockade of AMPA receptors in the nucleus accumbens core interferes with the expression of Pavlovian conditioned approach

Authors: *M. VEGA VILLAR[1], R. I. CAAMAÑO TUBÍO[2], J. C. HORVITZ[2];
[1]Psychology Dept., The Grad. Center, CUNY, New York, NY; [2]Psychology Dept., City Col. of New York, CUNY, New York, NY

Abstract: A large research literature implicates nucleus accumbens (NAc) dopamine in reward-related learning and reward-directed behavior. Research on the role of NAc glutamatergic transmission in reward-related learning and behavior has focused primarily on glutamate NMDA receptors, and less so on AMPA receptors. The aim of this work was to examine the role of NAc AMPA receptors in the expression of a simple Pavlovian conditioned approach response.
Male Sprague-Dawley rats received seven daily drug-free Pavlovian conditioning sessions. Each session was comprised of nine CS/US trials, and each trial consisted of (a) a VT 110-seconds inter-trial interval; (b) a seven-second tone and (c) the delivery of a food pellet six seconds after tone onset. On days 8 and 9, rats received pre-session intra-NAc microinfusions of either an AMPA antagonist (NBQX; 1μg/0.5 μl/side) or vehicle. Finally, rats received two additional drug-free sessions on days 10 and 11.
The results indicate that AMPA receptor antagonist NBQX infused to the NAc core suppresses

the expression of an already-acquired Pavlovian appetitive response. The relative influence of AMPA receptors in the NAc core on the hedonic value of the reward, the initiation of a reward-directed response and the animal's overall motor capacity is discussed.

Title: Electrophysiological responses within the prefrontal cortex to cue-induced binge ethanol intake

Authors: *D. N. LINSENBARDT, C. C. LAPISH;
Psychology, IUPUI, Indianapolis, IN

Abstract: A heightened reactivity to alcohol-associated cues is hypothesized to contribute to the compulsive drive to drink. As such, understanding the brain regions and neural processes that regulate cue-evoked alcohol seeking are critical for developing novel and effective treatment strategies for alcohol use/abuse disorders. Interestingly, neural activity within the prefrontal cortex (PFC), measured as changes in the BOLD response, is robustly altered after presentation of environmental stimuli associated with alcohol. While these data clearly implicate the PFC as necessary for integrating alcohol-paired cues, little is known regarding the changes in neural firing and oscillatory activity that underlie the altered hemodynamic response.
We used a novel model of cue-induced alcohol intake developed in our lab, dubbed "2-Way Drinking" (2WD) together with in vivo electrophysiology, to determine how neural activity in the PFC was altered during presentation of alcohol paired cues. Subjects were alcohol preferring 'P' rats and their non-genetically predisposed (heterogeneous) founding Wistar population. In the 2WD task, a light illuminated on either side of a rectangular operant box signaled the location and availability of 10% ethanol solution; animals were required to move to the illuminated side for 10s of alcohol access. Extinction of responding for ethanol was also evaluated using water in lieu of ethanol. Implanted electrodes attached to moveable microdrives were incrementally lowered through the PFC to maximize cell yield prior to electrophysiological recording and behavioral testing sessions.
In both rat populations there were increases in ethanol seeking behavior and total ethanol

consumed throughout 15 daily ethanol 2WD sessions, and decreases in these measures throughout 5 subsequent extinction sessions. However, the significant positive relationship between seeking and intake broke down during extinction sessions, but only in P rats, with increased seeking behavior relative to intake. There were a wide range of individual neuron responses to alcohol and alcohol-associated cues during 2WD sessions. Alterations in firing rate occurred in response to the light cue, the sound of the sipper extending and/or retracting, during fluid intake, and immediately following fluid intake.
These results provide additional support for the PFCs involvement in integrating information related to binge-alcohol intake and suggest that the 2WD model could be used to develop a more comprehensive understanding of how alcohol-related cues contribute to differences in the vulnerability of developing and maintaining alcohol use/abuse disorders.

Title: Adolescent intermittent ethanol exposure increased risk taking and decreased dopaminergic and cholinergic activity in adulthood

Authors: *N. BOUTROS[1], S. SEMENOVA[1], W. LIU[2], F. T. CREWS[2], A. MARKOU[1]; [1]Psychiatry, UCSD Dept. of Psychiatry, La Jolla, CA; [2]Bowles Ctr. for Alcohol Studies, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Binge drinking is prevalent during the adolescent period, a time of extensive neurodevelopment. Adolescent binge alcohol exposure may have long-term effects on brain and behavior which persist into adulthood. The present study investigated whether adolescent intermittent ethanol (AIE) exposure would alter adult risk-taking behavior and prefrontal dopaminergic and forebrain cholinergic neuronal marker levels in male Wistar rats. Adolescent (PND 28-53) rats received 5 g/kg of 25% (v/v) ethanol three times a day in a 2 days on/ 2 days off exposure pattern. In adulthood, risk-taking behavior was assessed in the probability discounting task under baseline conditions and after acute ethanol challenges (0, 1, 2, 3 g/kg). Immunohistochemical analyses assessed levels of tyrosine hydroxylase (TH), a marker for dopamine, in the medial prefrontal cortex, and choline acetyltransferase (ChAT), a marker for

cholinergic neurons, in the basal forebrain, in rats during adulthood (PND 215). Under baseline conditions, when the large reward was delivered with high probability, all rats showed a preference for the large reward. When the large reward became unlikely, control rats demonstrated a preference for the smaller, guaranteed reward. In contrast, AIE-exposed rats continued to prefer the risky alternative, even when large rewards were very unlikely. Acute ethanol challenges had no effect on risky choice and group differences were maintained, with AIE-exposed rats exhibiting more risky behavior than control rats. TH and ChAT immunoreactivity levels were decreased in AIE-exposed rats compared to control rats. Interestingly, risk-taking behavior was negatively correlated with ChAT, implicating decreased forebrain cholinergic activity in risky behavior in subjects exposed to AIE. Though risk-taking was not correlated with TH levels, the significantly reduced levels of TH and ChAT suggest that adolescent alcohol exposure has enduring neural effects and that these neural effects may result in behavioral phenotypes such as increased risk taking. In humans, increased risk taking could lead to maladaptive or dangerous behaviors and could also increase the likelihood of developing an alcohol use disorder in adulthood.

Title: Ganaxolone reinstates ethanol seeking in an operant procedure in mice

Authors: *M. RAMAKER, M. M. FORD, D. A. FINN;
Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Allopregnanolone (ALLO), an endogenous neurosteroid with potent positive allosteric actions at $GABA_A$ receptors, may be increased in brain and plasma following ethanol exposure. These increases are thought to contribute to ethanol's anxiolytic, anticonvulsant, and hypnotic effects. ALLO dose-dependently alters ethanol intake and reinstates ethanol seeking in rodents, consistent the idea that GABAergic neurosteroids modulate the reinforcing effects of ethanol. Recent work has studied ganaxolone (GAN), a synthetic analog of ALLO, due to its longer half-life and promising safety profile exhibited in clinical trials for epilepsy. Because GAN altered ethanol intake in several self-administration procedures in rodents, the present study examined whether GAN would reinstate ethanol seeking in mice. Using a sucrose fading procedure, C57BL/6 male mice were trained to lever press for access to a 10% v/v ethanol solution (10E) on a fixed ratio 1 schedule. The fixed ratio was increased every 2-3 sessions, and mice were then transitioned onto a response requirement 8, where mice had 20 minutes to complete 8 lever presses; upon successful completion of the 8 "active" lever presses, a cue light turned on, levers retracted, and 10E was available for 30 minutes. Presses on an inactive lever had no scheduled consequence. Mice were maintained on this schedule for 6 weeks, where they maintained a stable intake of ~0.8 g/kg ethanol per session during the last 4 weeks. Mice then underwent 3 weeks of extinction training where presses on either the previously active or inactive lever had no scheduled consequence. When lever presses on the previously active lever were consistently below 25% of the previous criterion of 8, the effect of systemic GAN (0, 10, and 15 mg/kg) on the ability to reinstate lever pressing was tested in a within-subjects design. There was a significant effect of GAN to reinstate active lever presses [$F(2, 20) = 3.575$; $p = 0.47$]; both 10 mg/kg ($p = 0.025$) and 15 mg/kg GAN ($p = 0.008$) significantly increased presses on the active lever. There was also a trend of GAN to increase presses on the inactive lever, indicating there may also be some non-specific motor effects of GAN contributing to the observed effect. Overall, the effect of GAN to increase the appetitive drive to seek ethanol is consistent with published effects of ALLO treatment. The results of this study add to the growing body of literature that GABAergic neurosteroids alter both consummatory and appetitive processes involved in ethanol self-administration.

Title: Ethanol concentration-dependent effects of binge drinking in the presence of HIV-1 infection

Authors: S. SARKAR[1], *S. L. CHANG[2];
[1]Inst. of NeuroImmune Pharmacol., [2]Seton Hall Univ., SOUTH ORANGE, NJ

Abstract: Binge drinking is a common form of acute alcohol abuse particularly in the young adult population. It has been correlated with neurocognitive deficits and is a high risk factor for developing behavioral problems that can lead to accidents, suicide and spread of sexually transmitted diseases (STD). Alcoholic beverages contain various concentrations of ethanol (EtOH). Young adults prefer to binge drink with high EtOH concentration beverages, which can result in increased risk-taking behavior and subsequently the spread of STDs including HIV-1. We hypothesized that there are EtOH concentration-dependent effects of binge drinking at both the molecular and behavioral levels, and these effects are enhanced during HIV-1 infection. In this study, young adult HIV-1 transgenic (HIV-1Tg) rats were binge-treated with solutions containing 0% (water), 20%, or 52% EtOH for 3 d, then expression of the HIV-1 viral gene, tat, was quantified in different areas of the brain, liver, and spleen. Tat expression increased in all three organs of the adult 52% EtOH-treated HIV-1Tg rats. In a subsequent study, blood EtOH concentration (BEC) as well as EtOH metabolism and neurotransmitter receptor gene expression were examined in young adult HIV-1Tg and F344 control rats administered 0% (water), 8%, or 52% EtOH for 3 d. BEC was higher in the 52% EtOH-treated HIV-1Tg rats than in the control rats. EtOH metabolism gene expression was increased in the liver of the 52% EtOH control group, but not in the HIV-1Tg rats. Neurotransmitter receptor gene expression was increased in the spleen of the 52% EtOH HIV-1Tg rats, but not in the control rats. To correlate the molecular changes with behavior, we examined the motor functions of the HIV-1Tg and control rats after 2, 24 and 72 hrs after binge exposure to 0% (water), 8%, or 52% EtOH for 3 d. Locomotor Activity was significantly reduced in the HIV-1Tg rats, but not the control rats, given 52% EtOH both 2 hrs and 24 hrs after final treatment, but not at 72 hrs. Our data indicate that there are EtOH concentration-dependent effects of binge alcohol drinking in the presence of HIV-1 infection at both molecular and behavior levels.

Title: Pre- and postsynaptic actions of alcohol at cerebellar granule cell extrasynaptic $GABA_A$ receptors

Authors: *J. KAPLAN, C. MOHR, D. J. ROSSI;
Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Cerebellar sensitivity to alcohol (EtOH) impairment is associated with increased risk for developing an alcohol use disorder, but it is unclear how differences in behavioral sensitivity are mediated at the cellular level. Previous reports in low-EtOH consuming Sprague-Dawley rats found that EtOH enhances tonic $GABA_A$ receptor ($GABA_AR$)-mediated inhibition of cerebellar granule cells (GCs) by increasing vesicular GABA release from Golgi cells, which increases the frequency of spontaneous inhibitory postsynaptic currents and the magnitude of tonic $GABA_AR$ currents. Since enhancement of GC tonic $GABA_AR$ currents powerfully dampens transmission through the cerebellar cortex, it likely contributes to behavioral impairment. We used voltage-clamp recording of GCs in cerebellar slices from high- and low-EtOH consuming C57BL/6J (B6) and DBA/2J (D2) mice, respectively, and tested whether the magnitude of EtOH-induced enhancement of tonic $GABA_AR$ currents differed across EtOH consumption phenotype, with the hypothesis that EtOH would be less efficacious at enhancing tonic $GABA_AR$ currents in the high-EtOH consuming B6 mouse strain. We found that while EtOH enhanced tonic $GABA_AR$ currents in low-EtOH consuming D2 mice (similar to GCs in Sprague-Dawley rats), it surprisingly suppressed the magnitude of the GC tonic $GABA_AR$ current in high-consuming B6 mice. In both mouse strains and Sprague-Dawley rats, the net response of GC tonic $GABA_AR$ currents to EtOH depended on the balance of two counteracting processes: 1) EtOH inhibition of nitric oxide (NO) production causing an increase in presynaptic vesicular GABA release, and 2) EtOH-induced inhibition of GC extrasynaptic $GABA_ARs$, dependent on the level of postsynaptic PKC activity. Our data indicate that genotypic variation in cerebellar nNOS expression and basal PKC activity levels determines the polarity and magnitude of EtOH modulation of GC tonic

$GABA_AR$ currents, which may play an important role in cerebellar-dependent EtOH-related behavioral phenotypes.

Title: Imaging of temporal activation of nicotinic and dopaminergic receptor stimulation following nicotine challenge in non-human primates

Authors: *C. MARTINEZ-RUBIO[1,2], B. K. JENKINS[3], J.-K. CHOI[3], S. R. PATEL[2], E. N. ESKANDAR[2];
[1]Clarissa Martinez-Rubio, Boston, MA; [2]Neurosurg., Massachusetts Gen. Hosp., Boston, MA; [3]Radiology, Martinos Ctr. for Biomed. imaging, Charlestown, MA

Abstract: Nicotine is one of the most addictive and widely abused drugs. Neuronal nicotinic acetylcholine receptors (nAChRs) are selectively modulated by nicotine exposure and are highly represented in limbic circuitry. Different combinations potentially have distinct patterns of channel conductance, agonist sensitivity, and activation/deactivation kinetics. Chronic drug abuse induces down-regulation in response to excessive stimulation as an adaptative mechanism. Evidence suggests that nicotine causes rapid desensitization and that this loss of receptor function promotes an up-regulation to compensate the decreased signaling of inactive receptors. These changes cause high affinity to nicotine, correlated with nicotine addiction. Another common feature of addictive drugs is the increase of dopamine (DA) levels in the ventral striatum, specifically the nucleus accumbens (NAcc). We have collected four data sets with nicotine challenge (phMRI only). Three naïve monkeys were scanned using a home-made 8

channel receive helmet coil. Continuous images using the IRON technique with injection of iron oxide contrast agent that allows for determination of changes in cerebral blood volume (CBV) before and after injection of nicotine were collected while simultaneous measurements of heart rate, blood pressure and end tidal CO2 were made. High dose nicotine injection (0.5 mg/kg) led to a number of changes in CBV that had very different time courses in different brain regions. We performed functional connectivity analysis using the time course of the CBV changes as a reference. The thalamus, region with the highest density of α4β2 receptors, showed a strong increase in CBV, transient with a peak at 2.8min and a return to baseline by 15min. This time course was also noted in the VTA. The orbital frontal cortex and the NAcc showed biphasic CBV changes with a short negative CBV component (peak at 2.8min) that switched to being positive with a longer time course (peak at 15min). The putamen shows only a long positive CBV time course (peak at 15min) that slowly returns to baseline over 60min. This rapid CBV component looks very similar to the rapid desensitization shown by α4β2 receptors in electrophysiological studies in response to nicotine. In contrast, the time course in dopaminergic regions such as NAcc and putamen is much slower showing a slow rise, a long peak, and a long time return to baseline that is more consistent with the time courses of nicotine-evoked DA release measured using microdialysis. Currently we are collecting simultaneous PET/phMRI with raclopride displacement to assess the DA response and model its time course.

Title: Strain-dependent performance in nicotine-induced conditioned place preference and striatal pCREB expression

Authors: *L. A. ORTEGA MURILLO[1,2], E. YILDIRIM[2], M. ADOFF[2], R. POOLE[2], T. GOULD[2];
[1]Psicologia, Univ. Autonoma de Bucaramanga, Floridablanca, Colombia; [2]Temple Univ., Philadelphia, PA

Abstract: The addictive nature of nicotine remains a significant health problem for society. Neural circuits underlying addiction extensively overlap with those that support motivation processes, and there are individual differences in the probability to develop an addiction to nicotine. Therefore, understanding the mechanisms underlying individual differences to the preference to nicotine may provide fundamental insights in unraveling the neurobiology of nicotine addiction. In the present study, a biased nicotine-induced conditioned place preference (CPP) protocol was assessed in eight inbred mice strains. As regions of dorsal striatum contribute to nicotine-induced CPP, and pCREB modulates learning, we also assessed the effects of nicotine on striatal pCREB expression. Animals were individually tested according to the following protocol. First, there was a habituation phase. Second, a drug-free preference for the chambers was determined. Third, CPP training started and animals were injected with nicotine (0.35 mg/Kg) or saline (control). Two CPP tests were performed. The first test was performed following three conditioning sessions and the second test after seven conditioning sessions. Finally, brains were dissected at the end of behavioral training and dorsal striatum was isolated to analyze pCREB levels using Western blots. Nicotine produced strain-dependent effects on CPP performance. Strains differences in CPP ranged from preference to the nicotine-paired chamber, no apparent CPP, to aversion to the place paired with nicotine. For some strains, the nicotine-CPP effects were dependent on the timing of the test, suggesting strain differences also for the acquisition and maintenance of CPP performance. Significant CPP effects were correlated with pCREB levels in the striatum, but only for some strains. These findings suggest that strain differences related to nicotine-induced preference involve differential pCREB activation in the dorsal striatum.

Title: Effects of orbitofrontal inactivation on dopamine cell activity during a delay-based decision task

Authors: Y. S. JO, *W. FOBBS, S. J. Y. MIZUMORI;
UW Psychology Dept, Seattle, WA

Abstract: An immediate outcome is preferred to a delayed outcome because animals discount the value of a reward if it is preceded by a delay. A large body of evidence suggests that both the midbrain dopamine (DA) system and the orbitofrontal cortex (OFC) play a critical role in delay-based decision making by encoding the subjective value of delayed rewards. However, only a few studies have investigated the interaction between the OFC and midbrain DA systems during delay discounting. In the current study, we investigated whether OFC inactivation altered DA cells' activity in a delay discounting task. Six Long-Evans rats were trained to choose between chocolate milk rewards of two magnitudes (0.05 or 0.3 ml) that were presented in food cups on either side of an elevated T-maze. Wooden barriers were placed before each food cup in order to prevent the rats from consuming the rewards until after they waited the appropriate delay period: 3 sec for small reward and 10 sec for large reward. The animals were implanted with recording tetrodes in the ventral tegmental area (VTA) and injection cannula in the OFC. Putative DA cells in the VTA were recorded during daily behavioral sessions consisting of two blocks of 18 trials (10 forced-choice and 8 free-choice). Prior to the second block, saline or muscimol (GABAA agonist) was injected in the OFC. Behaviorally, OFC inactivation decreased the preference for the large, delayed reward, when compared to baseline performance in the first block. Neuronal data showed that DA cells initially responded to the acquisition of reward, but over training, these reward responses disappeared. Instead, DA cells exhibited phasic responses when the wooden barriers were removed after the delay periods. The response shift was consistent with DAergic prediction error signaling. OFC inactivation caused two major effects on DA cells: 1) phasic responses to delay termination were significantly decreased; and 2) DA cells exhibited stronger phasic responses to reward acquisition as if the reward was unexpected. Together, these results support the view that the OFC contributes important information that allows the VTA to recognize a reward as expected, despite delays.

Title: Reward-sensitive neural responses in the periaqueductal gray during a spatial working memory task

Authors: *V. L. TRYON, E. FORMAN, S. J. Y. MIZUMORI;
Psychology, Univ. of Washington, Seattle, WA

Abstract: It is well established that ventral tegmental area (VTA) dopamine neurons play an important role in reward processing, decision making, and action selection. However, the brain areas that drive the VTA dopamine neurons are not as well established. Recent anatomical work shows that the periaqueductal gray (PAG) sends excitatory and inhibitory projections to both GABAergic and dopaminergic VTA neurons (Omelchenko & Seasack, 2010). In fact, the PAG provides the third heaviest subcortical glutamatergic input to the VTA (Geisler et al., 2007). The role of these PAG projections to VTA reward processing has not been extensively investigated. Rather the PAG is better known for its role in the behavioral responses to fear, vocalizations, and descending pain modulation. Therefore, our initial investigation of this question revealed the PAG contributes to the ability to discriminate different reward magnitudes. Reversible PAG inactivation during performance on a spatial working memory radial maze task resulted in a decreased preference to choose arms previously associated with large rewards before arms associated with small rewards. PAG inactivation also decreased consumption of the reward itself. The current study investigated PAG neural responses to reward encounters as a different group of rats performed on the same task as that used in the inactivation study. Long Evans rats were trained to retrieve large and small rewards (four or one 45 mg sucrose pellets) that were consistently found in the same locations on a radial eight arm maze. Once rats reached asymptotic performance levels on the task, they were implanted unilaterally with a 6 tetrode array aimed at the PAG. On test days, PAG neural activity was recorded while each rat performed five baseline trials followed by five trials with one of the following manipulations: large- and small-reward placement switch, unexpected reward omission, or no manipulation (as a control for time and experience on the maze). Initial analysis reveals that in a subset of PAG neurons, there was phasic excitation at the onset of reward encounters. Previous work from our lab utilizing the same task (Puryear et al., 2010; Jo et al., in press) has revealed that VTA dopamine neurons preferentially fire to large versus small rewards, and are inhibited by reward omissions. Thus, we expect further analysis to reveal similar patterns in reward-sensitive PAG neurons. These results, taken together with the inactivation study and anatomical evidence, suggest that the PAG may in fact play a role in reward related processing.

Title: Separate groups of dopamine neurons project to caudate head and tail

Authors: *H. F. KIM[1], A. GHAZIZADEH[1], K. S. SALEEM[2], M. K. SMITH[1], O. HIKOSAKA[1];
[1]NIH, NEI, LSR, Bethesda, MD; [2]NIH, NIMH, Bethesda, MD

Abstract: Many neurons in the monkey caudate nucleus respond to visual objects and change their responses as the monkey learns their values. Importantly, there are regional differences within the caudate: neurons in the caudate head (CDh) learn object values quickly (in several trials), whereas neurons in the caudate tail (CDt) learn object values slowly (across days) (Kim and Hikosaka, SFN 2011 & 2012). What are the synaptic mechanisms underlying such different time courses of learning? It has been widely suggested that dopamine (DA) plays a critical role in value-based learning. We thus considered two hypotheses; 1) same dopamine neurons project to both CDh and CDt, but regulate them differentially, 2) different populations of dopamine neurons project to CDh and CDt, and thus regulate them differentially.
To test which hypothesis is correct, we injected two different retrograde tracers into CDh (Diamidino yellow, DY) and CDt (CTB-alexa555, CTB555) in the same monkey, and examined retrogradely labeled cells in DA neuron areas: substantia nigra pars compacta (SNc) and ventral tegmental area (VTA). We found that neurons projecting to CDh and CDt were located in the ipsilateral SNc (not VTA), but were largely segregated. The CDh-projecting neurons were located relatively widely in the rostral-medial-ventral region of SNc. In contrast, CDt-projecting neurons were confined in the caudal-lateral-dorsal region of SNc. Notably, neurons projecting to both CDh and CDt (i.e., DY and CTB555 double-positive) were rare: 9 out of 1059 CDh-projecting neurons and 280 CDt-projecting neurons.
To examine whether the CDt-projecting neurons in SNc were DAergic. We double-labeled the sections with CTB555 and tyrosine hydroxylase (TH) antibodies. We found that most of the CTB555-positive cells were TH-positive, suggesting that the neurons in the caudal-lateral-dorsal SNc projecting to CDt are indeed DA neurons. We plan to do the same experiment for CDh.
Our data support the hypothesis that different populations of DA neurons modulate the synaptic plasticity of neurons in CDh and CDt with distinct time courses so that the monkey can adapt to both flexibly changing values and stably maintained values.

Title: Ventrolateral prefrontal cortical neurons encode the stable value and novelty of visual objects

Authors: *A. GHAZIZADEH[1], S. HONG[2], O. HIKOSAKA[1];
[1]LSR NIH, Bethesda, MD; [2]McGovern Inst. for Brain Res. MIT, Boston, MA

Abstract: Detection of object value or its novelty is crucial for directing attention and saccadic choice. Ventrolateral prefrontal cortex (vlPFC) is uniquely situated to influence object based decision making since it relays object identity information from inferotemporal cortex to frontal eye field and premotor structures which control behavioral outputs (Ungerleider et al 1989; Miyachi et al 2005, Gerbella et al 2011).Here we report that vlPFC neurons are strongly activated when visual objects are passively watched and can discriminate between them based on their reward history and familiarity. Two rhesus monkeys (Macaca mulatta) were trained on an object reward association task using more than 100 fractals over multiple sessions. Half of the fractals (good) were paired with big reward while the other half (bad) were paired with small reward. On separate days after initial training, animals passively viewed random presentations of good and bad fractals while fixating a central dot. Visually responsive neurons in vlPFC as a population fired significantly more to good objects compared to bad objects ($p<0.001$ ranksum). In fact, about 40% of neurons showed significant value discrimination even after accounting for object selectivity (two-way nested ANOVA value vs. object). Many of the task responsive neurons were also tested in a second experiment for differential responding to familiar vs. novel objects. Novel and familiar fractals with no reward history were intermixed and randomly presented to the animals while they maintained fixation in the passive viewing task. The population of task responsive neurons fired significantly more to passive viewing of novel objects compared to neutral familiar objects ($p<0.001$ ranksum). Interestingly, the strength of the novelty coding was significantly and positively correlated with the value coding (slope=0.4, $P<0.01$). In a separate task involving free viewing of objects, the monkeys made more saccades to and within good objects than bad objects as well as novel objects than familiar objects ($p<0.05$ t-tests). These results suggest that vlPFC may enable animals to attend and choose important (i.e., good or new) objects even in a passive condition based on long-term memory. Previous findings showed that substantia nigra pars reticulata (SNr) preferentially targets vlPFC through thalamus (Tanibuchi et al 2009). Importantly, SNr neurons have been recently found to strongly

encode stable values (Yasuda et al 2012). Whether novelty information reaches vlPFC via this nigrothalamocortical route or alternate routes remains to be examined.

Title: Functional territories in the primate substantia nigra separately signaling flexible and stable values

Authors: *M. YASUDA, O. HIKOSAKA;
LSR, Natl. Eye Inst., BETHESDA, MD

Abstract: Some objects change their values flexibly depending on behavioral context, but other objects do not change their values for a long time. How do animals and humans adapt to the flexible and stable values? Recent studies from our lab suggest that different regions in the basal ganglia encode flexible and stable values of visual objects separately. Notably, neurons in the caudate head (CDh) encode flexible values, while neurons in the caudate tail (CDt) encode stable values (Kim and Hikosaka, SfN 2011, 2012). A major target of both the CDh and CDt is the substantia nigra pars reticulata (SNr). Previously, we found a cluster of neurons in SNr that exclusively encoded stable values of many objects and sent the signal to the superior colliculus (SC) (Yasuda et al., J Neurosci 2012). Where, then, is the flexible value information processed? We hypothesized that different territories in SNr encode flexible and stable values. To test this hypothesis we widely explored SNr beyond the cluster of stable value-coding neurons, and found a separate cluster of neurons that encoded flexible values. Whereas the stable value-coding neurons were localized in the caudal-lateral-dorsal part of SNr, the flexible value-coding neurons were distributed in the rostral-medial-ventral part of SNr. The response patterns of the flexible value-coding neurons were less stereotyped than those of the stable value-coding neurons. Specifically, the flexible value-coding neurons were sometimes influenced by stable values, whereas the stable value-coding neurons were hardly influenced by flexible values. Some of the flexible value-coding neurons (72%) were inhibited by high-valued objects and excited by low-valued objects, while others showed opposite responses. In contrast, a great majority of the stable value-coding neurons (93%) were inhibited by high-valued objects and excited by low-valued

objects. Importantly, many of both the stable value-coding neurons and the flexible value-coding neurons were antidromically activated from the ipsilateral SC. These results suggest that the stable value information and flexible value information are processed separately throughout the basal ganglia and may converge on SC neurons that control saccadic eye movements.

Title: Negative feedback monitoring by lateral habenula and anterior cingulate cortex in monkey during a reversal learning task

Authors: *T. KAWAI[1,2,3,5], N. SATO[2], M. TAKADA[1], M. MATSUMOTO[3,4];
[1]Div. of Systems Neurosci., Primate Res. Institute, Kyoto Univ., Inuyama, Japan; [2]Grad. Sch. of Humanities, Kwansei Gakuin Univ., Nishinomiya, Japan; [3]Grad. Sch. of Comprehensive Human Sci., [4]Div. of Biomed. Science, Fac. of Med., Univ. of Tsukuba, Tsukuba, Japan; [5]JPSP Res. Fellow, Tokyo, Japan

Abstract: Neurons in both the lateral habenula (LHb) and the anterior cingulate cortex (ACC) respond to negative feedbacks. These signals have been proposed to play crucial roles in learning to avoid aversive events. It remains unclear, however, whether and how these signals cooperate for learning performance. To address this issue, we compared neuronal activities in the LHb and ACC in a monkey performing a reversal learning task. While the monkey was gazing a fixation point, two saccadic targets were presented on both the left and the right sides of the fixation point. The monkey was required to choose one of them. Saccade to one direction was followed by reward with 50% probability, while saccade to the other was not. After 20 to 30 trials, the rewarded direction was reversed without any instruction. The monkey learned to choose the rewarded direction by trial and error, and adaptively changed his choice based on the past reward history. Thus, the monkey chose the other direction with high probability as choosing one direction was repeatedly followed by no-reward. We recorded the activity of 38 LHb and 258 ACC neurons. Of these, 37 LHb and 117 ACC neurons showed a significant response to the feedback (reward or no-reward). Most of them (LHb, 37/37; ACC, 70/117) were more strongly

activated by no-reward. We found that the no-reward activation was influenced by past reward history only in the ACC. The no-reward activation in the ACC, but not in the LHb, was enhanced as no-reward trials were repeated, suggesting a parallel between the ACC signals and the monkey's choice behavior. The no-reward activation started later in the ACC than in the LHb. Furthermore, many neurons in the LHb and ACC responded to the fixation point. Only for the ACC neurons, this response was affected by the forthcoming decision as to whether the monkey might choose the left or right target. Notably, this "pre-choice" response was enhanced in the trials in which the monkey updated his choice from the previous trials. Our findings suggest that LHb neurons are useful to quickly detect negative feedback. On the other hand, ACC neurons convey history signals that would be relevant to learning to adaptively change behaviors.

Title: Co-release of glutamate and GABA in the lateral habenula

Authors: *S. SHABEL, C. D. PROULX, R. MALINOW;
UCSD, La Jolla, CA

Abstract: In the central nervous system excitation is generally balanced by inhibition. At synapses, this is primarily executed by local inhibitory interneurons mediating feedforward or feedback inhibition. However, some brain regions, such as the lateral habenula, lack inhibitory interneurons and therefore must use different mechanisms to regulate excitability. Here we've examined transmission between the entopeduncular nucleus (EP) and the lateral habenula (LHb), a pathway that may encode 'disappointment' and the presence of unpleasant stimuli. Recordings from LHb neurons in brain slices indicate that axons originating from the EP produce monosynaptic excitatory and inhibitory responses. Similar to feedforward inhibition in other neural circuits, monosynaptic inhibition suppressed neural activity evoked by high-frequency stimulation. Interestingly, EP neurons expressing the excitatory glutamate transporter VGlut2 or neurons expressing the GABA-producing enzyme GAD-67 each produce both glutamatergic and

GABA-ergic responses, indicating co-release of glutamate and GABA. Electrophysiological data suggest that glutamate and GABA are co-released from individual boutons and that co-release persists into adulthood. These findings demonstrate corelease of glutamate and GABA in the LHb, a process that may permit a local balancing of the net drive produced at specific input pathways and may be important for reward computations in the LHb.

Title: Effects of reward size and reward delay on ventral striatal tonically active neurons in monkeys engaged in an intertemporal choice task

Authors: *D. WEINTRAUB[1], J. WITTIG, Jr.[2], B. RICHMOND[2];
[1]Surgical Neurol. Br., NIH, Bethesda, MD; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Introduction:
Tonically active neurons (TANs) of the striatum are believed to be cholinergic interneurons. Their responses are sensitive to aspects of reward-associated stimuli. To investigate the influence of reward valuation on ventral striatal neuronal responses, we are recording single unit neuronal activity during an intertemporal choice task in which the size of a reward and the time delay required to obtain it are varied in a crossed-design.
Methods and Results:
Two rhesus monkeys were trained to associate visual cues with various combinations of liquid reward amount and delay during a bar touch and release task. In each trial, a visual cue indicates the reward size:reward delay combination. The monkey's task is to release the bar when a red target turns green. The offer indicated by the cue can be accepted (wait for green) or skipped (release early). The monkeys accepted the trials in a predictable and reliable manner_large rewards with short waiting times were most preferred.
We recorded extracellular activity from 43 neurons with the slow regularly irregular firing

characteristic of TANs. Many of these neurons showed the burst-pause-burst pattern elicited by reward predicting stimuli seen in TANs by others in the past. We analyzed the neuronal firing rates following cue presentation and reward delivery according to the size and delay components using a two factor ANOVA. Following cue presentation, 18/43 (42%), 7/43 (16%), and 5/43 (12%) neurons showed significant main effects on firing rate of both reward size and delay, reward size alone, and reward delay alone, respectively. Following reward delivery, 4/43 (9%), 4/43 (9%), and 4/43 (9%) neurons showed a significant main effect on firing rate of both reward size and delay, reward size alone, and reward delay alone, respectively. Interaction effects of reward size and reward delay were seen following cue presentation and reward delivery in 16/43 (37%) and 6/43 (14%) neurons, respectively.
Conclusion: Both reward size and reward delay are encoded by tonically active neurons in the ventral striatum. In this intertemporal choice task, the effects of reward size and delay on neuronal firing are more frequent after initial cue presentation than after reward delivery. We find evidence for both main effects and interaction effects of the two components of reward value on the activity of these neurons.

Title: Subthalamic and pallidal neurons represent reward-related signals in a multistep task in a monkey

Authors: *H. IWAMURO, I. TRIGO DAMAS, J. A. OBESO;
Movement Disorders Group, Neurosciences Division, Fima-ed.Cima, Univ. of Navarra, Pamplona, Spain

Abstract: One of the important roles of the basal ganglia is goal-directed and habitual control of behaviour. Several studies in rodents and primates have revealed that the dorsomedial and the dorsolateral striatum regulate goal-directed and habitual control, respectively. However, it is still unclear how the basal ganglia process neuronal signals in these two modes.
To investigate the signal processing of behavioural control in the basal ganglia, we recorded neuronal activity of the subthalamic nucleus (STN) and internal segment of the globus pallidus (GPi) in a monkey (Macaca fascicularis) performing a multistep task using a joystick and a

screen. The task consisted of three stages of variable difficulty: first, a reaching stage with a visible target, followed by a seeking period with an invisible target, which was considered more difficult than the previous one, and finally a simple button press for getting the reward.
A total of 70 STN and 123 GPi neurons were sampled. In the STN, 15 and 4 neurons showed phasic inhibitions and excitations of activity, respectively, after the target hits in both reaching and seeking stages. Since the physical movements at the moment of these neuronal modulations were different between the two stages, these neuronal responses were considered independent of movements. These neurons were found in the rostral part of the STN. On the other hand, in the GPi, 38 neurons which were distributed mainly in the rostro-medial part showed modulations of activity related to the target hit in both stages. According to the modulations around the target hit, they were categorized into four groups: 1) post-hit phasic inhibition type (n=9), 2) post-hit phasic excitation type (n=7), 3) post-hit long lasting excitation type (n=13), and 4) pre-hit predicting inhibition type (n=9). Each of them, except for type 4, showed the modulation in the same manner at both stages, although the seeking stage evoked stronger inhibition than the reaching stage in type 1 neurons as well as the STN neurons which showed inhibitions. In the type 4 neurons, the reaching stage inhibited their activity until the target hit, while the seeking stage hardly showed this pre-hit inhibition but evoked a phasic inhibition after the target hit. These results suggest that neurons in the rostral part of the STN and the rostro-medial part of the GPi process reward-related signals and their activity is affected by difficulty of accomplishment in goal-directed actions.

Title: Modulation of responses to the conditioned and unconditioned stimuli in the primate lateral hypothalamic area by an aversive option in Pavlovian conditioning

Authors: *A. NORITAKE, K. NAKAMURA;
Physiol., Kansai Med. Univ., Moriguchi, Osaka, Japan

Abstract: The value of a reward may change when a punishment is included as one of possible outcomes. The same reward may be valued higher relative to a punishment, compared with when it is valued relative to 'no reward'. On the other hand, a reward may be devaluated under such risk of danger. In our previous study, we found that neurons in the primate lateral hypothalamic area (LHA) convey information mainly on reward probability, uncertainty, and predicted values, but not on punishment ones in a Pavlovian conditioning task. In the study, however, because rewards and punishments were used in separate blocks of trials, it remains unclear how such value coding is influenced when both positive and negative outcomes may occur. To examine this issue, we trained two monkeys (Macaca fascicularis) a bivalent (BIV) version, in addition to the appetitive (APP) and aversive (AVE) version of a Pavlovian conditioning task. In BIV block, either a liquid reward or an air-puff was used as US. In APP block, either a reward or a neutral tone;in AVE block, an air-puff or a tone was used as US. In each block, there were cued and uncued trials. On the cued trials, after a timing cue, a white dot, was presented at the center of the screen, one of the three visual conditioned stimuli (CSs) was presented. Each CS signaled 0, 50, or 100% probability of unconditioned stimuli (USs). After the CS disappeared, there was a 1.0 s delay followed by US. On the uncued trials, the US was delivered unpredictably. The cued and uncued trials were intermingled in a given block. Consistent with the previous report, among 244 task-related neurons, one-third showed graded CS responses depending on outcome probability (n=88) and/or graded US responses depending on outcome predictability (n=81) in APP block. We found that, by an inclusion of an aversive option, over half of such neurons lost graded modulation in CS (51/88) and US response (44/81) in BIV block. Conversely, some neurons which originally did not exhibit graded CS and US responses in APP block now gained an ability to grade CS and US responses in BIV block. These results suggest that activity of the neurons in the LHA is influenced by the different ranges of outcome values.

Title: Deciding to take action: Striatum activation during reaching to targets of varying reward value

Authors: *E. A. POHLMEYER, S. GENG, N. W. PRINS, J. C. SANCHEZ;
Univ. of Miami, Miami, FL

Abstract: During activities of daily living, the environment presents many desirable and undesirable options to which an organism must respond. The striatum is believed to be part of a "limbic-motor" interface, providing integration of reward and motor information in order to contribute to the resulting behavioral actions. Better understanding of the information encoded by the striatum would provide new insights into how actions are influence by reward for developing theories of computational motor control. To do so, we recorded from a 16-channel microelectrode array in the striatum, targeting the nucleus accumbens (NAcc), of a marmoset monkey (*Callithrix jacchus*) while he performed two goal-directed reaching and grasping tasks. The first task focused on the monkey's decision of whether or not to reach for a single target item that was either desirable (one of two types of food items) or undesirable (a nonfood object). During each trial, the target item was presented at one of four spatial locations (orientated in a diamond pattern with the top and bottom locations providing a vertical target pair, and the left and right spots providing a horizontal target pair). The second task focused on the monkey's reach decision when two target items were presented simultaneously. All combinations of the three target items were used, with each trial's two target locations restricted to either the horizontal or vertical configuration. We found a large fraction of the recorded striatal neurons to be task correlated, exhibiting either excitatory or inhibitory responses (sometimes both), in a wide variety of activation patterns between the different task phases (e.g. decision making versus reach execution). Many cells responded during trial initiation, and/or the reveal of the target(s). Subpopulation of neurons appeared tuned to whether or not the monkey carried out a reaching movement (during either or both the decision and movement phases) with some neurons being explicitly tuned to whether movements were made to or withheld from targets at specific locations. When only one desirable target object was presented, we found little variation in the neural responses for the specific type of target. However, when the monkey had to decide between two target items, we observed cells whose tuning reflected both the specific type(s) of the potential targets as well as their locations. The variety of responses observed between the striatal neurons provides a rich pool of reward, decision making, and motor initiation information for computational motor controllers that mimic the brain's control processes.

Title: A single spiking neuronal model to account for the diverse spontaneous firing patterns of lateral habenula neurons

Authors: *A. LAVIALE[1], T. WEISS[2], R. W. VEH[3], M. T. MCGINNITY[4], L. MAGUIRE[4], K. WONG-LIN[4];
[1]ISRC, Derry, United Kingdom; [2]Centrum für Anatomie,, Charité-Universitätsmedizin Berlin, Berlin, Germany; [3]Centrum für Anatomie,, Charité-Universitätsmedizin Berlin, Phil, Berlin, Germany; [4]ISRC, Univ. of Ulster, Derry, United Kingdom

Abstract: It is hypothesised that the lateral habenula (LHb) plays an important role in reinforcement learning and mood regulation. Experiments have shown that the LHb is excited by aversive events, is causally involved in avoidance learning, and its dysfunctions are implicated in clinical depression. The LHb receives inputs from the limbic system and the basal ganglia, and projects to the major dopaminergic and serotonergic nuclei. Previously, we have explored the morphological and electrophysiological properties of LHb neurons in rat brain slices. The cells were categorised into neurogliaform, spherical, fusiform, polymorphic and vertical cells. Observed spontaneous firing patterns fell into 4 categories: silent, tonic regular, tonic irregular and rhythmic bursting (SIL, TR, TIR and BST). An interesting finding is that, with the exception of neurogliaform cells, the membrane properties of the neurons are very similar, and morphology does not correlate with the firing pattern. Importantly, the injection of small currents can change the pattern from SIL to TR to BST. Our current hypothesis is that these neurons are functionally similar, with slight variability resulting in heterogeneous spiking behaviour. In this work we explore this variability using computational modelling.
We use the adaptive exponential integrate-and-fire neuronal model to replicate the firing patterns observed in LHb neurons. This model has been shown to be able to replicate a wide range of realistic spiking patterns, while remaining simple and very efficient. To identify parameters corresponding to the observed diversity of spiking patterns, a systematic computational approach is used. For each potential combination of parameter values, the model is tested and features such as frequency or number of spikes per burst are extracted and saved. Finally, a sliding window approach is used to identify a small region of the feature map containing the desired proportions of each of the observed pattern.
The model demonstrates all behaviours so far observed in the LHb with very similar neuronal properties. In addition, small input variations can result in the LHb neurons crossing between regions with different behaviours, resulting in large output variations. This hints at neurocomputational properties similar to a switching mechanism. In further work, this single cell

model will be expanded into a biologically inspired model of the LHb and its relations to other brain structures.
In summary, our work suggests that LHb neurons may operate in the vicinity of multiple behavioural regimes. Our computational search algorithm can also be extended to solve other computational neuroscience problems.

Title: Neural activity in primate striatum and amygdala during novelty seeking

Authors: *V. D. COSTA, V. L. TRAN, B. B. AVERBECK;
Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Novelty seeking refers to the tendency of humans and other animals to explore novel and unfamiliar stimuli and environments in pursuit of potential reward. Although there is evidence that novel stimuli activate striatum and amygdala for purposes of orienting, it remains unclear how these two areas facilitate decisions to explore novel options. To examine the role of these two regions in novelty seeking, we simultaneously recorded single-unit neural responses in ventral striatum and amygdala in two rhesus monkeys, as they played a version of a three armed bandit task. During the task, the monkeys learned to choose between three, probabilistically rewarded images. Periodically one of the three choices was replaced with a novel image the monkey had not yet associated with reward. We used a reinforcement learning model to derive the initial value the monkeys assigned to novel stimuli, in addition to ongoing value estimates for the two remaining familiar choices. Behavioral analyses indicated that the monkeys displayed an overall novelty preference, initially selecting the novel option more often than the best alternative option, and initially assigning novel options a higher value than familiar options. Single-unit electrophysiological recordings in ventral striatum and amygdala are ongoing and will be the main focus of discussion.

Title: Encoding of reward-predictive cues in the ventral pallidum

Authors: *S. LARDEUX, S. M. NICOLA;
Psychiatry, Albert Einstein Col. of Med., BRONX, NY

Abstract: The nucleus acccumbens (NAc) has long been attributed a central role in linking motivation and action. Specifically, the NAc, under the influence of its dopaminergic innervation, facilitates cued reward-seeking when subjects must use "flexible approach" behavior to reach a fixed movement target from multiple possible starting locations (Nicola, J Neurosci. 2010). Many NAc neurons are excited by reward-predictive cues that trigger flexible approach; these excitations begin before onset of locomotion and predict the latency and speed of movement (McGinty et al., Neuron 2013). However, little is known about how these cue-evoked excitations in the NAc influence the activity of downstream structures in the basal ganglia to direct behavior.

To begin to answer this question, we recorded neuronal activity in the ventral pallidum, the major target of NAc projecting neurons, while rats performed a cued flexible approach task. In this discriminative stimulus (DS) task, rats had to make an operant response when the DS (an auditory stimulus) was presented but not when a non-predictive stimulus (NS) was presented; each stimulus was presented randomly on a 30 sec variable interval schedule. Animals were implanted with bilateral electrode arrays in the ventral pallidum. Most pallidal neurons we recorded were excited by the DS; we found three types of responses: a short activation, a longer activation or an inhibition. Most of the neurons activated by the DS responded also to the NS, but the activation was followed by an inhibition that was not present for the DS. Ongoing experiments characterize this firing in relation to cue-evoked flexible approach movement parameters, and future experiments will examine the effects of pharmacological manipulation of the NAc on pallidal cue-evoked activity.

Title: Activity of basolateral amygdala neurons during risky foraging decisions

Authors: *A. AMIR, S.-C. LEE, M. M. HERZALLAH, D. PARE;
Rutgers Univ. - Newark, NEWARK, NJ

Abstract: According to the evolutionary theory of emotions, fear is an inherited response tendency that promotes survival and reproductive success in the face of predatory risk. Previous work indicates that the amygdala plays a key role in the genesis of innate fear responses and the acquisition of new fear responses as a result of experience. However, there is little data on amygdala activity in naturalistic conditions, when animals must weigh the potential benefits of foraging against the increased risk of predation. To study this question, we recorded basolateral (BL) amygdala neurons in freely moving rats engaged in a foraging task. As in Choi and Kim (2010; PNAS), rats with restricted access to food were placed in an rectangular arena (8x2ft) divided in two compartments by a remote-controlled door: a dark nesting area (1ft) and a long brightly lit foraging area (7ft). Food pellets were placed in the foraging arena at various distances from the nest, in the absence or presence of a mechanical predator-like figure (Robogator). The Robogator was programmed to surge forward when the rat approached it. Even in the absence of Robogator, rats displayed cautious foraging behavior. When the door was opened, rats failed to approach the doorway in about 10% of trials. When they did, it took them 10 sec on average. Then, the rats waited by the doorway for up to 2 min before venturing into the foraging arena. After entering, they walked briskly, often along the wall, turned abruptly to take the food pellet and ran back to the nest to consume it. As the distance between the nest and food pellet was increased, so did the latencies to initiate foraging. When the Robogator was placed at the other end of the foraging arena, latencies increased further and the rats failed to initiate foraging in about 20% of trials. The vast majority of BL cells showed significant task-related activity. Upon approaching the doorway, the firing rates (FRs) of most presumed projection cells began decreasing, eventually reaching 20% of baseline by the time they retrieved the food pellet. In contrast, the FRs of presumed interneurons gradually increased, reaching 150-200% of baseline by the time the rats retrieved the food pellet. After food retrieval, FRs quickly returned to baseline in both cell types. Thus, even though predatory risk is enhanced during foraging, the activity of BL projection cells is suppressed, in part via the activation of BL interneurons. A

challenge for future studies will be to identify the origin of the top-down signals that suppress BL activity.

Title: Multiple neural circuits predict different types of financial risk taking

Authors: *C. C. WU, K. KATOVICH, B. KNUTSON;
Psychology, Stanford Univ., Stanford, CA

Abstract: To account for human financial risk taking, traditional finance models have focused on statistical moments of mean and variance. Higher order statistical moments such as skewness, however, can also influence choice. We have proposed that part of this influence may result from peoples' affective reactions to large but unlikely potential outcomes (e.g., wins in the case of lotteries, damage in the case of insurance). In this study, healthy human subjects (n=19) chose between risky gambles and certain gambles (i.e., 100% $0.00) for real money while being scanned with functional magnetic resonance imaging (FMRI). Gambles shared equal mean and variance, but varied in terms of skewness (i.e., positive skew: 25% +$5.25, 75% -$1.25, symmetric: 50% +$3.05 / 50% -$3.05; negative skew: 75% +$1.25, 25% -$5.25). Anticipatory neural activity (i.e., which occurred while subjects viewed gambles but before they selected their choice) was used to predict individuals' risky financial choices in both whole brain and volume of interest analyses. Whole brain analyses utilized GraphNet, a multivariate pattern analysis method optimized for FMRI, which implements a combination of regularization parameters designed to yield generalizable yet interpretable solutions (Grosenick et al., 2013), while volume of interest analyses used logistic regressions to regress localized brain activity on choice. Across all gamble types, the whole brain GraphNet solution predicted risky vs. certain choices at 65.8% (leave one subject out cross validation, $p<.001$). Visualization of features selected by the

GraphNet model revealed that positive features in the nucleus accumbens (NAcc) and negative features in the anterior insula predicted risky choice in general. Volume of interest analyses confirmed these associations over all gamble types, but additionally indicated that NAcc activity more robustly predicted risk seeking in positive skew trials, whereas anterior insula activity more robustly predicted risk avoidance in negative skew trials -- consistent with an anticipatory affect account (Wu et al., 2012). Together, these findings suggest that different neural circuits promote different kinds of financial risk seeking and imply that neurofinance models may account for choices that transcend the boundaries of traditional finance models.

Title: Environmental enrichment affects novel object and location preference in adolescent rats

Authors: *D. E. COBB[1], R. E. EICHORST[2], D. C. KELLER[3], A. M. DOYLE[1], M. C. ZRULL[2]; [2]Psychology, [3]Biol., [1]Appalachian State Univ., Boone, NC

Abstract: Adolescence is a period of change that can include increased risk-taking. Interestingly, environmental enrichment (EE), which can enhance brain development, learning and memory, has mixed effects on exploratory behavior, which is an important component of novelty and sensation seeking. In this study, we examined how EE affected novel object and location preference in adolescent rats. Young Long-Evans rats (n=16) were exposed to EE in cages with ramps, platforms, inanimate objects, and other rats for 1.5 hr/day for two of every three days between postnatal days (PND) 34 and 64. Age-matched rats (n=16) were not enriched controls. Two-trial object and location preference testing occurred between PND 66 and 75 (15, 30, 60 minute and 24 hour delays). On Trial 2, a novel object (NOP task) or familiar object at a novel location (NLP task) was present in the test field. On PND 78, 8 EE and 8 control rats were sacrificed after a final, 2 hour EE session or 2 hours in the quiet and dark, and those brains were processed to visualize the c-fos protein. Neural activation in the amygdala was examined using microscopy and stereology. For 15 to 60 minute delays before Trial 2 of the NOP task, the proportion of novel object contact time increased for control rats (+43%, 0.54 to 0.77) and dropped for EE rats (-34%, 0.59 to 0.39). This trend reversed for the 24 hour delay ($p<.05$) when EE rats spent more time contacting the novel object (0.64 vs. 0.59). During Trial 2 of the NLP

task, EE rats showed stable contact with the object at the novel location for 15 through 60 minute delays and a decrease in attention to the novel location after 24 hours (-28%, 0.70 to 0.48). In contrast, control rats showed a consistent proportion of contact time with the newly located familiar object (0.60) across all delays ($p<.05$). Behavioral data suggest EE promotes adaptation to unfamiliar objects within a known environment over periods up to 60 minutes and to rearrangement of familiar objects in a known space at one day after initial exposure. Histology revealed differences in numbers of active neurons between EE and control rats. In basolateral amygdala of EE brains, there was a 19% reduction in active neurons relative to controls. However, rats with a final EE session showed 135% more fos-positive neurons than controls. While a history of EE appears to reduce baseline activity in amygdala, a single EE session can increase amygdala activity over that baseline. The data seem to suggest that in our rat model enrichment during adolescence may promote relatively short-term adaptation to the introduction of novelty into a familiar environment as well as longer-term adaptation to alteration or re-organization of items in a known environment.

Title: Structural integrity of cortico-striatal white matter tracts and risk-taking correlates in adolescents

Authors: *D. GOLDENBERG[1], E. H. TELZER[2], A. J. FULIGNI[1], A. GALVAN[1]; [1]Psychology, UCLA, Los Angeles, CA; [2]Psychology, Univ. of Illinois at Urbana-Champaign, Champaign, IL

Abstract: In the United States, the majority of all deaths of youth aged 10-24 are from unnatural causes, due in large part to risky decision-making. Previous research suggests that risk-taking is associated with neural regions implicated in reward and cognitive control (i.e., striatum and prefrontal cortex), which undergo significant development during adolescence. The goal of this study was to use Diffusion Tensor Imaging (DTI) to examine the relationship between cortico-striatal white matter integrity and individual difference measures associated with risk-taking. Forty-eight adolescents (ages 14 -16 years, 56% female) were recruited from local schools. Endorsement of risk-taking correlates was assessed through well-validated measures, including the Zuckerman Sensation Seeking Scale (M=3.8, SD=1.5, range=0-10), Flinders Decision-Making Questionnaire (M=2.9, SD=.4, range=1-4), Benthin Risk-Perception Measure (M=2.0, SD=.7, range=1-7), and Conners Impulsivity Scale (M=1.9, SD=.5, range=1-4). Participants underwent magnetic resonance imaging (MRI) on a 3T Siemens scanner, during which a DTI sequence was collected to evaluate integrity of white matter microstructure.
Data were corrected for head motion, eddy current distortion, and signal loss. Each of the 64 direction files was then registered to the B0 image using a six-parameter registration in 2D to minimize eddy current distortions. Preliminary analyses suggest that individual differences in sensation seeking are associated with structural integrity of white matter connections between ventral striatum and medial prefrontal cortex. Planned analyses will implement Tract-Based Spatial Statistics (TBSS) to examine the relationship between fractional anisotropy (FA) values and self-endorsed risk-taking measures.
White matter architecture undergoes significant remodeling during adolescence. To our knowledge, no research has yet examined the link between white matter connectivity of cortico-striatal tracts and adolescent endorsement of risk-taking constructs. Risky behaviors at this time are likely associated with increased sensitivity to reward competing with a still-maturing ability to inhibit impulses. These analyses will elucidate the behavioral phenotypes (e.g. impulsiveness, sensation-seeking) associated with the structural integrity of connections between the multiple regions implicated in adolescent risk-taking. Research such as this will further inform our knowledge of networks involved in adolescent risk-taking, as the field moves towards a more integrated view of neural organization.

Title: Disadvantageous decision-making is related to increased motor impulsivity on a rodent gambling task

Authors: *M. M. BARRUS[1], J. G. HOSKING[1], F. D. ZEEB[2], M. TREMBLAY[1], L. COQUE[1], C. A. WINSTANLEY[1];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Impulsivity is understood as a range of behaviors that are lacking in foresight, inappropriately risky, prematurely expressed, and harmful to momentary and/or long-term success. Most component behaviors can be broadly classified as relating to choice or motor impulsivity, and the relationship between these forms is not well understood. Although high motor impulsivity is a key symptom of disorders like pathological gambling and addiction, in which decision-making on laboratory tasks is compromised, there have been no clear demonstrations that choice and motor impulsivity are related in the general population. Given that high levels of all forms of impulsivity co-occur in psychiatric disorders, the lack of concurrence between measures of impulsive choice and action in non-clinical subjects is potentially troubling, as this dissociation may mean that studying the regulation of impulsivity in normal populations cannot provide insight into the basis of impulse control disorders. The recurrent use of a rodent gambling task that measures both decision-making and motor impulsivity has provided our laboratory with data from a substantial number of animals (n = 221) which we evaluated to determine whether these two forms of disadvantageous behavior are related at the population level.
Our meta-analysis of these data revealed that motor impulsivity was positively correlated with poor decision-making under risk. Furthermore, when animals were divided into high-impulsive and low-impulsive groups based on their rate of impulsive action, clear differences were observed in choice preferences: more impulsive animals showed a stronger preference for the risky, less advantageous options. Highly impulsive rats were also slower to adopt an advantageous choice strategy and quicker to make a choice on individual trials. This work may represent the first demonstration of a clear relationship between choice and motor impulsivity in a non-clinical population.

Title: The interaction of reward sensitivity and executive function predicts substance use and neural signature of risk processing in adolescents

Authors: *N. LAUHARATANAHIRUN[1,2,3], J. KIM-SPOON[2], J. WALTERS[2], J. FARLEY[2], K. DEATER-DECKARD[2], W. K. BICKEL[1,2], P. CHIU[1,2,3], B. KING-CASAS[1];
[1]Virginia Carilion Res. Inst., Roanoke, VA; [2]Virginia Tech, Dept. of Psychology, Blacksburg, VA; [3]Salem VA Med. Ctr., Salem, VA

Abstract: Adolescence is a developmental period often characterized by increases in risky behaviors including substance use, reckless driving and risky sexual behaviors (Steinberg, 2007). Human neuroimaging and animal studies suggest that adolescents' proclivity toward risky decisions is likely related to differential development of subcortical and cortical regions (Casey et al., 2011; Steinberg, 2010). Immaturity in brain regions associated with cognitive control and enhanced sensitivity toward rewards combined with the lack of self-regulation ability to control impulses may explain adolescents' bias toward risky choices (Dahl, 2004; Luciana et al., 2012). The present study explores the extent to which the interaction between reward-seeking and cognitive control behavior are related to individual differences in behavioral and neural patterns of adolescents' risky decision-making.
To assess neural correlates associated with risky decision-making behavior, participants (N=24) engaged in a lottery choice task while their blood-oxygen-level-dependent response was monitored using functional magnetic resonance imaging. Adolescents were asked to make a series of decisions to either (i) accept the gamble at a cost, or (ii) reject the gamble. Gambles varied by risk level (low, medium, high) and expected value. In addition, reward sensitivity was measured using the Behavioral Activation System (BAS) and Behavioral Inhibition System (BIS) scales (Carver & White, 1994), while executive functioning was measured using standard neuropsychological tests (i.e., digit span, multi-source interference task, trail making, and Tower of Hanoi). Lastly, participants indicated their frequency of alcohol, cigarette, and marijuana use. Both behavioral and neural data indicate that adolescents with high reward sensitivity were likely to show higher levels of risky decision-making and substance use especially when paired with poor cognitive control. Specifically, adolescents with high BAS scores and low executive functioning scores exhibited greater bilateral insular activation relative to participants who had low BAS scores with high executive functioning. These data highlight how individual differences in reward sensitivity combined with executive functioning contribute to risky decision-making behaviors in adolescence.

Title: Voluntary alcohol intake, specifically during adolescence, produces arrested behavioral development resulting in enduring maladaptive and suboptimal risk preference in adulthood

Authors: *A. G. SCHINDLER, H. H. TONG, S. WARLOW, H. GILL, J. J. CLARK;
Univ. of Washington, Seattle, WA

Abstract: Alcohol is the most commonly abused drug among adolescents and shows the highest liability of all abused drugs. In humans, adolescent alcohol use can predict later drug abuse potential, and can lead to negative alterations in decision-making functions. We have previously demonstrated that voluntary consumption of alcohol by adolescent rats (20 days, 10% ethanol or control gelatin prepared with 10% glucose polymers) results in increased maladaptive risk-taking behavior on a probability discounting task when later tested as adults. Here we extend these finding to show that adult rats that voluntarily consumed alcohol for 20 days did not differ from controls on the same probability-discounting task when subsequently tested, demonstrating that this effect is specific to the adolescent time window. Adolescence is characterized by maturation and remodeling of key brain regions implicated in reward and decision making. The malleable nature of the adolescent brain renders it uniquely vulnerable to environmental insults such as alcohol exposure. Thus, we hypothesize that adolescent alcohol intake results in arrested development of specific brain regions and neurotransmitter systems involved in decision making and leads to subsequent arrested behavioral development. In support of this hypothesis, we found that naive adolescent rats exhibited significant risk preference and that adult rats exposed to alcohol during adolescence mimicked this maladaptive behavior. Conversely, control adult rats and adult rats exposed to alcohol during adulthood were risk neutral, again demonstrating age specificity. With the use of fast scan cyclic voltammetry (FSCV) to measure subsecond dopamine release, we have shown that rats exposed to alcohol in adolescence demonstrate increased phasic dopamine transmission within the nucleus accumbens in response to risky, but not to safe, options in adulthood. These findings suggest that changes in striatal dopamine release, as a consequence of adolescent alcohol exposure, could bias choice by assigning greater

value to the risky option. Persistent changes in GABAergic function are seen following chronic alcohol exposure, which could potentially modulate DA release. In order to investigate this phenomenon further, flow cytometry was used to measure expression of GABAA receptor subunits on individual neurons of the ventral midbrain. The results of these experiments provide unique insight into the specificity of alcohol exposure on risk preference and the potential role that GABAergic modulation of dopamine neurons plays in this aberrant behavior.

Title: Risk-taking, fear and anxiety in Balb/c, C57BL/6J and CD-1 mice tested singly or in pairs

Authors: *A. ENNACEUR[1], R. M. ABUHAMDAH[2], P. L. CHAZOT[2];
[1]Univ. of Sunderland, Sunderland, United Kingdom; [2]Dept. of Biol. and Biomed. Sci., Univ. of Durham, Durham, United Kingdom

Abstract: The present study examined anxiety response in three strains of mice that were exposed singly or in pairs to a novel open space anxiety test. The group allocation is shown in the table below:

Singly **BA** (n=17) **C57** (n=14) CD1 (n=18)

Paired **BA**, n=8 vs. **BA**, n=8 **C57**, n=16 vs. **BA,** n=16 **CD1**, n=17 vs. **BA**, n=17

Groups and number of animals tested either singly or in pairs.
BA=Balb/c; C57=C57BL/6J; CD1= CD-1 (ICR)

When exposed to an unfamiliar platform elevated with downward steep slopes attached on two opposite sides, all three strains of mice spent a large amount of time in the areas adjacent to slopes than in any other parts of the platform. However, C57BL/6J and CD-1 crossed onto and explored the slopes while BALB/c mice did not take a risk, and remained the entire 12 min session on the platform. This suggests that exposure to the elevated platform induce fear and

anxiety which is elevated in BALB/c mice and reduced in C57BL/6J and CD-1 mice.
In the presence of a companion, from the same strain (BALB/c) or from different strains (C57BL/6J and CD-1), BALB/c mice did not cross onto the slopes, and they spent a large amount of time in the center of the platform compared to BALB/c singly tested and compared to C57BL/6J and CD-1 mice. In addition, not all paired C57BL/6J and CD-1 crossed onto the slopes. They were 7 out of 16 C57BL/6J mice (44%) and 12 out of 17 CD-1 mice (71%) which did not cross onto the slopes. This seems to indicate that a C57BL/6J and CD-1 mice were affected by the presence of BALB/c mice. The presence of a companion does not appear to mollify anxiety in high anxiety strain of mice. It appears to have a negative influence in the least anxious strains of mice.
The present study demonstrates that it is possible to assess anxiety and social interaction within a single test condition, and that our novel open space anxiety test can be useful in behavioral phenotyping and drug screening, particularly in animal models of social anxiety, schizophrenia and autism.

Title: Effects of the chronic D2/3 agonist ropinirole medication on rodent models of gambling-related decision-making

Authors: *C. A. WINSTANLEY, M. TREMBLAY, J. G. HOSKING;
Univ. British Columbia, Vancouver, BC, Canada

Abstract: Objective: The aim of this project was to investigate the effect of chronic administration of the dopamine D2/3 agonist ropinirole in two different models of gambling behaviour in rats. The more traditional drug treatment for Parkinson's Disease (PD), L-DOPA, has shown over time to produce debilitating side-effects such as dyskinesia. Selective dopamine agonists that act on the D2/3 receptors such as pramipexole and ropinirole have been used to treat the motor symptoms of PD, but these drugs may lead to a variety of impulse control

disorders (ICDs) including pathological gambling in some patients. Few studies have looked at the effect of chronic ropinirole on impulsive or risky behaviours.
Methods: One group of rats (n = 24) learned the rat gambling task (rGT)- a rodent analogue of the Iowa Gambling Task used clinically to assess decision-making under risk. Here, rats chose between four options, each associated with differing probabilities of reward and punishment. The second group of animals (n = 24) performed the Betting task- a paradigm which measures biases towards or away from risk. Here, rats chose between a guaranteed reward versus a 50:50 chance of double that reward or nothing. Behavior was assessed before and following implantation and removal of an osmotic mini-pump delivering either ropinirole at 5mg/kg/day or a saline solution for 28 days.
Results: Chronic administration of ropinirole increased premature responses on the rGT, but did not affect choice of the risky option. In the Betting task, chronic administration of ropinirole led to an increase in choice of the uncertain lever regardless of the baseline preference for the safe or uncertain lever characteristic of each rat.
Conclusions: This study suggests that chronic administration of the D2/3 agonist ropinirole produces an increase in preference for uncertainty which may explain why some PD patients treated with selective dopamine medication develop gambling and other risky and maladaptive behaviours. We intend to follow up these findings by determining the impact of chronic ropinirole in a dorsostriatal 6-hydroxydopamine (6-OHDA) lesion model of PD. These studies will help characterise the specific type of impairments experienced by PD patients taking dopamine agonist therapy and provide knowledge of the neurological mechanism underlying them.

Title: A home-cage operant paradigm for studying behavioral inhibition in the mouse

Authors: *R. P. FAUST, J. HINKLE, X. ZHUANG, J. A. BEELER;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: With the emergence of sophisticated genetic tools that target specific neural circuits or signaling pathways, meaningful and sensitive behavioral paradigms are increasingly becoming the bottleneck in establishing a functional map of the nervous system. Operant conditioning paradigms are versatile paradigms that are commonly used to probe a variety of nervous system functions. However, they are typically labor intensive (weeks or months of daily sessions) and involve food or water deprivation that invariably alters the homeostatic system. Previously, we developed a semi-naturalistic and ethologically more relevant mouse home cage operant paradigm. Since mice live in this environment nearly undisturbed throughout the experiment and earn all their food via their operant responses (closed economy), food or water deprivation is not required. Moreover, it does not require much labor during the course of the experiment.
Here, we describe a behavioral inhibition paradigm adapting conventional Go/NoGo tasks to the home cage environment. Mice learn to inhibit operant responding for food reward during a discrete light cue, a 'NoGo' interval, and increase their responding when the cue is turned off, a 'Go' interval. The interval lengths are randomly distributed ranging between 10 and 120s and in continuous alternation. A NoGo interval does not terminate until the mouse has suppressed responding for the allotted period. The mice display pronounced learning curves in acquiring the task and reach asymptotic performance within 10-14 days. Unlike conventional Go/NoGo in mice, this paradigm does not require the use of aversive stimuli to motivate reliable and stable NoGo performance. Though less controlled than traditional, session-based paradigms, the homecage generates a much more extensive dataset that reflects entirely the mouse's self-regulated behavior in adapting to the task. This homecage version of Go/NoGo may offer an easier, higher throughput paradigm for assessing behavioral inhibition than current, conventional operant approaches, facilitating more rapid phenotyping of impulsivity in genetically altered mouse lines.

Title: A rapid method for evaluating risky decision-making in the rat using intracranial self-stimulation

Authors: *N. HOLTZ[1], S. TEDFORD[1], T. NAPIER[2];
[1]Dept. of Pharmacol., [2]Depts. of Pharmacol., Psychiatry, Rush Univ. Med. Ctr., Chicago, IL

Abstract: Impulsivity is a multifaceted behavioral feature common to a number of psychiatric disorders, including substance use disorders, ADHD, and impulse control disorders. One facet of impulsivity is increased risky decision-making. This is often investigated using probability discounting paradigms, in which subjects choose between small, certain reinforcers, and larger reinforcers delivered with varying uncertainty. Risky decision-making is characterized by a preference for the larger, uncertain (i.e., "riskier") reward. In studies with non human animals, food commonly serves as the reinforcer, often requiring food deprivation which can affect impulsivity itself. To circumvent this problem, we implemented intracranial self-stimulation (ICSS) of the medial forebrain bundle as the reinforcing stimulus for probabilistic discounting tasks (ICSS directly activates the neural circuitry involved with natural reinforcers) (Rokosik and Napier: J Neurosci Meth 198:260, 2011; Neuropsychopharm 37:1397, 2012). Our protocol consisted of nine phases that incrementally trained rats on increasing complex set of contingencies. The present study aimed to streamline this protocol. Following recovery from surgically implanting the bipolar stimulating electrodes, the rats were trained to associate the positively reinforcing electrical stimulation with a lever press using a forepaw (phase 1). Our prior studies had verified that 50Hz and 100Hz could serve as small and large reinforcers, respectively. Thus, rats were tested in FR-1 schedules of reinforcement at 50Hz and 100Hz (phase 2). Once rats distinguish between the two (phase 3), they were trained in the discounting task (phase 4). We present here several variations of the task attempted towards the development of a rapid method. Data collected thus far show that rats quickly acquire the task, omit fewer trials, and discount the larger reward at lower probabilities, suggesting that this abbreviated protocol retains the construct validity of the previous procedure, with the advantage of expedited data collection. This procedure may accelerate preclinical research examining the role of risky decision-making in psychiatric disorders, as well as a means to screen compounds for liability to enhance impulsivity.

Title: Distinct types of uncertainty encoding in the primate septum

Authors: *I. E. MONOSOV[1], O. HIKOSAKA[2];
[1]NEI/NIH, Bethesda, MD; [2]Natl. Eye Inst., Bethesda, MD

Abstract: A key feature of decision-making and learning is sensitivity to uncertainty. Uncertainty about an outcome may bias subjects to approach and learn or avoid and ignore, to perform an action or to wait, to speed up or to slow down. However, the neuronal circuits mediating these uncertainty sensitivities are not well understood. In the primate septum, we found two groups of reward uncertainty-selective neurons (Type-1 and Type-2). We recorded neurons throughout the septum while monkeys participated in a Pavlovian procedure in which visual cues (conditioned stimuli; CSs) predicted rewards and punishments, with 100, 50, and 0% chance. In the most dorsal region of the septum, we found uncertainty neurons (Type-1) that were tonically activated during the presentation of the CS indicating uncertain reward-delivery (50% reward CS), but were not activated by the reward certain CSs (100% and 0% reward CSs) or reward deliveries. Type-1 neurons did not respond to any of the punishment CSs or punishment deliveries. Type-2 neurons were preferentially distributed in the ventral septum, including the diagonal band of Broca. They exhibited an increase in activity during the presentation of the reward uncertain CS (50% reward CS) and that activity continued to increase until the outcome (reward or no reward) was revealed. Unlike Type-1 neurons, Type-2 neurons also increased their activity during CSs that predicted 100% or 50% punishment, and were phasically activated by the delivery of punishment. Interestingly, Type-1 and Type-2 neurons exhibited different time scales of learning as the monkeys learned the meanings of novel 100, 50, and 0% CSs. Unlike Type-1 neurons which quickly acquired their representation of reward uncertainty while monkey learned the meanings of the visual cues, Type-2 neurons strongly responded to the novel stimuli and slowly learned to signal reward uncertainty, over the course of ~3 days. Our findings suggest that the septum contains multiple mechanisms for the processing and integration of uncertainty-related information and suggests a novel role for this brain region in behavior.

Title: Financial risk attitude in Parkinson's disease patients

Authors: *S. KOBAYASHI[1], N. MATSUDA[1], Y. AKUTSU[2], Y. UGAWA[1];
[1]Dept Neurol., Fukushima Med. Univ., Fukushima-shi, Japan; [2]Dept Rehabil., Takeda Gen. Hosp., Aizuwakamatsu-shi, Japan

Abstract: Parkinson’s disease (PD) patients may exhibit impulse control disorders in relation to dopaminergic treatments. Previous studies examined PD patients using Iowa Gambling Task (IGT) and demonstrated their tendency of financial risk-seeking as a factor that biases reward-based decision-making. However, IGT requires multiple cognitive abilities including working memory and reward association learning, which may also be impaired in PD. To be free from such confounding, we developed Fukushima Gambling Task (FGT), in which reward magnitudes and probabilities of the choice options were explicitly indicated on the computer monitor. Subjects chose between safe (x yen with no risk) and risky (1000 yen at p%) options by pressing a button. The choice indifferent point X(p) was obtained for each p (5, 10, 25, 50, 75, and 90) by means of parameter estimation by sequential testing. In theory, risk-seeking behavior leads to greater X(p). The area under the indifference point curve was used as an indicator of risk attitude (FGT score). Cognitive functions were also assessed by Mini-Mental State Examination (MMSE), Frontal Assessment Battery (FAB), digit span, Raven Colored Progressive Matrices (RCPM), Rey-Osterrieth Complex Figure Test (ROCFT), Stroop Test, Wisconsin Card Sorting Test. IGT was also tested and risk attitude in IGT was scored by the difference in the number of choices between advantageous and disadvantageous card decks (IGT score). Learning during 50 IGT trials was evaluated by comparing the number of advantageous choices in the first and last 20 trials. Eight PD patients with MMSE score > 23 participated in the present study. FGT score indicated risk aversion in all subjects. In contrast, IGT score indicated risk-seeking behavior in three subjects and the effect of learning was absent in four subjects. FGT score showed negative correlations with the scores of MMSE, FAB, digit span, and ROCFT. Present study suggests that most PD patients are risk averse, and the risk-seeking behavior observed during IGT may be an overestimation due to other cognitive impairments. Interestingly, FGT demonstrated that PD patients with higher cognitive abilities chose a safe option at a price much smaller than the expected value of a risky option at all probability range, which is irrational and suboptimal for reward obtaining. It remains to be elucidated whether the risk aversion bias is a specific consequence of dopamine pathology in PD.

Title: The dual orexin receptor antagonist almorexant decreases motor impulsivity in highly impulsive rats performing a rat Gambling Task

Authors: *L. F. COQUE[1], C. A. WINSTANLEY[1], M. A. STEINER[2];
[1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Actelion, Allschwil, Switzerland

Abstract: High impulsivity is a key symptom of psychiatric disorders such as bipolar disorder, substance abuse and attention deficit/hyperactivity disorder. The term impulsivity encompasses a range of behaviors which can be broadly divided into impulsive action and impulsive choice. In humans, impulsive decision-making under risk is often measured using the Iowa Gambling Task, in which subjects choose between 4 decks of cards to try and win money. In order to maximize their returns, subjects must avoid the high-risk options associated with large gains but also disproportionately large losses, and choose instead options that yield smaller incremental rewards but also smaller penalties. We developed a comparable paradigm for rats in which subjects have 30 minutes to earn sugar pellets by choosing between 4 different options. Just as in the IGT, the optimal strategy on this rat gambling task (rGT) is to favor options associated with smaller per-trial rewards but fewer time-out penalties, and avoid options associated with larger rewards but longer and more frequent penalties. A well-validated index of motor impulsivity is the degree of premature responding- the emission of a prepotent response before the signal is given. Such responses are commonly measured using the five-choice serial reaction time task, but are also recorded in the rGT.
Even though numerous types of impulse control deficit co-occur clinically, different forms of impulsivity may be underpinned by independent neurobiological mechanisms. Motor impulsivity in particular may be related to high levels of arousal, as stimulant drugs such as amphetamine and cocaine increase this form of impulsivity. The orexin system is strongly implicated in wakefulness and arousal, and orexin antagonists decrease reinstatement of drug-seeking in animal models of relapse in addiction. Interestingly, orexin antagonists can block the reinstatement induced by the anxiogenic drug yohimbine- a compound also known to increase motor impulsivity. We therefore tested whether the dual orexin receptor antagonist almorexant would decrease premature responding and risky decision-making on the rGT. Almorexant significantly and dose-dependently reduced premature responding, particularly in animals that made more of these impulsive responses at baseline. Such highly impulsive animals also showed

a significantly greater preference for the high-risk high-reward options. Although almorexant reduced this maladaptive choice pattern, this effect did not reach statistical significance. These results indicate that further investigation of orexin antagonists as a treatment for impulse control disorders may be warranted.

Title: Unpredictable chronic mild stress in adolescent rats causes hyperactivity, decreased anxiety, and risk-seeking tendencies

Authors: *E. K. KIRSCHMANN[1,2,3], E. C. DONNY[3,4], A. F. SVED[2,4], E. THIELS[1,2,3]; [1]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for Neurosci., [3]Ctr. for the Neural Basis of Cognition, [4]Psychology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Adolescence is a period of many neural, physiological, and behavioral changes, and of heightened vulnerability for the development of neuropsychiatric disorders. Unpredictable chronic mild stress (UCMS) is a widely-used model for inducing emotional instability, including depressive- and anxiety-like behaviors, in adult rodents. We wanted to study the effect of UCMS exposure during adolescence on emotional behavior.
We exposed adolescent rats (starting age: postnatal day 28-31; p28-31) to 5 weeks of UCMS (n = 16) or control conditions (pair-housed; n = 16), and assessed the effect of UCMS on a series of measures: body weight (weekly), sucrose preference (SPT; weekly), activity in a 2-hr open-field test (OFT; before UCMS and in week 5 of UCMS), performance on the elevated plus maze (EPM; in week 5 of UCMS), and novelty-suppressed feeding (NSF; in week 5 of UCMS). Rats were sacrificed at p62-65 for collection of trunk blood and harvesting of brains in preparation for measurement of plasma hormone levels and levels of proteins of interest in brain. Prior to sacrifice, some rats were treated with dexamethasone and exposed to an acute stressor (5-min

swim), to assess negative feedback functioning of the hypothalamic pituitary adrenal axis. UCMS attenuated growth and resulted in a phenotype characterized by hyperactivity and reduced anxiety. Weight gain from p28-p62 was significantly lower among UCMS- compared to control rats. Horizontal and vertical exploration, as well as time spent in the center of the OFT arena, were significantly higher in UCMS- compared to control rats. Although the total number of entries or time spent in the open arms of the EPM did not differ between groups, the number of rats that entered the open arms with a high frequency (1 standard deviation above the mean of control rats) was significantly higher among UCMS- than control rats. Similarly, although the latency to initiation of eating in the NSF test did not differ between groups, the latency to the first exploration of the food in the center of the arena tended to be shorter for UCMS- compared to control rats. Sucrose preference increased slightly over the course of the 5-week period in both groups, with no difference between them. Analyses of plasma hormone levels and proteins of interest in limbic and striatal brain regions are currently under way, as are studies to examine whether the effects of UCMS vary depending on the peri-weaning experience (weaned and shipped by supplier on p21 vs. shipped with dam on p18 and weaned on p21). Taken together, our present results suggest that UCMS during adolescence does not induce an anxious or anhedonic phenotype but instead yields a hyperactive, risk-taking phenotype.

Title: Role of nucleus accumbens in the modulation of individual risk attitudes

Authors: C. G. SINON[1], M. S. MCMURRAY[1], *J. D. ROITMAN[2];
[1]Psychology, Univ. of Illinois at Chicago, Chicago, IL; [2]Psyc, Univ. of Illinois at Chicago, CHICAGO, IL

Abstract: The pursuit of natural rewards often involves making choices with uncertain potential for payoff. Variations in the consistency of the reward delivery and the magnitude of reward received can bias an individual's attitude toward future risky decisions. The Nucleus Accumbens

(NAc) is a brain region in the basal ganglia which is important for encoding the affective value of rewarding stimuli. To determine the extent of the influence of NAc on modulation of risk attitudes, we used in vivo electrophysiology to record single neuron responses during a risky decision making task. Rats were trained to lever press for rewards that differed in magnitude and probability. One lever was designated as 'certain', with all presses rewarded with a smaller magnitude sugar pellet reward. Presses of other, 'risky', lever led to a larger magnitude sugar pellet reward on a probabilistic schedule, such that on a portion of trials reward was omitted. The probability of risky reward receipt was varied randomly from session to session across consistencies ranging from 12.5% payoff to 75% payoff, and the size of reward varied between 1 and 6 sucrose pellets. In this way, we could compare neural responses when the same objective outcome (e.g. risky reward of 4 sucrose pellets) may be evaluated differently (e.g. in a session with risk level of 25% vs. 50%, or compared with certain reward of 1 vs. 2 pellets). A total of 265 neurons were recorded over the course of 55 recording sessions. We measured neural activity in response to cues that predict lever availability, lever presses and reward outcomes across individual behavioral response strategies. We found that NAc neuronal activity was modulated at the time of cue onset, but did not show a strong relationship with subsequent choice. However, responses were modulated by session risk level and reward outcome.

Title: Cholinergic modulation of decision making on the rat gambling task

Authors: *M. SILVEIRA[1], C. A. WINSTANLEY[1], M. SHOAIB[2];
[1]Univ. OF British Columbia, Vancouver, BC, Canada; [2]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Pathological gambling is characterized by persistent, maladaptive gambling behaviour that causes significant functional impairment in personal and professional life. Our lab has previously developed an animal model of gambling behaviour called the rat gambling task (RGT), which is based on the clinically administered Iowa gambling task (IGT). In this task rats must choose between four lever options that are each associated with the delivery of a different

amount of reward, as well as different probabilities of receiving said reward. Like the IGT, rats quickly learn to select the advantageous options characterized by smaller rewards with lower penalties, and to avoid the large, higher penalty reward options. Previous work has shown that dopaminergic (d-amphetamine) and serotonergic (8-OH-DOPAT) drug agonists impair choice performance on the RGT. However, the role of acetylcholine (Ach) in producing the choice patterns observed has yet to be investigated. Cortical Ach mediates the detection, selection, and processing of stimuli and associations, all of which are processes likely involved in RGT performance. Sixteen male, Long-Evans rats were trained in the task and given subcutaneous injections of oxotremorine, a nonspecific muscarinic agonist, or scopolamine, a muscarinic receptor antagonist. Although oxotremorine (0.01 - 0.1 mg/kg) had no effect on choice, the highest dose of scopolamine (0.01-0.1 mg/kg) significantly impaired RGT performance. Interestingly, the impaired choice profile observed with scopolamine is similar to that previously reported with amphetamine. In line with these findings, we are currently assessing whether administration of oxotremorine can antagonize the performance deficit produced by amphetamine on the RGT. Overall these data show that muscarinic antagonists can impair decision-making performance, and suggest that the cholinergic system is an important mediator of gambling-like behaviour. Determining exactly how the cholinergic system interacts with dopaminergic and serotonergic systems to regulate decision-making on the RGT is an interesting and exciting avenue for future research.

Title: Dopaminergic and serotonergic modulation of loss aversion in a rat gambling paradigm

Authors: *W. K. ADAMS[1,2], P. J. COCKER[1], R. D. ROGERS[3], C. A. WINSTANLEY[1];
[1]Psychology, [2]UBC Inst. of Mental Hlth., Univ. of British Columbia, Vancouver, BC, Canada;
[3]Dept. of Psychiatry, Univ. of Oxford, Oxford, United Kingdom

Abstract: Loss aversion refers to the cognitive bias whereby subjects, when facing a choice between a probabilistic or guaranteed loss, consistently prefer to choose the risky option over accepting a definite loss. An extension of this phenomenon is seen in both recreational and

pathological gamblers who often gamble continuously to recover losses or “loss-chase” despite the existence of, sometimes severe, financial and emotional burdens. Understanding the neurotransmitter systems involved in mediating loss aversion may provide insight into the mechanisms by which it becomes maladaptive in a clinical context. We recently reported that dopamine D2, but not D1, receptor blockade and serotonin 5-HT1A receptor activation modulates loss-chasing behaviour in rats performing a novel gambling task in which sequences of unfavourable choice outcomes can be assessed. Here we explored the pharmacological modulation of behaviour in a modified version of this paradigm in which unfavourable choice options were presented in parallel rather than sequentially. 15 male Long-Evans rats were trained to make operant responses that produced either food rewards or, unpredictably, impending time-out periods in which rewards were unavailable. At these decision points, rats had to choose between waiting for these time-out periods to elapse before resuming responding for rewards ('quit' responses), or selecting risky options with a 50% chance of avoiding the time-outs altogether and a 50% chance of time-out periods twice as long as originally signalled ('chase' responses). Chasing behaviour was assessed following systemic administration of the following compounds: d-amphetamine; the D2 receptor agonist, quinpirole; the D1 receptor agonist, SKF 81297; the D2 receptor antagonist, eticlopride; the D1 receptor antagonist, SCH23390; and the 5-HT1A receptor agonist, 8-OH-DPAT. In this experiment using this newly-amended procedure, the percentage of chase responses was significantly increased by treatment with SCH23390 whereas eticlopride or 8-OH-DPAT administration produced no marked changes. While there was a tendency for reduced chase responding following amphetamine treatment this did not reach statistical significance. These data suggest that dopamine D1 receptors may be involved in mediating the expression of loss aversion in rats. Further research is required to elucidate the extent to which such gambling behaviour in rodents relates to the human condition.

Title: Contributions of tonically active neurons and uncertainty to striatal learning

Authors: *N. T. FRANKLIN, M. J. FRANK;
CLPS, Brown Univ., Providence, RI

Abstract: Computational reinforcement learning models of the basal ganglia often assume a fixed learning rate, making them suboptimal for flexibly adapting to non-stationarity in the environment. An optimal learner takes their own uncertainty into account to decide how much to update action values based on any given outcome. Here we consider how giant, cholinergic, tonically active neurons (TANs) may provide a mechanism by which to modulate learning as a function of expected and unexpected uncertainty. Constitutively active TANs were added to a previously published neural model of the basal ganglia by Frank, 2006. Effects of M4-muscarinic receptors activation were simulated through direct inhibition of direct and indirect pathway medium spiny neurons (MSNs). Effects of M1-muscarinic receptor activation were simulated through a persistent increase in leak channel conductance in the indirect pathway. A stereotypical burst-pause TAN firing pattern of varying duration was simulated during reinforcement feedback. By modulating MSN activity and learning, TANs improved probabilistic reversal learning but with a tradeoff: long TAN pauses result in better asymptotic performance whereas short TAN pauses facilitate speeded learning following reversal. This tradeoff arises from TAN modulation of the degree to which MSNs are active during feedback and thus eligible for learning. Longer pauses were also related to decreases in entropy among MSN unit activity during learning, suggesting a relationship between TAN unit activity and uncertainty. Dynamically adjusting TAN pause duration to scale linearly with entropy improved the model's performance across different levels of stochasticity in the reward schedule, both in terms of asymptotic error rate and learning speed following reversal. Simulations with TAN pause length held constant across training were typically able to perform well for a single stochastic environment, but suffered degraded performance across multiple levels of stochasticitiy. These findings suggest that TAN pause duration may be dynamically controlled by entropy of MSN activity signaling uncertainty in action values, promoting both stable and flexible learning regimes that are robust to changes in environmental uncertainty.

Title: The insula cortex does not mediate reward expectancy in a rodent model of slot machine play

Authors: *P. J. COCKER[1], J. G. HOSKING[1], R. D. ROGERS[2], B. LE FOLL[3], C. A. WINSTANLEY[1];
[1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Psychiatry, Univ. of Oxford, Oxford, United Kingdom; [3]CAMH, Univ. of Toronto, Toronto, ON, Canada

Abstract: Gambling is a culturally and socially ubiquitous phenomenon that many people engage in without adverse effect. However, for a significant minority, gambling can become a maladaptive compulsion akin to drug or alcohol addiction. Cognitive theories of gambling have suggested subjective sensitivities to cognitive distortions or biases may underlie the development of pathological gambling. One of the most widely described cognitive distortions are near miss effects. Near misses are unsuccessful outcomes that are proximal to a win, such as matching two items on a pay-line and the third sliding by during slot machine play. Subjectively, near misses are experienced as aversive, but they have reliably been shown to galvanise further game play and may contribute to the purported virulence of slot machine play. Human imaging studies have shown increased insula cortex activation in response to near misses in healthy controls, although other investigations using pathological gamblers have yielded more equivocal results. We have developed a rodent slot machine task (rSMT) using standard operant chambers, wherein three flashing lights set to on or off following nose-poke responses. A win is signalled if all three lights set to on, whereas any other light pattern indicates a loss. Rats then choose between responding on a "collect" lever, which delivers sugar pellets on win trials but a 10 second time-out penalty on loss trials, or a "roll" lever which allows animals to start a new trial straight away. In a similar manner to humans, rats exhibit a near miss like effect, in that they show more erroneous collection responses on trials where 2-lights set to on i.e. that are structurally proximal to a win. Here, we demonstrate that the insula cortex is not critically involved in mediating slot machine play in rodents. Excitotoxic lesions to the granular insula failed to alter animals' ability to detect winning and losing outcomes or their reactivity to near miss trials. Likewise lesioned animals showed a broadly similar behavioural profile to control animals during extinction and reinstatement. In summary, it does not appear as though the insula cortex is critical for guiding reward expectancy during slot machine play.

Title: Evidence of motor skill specialization in wrist motion of skilled clinicians

Authors: *E. WADE[1], C. ZEISLER[1], J. CHEN[2], S. GHANIMANTI[2], J. WEI[2], C. TEMPLEMAN[2];
[1]Div. of Biokinesiology and Physical Therapy, [2]USC, Los Angeles, CA

Abstract: Quantifying motor ability in skilled surgeons may provide insight into novel training techniques that enhance our understanding of motor skill acquisition and motor ability. Significant differences occur in kinematic measures of wrist motion of surgeons performing a suturing task [1]. Our present goal is to determine the time evolution of this motion during a laparoscopic skills lab.

Using a cross-sectional, within- and between-subjects design, four right hand dominant laparoscopic surgeons performed a suturing technique in an animal lab setting (Two 'experts' with fellowship training and two 'competent' without fellowship training).

Each expert (E1, E2) was paired with a competent surgeon (C1, C2) to perform intra-corporeal suturing. Each surgeon wore a set of 3-axis accelerometer wristbands on each upper extremity during the exercise. Supported by their correlate pair, each surgeon performed a series of two interrupted sutures twice. Comparative analyses for the periods of active intra-corporeal suturing were performed. Right and left hand performances were analyzed with paired t-tests for mean values of the vector sum of acceleration taken for 2s epochs of data.

E1 and E2 showed higher mean values in the right hand as compared to the left ($p<0.001$). C1 had no difference in means, while C2 showed higher means in the left hand ($p=0.19$, $p<0.001$, respectively, Fig 1). There was greater wrist motion in E1/E2 early in the procedure as compared to later, while C1/C2 maintain a constant level of activity. Further, E1/E2 have significantly higher amplitude in the right hand throughout the procedure, while C1 indicates no difference, and the difference in C2 is suppressed. Here we quantify specialization of expert surgeons as an increase use of the dominant hand. These results may indicate that during laparoscopic fellowship training, an increased focus on mechanisms to develop this specialization will influence the acquisition of expert skill.

Title: Influences of Ia feedback on low-frequency fluctuations of plantar flexion torque

Authors: *R. N. WATANABE, L. A. ELIAS, A. F. KOHN;
Dept. de Telecomunicações e Controle, Univ. of São Paulo, São Paulo, Brazil

Abstract: Several feedback loops are potentially involved while a subject performs a plantarflexion. One of these loops encompasses the proprioceptive feedback from muscle spindle Ia afferents and the motoneurons (MNs). In this work, the objective was to investigate the role of the Ia feedback loop on the low-frequency fluctuations of the plantar flexion torque during the performance of a position task (PT) and a force task (FT). Experiments were conducted on nine young healthy subjects and provided reference data for the computer simulation studies using a biologically-based large-scale neuromusculoskeletal model. The model consisted of: i) conductance-based spinal MNs arranged in three motor pools (for the Soleus and Gastrocnemii muscles); ii) muscle spindle model providing Ia afferent feedback; iii) Hill-type muscle models;

iv) second-order system to model the foot during PT; v) stochastic point processes to represent the activities of the descending neurons and of the afferents, which provide the randomness of the system. In the computer simulations the torque produced was equivalent to 20% of the maximum voluntary contraction, the same value adopted experimentally. For experimental data, torque power spectrum for the PT presented peaks at two different frequencies (3.40 ± 0.48 Hz and 6.24 ± 1.66 Hz) while for the FT only one peak was observed (1.67 ± 0.52 Hz). Simulation results reproduced the experimental torque power spectrum when the Ia proprioceptive feedback was active, but with a higher synaptic gain in the Ia-MN synapses for the PT. For the simulated PT two peaks were observed at 3.05 Hz and 6.01 Hz, respectively, whereas for the FT only one peak at 1.81 Hz was obtained. It is worth noting that for the FT the peak vanished when the Ia proprioceptive feedback was absent (Ia-MN synapses were turned off). Therefore, these results provide evidence that Ia afferent feedback may be responsible for the low-frequency fluctuations of plantar flexion torque found experimentally. It should be stressed that the muscle spindles during FT are active due to the low compliance of the muscle tendon. Further research will exploit the contributions of additional feedback loops to the torque spectrum and analyze the impact of these fluctuations on motor control.

Title: A computational model of the kinematics of three-dimensional head-free gaze shifts

Authors: *M. DAEMI[1], D. CRAWFORD[2];
[1]Ctr. For Vision Res., Toronto, ON, Canada; [2]Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: We propose a kinematic model for the coordinated eye and head movements in order to make a gaze shift. Getting retinal error and initial eye and head orientations, this model

mathematically describes an experimentally-inspired sequence of rotations including saccadic eye movement, vestibule-ocular reflex (VOR) and head movement. The assumptions and constraints for solving the equations of the model are directly extracted from previous behavioral experiments in human and primates. Two main constraints are that the orientation of eye and head at the end of the gaze shift should respectively obey the Listing's law and the Fick law. This is a general model for the natural gaze shifts. We have defined two parameters in the model that control the amount of the head rotation such that for their very small values, the model is reduced to an experimentally-verified model for the head-fixed gaze shifts obeying all geometrical constraints for saccade. We also have defined another parameter in the model for controlling the amount of head rotation which contributes to gaze and the part of it which is cancelled out by VOR. This parameter subsequently determines the amount of VOR eye movement as well. These parameters are independent of the model structure and constraints so that they can be defined to be a function of any arbitrary variable like magnitude of gaze shift, initial eye and head positions and target saliency.
Based on this model and by arbitrarily setting the model parameters, the model accurately simulates the development of the spatial variables of the oculomotor system in different reference frames and in different situations. The model can predict where the gaze falls on a flat screen or where the image of the target falls on the retina during the gaze shift. The model can reproduce the behavioral differences between the symmetric and asymmetric gaze shifts. Having a 3-D model of gaze shift, we can use it to see how the torsional component of head and gaze are changing during gaze shift in different situations. Based on the mathematical relations in the model that have lead to the behavioral results, we can also think about the transformations that are required in the neural representation of such a model in order to implement a gaze shift.

Title: A scalable analysis of network fluctuations and its application in magnetoencephalography

Authors: M. Y. MAHAN[1], *A. C. LEUTHOLD[2], A. P. GEORGOPOULOS[3];
[1]Biomed. Informatics and Computat. Biol., Univ. of Minnesota, Minneapolis, MN; [2]Dept Neurosci, Univ. Minnesota, MINNEAPOLIS, MN; [3]Dept Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: Networks of interacting elements exhibit global behavior that cannot be accounted for by the behavior of individual constituent elements but reflect interactions among those elements. One way to measure that global behavior is by obtaining an average of the absolute values of all possible pairwise correlations in the network. Although calculating all possible correlations is in itself a straightforward procedure, it is not scalable to the size of the network, and it quickly becomes intractable, as the number of pairwise operations (i.e. correlations) increases rapidly as the square of the number K of the network elements. Therefore, a scalable measure of global network behavior would be very desirable. Here we present such a measure, called "Departure from Network Equilibrium" (DNE). The cost for computing this measure increases linearly with K and, hence, avoids the combinatorial explosion above. Previously, we applied a similar analysis on a network of developing brain cultures with 60 elements (Christopoulos et al., J. Neural Eng. 9:046008, 2012), where we documented its positive relation to the average pairwise crosscorrelation. In the present study we develop the DNE analysis systematically and extensively using artificial network simulations to derive confidence intervals for DNE distributions and to apply this knowledge to a DNE analysis on brain activity recorded using 248 magnetoencephalographic (MEG) sensors from 169 healthy human subjects (age 31-97 y). We found that the standard deviation of the time-varying DNE decreases as a power function of K network elements, independently of time series length N. An investigation of the interactions between MEG-derived DNE networks showed a strong negative interaction between the left and right hemispheres, which decreased significantly with age, such that it became less negative and tended to a plateau toward zero in advanced old age. By contrast, there was a strong positive interaction within each hemisphere, which became less positive with age in the left but not the right hemisphere. These findings document the promising utility of the DNE approach for scalable analyses of networks.

Title: EEG functional networks in motor processing during visual stimuli

Authors: *D. E. FRAIMAN[1,2], G. SAUNIER[3,4], T. LEMOS[4], E. MARTINS[4], C. VARGAS[4]; [1]Matematica y Ciencias, Univ. San Andres, Victoria, Buenos Aires, Argentina; [2]CONICET, Buenos Aires, Argentina; [3]Inst. de Ciencias Biológicas, Univ. Federal do Pará, Belem, Brazil; [4]Inst. de Biofísica Carlos Chagas Filho, Univ. Federal de Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: We herein address the time evolution of brain functional networks computed from electroencephalographic activity driven by visual stimuli. We describe how these functional network signatures change in fast scale when confronted to point light display stimuli depicting biological (BM) as opposed to scrambled motion (SM) in two different conditions. Whereas global network measures (average path length, average clustering coefficient and average betweenness) computed as a function of time did not discriminate BM from SM, local node properties did so. Contrasting BM vs. SM network local measures we found higher degree and betweenness values in the left frontal (F7) electrode, as well as higher clustering coefficient in the right occipital (O2) electrode for the SM condition. Conversely, for the BM condition we found higher degree values in central parietal (Pz) and clustering coefficient in the left parietal (P3) electrodes. These results add on the understanding of cortical networks enrolled in the coding of biological motion. Thus, functional network approach is of mathematical election for studying brain function in the time scale of cognitive processing, allowing a new level of understanding of the complex phenomena associated with brain function.

Title: A bio-inspired CPG model for hierarchical control of limbless locomotion

Authors: *J. ZHANG, G. LI;
FB Informatik, TAMS, Univ. of Hamburg, Hamburg, Germany

Abstract: This work presents a bio-inspired CPG model for locomotion control of limbless robots, concentrating specifically on the study of a hierarchical control architecture as steps toward developing limbless robots capable of 3D locomotion, fast reflex response and sophisticated response to environmental stimuli. The key issue for developing such a hierarchical control architecture is how to design a CPG based controller that not only can generate various gaits, but also provide a solution for realizing reflex mechanism as well as integrating sensory feedback.

To this end, we first design a CPG model inspired by the neuronal circuit diagram in the spinal cord of swimming lampreys. A set of interneurons described with sigmoid function and leaky integrators is incorporated into the design of the neural oscillator for rhythmic signal generation. Furthermore, according the connection between neural oscillators, a chained type and a cyclic type of CPG circuits are developed for generating traveling waves between oscillators. Through numerical simulations, the control parameters over relevant characteristics of the two types of CPG circuits are studied in detail.

We further design the proposed CPG model for limbless gaits implementation. Considering the configuration of limbless robots with pitch modules and yaw modules connected alternatively, two CPG circuits are applied to the pitch grouped modules and the yaw grouped modules, respectively. Both the necessary conditions for cooperation between the two CPG circuits and the control parameters for fast limbless locomotion are investigated. Four types of limbless gaits, i.e. side winding, rolling, turning and flapping have been realized. Results of simulations and experiments show the effectiveness of the proposed CPG circuits in generating limbless locomotion.

We also present the concept of sensory neuron and reflex arc. Since the proposed CPG model is derived from neural circuit in lampreys´ spinal cord and the existence of sensory neurons in lampreys have been proven, it is simple and natural to add sensory neurons into the proposed CPG model at the neuronal level. Based on the design of the sensory neurons, a reflex mechanism taking advantage of reflex arcs forms short pathways to bridge external stimuli and the CPG model. Thus fast response can be computed when the external stimuli is afferent to the CPG model. A ball hitting and a corridor passing experiments with multi-joint limbless robots confirm the feasibility of the reflex mechanism.

Title: Large-scale neuromusculoskeletal model used to investigate neurophysiological mechanisms behind upright stance control

Authors: *L. A. ELIAS, R. N. WATANABE, A. F. KOHN;
BME Lab, PTC, EPUSP, Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Several models have been employed to study the basic mechanisms underlying postural control in humans. Nevertheless, the vast majority of these models are based on a control engineering framework, so that the nervous system is approximated by a proportional-integrative-derivative (PID) linear model. While this may be a valid assumption, it fails in providing a close link between theory and physiology. In this study, our aim was to develop a biologically-based large-scale neuromusculoskeletal model intended to investigate the problem of upright stance control from a neurophysiological point of view. Some of its components are: i) conductance-based spinal neuron models (motor neurons and interneurons) arranged in three motor pools (for the Soleus and Gastrocnemii muscles); ii) muscle spindle model providing Ia and II afferent feedback; iii) Hill-type muscle models; iv) inverted pendulum model, which is a first approximation to the body biomechanics during upright posture. The randomness of the system is mainly due to the stochastic point processes that describe the descending neurons' and afferents' activities. The main findings were that the intrinsically unstable mechanical system might be stabilized by appropriately setting the level of fusimotor activity. The resultant values of COP RMS and mean velocity were compatible with those reported from vestibular loss subjects standing on a stable surface without visual information. In addition, there was a small cross-correlation peak at a lag around 300 ms between simulated COP and EMG from the Triceps Surae's muscles. The more interesting finding was that an intermittent pattern of muscle activation emerged from this posture control model, suggesting that the spinal architecture and organization, along with the modulation of afferent activity, may account for the apparent intermittent control that has been postulated by some researchers. From our knowledge this is the first large-scale neuromusculoskeletal model used to control an unstable biomechanical system which approximates human standing. Several other studies may be carried out using this model,

for instance, the investigation on how neuromuscular changes associated with aging or specific diseases influence postural control.

Title: Modified motor unit number index: A simulation study

Authors: *P. ZHOU[1,2], X. LI[1], W. RYMER[1], S. NANDEDKAR[3];
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Univ. of Sci. and Technol. of China, Hefei, China; [3]Natus Med. Inc, Middleton, WI

Abstract: Motor unit number index (MUNIX) that relies on the compound muscle action potential (CMAP) measurement and different levels of voluntary surface electromyogram (EMG) recordings has recently achieved much attention as a tool for evaluation of neuromuscular disorders. Our previous studies using a motoneuron pool and surface EMG simulation approach have revealed that reduction of individual motor unit action potential (MUAP) amplitude as a result of muscle fiber atrophy leads to substantial underestimation of the motor unit number with the MUNIX measurement. In this study, we introduce a novel concept of modified MUNIX, whose definition is correlated with the CMAP area of the examined muscle. The sensitivity of the modified MUNIX to reduced MUAP amplitude was explored by the motoneuron pool and surface EMG simulation approach. The results indicate that the MUNIX definition with a fixed surface EMG interference pattern area (20 mV•ms) is most suitable for

motoneuron diseases that demonstrate secondary evidence of muscle fiber reinnervation, while the modified MUNIX is applicable to atrophied muscles, where the atrophy is primarily induced from muscle fiber shrinkage rather than motor unit loss.
