Title: Epigenetic control of Hox paralogue group 5 induction in tangentially migrating precerebellar neurons

Authors: D. KRAUS[1], T. DI MEGLIO[1], C. F. KRATOCHWIL[1], S. DUCRET[1], *F. M. RIJLI[2]; [1]Friedrich Miescher Inst. for Biomed Res., Basel, Switzerland; [2]Friedrich Miescher Inst., Basel, Switzerland

Abstract: In mammals, cortical motor and sensory information is mostly relayed to the cerebellum via the hindbrain precerebellar pontine nuclei (PN), which include pontine gray and reticulotegmental nuclei. The developing hindbrain is rostrocaudally segregated into progenitor compartments, or rhombomeres (r1-r8), genetically defined by nested Hox gene expression. Mouse PN neurons are generated from r6-r8 lower rhombic lip (lRL) progenitors, undergo a long-distance caudorostral tangential migration via the anterior extramural stream (AES), and settle beside the ventral midline. Intrinsic expression of transcription factors and guidance receptors and extrinsic distribution of ligands are important for AES migration. We have recently shown that the AES has an intrinsic topographic organization (Di Meglio et al, Science 339, 204-7, 2013). Namely, the position and migratory path of distinct subsets of PN neurons within the AES is defined by their relative rostrocaudal origin in the progenitor compartment and nested Hox gene expression is mantained throughout migration and nucleogenesis.
Here, we investigated the molecular mechanisms governing the precise spatial and temporal regulation of Hox expression in AES neuron subsets. We found that, unlike other Hox genes, the expression of Hox PG5 genes is absent in lRL progenitor cells. We show that high levels of locally produced retinoic acid (RA) are in turn required to overcome an Ezh2-mediated repression and induce Hox PG5 expression at the onset of tangential migration in a specific subset of late-born neurons targeting the posterior PN.

Title: Glutamate signaling during neural tube formation

Authors: *P. A. CASTRO[1], E. B. SEQUERRA[1], L. TIAN[2], L. N. BORODINSKY[1];
[1]Dept. of Physiol. & Membrane Biol., [2]Dept. of Biochem., Univ. of California Davis Sch. of Med., Sacramento, CA

Abstract: One of the earliest events in the development of the vertebrate nervous system is the process of neurulation, when the folding of the neural plate is followed by the closure of the neural tube. The failure of neural tube formation leads to one of the most common birth defects known as neural tube defects. Antiepileptic drug use during pregnancy increases the incidence of neural tube defects in offspring by unknown mechanisms. Our previous studies have shown that glutamate signaling through NMDA receptors is important for the formation of the neural tube and suggest that antiepileptic drugs may alter neurotransmitter signaling during neurulation. In this study we investigate the molecular mechanisms by which glutamate is released and signals in the folding neural plate.

We assessed the expression of molecular components of neurotransmitter, SNARE complex-dependent, vesicular release and found by reverse transcriptase-PCR that transcripts of synaptobrevin, syntaxin, SNAP25 and synaptotagmin are all present in neural plate tissue of Xenopus laevis embryos. Another potential mechanism for neurotransmitter release is through the connexin-formed hemichannels. We detected transcripts for the connexins Cx43, Cx38, Cx46, Cx32 and Cx26 at these early developmental stages. In addition, transcripts of glutamate receptor subunits, GluR1 (AMPAR), GluR7 (KAR) and NR1 (NMDAR) are present in the

folding neural plate.
In order to determine the source of glutamate and the dynamics and mechanisms of its release during neural plate folding we expressed the membrane-anchored, extracellular glutamate-sensing fluorescent reporter, iGluSnFR, in developing Xenopus embryos by microinjecting the mRNA in one- and two-cell stage embryos. This approach renders a uniform protein expression in the whole embryo. In contrast, in vivo imaging of neurulating embryos reveals that the basal green fluorescence intensity is 3-fold higher in the dorsomedial region of the embryo, compared to dorsolateral tissue. This signal is diminished by 20% in the presence of the enzyme glutamate-pyruvate transaminase, which deaminates glutamate in the presence of pyruvate, decreasing available glutamate for binding to the probe. On the other hand, exogenous addition of 0.5-2 mM glutamate enhances the fluorescence intensity by 25% in the folding neural plate. These preliminary results suggest that the glutamate sensor reports in vivo dynamics of extracellular glutamate due to the release of glutamate in the folding neural plate.
Current efforts are focused on determining the mechanisms of glutamate release during neural tube formation.

Title: Anatomical impact of reelin haploinsufficiency and prenatal organophosphate pesticide exposure in mouse cerebellum

Authors: B. ROSS, B. MULLEN, *E. M. CARPENTER;
Dept. of Psychiatry and Biobehavioral Sci., UCLA Sch. Med., Los Angeles, CA

Abstract: Autism Spectrum Disorders (ASDs) are human developmental disorders characterized by a lack of innate social skills, impaired communication, reduced emotional response, and compulsive repetitious behaviors. ASDs are likely caused by a combination of genetic and environmental factors. In this study, we examined interactions between two possible contributing

factors, reduced expression of the reelin gene and prenatal exposure to an organophosphate pesticide. The reduced protein and mRNA levels in ASD patients suggest reelin is a candidate gene for ASD, and exposure to organophosphate pesticides has been linked to a higher incidence of autism in rural areas. Despite extensive study, few consistent anatomical changes have been observed in ASD patients. In this study, we specifically examined the organization and distribution of Purkinje cells in the cerebellum. Prior studies have shown a reduced Purkinje cell population in ASD patients, and loss of reelin expression has been shown to affect Purkinje cell death in reelin-deficient mice. Previous findings also show that the organophosphate pesticide CPO can also decrease the number of Purkinje cells. This study tested whether there will be an additive effect that would cause a more severe reduction of Purkinje cells in CPO-treated reelin-deficient mice than in either reelin-deficient or CPO treatment alone. Preliminary results suggest a loss of Purkinje cells and alterations in cerebellar foliation in CPO-treated reelin-deficient mice. Understanding the genetic and environmental influences that contribute to ASDs could culminate in preventative measures to reduce the prevalence or severity of ASDs in afflicted individuals.

Title: Ciliary length control and Hedgehog signaling in mouse development

Authors: J. SONG, H.-J. MOON, S. LEE, H. LEE, *H. KO;
Col. of Pharm., Dongguk Univ., Goyangsi, Korea, Republic of

Abstract: Most of mammalian cells including neuronal cells maintain single hair-like structures on the surface of extracellular membrane known as primary cilia. Physiological importance of primary cilia in mammals remains enigmatic for past century and recent advance in cilia biology research enlightened the crucial roles of primary cilia in animal development and disease. Although primary cilia are involved in multiple key developmental signaling pathways, Hedgehog (Hh) signaling pathway is best known and tightly regulated by primary cilia. Previously our lab identified the novel Hh signaling pathway component, Bromi, and loss of its expression *in vivo* causes dorsalized neural tube and diminished Hh signaling activity in mouse

neural tube development. To better understand the function of Bromi in neural tube development, we identified Bromi interacting protein, Cell cycle related kinase (CCRK), which is a homologue of long flagellar mutant 2 (LF2) in green algae, *Chlamydomonas*. The model system of *Chlamydomonas* has provided precious insight of mechanisms of ciliogenesis in mammalian system. Using this simplified model system, it has been isolated 4 different genes regulating flagellar length. We are interested in how ciliary length control impacts on transducing Hh signaling in mouse development. We generated KO mice for mouse homologue of LF gene and analyzed the developmental defects in LF gene KO mice. We observed that downregulation of mouse homologue of LF gene expression caused diminished Hh signaling and abnormal ciliogenesis. Multiple developmental organogenesis defects were manifested in mutant mice with misregulation of Hh signaling. Based on our findings, proper length of primary cilia throughout vertebrate development is critical for ensuring the proper animal development and homeostasis.

Title: Formation process of the cerebellar compartments that are determined by birthdate of Purkinje cells

Authors: *M. HASHIMOTO, K. YAMADA, T. MIYATA;
Aichi, Nagoya Univ. Med. Cell Biol., Nagoya, Japan

Abstract: The adult cerebellar cortex is organized into longitudinal compartments that are revealed by specific axonal projections (olivocerebellar and corticonuclear projections). The cerebellar compartments are thought to be the basic and functional subdivisions of the cerebellum. Using an adenoviral vector, we label Purkinje cells (PCs) born at embryonic day (E) 10.5, E11.5, and E12.5 and trace their fated positions in the mouse cerebellum. As a result, each cohort of birthdate-related PCs forms longitudinal compartments in the cerebellum, and furthermore, these compartments correlate strikingly with the compartments revealed by olivocerebellar projections. It suggests that there is close correlation between birthdate of PCs and the formation of cerebellar neuronal network. However, the formation process of the

cerebellar compartments has not been elucidated.
Using an adenoviral vector expressing enhanced yellow fluorescence protein, fluorescence-activated cell sorting, and DNA microarray analysis, we defined the genetic properties of E10.5-, E11.5-, and E12.5-born PCs. As a result, each cohort of birthdate-related PCs was characterized by the expression of a subset of particular genes, which was involved in regional specificity (e.g., EphA7) and neuronal function (e.g., EAAT4) in the cerebellum. Furthermore, we identified marker proteins for E10.5-born PCs and E11.5-born PCs. Using specific antibodies against these markers, we examined the distribution of E10.5-born PCs and E11.5-born PCs in the embryonic mouse cerebellum. 3D reconstruction of these distributions revealed the formation process of the cerebellar compartments in mouse cerebellum. E10.5-born PCs and E11.5-born PCs individually formed layers at E13.5 and these layers changed drastically into compartments after E14.5.

Title: Role of galanin in neuronal cell migration after brain injury

Authors: *H. KOMURO, J. FAHRION;
Lerner Res. Inst. Cleveland Clin., CLEVELAND, OH

Abstract: During the prenatal, perinatal, and postnatal periods, brains are very vulnerable to insults (such as traumatic injury and ischemia), which can cause permanent defects in neuronal

cytoarchitecture and lead to motor, cognitive, and learning deficits in children. To date, little is known about the mechanisms by which insults cause disruption of brain development. Because we thought that the neuropeptide galanin might be involved in the insult-induced disruption of brain development, we examined the role of galanin in the cerebellar growth of early postnatal mice after insults induced by freezing treatment (FT). In this study, to induce focal injury on the center of lobule VIb of postnatal (P) 10-day-old mouse cerebellum, a cooled (-70^{o}) 1 mm-diameter platinum probe was placed on the midline of the occipital bone (OcB) near the border between the OcB and interparietal bone for 10 seconds. In control animals, the probe, which was maintained at room temperature, was placed on the same site of the OcB. Here we show that galanin plays opposite and region-specific roles in the FT-induced defects in cerebellar cortical layer development through alterations in granule cell migration. First, FT caused decreased growth of cerebellar cortical layers in the region (lobule VIb) under the skull where the cooled probe was placed, but increased growth in the surrounding region (crus II). Second, FT decelerated granule cell migration in the frozen region (lobule VIb) where cortical layers became thinner, but accelerated the migration in the surrounding regions (crus II) where cortical layers became thicker. Third, FT increased galanin levels in regions (lobule VIb) where granule cell migration accelerates, but decreases galanin levels in regions (crus II) where granule cell migration decelerates. Fourth, *in vitro* studies revealed that the application of exogenous galanin accelerates granule cell migration in the EGL, ML, and IGL by altering Ca^{2+} and cAMP signaling, and Ca^{2+} transients via the activation of galanin receptors. Fifth, in vivo studies demonstrated that the injection of galanin or galanin receptor inhibitor can ameliorate the effects of FT on granule cell migration and cortical layer growth in both the frozen regions (lobule VIb) and surrounding regions (crus II). These results indicated that modification of galanin signaling provides crucial cues for restoring brain development after injury.

Title: Chondroitin sulfotransferase expression pattern in migrating motor neurons of the rat embryonic hindbrain

Authors: *M. WONG[1], M. LI[1], Y. S. CHAN[2], D. K. Y. SHUM[1];
[1]Biochem., [2]Physiol., The Univ. of Hong Kong, Hong Kong, China

Abstract: Chondroitin sulfate (CS) moieties of proteoglycans are extracellular matrix components that have been implicated in the timing and patterning of axon fasciculation during embryonic brain development. It, nonetheless, remains unclear if these moieties can also control neuronal soma migration in the developmental process. We hypothesized that the cranial motor neuron migration in the hindbrain is modulated by varying sulfation patterns of the chondroitins between the migrating and ready-to-migrate neurons. In this project, hindbrain explants of E11.5 Sprague Dawley rats were maintained in culture. In control cultures, time lapse video microscopy revealed advancement of neuronal cell bodies in the direction of the leading process away from the explant core. In test cultures treated with chondroitinase ABC, the neuronal cell bodies lost the directional movement but not the motility. Immunocytochemistry confirmed the presence of CS56 epitopes among Tuj-1-positive neurons not only in the explant core and those advancing beyond the core, but also in the environment surrounding the migrating neuronal cell bodies. In situ hybridization revealed the relatively abundant expression of chondroitin-4-sulfotransferase 2 (C4ST2) mRNA among cells heading away from the explant core. Taken together, the present results showed that CS moieties expressed by migrating neurons differ in sulfation pattern from those in the vicinity of non-migrating neurons.

Title: Neurodevelopmental toxicity caused by prenatal exposure to bisphenol A and di-isononyle phthalate

Authors: *K. E. RAKKESTAD, G. H. MATHISEN, M.-C. DELEBECQUE, R. E. PAULSEN; Univ. of Oslo, Sch. of Pharm., OSLO, Norway

Abstract: Environmental chemicals like bisphenol A (BPA) and phthalates may cause neurodevelopmental damage, and special concern is expressed for the neurotoxic effects on the developing nervous system of fetuses, babies and children. These compunds cross the placenta as well as the blood-brain-barrier. We use *in ovo* exposure of chicken as a model for in utero and neonatal exposure. In the cerebellum, tight regulation of the level of the transcription factor Pax6 is critical for correct development of granule neurons. We have exposed chicken embryos at

ED16 to BPA (~0.23 µg/g egg) for 24 hours before preparation of cerebellar granule cell cultures, and measured the Pax6 level on day 3 and 6 *in vitro*. We have also investigated whether prenatal exposure of mice pups to BPA induced changes in the Pax6 level in their granule neurons. These mice pups were obtained from mothers receiving BPA in the drinking water before mating, during pregnancy and during lactation. The Pax6 level was measured in the whole cerebellum from pups of various ages. Also, possible effects of prenatal exposure to BPA on the morphology of the cerebellum were investigated by measuring the thickness of the different layers in H&E stained cerebellar sections. In cultured chicken cerebellar granule neurons from BPA injected eggs we found that the Pax6 level was increased at day 6 *in vitro*. Further, we found that BPA induced an increase in the thickness of the external granule layer and also an increase in the total cerebellar Pax6 level in 11 days old mice offspring. The chicken model was also used for studies of prenatal di-isononyle phthalate (DINP) exposure. We injected solutions resulting in final concentrations inside the eggs of approximately 10nM, 100nM and 1µM. Preliminary results indicate that exposure to DINP *in ovo* reduces the Pax6 level measured in whole cerebella. Together these findings indicate that both bisphenol A and di-isononyle phthalate may affect neurodevelopment in the cerebellum.

Title: Activation of Hedgehog signaling pathway in the developing neural retina stimulates proliferation and disrupts optic fissure closure

Authors: *K. SAKAGAMI, X.-J. YANG;
Ophthalmology, UCLA, Jules Stein Eye Inst., LOS ANGELES, CA

Abstract: The mature vertebrate neural retina originates from the anterior neural plate and consists of seven major types of neuronal and glial cells. Accumulating evidence indicates that proliferation and cell fate specification of neural progenitor cells are regulated by both cell-intrinsic factors and cell-extrinsic cues. Among the known cell-extrinsic cues, the Hedgehog (Hh) family of molecules has been shown to regulate neural tissue patterning, cell proliferation,

laminar organization, and neuronal differentiation in the vertebrate retina. Previously, we have reported that conditional knockout of Smoothened (Smo), a receptor component of Hedgehog signaling, resulting in reduction of progenitor cell pool and increased retinal ganglion cell production in the embryonic retina. For gain-of-function experiments of Hh signaling, Rosa26-SmoM2 (R26-SmoM2) mice were crossed with Chx10-Cre driver mice. SmoM2 activation mutant shows enhanced proliferation and abnormal differentiation accompanied with increase of Sox2- and Sox9-positive progenitor cells in the embryonic retina. Immunohistochemistry also revealed increase of Pax2-positive cells in ventral retina and disrupted optic fissure closure, which mimics human coloboma. Current investigation is focused on understanding mechanisms of Hh signaling regulated eye morphogenesis and retinal development, and how disruption of Hh signaling leads to a congenital eye disease.

Title: The Gene Expression Database (GXD) for mouse development

Authors: *J. H. FINGER, T. F. HAYAMIZU, I. J. MCCRIGHT, C. M. SMITH, J. XU, J. T. EPPIG, J. A. KADIN, J. E. RICHARDSON, M. RINGWALD;
The Jackson Lab., BAR HARBOR, ME

Abstract: The Gene Expression Database (GXD) provides neuroscientists with a unique expression resource, where results and images from many assay types, anatomical structures, and developmental stages can be easily searched and analyzed. A free resource of mouse developmental expression data, GXD integrates results from RNA in situ hybridization, immunohistochemistry, knock-in reporter, RT-PCR, northern, and western blot experiments. Curators read the literature and enter the expression data therein. They also work with individual scientists and large-scale data providers to incorporate electronic submissions into the database. GXD includes over 1.3 million annotated results, more than 248,000 expression images, and data from 1,800 mouse mutants. Data are recorded and integrated by using standard gene and allele nomenclature, a hierarchical developmental stage-specific anatomy ontology, and a variety of controlled vocabularies. This makes it easy to search, navigate and compare the expression data.

Search parameters include gene or gene sets [defined by Gene Ontology (GO), phenotype, or disease], anatomical structure, developmental stage and assay type. GXD is part of the larger Mouse Genome Informatics (MGI) resource (www.informatics.jax.org), so scientists can explore the relevance of expression data through its integration with genetic, genomic, biological, and phenotypic information.
Recently, we have significantly enhanced the query and display capabilities of GXD. We have added new search functions to the Gene Expression Data Query form, and made the search form easier to use through an improved layout and other utilities. We have improved query performance so that even large sets of data can be returned quickly. Each search returns a summary that provides multiple views (via tabs) of the results, images, and genes. Most columns on these summaries are sortable, and export features have been added to download the data in text and spreadsheet formats. The summaries lead to enhanced assay detail pages that now include images alongside corresponding text annotations of the results.Visit the GXD homepage at www.informatics.jax.org/expression.shtml.

Title: Bone Morphogenetic Proteins (BMPs) regulate neural tube closure by cell cycle dependent mechanisms: A 4D time-lapse analysis

Authors: C. Y. BROWN[1], D. EOM[3], *S. AGARWALA[2];
[1]Inst. for Cell and Mol. Biol., [2]Mol. Cell and Developmental Biol., Univ. Texas at Austin, AUSTIN, TX; [3]Dept of Biol., Univ. of Washington, Seattle, WA

Abstract: During neural tube closure (NTC), a flat neural plate rolls up and closes to form a neural tube. This process depends upon the formation of a ventral midline hinge point (MHP), which buckles the neural plate and elevates the neural folds. MHP formation is marked by dynamic cell-shape changes, which result in wedge-shaped cells displaying increased basal: apical width ratios. Multiple models of cell wedging at the MHP have been put forward. These

include constriction of the apical adherens belt via cytoskeletal and junctional remodeling or via polarized endocytosis. These models do not fully explain how cell wedging occurs in the amniote where a single layer of bipolar progenitors spans the apicobasal axis/ventricular pial axis of the neural plate. These cells undergo interkinetic nuclear migration as they progress through the cell cycle, with large M phase cells occupying the apical surface and interphase (G1, G2, S) nuclei occupying the thickness of the neural plate. Cell wedging in such a tissue may simply involve keeping nuclei at basal locations via cell cycle dependent mechanisms. We have recently provided evidence that the blockade of Bone Morphogenetic Proteins (BMP) plays a critical role in MHP induction, where it induces basal nuclear retention or migration. Although we have provided evidence for BMP-mediated regulation of tight and adherens junctions, its role in regulating cell cycle kinetics has not been explored.
Here, we examined BMP-cell cycle interactions by combining in vivo PCNA-GFP and BMP manipulations with time-lapse analyses in 3-D midbrain explants.
We show that the cell cycle length is increased at ectopic hinges induced by BMP blockade by Noggin (controls: 11.55 ± 2.33 hr. Noggin: 21.46 ± 4.35hr). This increase does not alter M and G2 phase durations (M: controls: 0.44 ± 0.08hr; Noggin: 0.45 ± 0.13hr, p=0.89; G2: controls: 0.87 ± 0.81hr; Noggin: 1.04 ± 0.21hr, p=0.099). Instead, the increased cell cycle length comes from increased G1 (controls: 7.33 ±1.39hr; Noggin: 14.11 ± 1.51hr, p=0.003) and S durations (controls: 2.93 ± .67hr; Noggin: 5.85 ± 2.5hr, p=0.012). We note that the G2-M transition occurs at the apical surface in lateral neural plate, but sub-apically at the MHP. Interestingly, a subset of Noggin-electroporated cells also undergo G2-M transition sub-apically, recapitulating the MHP phenotype. These results suggest that BMP blockade reduces the apical surface at the MHP by preventing nuclei from becoming apical and mitotic. This is achieved by increasing G1 and S durations and by a sub-apical G2-M transition. These results suggest that BMP signaling regulates MHP formation by modulating both apical junctions and cell cycle kinetics.

Title: Mice with reduced Met signaling in cortex show altered cortical lamination

Authors: *J. M. SMITH, E. M. POWELL;
Anat. and Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Met, the receptor for hepatocyte growth factor/scatter factor (HGF/SF), has been implicated in a number of cellular processes, including proliferation, migration, survival, and process formation. MET has also been identified as a susceptibility locus for autism spectrum disorders (ASD). Both HGF/SF and Met are known to be expressed in the cerebral cortex during development, and Met signaling has previously been implicated in the development of the telencephalon. Alterations in cortical development and connectivity are thought to be involved in the etiology of neurodevelopmental disorders such as ASD.
Our lab has previously shown that mice expressing a kinase-dead Met in the cerebral cortex show altered cortical morphology, including regionally increased cortical volume and surface area, as well as increased thickness of the corpus callosum. We thus sought to determine if cortical lamination was altered in these mice, and which cell populations might be affected. We found that loss of Met signaling in the cortex had altered superficial layer morphology, while deep layers were unaffected. We confirmed this by examining the distribution of several layer-specific markers in these mice. In addition to changes in superficial layer thickness, we also found that cells expressing superficial markers were abnormally distributed in Met-deficient cortex. Notably, we did not find any alteration in the number of callosal projection neurons in Met mutant mice, suggesting that the change in callosal thickness in these mice is not due to an increase in the number of these neurons.

Title: A forward genetic screen in mice identifies mutants with abnormal cortical patterning

Authors: *S. HA[1,2], R. W. STOTTMANN[3,2], D. R. BEIER[1,2];
[1]Developmental Biol. and Regenerative Med., Seattle Children's Res. Inst., Seattle, WA; [2]Genet. Div., Brigham and Women's Hosp., Boston, MA; [3]Divisions of Human Genet. and Developmental Biol., Cincinnati Children’s Hosp. Med. Ctr., Cincinnati, OH

Abstract: Formation of a six-layered cortical plate and axon tract patterning are key features of cerebral cortex development. Abnormalities of these processes may be the underlying cause for a range of functional disabilities seen in human neurodevelopmental disorders. To identify mouse mutants with defects in cortical lamination or corticofugal axon guidance, *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis was performed using mice expressing *LacZ* reporter genes in layers 2/3 and 5 of the cortex (*Rgs4-lacZ*) or in corticofugal axons (*TAG1-tau-lacZ*). Four lines with abnormal cortical lamination have been identified. Positional cloning revealed one of these to be a splice site mutation in *Reelin* (*Reln*) that results in a premature stop codon and the truncation of the C-terminal region domain of reelin. Interestingly, this novel allele of *Reln* did not display cerebellar malformation or ataxia, and this is the first report of a *Reln* mutant without a cerebellar defect. Three lines with abnormal corticofugal axon development were also identified, one of which was found by whole-genome resequencing to carry a mutation in *Lrp2*. These findings demonstrated that the application of ENU mutagenesis to mice carrying transgenic reporters marking cortical anatomy is a sensitive and specific method to identify mutations that disrupt patterning of the developing brain.

Title: Disruption of BMP-FGF mutual inhibition leads to developmental delay and abnormal border formation in the developing telencephalon

Authors: E. S. FUNG[1], L. T. DOAN[2], J. S. HU[1], D. T. TRUONG[1], H. H. JUN[1], R. M. PHAM[1], K. POURHOSSEINI[1], *E. S. MONUKI[2];

Abstract: Patterning and specification of embryos and tissues is governed by morphogens. In many developmental systems, morphogens generate signaling gradients that are converted into switch-like (“ultrasensitive”) cellular responses, which produce discrete cell types separated by sharp borders. In the dorsal telencephalon, mutually inhibitory bone morphogenetic protein

(BMP) and fibroblast growth factor (FGF) signaling gradients interact within cells to generate ultrasensitive BMP target responses implicated in cell fate and border specification (Hu et al., PNAS 2008; Srinivasan et al., submitted). Presence of FGFs at sub-threshold BMP concentrations suppresses expression of BMP target genes but has little effect at maximal BMP concentrations. Addition of translation inhibitor cycloheximide abolishes this suppression suggesting FGF mediated effects are translation dependent (Fung et al., SFN abstract 2012). The question that remains is how FGFs are involved in the formation of a sharp, robust cortex-dorsal midline border. Here we further define the role of FGF signaling in this ultrasensitivity phenomenon. We hypothesize that disruption of FGF signaling will abolish ultrasensitivite BMP target responses leading to reduced refinement of cortex - dorsal midline border. Preliminary data suggests that FGF signaling mediates slow suppression of BMP target genes leading to refinement of cortex - dorsal midline border in the developing telencephalon. Disruption of FGF signaling leads to a failure of border refinement and developmental delay with possible partial catch up. Normal development will be studied in X-gal stained ex vivo explants and coronal sections of embryonic brains of BRE-gal reporter mice (Doan et al., Plos One 2012). FGF signaling will be disrupted using pan FGF receptor inhibitor PD173074 and effects will be observed in both ex vivo and in vivo. Our findings suggest that this mutual inhibitory signaling is crucial to sharp border formation in the developing telencephalon and may be a common mechanism in various biological systems.

Title: Sharp borders of gene expression in germinal layers identify a protomap of cerebral cortex folding

Authors: *C. D. ROMERO[1], C. BRUDER[2], V. BORRELL[1];
[1]Neurosci. Inst. Alicante, San Juan De Alicante, Spain; [2]Dept. of Microbiology, Tumor and Cell Biology,, Karolinska Institutet,, Stockholm, Sweden

Abstract: The cerebral cortex is a modular structure organized in distinct cytoarchitectonic and functional areas, limited by sharp borders and distributed along the rostro-caudal and latero-medial axes. In mammals with a folded cortex this modularity also requires the three-dimensional accommodation of the neuronal layers in order to form convolutions along the cortical mantle. All these different modules of cortical neurons appear during development from embryonic neural stem (eNSCs) and progenitor cells arranged in proliferative layers. We recently demonstrated that in several gyrencephalic species, including humans, the differential expansion of cortical domains correlates with sharp differences in eNSC proliferation between adjacent regions in germinal layers. Given the tight genetic regulation of the cell cycle and proliferation of germinal cells along cortical development, we proposed that proliferation differences between prospective folds and fissures might result from differences in expression of certain genes among cortical germinal layers during embryonic development. Here we performed a gene expression analysis of germinal layers in the developing cerebral cortex of the gyrencephalic ferret to characterize differences between adjacent cortical areas with different degrees of expansion/folding. We have found thousands of differentially-expressed genes that defined unique transcriptional fingerprints for each cortical area and germinal zone analyzed. We found the existence of mosaics of gene expression along each of the germinal layers correlating with gyrus/sulcus formation. Significantly, expression patterns were frequently characterized by sharp, step-wise changes in expression levels for genes which are otherwise present shallow gradients across the mouse cortex. Our findings are consistent with the existence of a transcriptional protomap of cortical folding in germinal layers. Differentially-expressed genes between gyrus and sulcus had a 7-fold bias towards genes mutated in human cortical malformations, including lissencephaly, microcephaly and polymicrogyria. This confirms the validity of our strategy to identify genes critically implicated in regulating cortical folding, and hence indicates that others of our differentially-expressed genes may be involved in patterning cortical folding. Furthermore, these findings also indicate that our list of genes differentially expressed is a valid entry point to search for genes mutated in human cortical malformations but for which specific genetic mutations have not yet been identified.

Title: Distinct critical periods for medio-lateral fate specification in the cortical primordium

Authors: *A. S. SHETTY[1], G. GODBOLE[1], E. MONUKI[2], S. TOLE[1];
[1]TIFR, Mumbai, India; [2]Univ. of California, Irvine, CA

Abstract: The cortical primordium requires LIM-HD transcrtiption factor Lhx2 for its specification. In the Lhx2 null mutant, two non cortical structures, the hem and the antihem, expand at the expense of the cortical primordium. This expansion is known to have a critical period that ends at E10.5, after which loss of Lhx2 does not cause expansion of the hem and the antihem (Mangale et al., 2008). Since the hem and the antihem normally form some distance from each other, at the medial and lateral extremes of the dorsal pallium respectively, we hypothesized that they may become specified at different times. We used a conditional Lhx2 knockout line and tamoxifen-inducible CreER to generate a precise temporal map of Lhx2 requirement in the E8.5-E10.5 window. We find that the critical period for hem specification ends significantly earlier than E10.5. Loss of Lhx2 in the E9.5-E10.0 window spares some medial cortex and causes a smaller expansion of the hem. In contrast, the antihem expansion is similar to that in the null mutant. Ongoing experiments are aimed at examining the consequences of these temporal differences in the role of Lhx2 in the earliest stages of cortical development.

Title: Immunohistochemical characterization of a cortical neuronal type expressing a combination of markers in the adult rat brain suggesting cell immaturity

Authors: *A. FERNANDES, N. GARCIA-CAIRASCO;
Physiol., Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: Cortical dysplasia is the most common cause of surgical treatment of drug-resistant seizures in children and it has been widely studied since described in the early 70's. In order to help understanding the mechanisms involved in the formation and pathophysiology of dysplastic lesions, scientists use animal models of disruption of the cortical structure including, as proposed by Dvorák and Feit (Acta Neuropathol. 15;38(3):203-12, 1977), a freezing insult to the developing brain cortex in newly born rodents causing the formation of a microgyrus.
Using the above mentioned method, we induced the cryogenic lesion in ice cold anesthetized neonatal rats (Ethics Committee approval 133/2009) and observed the alterations up to 6 months later. Intriguingly, besides the microgyrus formation, we observed the presence of an unusual neuronal type in the neocortex. We called it Abnormal Pyramidals (AP), due to their densely stained small pyramidal shape with Neu-N immunohistochemistry. These cells are normally organized with their apical processes towards the pial surface but it is not rare to find misoriented cells.
We used an immunohistochemical approach to study the cortical alterations caused by the cryolesion so the APs were studied using the following techniques: neuronal (Neu-N), glial (GFAP), Layer V pyramidal neurons (ER81), Layers III and VI pyramidal neurons (Tbr1) and GABAergic interneuron (Parvalbumin) markers. We found that regions presenting the microgyric lesion were absent of APs.
The APs are present in both experimental and control subjects of the two temporal windows (72 and 180 days) what suggests it is an unusual but stable alteration of the cortical anatomy. This was found in 56% (9/16) of controls and 60% (16/27) of experimental animals with no differences independently of time window or gender (Fisher exact test; $p>0.05$). Those cells were found exclusively in the neocortex, usually in the superficial layers of motor and somatosensory areas.
The analyses of the immunostaining markers showed that APs are stained for all the markers except Parvalbumin, that absolutely lacks in regions affected by the APs.
We first suspected of the anesthesia by cold as a possible culprit for the APs emergence but in a new group of 8 animals experiencing only maternal separation for 3 hours (as the experimental/sham groups) and no exposure to cold we found the same proportions of APs appearance. It is yet inconclusive the nature of those cells, however it is tempting to assume that due to the expression of the various markers but PV those cells could be, actually, immature neurons. Further experiments, coupled to electrophysiology, are needed to elucidate this question.

Title: Longitudinal change in cortical thickness: Freesurfer cross sectional and longitudinal processing streams

Authors: *S. L. WILLIS[1], P. RAST[2], D. MCLAREN[3], K. W. SCHAIE[1], T. J. GRABOWSKI[4]; [1]Seattle Longitudinal Study. Univ. of Washington, SEATTLE, WA; [2]Psychology, Univ. of Victoria, Victoria, BC; [3]Radiology, Massachusetts Gen. Hosp., Charlestown, MA; [4]Neurology, Radiology, Univ. of Washington, Seattle, WA

Abstract: It has been suggested that Freesurfer's longitudinal processing stream produces more accurate and significant results, yet an empirical comparison has yet to be conducted using longitudinal growth models. Here we report on findings on longitudinal change in cortical thickness in a healthy adult sample of N = 163 participants in the Seattle Longitudinal Study (Mage = 62 (age 52 - 87) at time of first scan using two Freesurfer methods. Subjects underwent three scans at two-year intervals (2007, 2009, 2011) on a Philips 3T Achieva scanner. Cortical thickness estimation was performed with FreeSurfer version 5.1 (http://surfer.nmr.mgh.harvard.edu/). The following analysis was conducted separately for the cross-sectional thickness estimations (CS) and the thickness estimates using the longitudinal processing stream (LP). Cortical thickness values for each of the 68 parcels defined by the Desikan parcellation (Desikan et al., 2006) were extracted by subject and timepoint. Multivariate multilevel models were applied using a stepwise modeling procedure to examine longitudinal change across 3 timepoints focusing on association cortices. The first step involved examination of changes in cortical thickness in frontal, parietal, temporal and occipital areas. We started with a baseline model, followed by introduction of explanatory variables (APOE genotype, hypertension) to obtain full models used to explain individual differences in rate of cortical thinning. LP models yielded a greater number of significant main and interaction effects. Findings indicated significant time main effects for the parietal and occipital regions, with a significant time effect for the temporal region only with LP. A Time x APOE interaction was found for CS and LP for the frontal region, but only for LP for the parietal and temporal regions.

A Time x AgeT1 was found for the frontal region for LP, but not CS; both analyses indicated a Time x AgeT1 for the temporal region. These results provide some evidence that the LP improves the significance even for more advanced modeling approaches through reduced within subject variance

Title: Inner fiber layer-like structures revealed with *In utero* electroporation in ferrets

Authors: *H. KAWASAKI[1,2], T. TODA[1,2], L. IWAI[2], K. TANNO[2];
[1]Sch. of Med, Kanazawa Univ., Ishikawa, Japan; [2]The Univ. of Tokyo, Grad. Sch. of Med., Tokyo, Japan

Abstract: Brain structures such as the inner fiber layer (IFL) and the outer subventricular zone (OSVZ) in the developing cerebral cortex are especially prominent in higher mammals such as primates. However, the mechanisms underlying the formation of these structures in the cerebral cortex of higher mammals are not completely understood, mainly because genetic manipulations that can be applied to the cerebral cortex of higher mammals was poorly available. At Neuroscience 2012 last year, we reported a rapid and efficient genetic manipulation technique for the cerebral cortex of gyrencephalic carnivore ferrets using in utero electroporation (Kawasaki et al., 297.01). Here we show that transgenes can be expressed most of cortical layers and germinal zones using in utero electroporation in ferrets. The morphology of GFP-positive cells in the OSVZ was clearly visible even without immunostaining, and multiple genes were efficiently co-expressed in the same cells. We also uncovered that fibers which seemed to correspond to those in the IFL of monkeys also existed in ferrets and were derived from newly generated cortical neurons. These results suggest that the IFL is conserved in primates and carnivores, and that it should be useful to combine ferrets and in utero electroporation for

investigating the mechanisms underlying the formation of the cerebral cortex in higher mammals.

Title: Bilateral Enucleation at birth alters intraneocortical connections in early postnatal development

Authors: *O. O. KOZANIAN, K. J. HUFFMAN;
Dept. of Psychology, UC Riverside, Riverside, CA

Abstract: Functional sensory and motor areas in the developing mammalian neocortex are generated through a complex interaction of cortically intrinsic mechanisms, such as gene expression, and cortically extrinsic mechanism such as those mediated by thalamic input. There is supporting evidence for the involvement of both mechanisms in cortical patterning and the establishment of areal boundaries in early development. However, the nature of the interaction between intrinsic and extrinsic processes is not well understood. We have previously used a perinatal bilateral enucleation mouse model to test some aspects of this interaction by reweighting sensory input to the developing cortex and examining gene expression, a read–out of a potential intrinsic mechanism. Ten days after bilateral enucleation, cortical gene expression and developing sensory intraneocortical connections (INCs) were examined. Visual deprivation at birth resulted in a shift of INCs at the border between somatosensory and visual cortex (S-V). These aberrant connections co-registered with ectopic *Ephrin A5* expression in the same location in enucleated mice (Dye et al., 2012). In the present study, we extend this research by investigating the development of the phenotype prior to post-natal day (P) 10. Somatosensory and visual INCs were indistinguishable between P1 mice bilaterally enucleated at birth and P1 controls. By P4, a medial shift of retrogradely labeled cells resulting from a somatosensory cortex dye placement was observed in enucleated mice. These ectopic cells were present in an area that would be designated visual cortex in a normal, sighted mouse. Thus, the phenotype we observed previously in the P10 mouse bilaterally enucleated at birth begins to form as early as P4, just 4 days after bilateral enucleation, and 8 days prior to eye opening.

Title: The development of the corpus callosum is dependent on FGF8 signaling

Authors: *K. M. CORELLA[1], W. C. J. CHUNG[1,2];
[1]Sch. of Biomed. Sci., [2]Biol. Sci., Kent State Univ., Kent, OH

Abstract: Agenesis of the corpus callosum (ACC) is one of the more common clinical brain malformations found in patients with mental retardation, seizures, visual problems, and in more severe cases, holoprosencephaly. Yet, there is still little known about the underlying cause of ACC in these patients. Here, we explored whether fibroblast growth factor (FGF) signaling plays a role in the development of the corpus callosum. Specifically, FGF 8 has been shown to be especially important for normal embryonic neocortical development. For instance, *Fgf8* hypomorphic mice have severe morphological defects in developing neocortical-related structures, including an absence of the corpus callosum and cortical thinning. Since FGF8 has previously been implicated in axonal guidance, we hypothesized that the failure of corpus callosum formation is due to abnormal local FGF8 signaling through its cognate receptor FGF receptor (FGFR) 1. This defect in FGF8/FGFR1 signaling may have disrupted midline guidance cues. Using in situ hybridization, we showed that *Fgfr1* mRNA expression was reduced in the indusium griseum of homozygous *Fgf8* hypomorphic mice at postnatal day (PN) 0. In a second study, we found that glial fibrillary acidic protein-expressing astrocytes that form the glial midline zipper region were eliminated in PN 0 homozygous *Fgf8* hypomorphic mice as compared to their wildtype littermates. Furthermore, we have preliminary evidence indicating that corpus callosum dysgenesis may, in part, be the consequence of the abnormal neocortical organization found in *Fgf8* hypomorphic mice. Indeed, *Dickkopf* (*Dkk*) 3 mRNA expression, a marker specific for cortical layers IV/V, was reduced in homozygous *Fgf8* hypomorphic mice. In contrast, *FERM domain containing* 4b (*Frmd4b*) mRNA expression, a marker specific for cortical layers I/II, seemed to be unaffected by the deficiency in FGF8 signaling. Together, we infer that ACC in mice may be related to the FGF8-dependent loss of *Dkk3* expression in the cortical layers IV/V, in which a subset of callosal projecting neurons reside.

Title: Identification of proteins that interact with neocortical arealization factors in the developing neocortex

Authors: *T. T. KROLL[1], J. A. GROVES[2], M. J. MULLAN[1], J. BERG[1], C. MILLER[1], A. M. MILLER[1], N. MEYERS[1];
[1]Chem., Central Washington Univ., Ellensburg, WA; [2]Biol. Chem., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The landscape of the rodent neocortex is dominated by four major areas that process discrete classes of information. The size and position of these areas is regulated by a group of neocortical arealization factors that include Emx2, Sp8, and Pax6. These proteins share three common traits: (1) they are all transcription factors, (2) they are each expressed in a graded fashion within the neocortical progenitor cells, and (3) they are not seen in significant concentrations within the daughter neurons that later compose the mature neocortex, indicating that they acquire their positional information from their respective progenitor cells. When considering the general importance of protein-protein interactions in mediating transcription factor activity, there is a surprising lack of knowledge as to the role that these types of contacts play in regulating neocortical arealization. In order to fill this void, we have initiated a series of screens to identify these protein-protein interactions, beginning with Emx2 and continuing with Sp8 and Pax6. Here, we report our initial results obtained using full-length Emx2 and significant fragments of Sp8 and Pax6 in yeast two-hybrid screens. Two of the proteins retrieved from the Emx2 screen include QkI-7, an RNA-binding protein, and Cnot6l, which belongs to the large CCR4-NotI complex and contains 3'-5' poly(A) exoribonuclease activity. Potential Pax6 binding partners identified in the yeast two-hybrid screen include (poly)ubiquitin C, rRNA promoter binding protein, and ribosomal protein S20-like. Finally, we have identified potential binding

partners for Pax6 that include Celf1, an RNA binding protein involved in mRNA splicing and translation, as well as ribosomal protein S20-like, and eIF5A. Collectively, these screens suggest a potential role for the transcription factors involved in neocortical arealization that extends beyond regulating transcription. We propose that these protein-protein interactions may be regulating the packaging, transport, and translation of transcripts that are directed to the newly generated daughter cells during neocorticogenesis, thus providing these neurons with the positional information necessary to carry out their future functional roles within the neocortex.

Title: Neuronal patterning in the cerebral cortex of forebrain-specific Ctgf Knockout Mice

Authors: *K.-C. CHEN;
Anat. and Cell Biol., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Connective tissue growth factor (CTGF), a member of CCN family, plays important roles in cell adhesion, migration, differentiation and survival. In the cerebral cortex, Ctgf is primarily expressed in subplate neurons. In order to comprehend the roles of Ctgf in cortical development, a forebrain-specific *Ctgf* knockout mouse model was generated by crossing *Ctgf* $^{flox/flox}$ mice with Emx1-*Cre* transgenic mice. *Ctgf* $^{flox/flox}$; Emx1-*Cre* mice were fertile and developed normally. The expression of Ctgf in the subplate was abolished in knockout mice while other subplate markers such as Nurr1 and Complexin 3 were still present, indicating that the identity of subplate neurons was not affected by *Ctgf* deletion. Compared with wildtype and *Ctgf* $^{+/+}$; Emx1-*Cre* mice, no gross abnormality was noticed in the brain and the body of forebrain-specific CTGF knockout mice. In the cerebral cortex, the distribution of NeuN-, Gad67- and Iba1-positive cells were comparable between genotypes, suggesting the migration and survival of cortical neurons and microglia were not affected while Ctgf was devoid in the subplate. Together, our data suggest the cortical neuronal patterning was not determined by Ctgf expression in the subplate.

Abstract: Non-human primates provide a useful test bed for studying neurodevelopment, allowing many of the same experimental controls possible with rodent models, while also having brains that diverged from the human lineage much more recently. Here, we present a transcriptome-wide survey of the male rhesus monkey hippocampus in the newborn (0 months), infant (3 months), juvenile (12 months) and young adult (48 months), with major anatomical and cellular partitions independently isolated using laser microdissection and profiled using DNA microarrays. This design allowed us to pursue several parallel avenues of transcriptional analysis using a single data set. We first sought to identify genes showing differential expression patterns between hippocampal compartments. Several thousand genes separated subregions into three groups based on primary cell type--pyramidal, GABAergic and glial, or granule cells--representing by far the largest transcriptional effect. Furthermore, we could identify genes specifically enriched in nearly all compartments. We next looked for genes showing changes in expression patterns across postnatal development. Many such genes showed an increase or decrease in expression between newborn and infancy, consistent with the anatomical observation that portions of the hippocampus continue to develop postnatally. Interestingly, the subgranular zone, which is one of only two brain areas with confirmed neurogenic potential in adult, shows

the most striking changes with time of any hippocampal compartment. As a final analysis, we compared these data to comparable transcriptome-wide assays in mouse to identify common signatures of postnatal neurogenesis. We find that the subgranular zone contains diverse cell types, including progenitor and dividing cells, immature granule cells, astrocytes, oligodendrocytes, and GABAergic interneurons, and that genes expressed in this layer subdivide based on temporal profiles reflecting maturation of glia versus granule neurons. One such neurogenesis-related gene network has decreasing postnatal expression that is highly correlated with the number of proliferating cells in the dentate gyrus of rhesus monkey, and contains many genes showing similar postnatal downregulation in mouse. Together these results present a comprehensive look at the developing rhesus monkey hippocampus, and provide insight into a biological mechanism conserved between species. All data described herein are publicly accessible through the Allen Brain Atlas data portal at www.brain-map.org.

Title: Foxg1 modulates midline axon crossing in the zebrafish telencephalon

Authors: *F. CHIARA, C. HOUART;
MRC Ctr. for Developmental Neurobio., King's Col. London, London, United Kingdom

Abstract: Commissural axons cross the midline and connect the left and the right side of the nervous system. Various molecules have been implicated in this fundamental process. However, it is still poorly understood how these cues interact with each other to facilitate the precise wiring between the two hemispheres. In zebrafish, axons arising from the anterior dorsal telencephalic neurons (ADt) fail to project rostrally into the anterior commissure in the absence of the transcription factor Foxg1. Instead, they remain in the rostral telencephalon. Transplant experiments show that this phenotype is not caused by a Foxg1 cell-autonomous mechanism. Instead, we found changes in the expression of known axon-guidance genes, such as Netrin and

Slits, in Foxg1 morphants. Taken together, these findings suggest a defect in the correct specification of commissural glia. The transcription factor Foxg1 has been widely studied as a critical regulator of cortical neurogenesis and its loss of function leads to dramatic defects in the organisation of the telencephalon. Here, we present an unexplored role for Foxg1 in the specification of the commissural plate.

Title: Characterizing the role of LIM homeobox 2 in area patterning

Authors: C.-F. WANG, *S.-J. CHOU;
ICOB, Academia Sinica, Taipei, Taiwan

Abstract: The neocortex is the largest region of the mammalian cerebral cortex and is responsible for sensory perception, cognition and control of movement. Tangentially, neocortex is organized into areas, which are functionally unique subdivisions with different cytoarchitecture and gene expression profiles. Previous studies of the mechanisms that pattern the neocortex into areas have led to a model in which transcription factors (TFs) expressed in graded fashion in the ventricular zone (VZ) of dorsal telencephalon (dTel) determine the size and position of the primary areas. LIM homeobox 2 (Lhx2), a LIM-homeodomain transcription factor, has been shown to play critical roles in early cortical development. Deletion of Lhx2 at an early stage alters regional fate specification of the dorsal telencephalon, and results in decreased number of cortical progenitors and premature neuronal differentiation. As Lhx2 is expressed in a high caudal to low rostral pattern in the dTel VZ, it is likely Lhx2 is also involved in area patterning. Using conditional gene inactivation as well as in utero electroporation approaches, we attempt to elucidate the role of Lhx2 in area patterning.

Title: Sensory cortex regulates top-down plasticity in thalamocortical circuits

Authors: *A. B. ZEMBRZYCKI[1], S.-J. CHOU[1], R. ASHERY-PADAN[2], A. STOYKOVA[3], D. D. M. O'LEARY[1];
[1]Mol. Neurobio. Lab, Dennis O'Leary, Salk Inst. For Biol. Studies, La Jolla, CA; [2]Dept. of Human Genetics, Sackler Fac. of Med., Tel Aviv Univ., Tel Aviv, Israel; [3]Dept. of Mol. Cell Biol., Max Planck Inst. for Biophysical Chem., Goettingen, Germany

Abstract: Primary somatosensory cortex (S1) contains a complete body map that mirrors subcortical maps developed by peripheral sensory input projecting to hindbrain, thalamus, then S1. Peripheral changes during development alter these maps through ‘bottom-up’ plasticity. Unknown is whether S1 size influences map organization and if an altered S1 map feedbacks to affect subcortical maps. We show that cortex-specific deletion of Pax6 reduces S1, resulting in a reduced cortical map and reproducible loss of body representations by exclusion of later-differentiating thalamocortical input. An initially normal thalamic map is re-patterned to match the aberrant cortical map by apoptotic deletion of thalamic neurons that represent body parts whose axons are excluded from S1. Absent body parts are rescued by reducing competitive imbalance between thalamocortical axons within S1 or increasing S1 size. We conclude that S1 size determines resolution and completeness of body maps and drives ‘top-down’ plasticity that re-patterns thalamus to match S1.

Title: miRNA135a levels determines cortical hem and hippocampus size by modulating embryonic Wnt/BMP signaling

Authors: *G. CARONIA-BROWN[1], A. ANDEREGG[1], R. AWATRAMANI[2];
[2]Neurol., [1]Northwestern Univ., Chicago, IL

Abstract: microRNAs (miRs) regulate gene expression in diverse physiological scenarios, but their role in modulating morphogen function has been less studied, particularly in embryonic CNS. Here, we define a new role for miR135a2 - that of influencing the size of the cortical hem, possibly by modulating Wnt/BMP signaling. miR135a2 was identified as robustly expressed in the cortical hem, the hippocampus (Hp) primordium, and choroid plexus, overlapping expression of several Wnts/BMPs. miR135a2 is predicted to target several molecules in the Wnt/BMP pathways. To investigate a potential role for miR135a2 in modulating Wnt/BMP signaling, we conditionally over-expressed miR135a2 in the dorsal forebrain using Emx1-Cre line as a driver. In E12.5 Emx1::Cre;miR135a2OE, we observed a reduction in the size of the hem and the Hp primordium; the choroid plexus was reduced in its complexity and the cortical domain was much smaller than in controls. Overall, early over-expression of miR135a2 phenocopied reduced Wnt/BMP signaling. According to expectations, the smaller hem resulted in a reduction of all Hp structures in Emx1::Cre;miR135a2OE. When Nestin::Cre, which initiates recombination at ~E11.0, was used as a driver, we observed no change in hem or hippocampus size, suggesting that miR135a2 levels determine hem size during an early time window.

Title: Mapping the gene regulative networks of cortical development

Authors: *U. BORELLO[1], M. MADHAVAN[2], K. CAMPBELL[2], C. DEHAY[1];
[1]INSERM U846 / Stem Cell and Brain Res. Inst., Bron, France; [2]Div. of Developmental Biol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: The transcriptional network regulating cortical development remains relatively unknown. Molecules secreted by the different forebrain signaling centers establish the expression gradient of specific transcriptional factors, which are necessary for the patterning and differentiation of the distinct structural and functional domains of the cerebral cortex.
To get new insights in the transcriptional regulation of corticogenesis, we have focused on the role of Sp8, a zinc finger transcription factor involved in early patterning and arealization of the cortex.
In order to decipher the molecular mechanisms of Sp8 regulation, we have used a new genetic system to over-express Sp8 specifically in the forebrain at different time points during development. Gain-of-function approach allowed us to examine the role of Sp8 in proliferation, survival and differentiation of cortical progenitors and, importantly, its relationship with Fgf signaling. We have identified a novel regulatory feedback loop at the core of the molecular mechanism controlling patterning and growth of the developing cortex.
Given the fundamental role of Sp8 in patterning the developing cortex and maintaining the balance between neural progenitor cell renewal/differentiation, we are studying the network of genes upstream and downstream of Sp8. We are implementing a genome wide analysis of the Sp8 downstream genes in the gain-of-function as well as loss-of-function Sp8 mouse mutants. In parallel, we are studying the enhancers regulating Sp8 expression during corticogenesis to identify the gene upstream of Sp8.
A comparative analysis of the molecular mechanisms regulating gene expression between mouse and non-human primates will allow us to understand how evolution shaped the primate brain.

Title: Fate-labeling of Islet1 population shows pervasive progeny in mouse forebrain

Authors: *F. SIDDIQI[1], A. L. TRAKIMAS[2], T. T. CLARKE[1], E. D. MARSH[1,3], J. H. WOLFE[1,3];
[1]Dept. of Neurol., Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Biol., [3]Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: In developing mammalian ganglionic eminence (GE), unique progenitor domains exist that are defined by their respective transcription factor expression patterns known to generate interneuron subtypes. Specifically, the LIM homeodomain gene, Islet1, is expressed in the ventral division of the LGE and is known to generate striatal neurons. It remains unknown if Islet1 derived progeny migrate beyond the basal ganglia and inhabit other forebrain structures, indicating a larger unidentified role of Islet1 in brain development. In the current study, we sought to determine the complete lineage generated by Islet1 progenitor pool. Immunostaining showed that Isl1 is expressed at embryonic day (E) 12.5 in developing thalamus and ganglionic eminence and is down-regulated postnatally. We thus utilized a Cre/loxP mediated knock-in mouse line whereby the Islet1 gene locus drove expression of Cre recombinase and was crossed with floxed R26-stop-eYFP mutant mice to permanently label Islet1-derived cells following recombination. At postnatal day (P) 0, eYFP+ cells derived were found in multiple forebrain structures. Cells were located in olfactory bulb, hippocampus, thalamus and cerebral cortex, in addition to striatum. Based upon morphology, these cells were immature neurons. In neocortex, eYFP+ neurons were both radially and tangentially aligned and spanned multiple cortical layers. At P21, eYFP+ cells persisted into adulthood in the above mentioned structures indicating a postnatal function of Islet1-derived progeny. Immunohistochemistry showed some of these cells were glia. Overall, these findings suggest Islet1+ progenitors regulate production, differentiation, and migration of multiple neuronal and glial subtypes.

Title: Emx1 influences area patterning in a background dependent fashion

Authors: *A. M. STOCKER[1], S. SAHARA[1], A.-L. S. DONAHOO[2], L. J. RICHARDS[2], D. D. M. O'LEARY[1];
[1]Mol. Neurosci., Salk Inst., LA JOLLA, CA; [2]Queensland Brain Inst., The Univ. of Queensland, Brisbane, Australia

Abstract: Establishing appropriate area patterning in the neocortex is a critical developmental event, and several graded transcription factors expressed by cortical progenitors have been implicated in this process, including Emx2. Despite the close homology to Emx2, both in sequence and cortical expression, Emx1 has not been implicated in area patterning. Emx1 is expressed in a low anterior-lateral to high posterior-medial gradient across the embryonic cortex, in both progenitors and neurons. To determine if Emx1 does influence area patterning, we examined two different KO lines on different genetic backgrounds. A constitutive Emx1 deletion on a C57BL/6 background that had been backcrossed for 9 generations did not exhibit any area patterning phenotype. However when the backcrossed C57BL/6 Emx1 KOs were crossed with 129S mice to generate a mixed genetic background, we observed an areal phenotype reminiscent of the Emx2 heterozygous KO. Specifically, we find that in these KOs anterior areas (frontal/motor) increase in relative size, posterior areas (visual and auditory) decrease in size, and overall, areas shift posteriorly. We also observed changes in area patterning in the second Emx1 KO line, where Cre-recombinase has been knocked into the Emx1 locus on the C57BL/6 background (Emx1 KI). However these animals exhibit a large decrease in overall cortical size, making it difficult to determine changes specific to area patterning. To circumvent these issues we crossed the Emx1 KI and Emx1 KOs, with the mixed genetic background, to generate another Emx1 KO (Emx1 KI/KO). An overall posterior shift in areas was also observed in these new Emx1 KI/KOs, where posterior areas decreased in size and anterior areas increased in size. The areal phenotype of the Emx1 KI/KOs was similar to that seen in KIs without the dramatic reduction in cortical size, and more pronounced than that of the KOs on a mixed background. In conclusion, we show that Emx1 does play a significant role in specifying area identities.

Title: FGF2-induced gyrification of the mouse cerebral cortex suggests that the emergence of gyri and sulci is molecularly encoded in the primordial cortical wall

Authors: *S. TOMASI[1], B. G. RASH[1], H. D. LIM[1], C. SUH[1], F. M. VACCARINO[1,2,3];
[1]Child Study Ctr., [2]Dept. of Neurobio., [3]Kavli Inst. for Neurosci., Yale Univ., New Haven, CT

Abstract: The cerebral cortex is made of modular units, the cortical columns, whose number in each cortical area is thought to affect processing power and therefore specific cognitive abilities. The number of cortical columns affects cortical surface area, and hence the folding of the cortical mantle, which varies considerably across species and evolution. Gyrification is thought to represent an optimal evolutionary strategy to increase cortical area considerably, allowing for greater functionality without increasing cranial size. Fibroblast Growth Factors (FGFs) were previously shown to play a critical role during brain development by regulating the rate of proliferation of progenitor cells and their differentiation into mature neurons, therefore we investigated whether excess FGF signaling would affect the trajectory of neurogenesis and induce an overall change in brain size and shape. Injections of FGF2 protein into E11.5 brain primordia (prior to the onset of neurogenesis and the formation of axonal connections) induced the formation of prominent bilateral gyri and sulci in the rostrolateral cortex, a phenotype not induced by FGF8b, another FGFR ligand involved in brain patterning. Corresponding to FGF2-induced gyrification was increased tangential growth of the rostral ventricular zone (VZ) as well as increased proliferation of Tbr2+ intermediate neuronal precursors in the subventricular zone (SVZ), with ectopic Er81 expression and elevated Tbr1+ neurogenesis. However, preliminary analyses by means of both single BrdU injections and combined CldU-IdU administration did not reveal substantial alterations in cell cycle length and cell cycle exit in response to FGF2 in both VZ and SVZ of the gyrus-forming region, suggesting that other processes, such as cell fate or cell death, may be involved. .In addition to rostral expansion, FGF2 induced shrinkage of the caudal cortical primordium, including the hippocampus, by disrupting Wnt signaling as revealed by decreased Wnt3a and Lef1 expression in the cortical hem and dentate gyrus, respectively. To elucidate the functional role of single FGF receptors in the gyrification of the cortex, we carried out FGF2 injections in FGFR3+/- mutants and preliminary analysis revealed that some of the FGF2 effects in the enlargement of anterior brain could be at least partially antagonized. To understand the molecular underpinnings of cortical gyrification, our current analysis includes gene expression profile analysis comparing control and FGF2-injected brains using RNA-sequencing. Our data suggest that the location for emergence of cortical gyri and sulci is molecularly encoded in the primordial cortical wall.

Title: A metric for non-uniform expansion of cortical sheet during neural development

Authors: *D. D. FERRANTE, Y. WEI, A. KOULAKOV;
Cold Spring Harbor Labs., Cold Spring Harbor, NY

Abstract: Cortical sheet undergoes substantial expansion of its area during neural development. It is not clear how non-uniform this expansion is across the 2D surface of cortex and how these potential non-uniformities are introduced. To investigate the non-uniformity of cortical expansion, we developed a method for isometric embedding of cortical sheet into the 3D space. Isometric embedding in differential geometry preserves in-plane metric at every point of embedded manifold. Isometric embedding leads to the unfolding of cortical sheet by introducing bending deformations only without substantial stretching. We show that curved geometry of cortical sheet could not have been generated without substantial differential neurogenesis. To quantify such a non-uniform expansion we propose a model for cortical neurogenesis that allows to predict differentials in neurogenesis across cortical sheet as a function of time.

Title: Mapping cortical connectivity during early postnatal development

Authors: *L. A. COCAS, S. J. PLEASURE;
Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Unraveling the details of mammalian neuronal circuit formation is fundamental in order to understand how the development of neuronal connectivity is affected in developmental disorders such as autism and schizophrenia. Mapping mammalian neural circuitry in vivo has been a challenging biological question that, until recently, was exceedingly difficult to address with existing research tools. A recent technique developed in the Callaway lab using an attenuated rabies virus that spreads monosynaptically and retrogradely to connected neurons has made it possible to analyze presynaptic monosynaptic connections in vivo (Wickersham, et al., 2007). This strategy did not allow for analysis of cell-type specific connectivity, and required two viral injections, making analysis of the earliest developing circuits challenging. We have combined this circuit tracing strategy with genetically labeled mice using a Cre/Tet approach to target different neuronal subtypes during early postnatal cortical development. This approach allows us to analyze the presynaptic connectivity of a variety of different neuronal types using Cre-based cell subtype targeting. It also allows us to control the timing of viral protein expression in vivo as well as timing of infection by driving expression of the viral proteins TVA and G that are necessary, respectively, for infection and monosynaptic spread, with a Tet responsive Cre- dependent reporter. We are able to determine the presynaptic connectivity of excitatory and inhibitory interneurons during early postnatal cortical development. In our hands this approach is a powerful tool to map developing cortical circuits in vivo.

Frankfurt; Focus Program Translational Neurosciences (FTN), Univ. of Mainz, Germany, Frankfurt am Main, Germany

Abstract: Midbrain dopaminergic neurons (MbDN) are located in the ventral tegmental area (VTA) and substantia nigra (SN) and are involved in various brain functions including motor control and reward-associated behavior. During embryogenesis, MbDN are generated in a progenitor domain in the ventral midbrain from where they have to migrate and assemble into the laterally positioned SN and the medially located VTA. The migratory behavior of MbDN and the mechanisms regulating MbDN migration are not well understood. Using genetic inducible fate mapping, we can heritably mark two distinct MbDN progenitor populations, which preferentially give rise to either MbDN in the SN or the medial VTA. Analysis of the temporal-spatial changes in the distribution and morphology of these two MbDN subpopulations as well as time-lapse imaging of migrating MbDN in organotypic slice cultures reveals two distinct modes of migration: MbDN destined for the SN migrate first radially from their progenitor domain to the forming mantle layer and subsequently switch to tangential migration to reach their final position in the lateral midbrain. In contrast, neurons destined for the medial VTA only undergo radial migration. We further show that the components of the Reelin signaling pathway are specifically expressed in a lateral MbDN subpopulation during embryonic development, while chemokine receptors are expressed in medially-located MbDN. Using time-lapse imaging and analysis of mouse mutants we demonstrate that Reelin signaling regulates the speed and trajectory of tangentially migrating MbDN and the formation of the SN, while chemokine signaling modulates the radial migration of MbDN. In this study we characterize in detail the distinct migratory pathways taken by MbDN destined for the SN or the medial VTA and we provide insight into the mechanisms that control different modes of MbDN migration.

Title: Sleep-dependent neural activity in the medial septum as hippocampal theta emerges in newborn rats

Authors: *D. MUKHERJEE, M. S. BLUMBERG;
Psychology, The Univ. of Iowa, Iowa City, IA

Abstract: Sensory feedback from self-generated twitches during active sleep triggers neural activity in the hippocampus of newborn rats. Another key feature of active sleep is the firing of hippocampal neurons at theta frequency (4-14 Hz). Direct inputs from the medial septum generate low-frequency theta during quiet wakefulness and tonic active sleep. In contrast, the medial septum mediates high-frequency theta via entorhinal cortex during phasic active sleep (when twitching occurs) and active wakefulness. Mohns and Blumberg (2008, 2010) showed that hippocampal unit activity is tightly coupled to peripheral twitching during active sleep before the emergence of theta at postnatal day (P) 8. Moreover, when theta emerged at P8, it occurred in short bouts that were also tightly coupled to twitching. Given that septo-hippocampal pathways are well established at birth, we hypothesized that sensory feedback from twitches is conveyed to the medial septum, which then exhibits twitch-dependent activity before and after the emergence of theta. After P8, we hypothesize that septal activity generates theta directly, or perhaps indirectly via effects on entorhinal cortex. To test these hypotheses, we recorded extracellular unit activity in the medial septum in unanesthetized rats from P3 to P10. Pups were head-fixed and recordings were performed as they cycled normally between sleep and wakefulness. As predicted, preliminary data in P3-7 rats reveal the presence of sleep-dependent activity of the medial septum in newborn rats, with some units exhibiting increased activity within 200 ms of a twitch. These findings suggest a role for sleep-related twitches in the activity-dependent development of the septo-hippocampal system, which plays a pivotal role in learning and memory in later life.

Title: Developmental and maternal regulation of infant brain state

Authors: E. C. SARRO[1,2], R. M. SULLIVAN[1,2], *D. A. WILSON[1,2];
[1]Child and Adolescent Psychiatry, NYU Sch. of Med., New York, NY; [2]Emotional Brain Inst., Nathan Kline Inst. for Psychiatric Res., Orangeburg, NY

Abstract: The survival of the infant is highly dependent on identifying, learning and approaching the maternal caregiver. This process results in the formation of an attachment to the caregiver. However, while it is clear that the maternal caregiver can exert long lasting changes to brain function and behavior, it is not known how neural activity in the infant is directly influenced by interactions with the caregiver or littermates in their natural environment. Here we addressed this by implanting infant rat pups (PN12) with bipolar stainless steel electrodes, targeting the amygdaloid complex and connected to a wireless transmitter (DSI) implanted subcutaneously. We recorded spontaneous local field potential (LFP) activity daily for 7 consecutive days in freely behaving infants. This period includes several important developmental milestones relative to attachment and maturation. Recordings were taken while infants were in their natural environment: with mother and litter in the nest as well while alone, without contact with the mother or litter. Fast Fourier Transform analysis (2.4 Hz bins) was used to quantify LFP oscillatory power in theta (5-15Hz), beta (15-35Hz) and gamma (35-60Hz) bands. Using the alone recording sessions, we were able to make within animal comparisons and describe generalized changes to LFP oscillatory power as animals progress through this period of early development. Moreover, using the daily recording sessions that included mother and littermates, we were able to assess changes in LFP activity during interactions with the mother and littermates, as well during periods of specific behavioral states (i.e., nursing, grooming, milk ejections). We found persistent changes to beta and gamma activity when the mother is away from the nest for long periods of time (e.g., enhanced beta) compared to when the mother is inside the nest. We also found long-lasting suppression in, beta and gamma activity levels when the infant is nursing or in contact with the nipple, and dramatic surge in power across all frequency bands during milk ejections. Our results demonstrate that during this phase of early development, the maternal caregiver is a primary influence on infant brain activity, with both

transient (seconds) and more long-term (many minutes) effects. Given the important role of neural activity in shaping circuit development and refinement during development, this suggests a powerful direct maternal influence on brain development. Quality of care may be one factor imposing variability of brain circuit development and function.

Title: Adolescent rat amygdala contains an actively dividing cell population that is positive for doublecortin but not NeuN

Authors: *M. L. SAUL[1], D. L. HELMREICH[2], J. L. FUDGE[1,2];
[1]Neurobio. and Anat., [2]Psychiatry, Univ. of Rochester, Rochester, NY

Abstract: The amygdala is part of the limbic system circuitry that mediates emotional learning and social behavior. These functions undergo tremendous development during adolescence, suggesting changes in amygdala organization. Our previous work showed that dividing cells, marked by bromodeoxyuracil (BrdU), are present in the amygdala of both adolescent (post natal day (PND) 30) and adult (PND 62) male Sprague-Dawley rats. Further characterization of these cells using double-labeling techniques and confocal microscopy showed that BrdU and doublecortin (DCX) double-labeled cells make up approximately 30% of dividing cells in the amygdala in both adolescence and young adulthood. In the present study, we aimed to determine if the BrdU+ cells were migrating into or dividing within the amygdala, and if BrdU/DCX+ cells in the amygdala eventually express the mature neuronal marker, NeuN. Adolescent male rats were given BrdU injections (200 mg/kg x 4) and sacrificed at one of five time points after final injection (24 hours, 5, 10, 28 or 56 days) to determine when BrdU+ cells were present in the amygdala, and if they co-expressed DCX or NeuN. Time points were based on hippocampal studies showing peak BrdU and BrdU/DCX cell numbers at 7-10 days and the emergence of NeuN at 28 days. BrdU+ cells were found in peak numbers in the amygdala at 24 hours and decreased across time points to their lowest level at 56 days ($p < 0.05$). In this population we again found a subset of cells, approximately 30%, that are BrdU/DCX+ double-labeled. These cells were also observed at peak numbers at 24 hours, and decreased to their lowest point at 56

days ($p < 0.05$). Notably, while both cell populations decreased as time progressed, the percentage of total BrdU+ cells that were DCX+ were not significantly different across time. To examine if BrdU cells differentiated into mature neurons, we looked for BrdU/NeuN double-labeled cells. No BrdU/NeuN+ cells were present at either the 24 hour or 28 day time points. These data suggest that cells are actively dividing in the adolescent amygdala. These dividing cells do not increase in number between 24 hours and 5 to 10 days, as in the hippocampus, suggesting a different cell division timeline compared to what is known in the hippocampus. The observed decrease in cells across time is probably due to cell death or dilution of BrdU after repeated cell division. Additionally, the normal decrease in the number of dividing cells across time does not preferentially favor cells that are DCX+. BrdU/NeuN+ cells were not seen at 28 days, as expected based on hippocampal studies, suggesting that at least up until 28 days the cells that divide in the amygdala are not fated to become mature neurons.

Title: Fluoxetine exerts age-dependent effects on myelination

Authors: *Y. KROEZE[1,2], D. G. A. PEETERS[1,2], H. ZHOU[3,4], J. R. HOMBERG[1,2];
[1]Donders Inst. for Brain, Cognition and Behaviour, [2]Dept. for Cognitive Neurosci., [3]Dept. of Human Genet., Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands; [4]Dept. of Mol. Developmental Biol., Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: The selective serotonin reuptake inhibitor (SSRI) fluoxetine is widely prescribed for treatment of depression and anxiety disorders. The safety of fluoxetine for adults is well established, but adverse outcomes, such as autism- and anxiety-like manifestations, have been reported in prenatally SSRI exposed children and rats. Strikingly, fluoxetine treatment is, amongst others, used to reduce autism- and anxiety-related symptoms during adulthood, suggesting that prenatal versus adult SSRI exposure is associated with opposing outcomes. The mechanisms underlying these age-dependent effects of SSRIs are unknown. Because there is increasing evidence that fluoxetine treatment during adulthood exerts therapeutic effects through neurotrophic mechanisms (For review see Kroeze et al., 2012), we hypothesize that early-life

fluoxetine exposure will target similar pathways but has opposite effects. To test this hypothesis we performed genome-wide gene expression studies on hippocampus tissue of rats treated with fluoxetine at adulthood and rats prenatally exposed to fluoxetine. Gene expression profiling was performed by RNA-seq, and RT-qPCR validations were performed in independent samples. We show that fluoxetine has an effect on genes involved in myelination and that these myelin-linked genes are regulated in opposite direction between early life fluoxetine exposure and fluoxetine treatment during adulthood. Genes involved in myelination are down-regulated after prenatal fluoxetine exposure and up-regulated after adult treatment. One of these genes is ciliary neurtrophic factor (*Cntf*), a survival factor for neurons and oligodendrocytes, which induces myelination of axons (Stankoff et al., 2002; Nash et al., 2011) and mediates neurogenesis (Yang et al., 2008). These results could give us new insides into the mechanisms underlying the opposing effects of early-life and adult fluoxetine exposure on autism and anxiety-like behaviour. As the level of myelination is essential for communication between neurons and therefore brain regions, changes in the expression of genes that regulate myelination could be an important factor by which fluoxetine influences functional brain connectivity, long-term behavior and disease risk.

Title: Fewer accumbens neurons projecting to the ventral tegmental area in adolescent versus adult rats is not a simple reflection of fewer accumbens neurons in adolescents

Authors: *K. P. PARSLEY, R. A. REICHARD, D. S. ZAHM, L. YETNIKOFF;
Pharmacol. and Physiological Sci., St. Louis Univ. Sch. of Med., Saint Louis, MO

Abstract: The mesocorticolimbic dopamine (DA) system has long attracted the interest of researchers concerned with the unique gamut of behavioral and mental health vulnerabilities associated with adolescence. Accordingly, the development of the mesocorticolimbic system has been studied extensively, but almost exclusively with regard to DAergic output. To the contrary, the ontogeny of inputs to the ventral tegmental area (VTA), the source of mesocorticolimbic DA, has been neglected. This is not a trivial oversight, as the activity of VTA neurons, which reflects

their capacity to transmit information about salient events, is sensitively modulated by inputs. To address this issue, we recently compared the organization of VTA afferents in adolescent and adult rats and found fewer inputs to the VTA from an interconnected network of cortical and ventral striatopallidal forebrain structures during adolescence as compared to adulthood (Yetnikoff et al. Soc Neurosci Abst 2012: 790.05). Strikingly fewer VTA-projecting neurons were observed in the adolescent as compared to adult nucleus accumbens (Acb). The present study was undertaken to evaluate the possibility that this observation is a simple reflection of fewer neurons in the adolescent Acb. Groups of four adolescent (postnatal day 39) and four adult (> postnatal day 60) rats were perfused and the brains were sectioned at 50 μm. Three and five adjacent series of sections from the adolescent and adult brains, respectively, were collected. One series of sections from each brain was mounted in rostrocaudal sequence and Nissl stained. The numbers of neurons in the Acb were estimated by the optical fractionator method with the aid of the StereoInvestigator hardware-software platform (MBF Bioscience, Williston, VT). The StereoInvestigator Cavalieri probe was used to assess the volume of the Acb. Differences in numbers or density of neurons in the Acb or Acb volume were not observed. The results indicate that the protracted maturation of afferent connections to the VTA from the Acb is not due to fewer neurons in the Acb during adolescence as compared to adulthood.

Title: Combined exposure to tobacco smoke and ethanol during adolescence leads to short- and long-term modulation of anxiety-like behavior

Authors: *M. CORREA SANTOS[1], A. MANHAES[2], C. FILGUEIRAS[2], C. CAVINA[3], V. NAIFF[2], A. CARVALHO[2], Y. VILLACA[2];

[1]Dept. de Neurofiologia, Univ. Do Estado Do Rio De Janeiro, Rio De Janeiro, Brazil;
[2]Neurociencias, [3]Neirociencias, Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Tobacco smoking is frequently associated with alcohol drinking and consumption of both drugs typically begins during adolescence. Since anxiety is considered a relevant factor for both smoking and drinking due to its motivating force for a continued consumption, anxiety alterations shared by these two drugs could explain their co-use and co-abuse. Here, we investigated the short- and long-term effects of adolescent tobacco smoke and/or ethanol exposure on anxiety levels. From postnatal day 30 to 45, Swiss mice were exposed to tobacco smoke (SMK - whole body exposure, 8 h/day) and/or ethanol (ETOH - 25% solution, 2 g/kg i.p. injected every other day) as follows: 1) SMK+ETOH exposure; 2) SMK exposure; 3) ETOH exposure; 4) Control. Anxiety levels were assessed with the elevated plus maze (EPM) and open field (OF) tests. By the end of exposure, SMK female mice presented an anxiolytic response in the EPM and this response was intensified by co-exposure to ethanol. A short-term deprivation from SMK elicited an anxiogenic state in females in the EPM. Although neither smoke nor ethanol effects persisted one month post-exposure, SMK+ETOH male and female mice exhibited an anxiogenic response in the OF. Adolescent female mice are more susceptible to the anxiolytic effects of SMK. The stronger effect in SMK+ETOH group suggests that, in females, the combined leads to lower anxiety levels. Anxiety levels do not seem to be relevant during a short-term SMK+ETOH deprivation, however, increased anxiety during long-term smoking and drinking deprivation demonstrate late-emergent effects both in males and females.

Title: Postsynaptic effects of Cajal-Retzius cells onto interneurons and pyramidal cells of the hippocampal formation

Authors: *G. QUATTROCOLO, G. MACCAFERRI;
Physiol., Northwestern Univ., Chicago, IL

Abstract: The computational functions of hippocampal Cajal-Retzius cells have long remained elusive because of the lack of data on their anatomical and functional connectivity.
We have decided to address this question directly, by genetically driving the expression of a channelrhodopsin variant in hem-derived Cajal-Retzius cells, and by studying the postsynaptic effect of their optogenetic activation on a variety of target neurons.
We initially verified that short pulses (1 ms) of blue light were able to trigger action potentials in Cajal-Retzius cells recorded under either cell-attached (n=9) or whole cell configurations (n=11). The direct measurement of light-induced currents in Cajal-Retzius cells held at -60 mV in voltage-clamp revealed amplitudes of ~50 pA (n=8).
When we examined the effects of their optogenetic activation on potential postsynaptic target cells, we found that both NBQX- and D-AP5-sensitive currents (n=3 and 3, respectively) were routinely detected on stratum lacunosum-moleculare neurogliaform interneurons, with local dendritic and axonal arborizations. The amplitude of the NBQX-sensitive current measured at a holding potential of -60 mV was ~100 pA, similar to the amplitude of the D-AP5 current recorded at +60 mV. Furthermore, preliminary results suggest that optogenetic stimulation of Cajal-Retzius cells can lead to action potential generation in interneurons.
In contrast, when recording from CA1 pyramidal neurons, very rarely did we observe any type of monosynaptic response (only in one case out of ten recording).
In summary, our results suggest the following conclusions: first, that the major neurotransmitter released by Cajal-Retzius cells is glutamate, and, second, the presence of a strong cell type-specificity of their output. Our findings predict that Cajal-Retzius cell activity is likely to be involved in the development of the synaptic dialogue between the entorhinal cortex and the hippocampus.

Title: Suboptimal maternal diet alters D1R binding in the offspring brain

Authors: *P. K. THANOS[1], J. ZHUO[2], M. ANANTH[2], R. KIM[2], N. GRISSOM[3], B. GEORGE[4], N. VOLKOW[5], T. M. REYES[4];
[1]Med. Dept, NIAAA / NIH and Brookhaven Natl. Lab., UPTON, NY; [2]Stony Brook Univ., Stony Brook, NY; [3]Univ. of Pennsylvania, Philadelphia, PA; [4]U of Penn, Philadelphia, PA; [5]NIH, Bethesda, MD

Abstract: Suboptimal maternal diet can negatively impact neurodevelopment. Maternal obesity can predispose to both offspring that are large for gestational age (LGA) via overnutrition, and offspring that are small for gestational age (SGA) via placental dysfunction. In humans, both LGA and SGA are biomarkers for an increased risk of multiple mental disorders, particularly Attention Deficit/Hyperactivity Disorder and schizophrenia. Our lab has previously shown that mouse models of LGA (maternal high fat diet) and SGA (maternal low protein diet) produce offspring with profound alterations in mesocorticolimbic gene expression regulating dopamine and opioid function, indicating that the development of these brain regions is particularly vulnerable to gestational insults. Importantly, these two maternal diets affected dopamine and opioid systems in opposing directions (e.g., SGA mice are generally hyperdopaminergic with reduced opioid expression, and the reverse is found for the LGA offspring). These data suggest that specific adverse experiences in gestation can drive dissociable dysfunction in transcription within the same brain regions, but do not establish whether these transcriptional changes are reflected in receptor function.
In this study control, SGA and LGA offspring were generated from dams fed control, low protein or high fat diet, respectively, throughout pregnancy and lactation. At weaning, mice were placed on the control diet and were sacrificed at 12 weeks of age. Brains were flash-frozen, sectioned and D1R autoradiography (Tarazi et al., 1997) was performed using [3H] SCH 23 390. D1R binding was measured in the following brain regions: olfactory tubercle (Tu), nucleus accumbens shell (AcbSh), Acb core, dorsal medial caudate putamen (DM CPu), dorsal lateral CPu (DL CPu), ventral medial CPu (VM CPu), ventral lateral CPu (VL CPu), DL CPu tail, VL CPu tail, and substantia nigra. Additional analyses on mu-opioid receptor and dopamine transporter binding in the same regions are ongoing and will be presented at the meeting. Results showed that the SGA mice (males and females) had significantly higher D1R binding than the standard chow control group in the Tu (20%), Acb (24%), and CPu (23%), while no differences were observed between the LGA and control mice. In conclusion, SGA but not LGA offspring show significantly elevated D1R level in the brain thus affecting DA signaling. These findings advance the current understanding of the how suboptimal gestational diets can adversely impact neurodevelopment and increase the risk for disorders such as ADHD, obesity and addiction.

Title: The role of structural parietal characteristics in visuospatial development in pre- and primary-school children: Contributions of retrosplenial cortex

Authors: *S. K. KROGSRUD[1], C. TAMNES[2], H. GRYDELAND[2], J.-L. CHEPKOECH[2], A. FJELL[2], L. MORK[2], K. WALHOVD[2];
[1]Dept. of Psychology, Res. Group For Lifespan Changes In Brain and Cognition, Oslo, Norway; [2]Dept. of Psychology, Res. Group for Lifespan Changes in Brain and Cognition, Oslo, Norway

Abstract: Visuospatial abilities are known to rely heavily on parietal brain structures, and both show early developmental changes. However, the role of structural brain characteristics in development of visuospatial skills is largely unknown. We investigated performance on visuospatial span and visuospatial construction tasks, and cortical thickness in inferior and superior parietal, precuneus, retrosplenial and posterior cingulate regions in a sample of 342 children aged 4-9 years. Measures used were structural magnetic resonance imaging (MRI), Wechsler Memory Scale (WMS) Spatial Span, Wechsler Preschool and Primary Scale of Intelligence (WPPSI) Block Design, and Wechsler Abbreviated Scale of Intelligence (WASI) Block Design scores. For the WPPSI Block Design and WASI Block Design analysis, two different samples were used (<6.5 years of age and ≥6.5 years of age, respectively). Linear regression analysis controlling for sex showed a significant ($p<.001$) effect of age on all three behavioral measures; WMS Spatial Span ($N=346$, $\beta=.68$), WPPSI Block Design ($N=240$, $\beta=.70$), and WASI Block Design ($N=98$, $\beta=.40$). A general linear model analysis with hemisphere, ROIs, age and sex, showed no significant hemisphere main or interaction effects, so mean values of the left and right cortical thickness were used. Regressing out the effect of age and sex, the results showed significant relationships between WMS Spatial Span and retrosplenial thickness ($\beta=-.18$, $p=.018$), significant relationships between WPPSI Block Design and inferior parietal ($\beta=-.14$, $p=.039$), superior parietal ($\beta=-.19$, $p=.006$), and precuneus ($\beta=-.19$, $p=.006$) corties, and a significant relationship between WASI Block Design and retrosplenial cortex ($\beta=-.22$, $p=.045$). Thus, in all instances, better visuospatial task performance was associated with thinner parietal cortices. The results indicate structural maturational effects of medial and lateral parietal cortices on visuospatial abilities among young children.

Title: Placental tryptophan metabolic dysfunction: a potential pathway for the developmental programming of mental disorders

Authors: *N. GOEDEN[1], A. BONNIN[2];
[2]Cell and Neurobio., [1]USC, Los Angeles, CA

Abstract: Serotonin (5-HT) has been increasingly implicated as a critical modulator of neurodevelopmental processes, from cell proliferation and migration, to later developmental events such as axon guidance and circuitry formation. Depending on the gestational timing, even modest disruptions of 5-HT signaling can have profound effects on the developing fetal brain that persist throughout development and adult life. Recent evidence indicates that the placenta is directly responsible for the synthesis and delivery of 5-HT to the fetus during critical periods of development, leading to the possibility that genetic and environmental perturbations affecting placental tryptophan metabolism may evoke a host of neurodevelopmental abnormalities in the fetal brain, ultimately contributing to the developmental origin of neuropsychiatric disorders. We investigated this issue using a variety of molecular techniques, including a novel ex-vivo placental perfusion system. We demonstrate that maternal exposure to the immunostimulants lipopolysaccharide (LPS), or polyinosinic:polycytidylic acid (poly I:C), induce differential changes in gene expression of enzymes responsible for 5-HT metabolism and synthesis from maternally derived tryptophan in the placenta and fetal brain. Changes in gene expression in the fetus and placenta were observed as quickly as 24 hours after maternal exposure to LPS. Additionally, these changes are spatially quantified both in the placenta and in the fetal brain through the use of a novel in situ hybridization based technology. Furthermore, through HPLC measures of placental and fetal brain tissues, as well as measures of enzymatic activity following immunostimulant exposure, we demonstrate that several key tryptophan metabolites are disrupted by maternal exposure to LPS or poly I:C. Our results indicate that maternal exposure to

infectious agents may lead to disruption of placental 5-HT synthesis, which can adversely impact neurodevelopmental processes in the fetal brain.

Title: Dynamic regulation of nicotinic synaptic transmission by postsynaptic Group I mGluRs

Authors: *V. RUPPRECHT, Y.-G. SUN, M. BEIERLEIN;
Dept. of Neurobio. and Anat., UTHealth/ Univ. of Texas Med. Sch., Houston, TX

Abstract: Activation of postsynaptic mGluRs in neurons throughout the brain triggers distinct forms of short- and long term plasticity at both glutamatergic and GABAergic synapses. However, a possible mGluR dependent regulation of cholinergic synaptic signaling has never been investigated. We have recently shown that stimulation of cholinergic afferents from the basal forebrain and the brainstem generates biphasic postsynaptic responses in neurons of the thalamic reticular nucleus (TRN), mediated by the activation of both α4β2 nicotinic and M2 muscarinic receptors. To examine a possible role of Group I mGluRs in controlling cholinergic synaptic strength, we isolated cholinergic synaptic inputs to TRN neurons in thalamocortical slices of mice (P13- 16), by pharmacologically blocking fast glutamatergic and GABAergic synaptic transmission. Bath application of the Group I mGluR agonist DHPG led to a long-term potentiation (LTP) of isolated nicotinic EPSCs (nEPSCs) compared to control (174± 9%, n=12), while muscarinic IPSCs remained unchanged (102± 5%, n= 6), indicating a postsynaptic expression. DHPG-induced LTP of nEPSCs required postsynaptic calcium increases and the activation of phospholipase C (PLC). In addition, LTP induction required the synergistic activation of both mGluR1 and mGluR5, as application of either the mGluR1 antagonist CPCCOEt or the mGluR5 antagonist MPEP eliminated LTP. Interestingly, CPCCOEt application led to a reduction of nEPSCs (76 ± 7%, n= 5), while MPEP had no significant effect (96 ± 11%, n= 6), indicating a persistent activation of mGluR1 under baseline conditions. Bath application of the glutamate transporter blocker TBOA led to a transient increase in nEPSC amplitude (175± 22%, n=5), blocked by either CPCCOEt or MPEP, suggesting that mGluRs are sensitive to increases in ambient glutamate levels. Taken together, our data show that the

synergistic activation of mGluR1 and mGluR5 can lead to both short- and long-term increases in nicotinic synaptic transmission.

Title: Cholinergic modulation of neocortical pyramidal neurons

Authors: *T. HEDRICK[1], J. WATERS[2];
[1]Physiol., Northwestern Univ, Fienburg Sch. of Med., CHICAGO, IL; [2]Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL

Abstract: Acetylcholine (ACh) shapes cortical function during sensory perception, motor control, arousal, attention, learning and memory. Cortical cholinergic dysfunction is tied to conditions such as Alzheimer's disease. We investigated postsynaptic responses of neocortical pyramidal neurons to synaptic ACh release.
We expressed channelrhodopsin-2 in cholinergic neurons in nucleus basalis and axons in cortex. To evoke ACh release in acute slices, we stimulated cholinergic axons via widefield illumination with a blue LED. In whole-cell recordings from pyramidal neurons, ACh release evoked muscarinic ACh receptor (mAChR) and nicotinic AChR (nAChR)-mediated potentials. In this study we focused on the nAChR component.
nAChR-mediated responses had an amplitude of 2.6 ± 0.36 mV (60 neurons), rise and decay time-constants of 32 ± 5 ms and 161 ± 14 ms (15 neurons), and a latency of 7.2 ± 0.7 ms (15 neurons). nAChR-PSPs were insensitive to mAChR, glutamate and GABA-receptor antagonists (5 of 5, 5 of 5, 8 of 8 neurons, respectively), but were eliminated by nAChR antagonist mecamylamine (11 of 11 neurons). We conclude that the nAChR-mediated response is a monosynaptic nAChR-mediated PSP.
When the neuron was suprathreshold, nAChR activation increased spike frequency. With the

neuron subthreshold, nAChR activation reduced the rheobase by 11.6 ± 3.7 pA and evoked persistent spiking lasting several seconds. Persistent spiking depended upon nAChR activation and a rise in internal calcium, but was unaffected by mAChR, glutamate and GABA receptor antagonists. We show that nAChR-activation can transiently increase pyramidal neuron spiking, or dramatically increase spiking over several seconds via persistent spiking.
nAChR PSPs were evoked in all layers of primary motor, visual and prefrontal cortices, but there were local variations in nAChR PSP occurrence. In visual cortex, nAChR PSPs were common in pyramidal neurons in all layers (layer 2/3: 83%, layer 5: 82%, layer 6: 89%); in prefrontal cortex, common only in layer 6 (layer 2/3: 30%, layer 5: 15%, layer 6: 63%); and in primary motor cortex, common only in deep layers, particularly layer 5 (layer 2/3: 19%, layer 5: 90%, layer 6: 50%).
Presumably, by enhancing pyramidal neuron spiking in some layers, nAChR activation enhances sub-circuits within each of these cortical regions. It is unclear why nAChR activation stimulates pyramidal neurons in different layers in different cortical regions, but presumably ACh serves different functions in these diverse circuits. Our results indicate that ACh enhances cortical circuits via nAChRs on pyramidal neurons, but that the effects of ACh differ significantly between cortical regions.

Title: Effect of chlorpyrifos exposure on the development of cholinergic neurons

Authors: *E. A. FRADINGER[1], G. X. GARCIA[1], J. M. TILGMAN[2], O. MAC[1], A. JIMENEZ[1], D. BOURGAIZE[1], F. WATSON[2];

[1]Biol. Dept., Whittier Col., WHITTIER, CA; [2]Dept. of Biol., Washington and Lee Univ., Lexington, VA

Abstract: Organophosphate pesticides are known to inhibit acetylcholine esterase, an enzyme that degrades acetylcholine at the cholinergic synapse. In this study PC-12 cells, *Caenorhabditis elegans* and *Xenopus leavis*, were used to understand the impact of the organophosphate pesticide chlorpyrifos on the development of the cholinergic nervous system. Chlorpyrifos at concentrations greater than 100µM was lethal to differentiated PC-12 cells, *C. elegans* and *X. leavis*. It was found that PC-12 cells were most susceptible to chlorpyrifos-induced cell death at later stages of development. To understand the *in vivo* effects of chlorpyrifos on developing cholinergic neurons, we used transgenic *C. elegans* and *X. leavis* expressing GFP-labeled cholinergic neurons. *C. elegans* these cholinergic neurons show that exposure to chlorpyrifos at concentrations above 10 µM results in changes to the DA and DB cholinergic ganglia at the L1 stage. Embryos exposed to concentrations above 10 µM do not survive past the L1 stage. The effect of chlorpyrifos exposure on GFP-expressing neurons in *X. leavis* somites will be examined by confocal microscopy to determine whether the number of cholinergic neurons and their ability to form functional synapses is affected. Since many organophosphate pesticides are USDA approved for use in agriculture, knowing their impact on neuronal development is critical.

Title: Reactivation of zebrafish acetylcholinesterase by novel oxime compounds following inhibition by organophosphate pesticides

Authors: *H. R. SCHMIDT[1], Z. RADIć[2], P. TAYLOR[2], E. A. FRADINGER[1];
[1]Biol., Whittier Col., Whittier, CA; [2]Skaggs Sch. of Pharm. and Pharmaceut. Sci., UCSD, La Jolla, CA

Abstract: Organophosphates (OPs) are a class of pesticides and nerve agents whose mechanism of toxicity involves irreversible inhibition of acetylcholinesterase (AChE). This leads to hyperstimulation by cholinergic neurons due to a slower catalytic hydrolysis of acetylcholine released at the synaptic cleft. Current antidotal treatment involves the use of oxime reactivators such as 2-PAM, which have limited efficacy *in vivo* due to their inability to cross the blood-brain barrier. Similarly, passage of 2-PAM as a quaternary antidote into the circulation and CNS of fish may be limiting. Here, we examine the suitability of the zebrafish (*Danio rerio*) model system for *in vitro* and *in vivo* tests of antidotal efficacy by comparing the inhibition and reactivation kinetics of purified human AChE with zebrafish AChE isolated from tissue homogenates. Inhibition kinetics for zebrafish AChE was determined for two OPs, chlorpyrifos oxon and dichlorvos. Chlorpyrifos oxon was found to be a more potent inhibitor of AChE activity than dichlorvos. We then compared the zebrafish AChE reactivation kinetics of two tertiary amine containing oximes, to the quaternary antidote, 2-PAM. All three oximes reactivated zebrafish AChE after OP inhibition, enabling us to begin to compare *in vitro* reactivation kinetics with protection from OP toxicity. Data revealed that zebrafish AChE demonstrated similar inhibition and reactivation kinetics to human AChE. Therefore, the zebrafish emerges as an appropriate and convenient model system for the *in vivo* study of novel oxime AChE reactivators.

Title: USDA-approved organophospate pesticides, cause developmental abnormalities in two aquatic vertebrate models

Authors: J. GREGG[1], J. M. TILGHMAN[3], H. SCHMIDT[2], *F. L. WATSON[4], E. A. FRADINGER[2];
[1]Dept. of Biol., [2]Dept. of Biolog, Whittier Col., Whittier, CA; [3]Dept. of Biol., Washington and Lee Univ., Lexington, VA; [4]Biol., Washington & Lee Univ., LEXINGTON, VA

Abstract: Acetylcholine esterase (AChE) degrades acetylcholine at the cholinergic synapse and is necessary for proper nerve function. Organophosphate pesticides, widely used in agriculture, act by inhibiting AChE. To evaluate organophosphate toxicity, Danio rario and Xenopus laevis embryos were exposed to chlorpyrifos, dichlorvos, and diazinon at concentrations ranging from 0.1 µM to 1 mM over a 10 day period. In D. rerio, all three pesticides were found to be toxic to developing embryos at concentrations at or above 100 µM. However, disruption of cholinergic activity, observed as increased spontaneous movements, decreased heart rate, and impaired larval swimming ability, was only seen in embryos exposed to chlorpyrifos and dichlorvos. Similarly, day 10 survival of X. laevis embryos decreased to zero or at concentrations of 100 µM of chlorpyrifos and dichlorvos, and toxicity was observed at concentrations of 1 µM and 0.1 µM for chlorpyrifos and dichlorvos, respectively. Gross morphological abnormalities such as spinal curvature and decreases in overall length, swimming ability, and heart rate were observed at and above these toxicity thresholds. Such abnormalities are indicative of disruption of cholinergic activity. In agreement with results for D. rerio, 100 µM diazinon decreased survival at day 10 to near zero, but it did not cause spinal curvature at lower concentrations in X. laevis. Since many organophosphate pesticides are USDA approved for use in agriculture, knowing their impact on aquatic vertebrate species living in run-off areas is critical.

Title: Inducing hippocampal network plasticity by coincident septal inputs

Authors: *Z. GU, J. YAKEL;
Lab. of Neurobio., NIEHS/NIH, RTP, NC

Abstract: It is well established that septal cholinergic inputs to the hippocampus play a central role in modifying hippocampal network activities and higher brain functions. However, much remains to be known about the underlying mechanisms. Here we induced hippocampal theta oscillations by co-activation of septal cholinergic inputs and local hippocampal Shaffer collateral

inputs to the CA1 in a septal-hippocampal co-culture system. Moreover, after 3-5 times of co-activation, hippocampal theta oscillations could then be induced by only a single-pulse Shaffer collateral stimulation. This induction of theta oscillations during the co-activation period was blocked by either muscarinic or α7 nicotinic AChR (acetylcholine receptor) antagonists, or by NMDAR antagonists. However after the co-activation period, the theta oscillations could not be blocked by any of the AChR antagonists; they were still completely blocked by NMDAR antagonists. These results suggest that coincident septal cholinergic inputs, through activation of muscarinic and α7 nicotinic AChRs, can induce lasting modifications of hippocampal network connectivity, providing a mechanism by which stable patterned hippocampal network activity can be achieved by local hippocampal inputs.

Title: Striatal cholinergic interneurons cause disynaptic axoaxonic inhibition of output neurons via dopamine neuron terminals

Authors: *A. B. NELSON[1], N. HAMMACK[2], R. SEAL[3], A. KREITZER[2];
[1]Neurol., Gladstone Inst. of Neurolog. Dis., San Francisco, CA; [2]Gladstone Inst., San Francisco, CA; [3]Pittsburgh Univ., Pittsburgh, PA

Abstract: As the input nucleus of the basal ganglia, the striatum integrates sensorimotor information and feedback about the rewarding or aversive outcomes of actions, allowing it to participate in action selection. Striatal cholinergic interneurons are known to have a burst-pause-burst firing pattern in vivo which aligns with salient events such as reward-predictive cues. However, the mechanism by which striatal cholinergic interneurons affect striatal output is not fully understood. Recent experiments have shown that optogenetic activation of cholinergic interneurons in evokes disynaptic inhibitory responses in striatal output neurons. To address the question of how this inhibition is mediated, we have made whole-cell recordings from brain slices containing the striatum, in which we optogenetically stimulate cholinergic interneurons.

Such activation triggers inhibitory responses in striatal output neurons, which is blocked by antagonists of nicotinic receptors, and can be reconstituted by puffing carbachol directly onto striatal output neurons. We also have found evidence that these inhibitory responses are mediated axoaxonic neurotransmission through nigrostriatal dopamine terminals, as it can be blocked by toxin-mediated killing of dopaminergic neurons, or reversible inhibition of synaptic vesicle loading in these neurons. We propose that optogenetic activation of cholinergic interneurons leads to activation of nicotinic receptors on the terminals of dopamine neurons, which in turn release GABA onto striatal output neurons, causing inhibitory synaptic responses. These results suggest an intimate relationship between striatal cholinergic interneurons and nigrostriatal dopamine neurons, both of which signal reward-related cues and can profoundly influence striatal output.

Title: Morphological evidence for direct glycinergic input to cholinergic neurons in the mouse basal forebrain

Authors: Z. BARDÓCZI[1], M. WATANABE[2], L. ZÁBORSZKY[3], Z. LIPOSITS[1,4], *I. KALLO[1,4];
[1]Dept. of Endocrine Neurobio., Inst. Exptl. Med. - HAS, Budapest, Hungary; [2]Dept. of Anat., Hokkaido Univ. Sch. of Med., Sapporo, Japan; [3]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ., Newark, NJ; [4]Dept. of Neuroscience, Fac. of Information Technol., Pázmány Péter Catholic Univ., Budapest, Hungary

Abstract: Glycine is a major inhibitory neurotransmitter in the mammalian central nervous system and an important regulator of glutamate neurotransmission; its extracellular concentration is regulated by glycine transporters (GLYT-1 and GLYT-2), which are present in the cell membrane of a subset of glial cells and neurons. Glycine transporter positive glial cells and neuronal processes have been detected in basal forebrain areas rich in cortically projecting cholinergic neurons. Cholinergic neurons have been implicated in cortical activation, attention, motivation, memory, and show demise in neuropsychiatric disorders, including Alzheimer's disease. The aim of the present study was to reveal whether or not cholinergic neurons in the basal forebrain are in morphological relationship with GLYT1- and/or GLYT2-immunoreactive (IR) cells. Double-label immunohistochemical methods were used to detect either of the transporters and the cholinergic neuronal marker choline acetyltransferase (ChAT) in mouse brain sections. Distinct fluorescent or electron dense markers were employed, respectively, for subsequent confocal or electron microscopic analyses. Under fluorescence microscope, strong GLYT1-immunoreactivity was identified in the medial septum (MS), vertical and horizontal diagonal bands of Broca (VDB and HDB), ventral pallidum (VP) and substantia innominate (SI). A striking overlap was observed with ChAT-IR neurons in most major areas where cholinergic neurons occur. At the ultrastructural level, GLYT-1-immunoreactivity was detected in glial elements; in some cases these GLYT-1-IR structures were found in close proximity to cholinergic dendrites and cell bodies receiving unlabeled synaptic inputs. Immunoreactivity for GLYT-2 (the marker protein of glycinergic neurons) was detected in varicose axons. Confocal microscopic analysis of the different subpopulations of ChAT-IR neurons demonstrated appositions among GLYT-2-IR axon varicosities and cholinergic cell bodies and dendrites. Appositions in the HDB were further studied at the electron microscopic level and symmetric and asymmetric synapses were identified between glycinergic axons and ChAT-IR neurons. Our results suggest that glycine have a direct influence on basal forebrain cholinergic neurons by demonstrating (1) synaptic connections between glycinergic axons and cholinergic neurons and (2) strong presence of glial and neuronal transporters in the vicinity of cholinergic neurons capable to tightly regulate extracellular levels of glycine. Identification of the participating receptor mechanisms, however, needs further studies.

Title: Optogenetic analysis of basal forebrain cholinergic neurons: Comparison of wild-type and type III neuregulin 1 mutant mice

Authors: *G. Y. LOPEZ, D. A. TALMAGE, L. W. ROLE;
Stony Brook Univ., Stony Brook, NY

Abstract: Deficits in acetylcholine (ACh) transmission have been related to some of the cognitive and behavioral impairments associated with neurodegenerative and neuropsychiatric diseases. It has been difficult to dissect the physiological functions of ACh, mainly due to the sparse nature of cholinergic neurons and the broad and diffuse distribution of their projections. A principal source of cholinergic neurons projecting to the cortex is the nucleus basalis of Meynert (NBM). We use gene delivery of a viral vector (AAV1-DIO-oChIEF-dsTomato) and the Cre-lox system to express the light-activated protein ChIEF in NBM cholinergic neurons of a ChAT-Cre/eGFP-Tau mouse line. Whole-cell patch clamp recording in acute brain slices and optogenetic stimulation were combined to examine the effects of selective activation of NBM cholinergic neurons. We first obtained an electrophysiological profile of cholinergic neurons in the NBM and compared their electrical properties to non-cholinergic neurons. A prominent difference between cholinergic and non-cholinergic neurons was the lower firing frequency of cholinergic neurons during depolarizing current injection (13.5 ± 2.6 Hz vs. 53.2 ± 9 Hz). The electrical properties of cholinergic neurons expressing ChIEF channels were not significantly different from control cholinergic neurons. Light-evoked action potentials and inwards currents were evident following train stimulation in cholinergic neurons. ChIEF+ cholinergic neurons were able to follow trains of opto-stimulation with increasing frequencies, 1 - 20 Hz. However, the percent efficiency in following opto-stimulation decreases with increased frequency of stimulation (< than 20 % at 20 Hz). To examine possible alterations in NBM neurons and cholinergic circuits in a genetic mouse model of schizophrenia we are now extending our work to type III neuregulin 1 mutant mice. The knowledge gained from my studies will advance our understanding of ACh actions in health and disease.

Title: Cholinergic system in brain is extremely adaptable

Authors: *A. HRABOVSKA[1], E. KREJCI[2];
[1]Fac. of Pharmacy, Comenius Univ., Bratislava, Slovakia; [2]CESeM, CNRS UMR 8194, Univ. Paris Descartes, Paris, France

Abstract: Cholinergic system in brain is believed to be essential for many physiological functions, especially cognitive and motor functions. Its impairment has been described in some severe neurological pathologies, e.g., Alzheimer's disease, Parkinson's disease and Huntington's disease. We generated a mouse model in which cholinergic system in brain is disturbed. By deletion of gene for proline-rich membrane anchor (PRiMA) which organizes and attaches tetramers of acetylcholinesterase (AChE) to the outer neuronal membrane, 95% of AChE activity is removed from brain. This results in 300-fold increase in the level of acetylcholine. Nevertheless, mutant mice do not develop any obvious change in the phenotype. They are undistinguishable from wild-type littermates. Detailed comparative behavioral studies do not show any significant change in learning or memory capabilities. Only subtle motor deficits are observed in mutant mice2. The phenotype seems to be preserved due to sever downregulation of muscarinic and mild downregulation of nicotinic receptors. In contrast, genetic manipulations resulting in removal of AChE activity at the periphery (with or without changes of AChE activity in CNS) severely change the phenotype. Our results suggest extreme plasticity of cholinergic system in CNS.

Title: Molecular physiology of the behavioral switch to ecdysis in *Drosophila* melanogaster

Authors: D.-H. KIM[1], M. HAN[2], Y.-J. KIM[2], *M. E. ADAMS[1];
[1]Univ. of California, Riverside, CA; [2]Life Sci., Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of

Abstract: Ecdysis, the shedding of old cuticle at the end of each molt in insects, occurs through performance of an innate, chemically-coded behavioral sequence. In Drosophila, ecdysis triggering hormones (ETH) initiate and schedule three distinctive behavioral subunits at pupation - pre-ecdysis, ecdysis, and post-ecdysis. ETH initiates and schedules the stereotypic sequence through direct and sequential activation of peptidergic ETH receptor (ETHR) ensembles in the central nervous system (CNS). We examined functional roles of individual ETHR ensembles in the switch from pre-ecdysis to ecdysis behavior by systematic ablation and electrical inactivation. The minimal peptidergic circuit necessary for the behavioral switch from pre-ecdysis to ecdysis consists of central neurons that co-release the peptides CCAP, Ast-CC, MIP, and bursicon. Targeted activation of this minimal circuit via temperature-sensitive TRPM8 channels initiates ecdysis behavior, but recruitment of additional CCAP neurons is necessary for its full expression. Timing of the switch to ecdysis can be altered in predictable ways by changing ETHR density in bursicon neurons: reduction in ETHR expression delays the switch to ecdysis, while increased ETHR expression accelerates it. Similarly, the level of ETHR expression alters the timing of ETH-induced calcium dynamics in bursicon neurons. Manipulation of G protein function in bursicon neurons suggests they receive both excitatory and inhibitory inputs, and that disinhibition determines precise timing of the switch to ecdysis.

Title: Cell-specific modulation by octopamine and proctolin in *Drosophila* melanogaster

Authors: *K. G. ORMEROD[1], L. DEADY[2], A. J. MERCIER[1];
[1]Biol. Sci., Brock Univ., St. Catharines, ON, Canada; [2]Neurosci., Western New England Univ., Springfield, MA

Abstract: The nervous system utilizes a diverse array of signalling molecules to convey information. Drosophila melanogaster contains a large number of substances such as peptides and biogenic amines that act either as transmitters or modulators of synaptic efficacy. Since many of these substances elicit virtually identical effects, they are often thought to act in a functionally redundant manner. We examine an alternative view, that signalling molecules can elicit similar effects but act on specific cells or subsets of cells that may be mutually exclusive. We previously reported that a peptide (DPKQDFMRFamide), which is thought to function as a neurohormone, elicits cell-specific effects on muscle fibers, decreasing input resistance and nerve-evoked contractions to a greater extent in some fibers than others. We now expand our investigations of muscle-cell specific effects of modulatory substances that are thought to be released as co-transmitters onto muscle cells of 3rd instar Drosophila larvae. Octopamine increases EJP amplitude and nerve-evoked contractions to a greater extent in some fibers (12, 13) than others (6, 7) [EJP 10-5 M: 41 + 2.0 and 28 + 3.6% respectively; Muscle Force: 10-5 M: 34.64 + 0.9 and 24.09 + 0.6% respectively]. Proctolin (RYLPT), on the other hand, alters EJP amplitudes in muscle fibers 12 and 13 but has no effect on EJP amplitude in fibers 6 and 7. These observations indicate that co-transmitters can act on specific sub-sets of muscle fibers. We are currently examining the mechanisms underlying such cell-specificity, and future work will examine the physiological implications of cell-specific actions of co-transmitters at neuromuscular junctions.

Title: The influence of GABA on the feeding behavior of the cockroach Rhyparobia maderae

Authors: *E. M. DUBON, R. W. COHEN;
Biol., California State University, Northridge, Northridge, CA

Abstract: The central nervous system in vertebrates and invertebrates displays inhibitory neurotransmission that is primarily achieved by activity of the neurotransmitter GABA and its various receptors. GABA has been shown to be a ubiquitous neurotransmitter in vertebrates and, important to this study, in insects. It has been observed that GABA is primarily found in the insect central and peripheral nervous systems, including the mushroom bodies, a prominent region for behavioral regulation. Previous research has indicated that GABA inhibits insect muscle contraction when GABA receptor-linked chlorine channels hyperpolarize the resting membrane potential. GABA has also been shown as having a prominent role in controlling learning and memory in the cockroach olfactory system. Our lab focuses on the neurotransmitter regulation of feeding behavior in insects; specifically how certain neurotransmitters (serotonin, octopamine and dopamine) regulate nutrient self-selection in cockroach nymphs. In this poster, experimentation was begun to examine whether GABA has a direct effect on food consumption and choice in the cockroach *Rhyparobia maderae*. Initially, large cockroach nymphs were selected and placed in a warm incubator with a constant temperature of 28° C and had free access to water but no food. After seven days of starvation, the nymphs were divided equally into experimental and control groups. The experiment nymphs were injected with 1 [[Unsupported Character - Symbol Font ]]l of the effective GABA agonist muscimol (concentration= 1mg/kg). The control group nymphs were injected with an identical volume of insect saline (0.7% NaCl). Immediately after injection, the nymphs were placed in feeding arenas containing water and a choice between pure sucrose and casein cubes. After 24 hours of feeding, cubes were removed, dried in an oven, and weighed to determine the amount eaten. Results indicated that the experimental muscimol group consumed the same amount of casein, but significantly less sucrose compared to the control saline group. In light of these self-selection results, we continue to discover the role of GABA in cockroach food selection, including the use of selected antagonists (picrotoxinin) and the immunostaining of the cockroach brain to detect the exact location of GABA. With these strategies we should establish how GABA affects food choice in *Rhyparobia maderae* nymphs.

Title: Protein kinase C enhances voltage-gated Ca2+ influx and secretory efficacy to facilitate peptide release in neuroendocrine cells

Authors: *C. J. GROTEN[1], N. S. MAGOSKI[2];
[1]Physiol., [2]Queen's Univ., Kingston, ON, Canada

Abstract: Neuroendocrine cells present periodic enhancement of excitability and hormone secretion to initiate fundamental behaviors such as reproduction. Such plasticity is conferred by protein kinase-dependent phosphorylation. A tractable system for studying this process is provided by the bag cell neurons of the marine mollusc, Aplysia californica. Following stimulation, these neuroendocrine cells undergo an afterdischarge, during which egg-laying hormone (ELH) is secreted to trigger reproduction. During the afterdischarge, several kinases are upregulated, including protein kinase C (PKC). An established role for PKC is to initiate the membrane insertion of a separate class of voltage-gated Ca2+ channels; however, the contribution of these channels to peptide secretion remains unknown. In addition to altering Ca2+ influx, PKC has the potential to facilitate hormone release through regulation of the secretory process. To examine the function of PKC in controlling peptide secretion, whole-cell recordings of fura-loaded cultured bag cell neurons were performed, allowing for measurement of secretion, with capacitance tracking under voltage-clamp, and intracellular Ca2+, with fluorescence microscopy. To quantify secretion, membrane capacitance was measured before and after a 1-min, 5-Hz train of depolarizing steps. We initially established that stimulus-induced capacitance changes were related to hormone secretion by ELH knockdown. Treatment of cultured bag cell neurons with ELH dsRNA caused a significant reduction in the magnitude of anti-ELH staining and train-induced capacitance responses. The effects of PKC activation were tested with the diacylglycerol analogue PMA. Treatment with 100 nM of PMA caused a two-fold increase in the train-evoked membrane capacitance response. Preventing PKC-dependent channel insertion by disrupting the actin cytoskeleton, with 10 µM latrunculin, attenuated the PMA effect. To test if PKC influences secretion independently of Ca2+ channel regulation, PMA was applied subsequent to establishing whole-cell recording, which prevents Ca2+ channel insertion. This online PMA treatment significantly increased the stimulus-evoked capacitance

change and the magnitude of secretion to repeated train stimuli. Thus, PKC prepares the bag cell neurons for ELH secretion by enhancing Ca2+ influx and directly regulating the secretory process. Consequently, PKC appears to act as a gate for the transition in neuronal output required for reproduction and species propagation.

Title: Comparison of serotonin 1a and 2 receptor subtype mRNA expression across tissue, ganglia, and single neurons in the opisthobranch mollusc Tritonia diomedea

Authors: *A. TAMVACAKIS, P. KATZ;
Georgia State Univ., Atlanta, GA

Abstract: Serotonin (5HT) is a neuromodulator that affects several behaviors in the sea slug Tritonia diomedea. Identifying the 5HT receptor (5HTR) subtypes that are involved in these behaviors would aid in the study of their neural mechanisms. Opisthobranch molluscs have five known 5HTR subtypes (Nagakura et al., 2010, J. Neurochem). Serotonergic neurons innervate peripheral tissues to affect sensory and motor behaviors (Moroz et al., 1997, J. Comp. Neurol). Each ganglion of the CNS plays a different role in 5HT-mediated behaviors as do individual identified neurons. We therefore investigated whether these differences were reflected in the expression patterns of two 5HTR subtypes.
Quantitative real-time PCR (qPCR) was used to compare mRNA expression of 5HTR subtypes 1a and 2 in: 1) peripheral tissue [rhinophores, gills, oral veil, and oral groove], 2) whole ganglia [cerebro-pleural, pedal, and buccal ganglia], and 3) single cell-types [the giant serotonergic cerebral cell, pedal neuron 5, and pedal neuron 6].
Preliminary results showed differences in subtype expression across tissue types. In peripheral

tissues, 5HTR1a mRNA expression was higher in the oral groove and rhinophores compared with the oral veil and gills, which showed low 1a expression. 5HTR2 mRNA was relatively highly expression in rhinophore and oral veil, but showed no measurable expression in gill or oral groove tissue. In comparing the CNS ganglia, 5HTR1a mRNA expression was significantly higher in the cerebro-pleural and buccal compared to the pedal ganglia, but all three ganglia exhibited lower 5HTR1a expression compared with oral groove and rhinophore tissue. The different ganglia did not show a significant difference in expression of 5HTR2 mRNA, and were similar to expression levels observed in rhinophore and oral veil tissue. Of the three cell types compared, none showed expression of either 1a or 2 subtypes, although pre-amplification of single-cell mRNA may be necessary for accurate detection of low-copy number transcripts such as 5HTRs.
Identifying 5HTR subtypes expressed in various tissues is important for understanding how neuromodulatory signaling facilitates different behaviors. Differences in 5HTR expression in peripheral tissues may mean that distinct 5HTR subtypes play different roles in sensory and effector systems. Lower expression of 5HTR1a in the pedal compared with other ganglia may indicate that 5HTR1a is not involved in activation of many serotonin-responsive pedal neuron functions. Further study of the other 5-HTR subtypes will provide additional information about the roles of 5-HT in Tritonia.

Title: Electrophysiological properties of ASE neurons of *C. elegans*

Authors: *T. SHINDOU[1], M. OCHI-SHINDOU[1], T. MURAYAMA[2], T. SASSA[2], J. R. WICKENS[1], I. MARUYAMA[2];
[1]Neurobio. Res. Unit, [2]Information Processing Biol. Unit, Okinawa Inst. Sci. Technol., Okinawa, Japan

Abstract: The ASE chemosensory neurons, which are composed of a pair of ASEL and ASER neuron, are the main taste receptors of C. elegans and play a critical role in chemotaxis to salts. The recent studies including optical recordings of calcium imaging have revealed that ASEL

preferentially senses Na+ and serves as ON cell to NaCl, whereas ASER preferentially detects Cl- and acts as OFF cell to NaCl. However, the physiology of ASE neurons to chemotaxis remains unknown and the electrophysiological characterisation of ASE neurons is needed to determine what mechanisms involve responses to chemotaxis. We tried in vivo patch-clamp recording in C. elegans and investigated electrical properties of identified ASE neurons. ASE neurons had a membrane potential of around -60 mV and an input resistance of more than 1 GΩ. Spontaneous small depolarizing events (<5mV amplitude) were observed at a resting membrane potential. Voltage response to depolarising current injections was linearly graded depending on the current intensity, but after reaching around -40 mV, broad and large depolarisations were induced, indicating the nonlinear voltage response to current injections. For comparison, we also recorded AVA neurons (one of command interneurons). AVA neurons had a more silent spontaneous activity than ASE neurons and showed a linear increase of voltage responses by current injections, indicating the graded potentials. The active membrane properties of ASE neurons may contribute to effective signalling as a sensor to NaCl.

Authors: *D. TOUROUTINE[1], R. BHATTACHARYA[2], M. FRANCIS[2];
[1]Univ. of Massachusetts Med. Sch., Worcester, MA; [2]Neurobio., Univeresity of Massachusetts Med. Sch., Worcester, MA

Abstract: Functional connections between neurons of the brain are not static, but instead show remarkable functional plasticity that can be altered through environmental cues, experience, or in the context of specific behaviors. This functional plasticity is often mediated by neuromodulators which activate G-protein coupled receptors to modify neuronal dynamics, excitability, and synaptic efficiency. Neuromodulators include diverse families of neuropeptides. To investigate roles for neuropeptide signaling in the regulation of neural circuit activity, we have been studying neuropeptide actions in motor circuit of the nematode C. elegans. We developed a

transgenic strain harboring a gain-of-function (gf) mutation in a ionotropic acetylcholine receptor (L-AChR) localized to the neuromuscular junction. Expression of L-AChR(gf) in muscle caused prolonged postsynaptic current responses and produced easily identifiable locomotory phenotypes: decreased speed and exaggerated muscle flexures during movement. Using a candidate gene approach, we identified the pro-neuropeptide family member nlp-12 as a strong modifier of the behavioral changes caused by L-AChR(gf) expression. NLP-12 shares greatest similarity to vertebrate cholecystokinin, and is expressed in a single mechanosensory interneuron, DVA. To identify components of the NLP-12 signaling pathway, we overexpressed NLP-12 in DVA neurons. Interestingly, overexpression of NLP-12 (OexNLP-12) caused dramatic changes in movement, suggesting direct actions of this neuropeptide on motor circuit activity. The C. elegans genome encodes two genes that are similar to mammalian cholecystokinin receptors, ckr-1 and ckr-2. Combined mutation of ckr-1 and ckr-2 completely suppressed the effects of NLP-12 overexpression, suggesting the receptors act redundantly. Expression studies indicate that CKR-1 and CKR-2 are expressed throughout the nervous system. We are currently identifying subsets of neurons expressing both receptors and conducting rescue experiments using neuron-type specific promoters to identify the relevant sites of NLP-12 action. Additionally, we are testing how NLP-12 affects signaling in the motor circuit using electrophysiology. The results of these experiments will be presented

Title: Gene expression of a serotonin receptor following aggressive behavior in the crayfish, Procambarus clarkii

Authors: *A. J. TIERNEY[1], K. K. INGRAM[2], E. SHOLL[2], M. RICHARDS[1], K. ANDREWS[1], M. WHITE[1];
[1]Dept. of Psychology, [2]Dept. of Biol., Colgate Univ., Hamilton, NY

Abstract: Serotonin (5-HT) plays a role in aggressive behavior in many taxa, and the receptors that mediate this behavior have been extensively investigated in vertebrates. However, relatively little is known about how 5-HT receptors function to mediate aggression and social status in invertebrate species. We used a well-known model organism, the crayfish *Procambarus clarkii*, to investigate the effects of fighting and changes in social status on the expression of the 5-HT2β receptor. Crayfish were arranged in same-sex size-matched pairs, isolated for seven days, and then allowed to fight for 30 minutes. A clear dominance hierarchy, in which one crayfish (designated the subordinate) persistently retreated from its opponent (designated the dominant), was established in all pairs. Control animals did not interact with a conspecific, but were otherwise treated identically. Fights were video taped and the level of aggression displayed by each pair was quantified. One h (n = 10 pairs) or 48 h (n = 10 pairs) after fighting, the brain and abdominal nerve cords were removed from each animal and separately snap-frozen in liquid nitrogen. We designed intron-crossing primers and probes for 5-HT2β and 18S (control gene). Relative mRNA expression was measured using quantitative rt-PCR and quantified using the ΔΔCt method. Preliminary analysis found no significant differences in mRNA expression in dominant and subordinate animals sacrificed one hour after fighting. However, in brains but not abdominal nerve cords, we found a positive correlation between expression of 5-HT2β mRNA and level of aggression. Also, both dominant and subordinate animals displayed higher levels of 5-HT2β mRNA than did control animals. These findings suggest that aggressive interactions can induce rapid changes in the expression of 5-HT receptors in *P. clarkii*, a change that might have lasting affects on behavior. Ongoing work will determine levels of mRNA expression in tissue taken 48 h after fighting and will quantify mRNA expression of a second 5-HT receptor cloned from *P. clarkii* (5-HT1α).

Title: The effects of mushroom body lesions on the feeding behavior of the cockroach Rhyparobia maderae

Authors: *F. R. LIBBY, R. W. COHEN;
Biol., California State University, Northridge, Northridge, CA

Abstract: The effects of neurological cell death or injury may have many downstream effects on the resulting behavior it regulates. Physical disruption of these cellular pathways may have significant behavioral consequences depending on the area of the brain affected by injury. In insects, past studies have shown that the paired mushroom bodies in the protocerebrum are associated with learning and memory, and other higher-level behaviors. Our lab has shown that insects self-select an optimal diet when faced with nutrient choices, and that this self-selection is regulated by specific neurotransmitters (serotonin, octopamine, dopamine) in the brain. But the actual brain location for this nutrient regulation has not yet been discovered in insects. In this study, we wanted to determine if the mushroom bodies were directly involved in food choice by lesioning specific regions of the cockroach brain then examining subsequent feeding behaviors. Past studies utilizing insect brain lesioning have done so blindly using non-surgical, invasive techniques with electrolytic probes. Here, we developed a protocol that permits the animal to survive after physically opening up the head cavity to visually access the brain and lesion the mushroom body. After exposing the cockroach brain, a small, heated acupuncture needle was used to ablate bilaterally the mushroom bodies of the cockroach brain. A control group had their head cavity opened gently touched their mushroom bodies with an unheated needle. To study the effects of mushroom body lesioning on food choice, we lesioned large *Rhyparobia maderae* cockroach nymphs and allowed them to recover for 24 hours with a pellet of rat chow and water provided *ad libitum*. After the recovery period, we removed the food and allowed the cockroaches to fast for three days. At the end of this fasting period, we provided the nymphs with a small cube of casein (protein) and one of sucrose (carbohydrate) and allowed them to feed *ad libitum* for 24 hours. In the lesioned group, the nymphs ate an average of 2.93 mg (casein) and 34.3 mg (sucrose), while the control nymphs ate an average of 5.1 mg (casein) and 86.6 mg (sucrose). The lesioned group also ate at a reduced rate compared to the control group. The lesioned group also showed a distinct difference in nutrient selection: 8% casein versus 92% sucrose for the lesioned nymphs compared to the control group who ate 5.6% casein and 94.4% sucrose. These results indicate that the mushroom body ablations may have an influence in the total amount of food that was eaten as well as alter the nymph's choice of available nutrients.

Title: Post-embryonic development of serotonergic neurons in a Tenebrionid beetle: Time-course and hormonal dependence

Authors: *R. C. ELSON, J. FREGOSO, R. SMITH, J. SOCH;
Point Loma Nazarene Univ., San Diego, CA

Abstract: During post-embryonic, metamorphic development of the mealworm, *Zophobas morio* (Coleoptera: Tenebrioninae; members of a basal order of holometabolous insects), the pattern of motor and interneurons expressing serotonin-like immunoreactivity (SLI) changes within the terminal abdominal ganglion, a neural center involved in the control of digestive and reproductive organs. In this accessible model system, we tracked the normal time-course of changes in SLI and its sensitivity to exogenous doses of the pesticide pyriproxyfen, a juvenile hormone analog (JHA).

Developmental changes in the number and type of neurons expressing SLI begin in the prepupal phase of the last larval instar and are largely complete by the middle of the pupal stage (i.e., during the formation of the adult). Of two pairs of serotonergic motor neurons that innervate the hindgut in the larva, one pair stops expressing the transmitter in the prepupal phase and regains little SLI thereafter. Of three pairs of interneurons present in the larva, one pair stops showing SLI when the larva becomes a prepupa; at the same time, a new, different pair of interneurons first appears. Up to four more "new" pairs of serotonin-containing interneurons appear progressively during the first half of the pupal stage, completing a segmental pattern. Little change occurs in this established pattern after the adult has emerged.

These developmental changes can be inhibited by applying JHA during the prepupal period, at the time when a large surge (the “prepupal peak”) of ecdysteroid is known to occur. The added JHA must supplement the actions of native juvenile hormone, which is normally present at moderate levels during the ecdysteroid surge. This potent agonist likely inhibits ecdysteroid release, suppressing the surge; at the same time it may antagonize genetic programs of development normally initiated by ecdysteroid at this time. Our findings indicate that balanced, timed hormonal actions are crucial for up- and down-regulating transmitter expression during the development of a set of segmental serotonergic neurons.

Title: Mass spectral characterization of circadian rhythm-related neuropeptide secretion during light-dark cycle in crustacean via *In vivo* microdialysis

Authors: *Z. LIANG, C. SCHMERBERG, L. LI;
Univ. of Wisconsin-Madison, MADISON, WI

Abstract: Circadian rhythm, driven by circadian clock, allows biological events to anticipate and adapt to changing environmental conditions. Neuropeptide (NP), as an important class of neuromodulators regulating a wide variety of physiological processes, has an important role in this process. For example, in crustaceans, pigment-dispersing hormone(PDH), which are involved in adaptation of the retina to ambient light changes, have been proven to have altered expression levels at different points of the light-dark cycle. NPs are known to act upon the decapod crustacean stomatogastric nervous system (STNS), which has long been used as a model for the study of neuromodulation and generation of rhythmic firing patterns in the coordinated movements of the muscles of the stomach. Here, we employed a multi-faceted mass spectral (MS) platform to identify and quantify NPs secreted from the pericardial organ (PO) into hemolymph in the light-dark cycle of Jonah crab, Cancer borealis.
In this study, in vivo microdialysis sampling of hemolymph from crabs was conducted to collect samples continuously in12 hr: 12 hr light/dark cycle, and the resulting dialysate was analyzed by MS. Preliminary results revealed the secretion of numerous NPs in the hemolymph, including orcokinin, A-, B- and C-types allatostatin (AST), RFamide (RFa), crustacean hyperglycemic hormone precursor-related peptide (CPRP), crustacean cardioactive peptide (CCAP), and PDH families. Concentration changes for several NPs in the microdialysate were observed. A sharp decrease was observed for PDH soon after the light period was initiated; suggesting the involvement of PDHs in the light to dark transitions. A decrease in CCAP was also detected. Elevation of members of AST-A and -B families were observed toward the end of light period and continued to build within 2 hr after the light turned off, which may indicate an opposite role.

Interestingly, similar changing pattern was also observed for orcokinin. These results support previous studies which indicated that under external stimuli, AST and CCAPs may play important roles in regulating and coordinating the activities of the heart and other organs. No clear changing patterns were observed for NPs from the RFa, AST-C and CRRP families. This comparative peptidomic data aids in the identification of NPs that may be important signaling molecules in coordinating crustacean's circadian clocks, and this platform demonstrate the capability for studying highly dynamic NPs changes under environmental alterations.

Title: Overexpression of TDP-43 inhibits NF-κB activity by blocking p65 nuclear translocation

Authors: *J. ZHU, W. JIA;
Brain Res. Ctr., Vancouver, BC, Canada

Abstract: TDP-43 (TAR DNA binding protein 43) is a heterogeneous nuclear ribonucleoprotein (hnRNP), its aberrant cleavage and aggregation have been found to be mainly responsible for neurodegenerative diseases recently. Its involvement in nuclear factor-kappaB (NF-κB) pathways has been reported in neuron and microglial cells that are linked to amyotrophic lateral sclerosis (ALS). NF-κB pathway targets more than hundreds of genes that are involved in inflammation, immunity and cancer. In nervous system, it plays an important role in neuroinflammation. However, NF-κB only has functions in nucleus that after transporting from cytoplasm by importinα3 (KPNA4) which could also take TDP-43. In our study, we report that TDP-43 overexpression could block TNF-α induced p65 nuclear translocation dose-dependently that further inhibits p65 transactivation activity. Furthermore, the inhibition by TDP-43 is not through preventing IκB degradation but probably by competing the nuclear transporter-importinα3 (KPNA4) and this competition is dependent on the presence of NLS in TDP-43. Silencing TDP-43 by a specific siRNA also increased p65 nuclear localization upon TNF-α stimulation, suggesting that endogenous TDP-43 may be a default suppressor of NF-κB pathway. The above results indicate that TDP-43 may play an important role in regulating the levels of NF-κB activity by control the nuclear translocation of p65. Our finding that TDP-43

constitutively inhibits NF-κB pathway by blocking nuclear transportation of p65 suggests a novel and important role of TDP-43 in inflammatory response in neurodegenerative diseases.

Title: Toll-like receptor 4 contributes to opioid ligand binding in brain homogenates

Authors: *J. THOMAS[1], A. A. SOMOGYI[1], K. C. RICE[2], M. R. HUTCHINSON[1];
[1]Univ. of Adelaide, Adelaide, Australia; [2]Natl. Inst. on Drug Abuse, Bethesda, MD

Abstract: In the infancy of opioid binding research, attention was focused directly toward the stereoselective receptors that were discovered to be critical for opioid analgesic responses. However, opioids can paradoxically increase pain sensitivity in humans and rodents leading to hyperalgesia and tolerance. Work by the Hutchinson and Watkins groups has demonstrated that genetic removal of immune receptors such as toll-like receptor 4 (TLR4) significantly reduces the development of hyperalgesia whilst simultaneously increasing anti-nociception. It is thought that opioids bind non-stereoselectively to TLR4 leading to a neuroinflammatory response within the CNS, compromising opioid-induced analgesia and contributing to various unwanted actions. The existing data on the non-stereoselective receptor binding kinetics of opioids is limited and requires further investigation. This study set out to examine the receptor binding kinetics of (-)naloxone in both WT and $TLR4^{KO}$ animal brain homogenates and to determine whether further cell base assays are warranted. Wildtype (WT) and $TLR4^{KO}$ mouse brains were harvested and homogenised in a highly precise manner using the gentleMACS™ Octo Dissociator. Homogenates were diluted to 10 mg/mL and $^{[3H]}$(-)naloxone added to 1.63 nM. One mL aliquots were vacuum filtered and washed with 5 mL of 0.9% PBS at required time points. $^{[3H]}$(-)Naloxone dissociation was initiated by adding 1 µM of cold drug. Data were analysed using non-linear regressions. Our pilot data has demonstrated a significant change in (-)naloxone binding association kinetics between WT mouse brain homogenates ($2.28x10^{-9}$ sec n=6) and $TLR4^{KO}$ homogenates ($1.33x10^{-9}$ sec n=6). This was represented by faster (-)-naloxone association in the genetic absence of TLR4 compared to wildtype conditions ($P<0.0005$).

However, unexpectedly we did not observe a change (P>0.5) in total $^{[3H]}$(-) -naloxone binding between the WT (12982 DPM +/- 847 n=3) and TLR4^{KO} (13895 DPM +/- 1169 n=3) brain homogenates. We also did not observe any $^{[3H]}$(-)naloxone displacement by classical TLR4 and MD-2 drugs such as LPS or curcumin. These results further suggest an involvement of TLR4 in opioid pharmacology, but the complexity underlying this TLR4 opioid interaction is still enigmatic.

Title: Characterization of Galanin receptor 1 knock-out mice in animal models of seizures

Authors: *S. A. GAGANGRAS[1], C. METCALF[2], E. DAHLE[1], B. KLEIN[1,2], H. WHITE[1,2]; [1]Pharmacol. and Toxicology, Univ. of Utah, Salt Lake City, UT; [2]NeuroAdjuvants, Inc., Salt Lake City, UT

Abstract: Galanin is known to play a crucial role in the control of neuronal excitability. However, the contribution of each of the 3 identified galanin receptors is not known. Transgenic animals have been useful in studying the discrete role of each galanin receptor subtype. Previously, it was reported that galanin overexpressing mice show delayed kindling, suggesting the potential role of galanin in epileptogenesis. In the present study, Galanin receptor 1 knock-out C57BL/6J male mice were evaluated for their kindling acquisition rate and we report that the protection in corneal kindling model is afforded by GalR1. GalR1 KO animals show lower threshold to electroconvulsive stimuli in the initial phase of kindling and attain stage 5 generalized seizures in 7.25 ± 1.05 stimulations relative to 12.44 ± 1.76 stimulations in WT ($p<0.05$). However, the total number of stimulations required to acquire the fully kindled state was not different between groups. Furthermore, no significant differences were observed in the seizure thresholds of WT and GalR1 KO mice in 6 Hz psychomotor seizure test. Using quantitative RTPCR analysis from hippocampal tissue of 5 week old male mice, we report that GalR1 KO mice display a ~2-fold increase in the expression of GalR3 (1.78 ± 0.05, $P<0.05$)

relative to WT animals without any significant changes in GalR2 expression. These preliminary results suggest that GalR1 plays a crucial role in network excitability of the corneal kindled mouse and that disruption of GalR1 results in compensatory change in expression of GalR3. Possible implications of GalR3 upregulation in GalR1 KO mice are being currently investigated in different behavioral models.

Title: Galanin localization and actions in the guinea pig cardiac plexus

Authors: *J. C. HARDWICK[1], A. A. LINTON[2], E. N. POWERS[3];
[1]Ithaca Col., ITHACA, NY; [3]Biol., [2]Ithaca Col., Ithaca, NY

Abstract: Peptidergic modulation of autonomic neurons is an important factor in regulating overall autonomic output. Galanin has been shown to modulate parasympathetic neuronal activity in several vertebrate systems, including the cardiac control pathways. In the current study, we examined the localization and function of galanin in the guinea pig cardiac plexus. Galanin immunreactivity was observed in cell bodies and fibers within the ganglia using an antibody against the human form of galanin. The galanin-immunoreactivity showed no co-localization with the sensory peptide, substance P, but did show some co-labeling with choline acetyltransferase. Using intracellular voltage recordings from whole mount preparations of the guinea pig cardiac plexus, we examined the modulatory effects of galanin on neuronal properties. Direct application of galanin (10-4M) by local pressure ejection, or by inclusion in the bath solution (10-7M) produced a depolarization of the membrane potential and a decrease in input resistance. Some cells also demonstrated an increase in neuronal excitability, as seen as a

decrease in rheobase and/or an increase in the number of evoked action potentials with depolarizing current steps. These results indicate that galanin is found within the cardiac plexus and the peptide can directly affect intracardiac neurons. Thus, galanin may be an important modulator of neuronal function and overall parasympathetic output.

Title: Wnt5a regulates expression of ROCK2 and SYNGAP1 through Mir-101b in rat hippocampal neurons

Authors: *J. CODOCEDO, N. C. INESTROSA;
Pontificia Univ. Catolica De Chile, Santiago, Chile

Abstract: In rat hippocampal neurons, Wnt5a stimulation generates an increase in the clustering of PSD-95 as well as an increase in the density of dendritic protrusions. Additionally, experiments in rat hippocampal slices showed that Wnt5a modulates synaptic activity increasing long-term potentiation.
On the other hand, microRNAs (miRNAs) are a family of endogenously small non-coding RNAs, which control gene expression of their mRNAs targets by hybridization with complementary sequences in the 3' UTR inhibiting its translation. Emerging evidence indicates that the miRNAs are actively involved in the regulation of synaptic plasticity processes mediated by substances such as serotonin, glutamate and BDNF.
Considering that in many models of synaptic plasticity, it has been described that remodeling processes of dendritic spines are dependent on protein translation, we propose that the effects of Wnt5a, are mediated by the action of miRNAs which in turn control the translation of synaptic proteins.

By PCR arrays, we determined the effect of Wnt5a on the expression of 263 miRNAs in rat hippocampal neurons. Using bioinformatics, we determined the predicted mRNA targets as well as their potential role on different signaling pathways. By western blot and inmunofluorescence analysis, we determined the expression change of different targets in neurons treated with Wnt5a. 31 miRNAs decreased and 3 miRNAs increased their expression levels in the presence of Wnt5a. One of the miRNAs that showed a robust decrease in the presence of Wnt5a is miR-101b.
The expression levels of 3 predicted targets of miR-101b, ROCK2, SYNGAP1 and COX-2, showed a significant increase in their expression levels in the presence of Wnt5a.This is the first report showing that Wnt5a is able to regulate the levels of miRNAs in hippocampal neurons. Interestingly, the signaling pathways regulated by the predicted targets correspond to processes in which Wnt5a has a key role, including cancer and regulation of the actin cytoskeleton. The regulation through miRNAs, of targets like ROCK2 and SYNGAP1 can help to understand the role of Wnt5a in the synaptic modulation.

Title: D-amino acid-containing peptides in the nervous systems of vertebrate and invertebrate models

Authors: LIVNAT[1], H.-C. TAI[2], S. RUBAKHIN[2], J. V. SWEEDLER[2];
[1]Chem., Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]Univ. of Illinois in Urbana-Champaign, Urbana, IL

Abstract: Many neuropeptides are post-translationally modified in the process of producing the final, bioactive peptide; these modifications can be difficult to predict from sequence information alone, requiring their measurement. Peptide isomerization is a rare post-translational modification (PTM) where one residue of a peptide is enzymatically converted from an L-amino

acid to a D-amino acid, resulting in a D-amino acid-containing peptide (DAACP). Isomerization usually occurs near the C- or N-terminus and produces significant changes in the peptide's structure and bioactivity, as well as increases its resistance to degradation by peptidases. Only a small number of DAACPs have been discovered. Our hypothesis is that there are a small number of known DAACPs, at least in part, because the L- to D- conversion does not alter a peptide's mass, and mass spectrometry has become the method used to characterize neuropeptides. To address this issue, we created an alternative strategy to discover new DAACPs that take advantage of the properties conferred by isomerization. Briefly, potential DAACPs are determined by their resistance to degradation by a leucine aminopeptidase, aminopeptidase M (APM) or by homology of a peptide's sequence to known DAACPs. Potential DAACPs are purified using liquid chromatography and then acid hydrolyzed into their component amino acids. The chirality of these amino acids is assayed by derivatization with Marfey's reagent (1-Fluoro-2,4-dinitrophenyl-5-L-alanine amide, FDAA) and determined using LC coupled to a triple-quadrupole mass spectrometer. These techniques are being applied to the central nervous system of the mollusk Aplysia californica. We have already identified a novel DAACP, GdFFD, where the dF indicates that isomerization occurs at the second residue from the N-terminus. For GdFFD, the all L-peptide is much less active on the feeding network than the DAACP. In addition, other putative DAACPs in A. californica have been observed, such as LAARLI, a peptide from the procerebrin prohormone where isomerization appears to occur at the second residue from the N-terminus, an alanine. Importantly, the advantage of the described approach is that it is not limited to a particular model system and can be applied to determination of putative DAACPs from the mammalian nervous system.

Title: Endogenous substance p regulates microglial density in substantia nigra through neurokinin-1 receptor-nadph oxidase axis-mediated chemotaxis

Authors: *Q. WANG[1], C.-H. CHU[2], S.-H. CHEN[2], B. WILSON[2], J.-S. HONG[2];
[1]Neuropharm. Section, NIEHS, RTP, NC; [2]NIEHS, RTP, NC

Abstract: The distribution and density of microglia differ greatly among brain regions. We have previously reported the density of microglia in the substantia nigra (SN) is 5 fold higher than other brain regions, implicating why the SN is selectively more sensitive to the neuroinflammation-mediated pathogenesis of Parkinson's disease (PD). However, the reason for the high density of nigral microglia is not known. We hypothesized that substance P (SP), a major endogenous pro-inflammatory peptide stored at high concentrations in the SN, is a major regulator for the high density of nigral microglia. Developmental studies revealed that nigral microglial density peaked around postnatal 30 (P30). In contrast, SP was detected at high levels in SN as early as P1. Transgenic mice incapable of producing SP (*TAC1*$^{-/-}$) exhibited reduced nigral microglial density compared to wild type (WT) controls. This finding led us to speculate that SP may attract the migration of microglia toward to the SN. We confirmed the chemotactic property of SP *in vitro* by demonstrating that SP induced the migration of microglia in a transwell culture system. *In vivo* studies further showed facilitated directional migration of transplanted enhance-green fluorescent protein (EGFP)-labeled microglia towards the brain region injected with SP in *TAC1*$^{-/-}$ mice. Additional studies on the signaling pathways mediating chemotaxis by SP revealed that both neurokinin-1 receptor (NK1R), the G-protein coupled receptor for SP, and NADPH oxidase (NOX2, a key superoxide-producing enzyme on microglia) are necessary for the chemoattractant properties of SP. Results showed that SP-induced migration of microglia prepared from either NK1R$^{-/-}$ or NOX2$^{-/-}$ mice was greatly reduced. Furthermore, pharmacological inhibition of NK1R or NOX2 showed a similar inhibition. Evidence suggesting a cross talk between NK1R and NOX2 was observed by a finding showing SP-stimulated NOX2 activation, as measured by membrane translocation of p47^{phox} (a cytosolic subunit of NOX2) and subsequent release of superoxide were mediated through NK1R/β-arrestin1-dependent pathways. In summary, these results strongly suggest that SP is capable of recruiting microglia to the SN through a novel NK1R-NOX2 axis-mediated pathway, accounting for the high microglial density in the SN.

Title: HMGB1 nucleocytoplasmic mobilization and release from neurons through decreased HDAC activity

Authors: *J. Y. ZOU, F. T. CREWS;
Univ. North Carolina, Chapel Hill, CHAPEL HILL, NC

Abstract: High-mobility group box 1 (HMGB1) is a ubiquitous nuclear protein that functions as an endogenous danger signaling molecule upon release into the extracellular space during sterile inflammation and infection. HMGB1 release and inflammatory activity in brain remain elusive. The present study uses an *ex vivo* model of organotypic hippocampal-entorhinal cortex (HEC) slice cultures to investigate HMGB1 mobilization and its role in mediating inflammatory activation in brain. Stimulation of HEC slices with various reagents including lipopolysaccharide (LPS), cytokine TNFα, ethanol, glutamate/NMDA and mGluR agonists as well as HDAC inhibitors triggers robust releases of HMGB1 from neurons into culture media. Active secretion (without causing cell death) of neuronal HMGB1 is associated with movement of HDAC1/4 and HMGB1 proteins from nuclear to cytosolic fractions. Co-immunoprecipation analysis indicates that actively secreted neuronal HMGB1 is associated with increased acetylation of HMGB1. We further examined HMGB1-mediated neuroimmune activation in response to LPS and ethanol. Induction of proinflammatory molecules such as TNFα and IL-1β by LPS and ethanol was blunt by siRNAs to HMGB1 and TLR4, HMGB1 neutralizing antibody, HMGB1 inhibitor glycyrrhizin as well as TLR4 antagonist naltrexone. Blockade of microglial activation with minocycline also blunt expression of proinflammatory cytokines induced by ethanol and LPS, suggesting microglial TLR4 may initiate HMGB1-mediated neuroimmune activation in brain. On the other hand, passively released HMGB1 from damaged neurons induced by higher concentrations of glutamate/NMDA was correlated with extend of neuronal cell death. HMGB1 is depleted in nuclei of damaged neurons but uniquely accumulated in neuronal cytoplasm and processes. By using conditioned medium (CM) generated from NMDA-stimulated slice cultures, which contains HMGB1 level about 11ng/ml, we demonstrated that HMGB1 in CM can exert paracrine signaling roles in sensitizing neuronal cells more vulnerable to glutamate/NMDA-induced excitotoxicity, inducing neuroimmune activation and expression of proinflammatory

molecular genes such as TNFα, IL-1β and MMP-9, and stimulating proliferation of microglial progenitors; all danger molecule-like effects of HMGB1 were reduced by HMGB1 neutralizing antibody and/or HMGB1 inhibitor glycyrrhizin. These novel findings underlie the key role of danger signal HMGB1 released from neurons in mediating neuron-glia neuroimmune communication. Our results support the hypothesis that HDACs modulate HMGB1 release and brain neuroimmune activation.

Title: Cytokines regulate photoreceptor differentiation and survival *In vitro*

Authors: *A. SHOLL-FRANCO, A. S. AGOSTINI;
Inst. Biofisica - IBCCF, Univ. Fed Rio De Janeiro, Rio De Janeiro, Brazil

Abstract: Interleukins (ILs) are important members of a class of cytokines that regulate several body functions. In this way, IL-4 and IL-10 were characterized as prototypical anti-inflammatory cytokines with neuromodulatory effects. They have been implicated with neural cell differentiation and survival, as well in inflammatory responses within nervous system. In this work we investigated the effects of IL-4 and IL-10 upon rod photoreceptor differentiation and survival in the developing mouse and rat retina, using monolayer and organotypic cultures to study putative regulatory effects of these cytokines on the development and survival of photoreceptors cells. Cultures were prepared using postnatal day 0 (P0) C57bl/6 mouse or postnatal day 7 (P7) hooded rat retinas maintained for 1, 2, or 3 days in vitro (DIV). For the in vivo studies, we used retinas from P0 to P18 animals. The expression of rhodopsin, IL-4 and IL-10 was analyzed by western blotting and immunocytochemistry using specifics antibodies (polyclonal antibodies against IL-4 and IL-10 - Santa Cruz; monoclonal antibody Rho4D2

against rhodopsin, kindly provided by Dr. R. Molday). On the in vivo retina, rod photoreceptors begin to appear at P0, and in both cultures systems, Rho4D2-positive cells were identified after 1 DIV in a pattern similar to that observed in vivo. IL-4 is expressed both in neural retina and non-neural ocular tissue, while IL-10 was found mainly in non-neural tissue. Our results demonstrated that both cytokines promoted a dose-dependent stimulatory effect, increasing the number of Rho4D2-positive cells (165% and 150%, respectively after 3 DIV with IL-10 or IL-4 treatment). Pretreatment with IL-10 do not prevent cobalt chloride induced specific rod photoreceptor cell death. However, IL-4 pretreatment prevent rod photoreceptor cell death in P7 rat retina in a dose- and time-dependent manner. Blocking antibodies against IL-4 inhibit the protective effect of IL-4, as well as the co-treatment with PKC and tyrosine kinases inhibitors. Overall, these results demonstrate that IL-4 and IL-10 can influence rod photoreceptor differentiation, but only IL-4 block rod photoreceptor cell death induced by cobalt chloride. Moreover, this survival effect is highly specific and is mediated through PKC and tyriosine kinase signaling activation.

Title: IL-13 dynamically alters the excitability of dopamine neurons in the ventral tegmental area in wild type but not IL-13Rα1 knockout mice

Authors: M. A. HERMAN[1], *M. ROBERTO[1], B. CONTI[2];
[1]CNAD, [2]Chem. Physiol., Scripps Res. Inst., LA JOLLA, CA

Abstract: The dopamine (DA) system in the ventral tegmental area (VTA) is critically involved in regulating motivation and reinforcing behaviors. Alterations in DA neuron firing have been implicated in a number of clinical disorders including schizophrenia, addiction and attention deficit hyperactivity disorder. The pro-inflammatory cytokine IL-13 binds IL-13 Rα1 which forms a heterodimer with IL-4Rα and initiates a signal cascade involving Stat6 and JAK phosphorylation. IL-13 Rα1 is abundantly expressed in DA neurons in the VTA, however no studies have examined the role of IL-13 in overall activity of DA neurons. In the present study we performed whole cell current-clamp recordings of DA neurons and applied IL-13 to

determine if acute application produced any measurable effects on DA neuron firing in wild-type (WT) and IL-13 Rα1 knockout (IL-13 Ra KO) mice. DA neurons were identified by previously described membrane properties and action potential characteristics. Acute application of IL-13 (10 ng/ml) to DA VTA neurons from WT mice significantly decreased the resting membrane potential from -46.3 ± 1.1 mV to -54.6 ± 2.1 mV and significantly decreased firing from 15.5 ±2.8 Hz to 3.9 ± 3.3 Hz and in some cases inhibited firing altogether ($p<0.05$ by paired t-test; n = 9). The hyperpolarization and decrease in firing with IL-13 application displayed an almost immediate onset and was reversible upon washout. Whole cell current-clamp recordings were also performed in VTA DA neurons from IL-13 Rα1 KO mice, which displayed no significant change in resting membrane potential but a significantly lower baseline firing rate as compared to WT mice (9.7 ± 1.4 Hz as compared to 18.4 ± 3.0 Hz); $p<0.05$ by unpaired t-test; n = 29 and 17, respectively). In addition, acute application of IL-13 to IL-13 Ra KO mice did not significantly alter resting membrane potential or firing rate. Collectively these data demonstrate that IL-13 can dynamically and reversibly alter DA neuron activity through actions at IL-13 Rα1 in the VTA, suggesting a more immediate intersection of immune and/or stress responsivity and neural excitability in the VTA.

Title: Il-1β and Il-1RA release in the brain as measured by *In vivo* microdialysis and its dependence on P2X7 receptor activation

Authors: D. SONG[1], H. ZHOU[1], A. T. HOPPER[2], *G. N. SMAGIN[1];
[1]Neuroinflam. DBU, [2]Medicinal Chem., Lundbeck, Paramus, NJ

Abstract: Neuroinflammation (NI) is a central component of several neurological disorders and is primarily mediated by microglia, the myeloid cell population of the CNS. IL-1β is a central mediator of NI, which is released from activated microglia. This process involves a priming step to induce pro-IL-1β and a triggering event leading to the processing and release of mature IL-1β. This “double hit” paradigm is experimentally mimicked by priming with lipopolysaccharide (LPS) and activation of the P2X7 receptor with an agonist such as BzATP. IL-1 receptor

antagonist (IL-1RA) is a member of the IL-1 cytokine family. IL-1RA is secreted by various types of cells including immune cells, and is an endogenous inhibitor of the pro-inflammatory effect of IL-1β. This protein inhibits the activities of ILs 1α and β and modulates a variety of IL-1 related inflammatory responses. In this study we investigated the BzATP-stimulated release of IL-1β and IL-1RA in the CNS by microdialysis and their dependence on P2X7 receptor activation.
Rats were implanted with the guide cannula placed into the prefrontal cortex (PFC). An additional cannula (22 ga, 4.5 mm long) for i.c.v. injections was implanted into the lateral cerebral ventricle. One week after surgery, a microdialysis probe (4 mm active membrane, 3000 kDa MWKO) was implanted. The LPS and P2X7 agonist BzATP alone or in a "double hit" paradigm were administered i.c.v. A selective P2X7 antagonist was systemically administered one hour prior to BzATP. Microdialysis samples were analyzed for IL-1β and IL-1RA by an MSD platform assay.
LPS (3 µg) or BzATP (50 µg) alone did not affect IL-1β or IL-1RA concentrations in microdialysates, with the stable basal levels at 12 and 310 pg/ml, respectively. Administration of BzATP (87 µg) 1 hour after LPS ("double hit") increased IL-1β and IL-1RA concentrations in microdialysates collected from the PFC to 250 and 1000 pg/ml respectively, with the maximum at 2 h after BzATP administration. Administration of the P2X7 antagonist attenuated the LPS/BzATP-induced increase of IL-1β and IL-1RA.
We demonstrate that an improved collection method enables the study of changes of cytokine concentrations in the brain. The results demonstrate that after priming with LPS, the release of IL-1β in the brain is stimulated by a P2X7 agonist and attenuated by a P2X7 antagonist in vivo. Increase in IL-1RA concentrations in the microdialysates occurs approximately at the same time as IL-1β. We show that a brain-penetrant P2X7 antagonist can reduce CNS IL-1β and IL-1RA concentrations in extracellular fluid and might provide an entry point for therapeutic intervention.

Title: Interferon-β alters neurotrophin-3 TrkC receptor expression and signaling in differentiated human SH-SY5Y neuroblastoma cells

Authors: S. DEDONI, M. C. OLIANAS, *P. ONALI;
Univ. of Cagliari, Monserrato (Ca), Italy

Abstract: Both type I interferons (IFNs) and neurotrophins act on neuronal cells to regulate survival, growth and differentiation. However, relatively little is known on the interaction between these two classes of regulatory proteins. We have previously reported that IFN-β causes down-regulation of the brain-derived neurotrophic factor/TrkB receptor function and up-regulation of the nerve growth factor/TrkA/p75 receptor complex. In the present study, we investigated the effects of long-term exposure to IFN-β on the functional activity of the neurotrophin 3 (NT3)/TrkC receptor system in differentiated SH-SY5Y human neuroblastoma cells. We found that IFN-β treatment curtailed NT3-induced activation of distinct signaling molecules regulated by TrkC receptor, including protein kinase B/Akt, phospholipase Cγ1 and extracellular signal-regulated kinase 1 and 2. Analysis of TrkC receptor expression showed the presence of both 140 kDa full-length and 90-100 kDa kinase-deficient truncated isoforms. Exposure to IFN-β induced a predominant enhancement in the levels of the truncated TrkC receptor isoform in a time-dependent fashion. As the main function of the truncated receptor is the inhibition of the kinase-active TrkC receptor isoforms, our data suggest that long-term exposure to IFN-β down-regulates NT3 signaling by altering the balance between kinase-active and inactive TrkC receptor isoforms.

Title: Tonic activation of α7 nicotinic acetylcholine receptors (nAChRs) controls glutamatergic inputs to striatal and parietal cortical neurons in guinea pig brain slices

Authors: *E. X. ALBUQUERQUE, E. F. R. PEREIRA, M. ALKONDON;
Div. of Translational Toxicology, Dept Epidemiology and Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD

Abstract: Recent studies from our laboratory have shown that in rat hippocampal slices tonically active α7 nAChRs modulate spontaneous GABAergic and glutamatergic synaptic transmission in CA1 pyramidal neurons (JPET 341: 500, 2012; Biochem Pharmacol 84: 1078, 2012). The present study was designed to test the hypothesis that this mechanism is conserved in brain regions known to be sensitive to the toxic effects of irreversible inhibition of acetylcholinesterase, the enzyme that hydrolyzes acetylcholine. To this end, whole-cell patch clamp recordings were obtained at -60 mV from various neurons of guinea pig striatal and parietal cortical (PC) slices from 32-52 day-old female guinea pigs. Recordings were done in ACSF containing the muscarinic receptor antagonist atropine (0.5 μM) and the $GABA_A$ receptor antagonist picrotoxin (50 μM). Biocytin was included in the pipette solution, and at the end of the recording, slices were processed and the neuron types identified. A 15-min bath application of α7 nAChR antagonist methyllycaconitine (10 nM) decreased the frequency of excitatory postsynaptic currents (EPSCs) without changing the mean peak amplitude, 10-90% rise time, and decay time constants of these currents. The reduction in the frequency of EPSCs was observed in two out of three striatal neurons and two out of four PC neurons. Biocytin images revealed that the studied neurons were the pyramidal type located in layers III and IV of the PC, and medium spiny neurons in the striatum. These results support the hypothesis that tonically active α7 nAChRs control glutamate transmission in the PC and striatum of guinea pigs.

Title: Presence of non-α7 nAChRs in CA1 pyramidal neurons in rat hippocampal slices

Authors: *M. ALKONDON, E. F. R. PEREIRA, E. X. ALBUQUERQUE;
Div. of Translational Toxicology, Dept. Epidemiology and Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD

Abstract: Electrophysiological studies from several laboratories have confirmed the presence of both α7 (methyllycaconitine (MLA)-sensitive) and non-α7 (dihydro-β-erythroidine-sensitive) functional nAChRs in various interneurons in hippocampal slices. Few studies have shown the presence of α7 nAChRs in CA3 and CA1 pyramidal neurons. Tonic activation of these α7 nAChRs maintains the frequency of spontaneous glutamate excitatory postsynaptic currents (EPSCs) in CA1 pyramidal neurons. Further, activation of mecamylamine (MEC)-sensitive non-α7 nAChRs by basal levels of acetylcholine in hippocampal slices or by exogenously applied agonists results in glutamate release onto stratum radiatum interneurons. However, the location of MEC-sensitive nAChRs and its influence on other pyramidal neurons have never been studied. To address this issue, we obtained whole-cell patch clamp recordings from CA1 pyramidal neurons in rat hippocampal slices. In the presence of the muscarinic receptor antagonist atropine (0.5 μM), the $GABA_A$ receptor antagonist bicuculline (10 μM), and the α7 nAChR antagonist MLA (3-10 nM), U-tube application of acetylcholine (0.1 mM) induced inward currents at -60 mV. These currents persisted in presence of NMDA receptor antagonist APV (50 μM), but were suppressed in presence of 3 μM MEC. On the other hand, U-tube application of acetylcholine (0.1 mM) to CA1 pyramidal neurons held at +40 mV induced outward-going EPSCs that were suppressed by APV (50 μM), kynurenic acid (100-200 μM) or MEC (3 μM). These results support the notion that MEC-sensitive non-α7 nAChRs are located on somatodendritic regions of CA1 pyramidal neurons and their activation results in glutamate release on to neighboring pyramidal neurons.

Title: Probing α7 nicotinic acetylcholine receptor-mediated signaling pathways in cultured hippocampal neurons

Authors: *Q. CHENG, J. L. YAKEL;
Lab. of Neurobio., NIEHS, Durham, NC

Abstract: The activation of α7 nicotinic acetylcholine receptors (nAChRs) have been shown to improve hippocampal-dependent learning and memory, and rescue the deficits in mossy fiber

LTP. Therefore, it is important to understand the molecular mechanism of α7 nAChRs' action. Since the α7 nAChRs are highly permeable to calcium, some studies have suggested that activation of nAChRs could activate calcium-dependent signaling molecules, as well as protein kinase A (PKA). Moreover, a recent study showed that the α7 nAChR is associated with adenyl cyclase I (AC1) within lipid rafts. However, the direct link between the activation of the α7 nAChR and cyclic adenosine monophosphate (cAMP) signaling in neurons is still lacking. To address this question, we used a Förster- Resonance Energy Transfer (FRET)-based sensor (mTurquoise-Epac(CD, ΔDEP)-^{cp173}Venus-Venus) to monitor the intracellular level of cAMP in cultured hippocampal neurons. We found that application of the α7 nAChR agonist, PNU 282987, induced a significant increase in intracellular cAMP levels measured with this FRET-based sensor. To determine the requirement for the α7 nAChR, we will compare α7 nAChR agonist-induced cAMP changes between wild type and α7 nAChR knockout neurons. To determine the involvement of AC1, we will test the effect of shRNAi against AC1. Lastly, we will attempt to correlate the changes in cAMP levels with neurotransmitter release via a pH-sensitive reporter protein (synaptophysin-pHTomato). Our findings may yield some insight into the molecular mechanisms of the positive cognitive actions of α7 nAChR agonists, and development of therapeutic treatments for cognition impairments.

Title: Shedding some light on nAChRs: Discovery of fluorescent α7 agonists and antagonists

Authors: J. BURGI[1], *J. S. SPROUSE[2], S. BERTRAND[3], E. NEVEU[3], T. SCHAER[3], J.-L. REYMOND[1], D. BERTRAND[3];
[1]Dept. of Chem. and Biochem., Univ. of Berne, Berne, Switzerland; [2]Sprouse Consulting LLC, Stonington, CT; [3]HiQScreen, Geneva, Switzerland

Abstract: The introduction of fluorescent tools has provided significant advantages in various fields of biology with the possibility of localizing cells and proteins down to the single molecule level. While fluorescent labeling of nicotinic acetylcholine receptor (nAChR) antagonists has been successfully achieved with, for example, the snake toxin α-bungarotoxin (α-Bgt), attempts to develop fluorescent small molecule agonists have so far been largely unsuccessful.

In this work we have investigated the combination of α7 nAChR-selective chemical scaffolds with fluorophores in an attempt to develop α7 specific agonists that could be used for histological localization of the receptors as well as for electrophysiology. Knowledge gained from virtual and functional screening allowed us to engineer new agonist molecules retaining high affinity for the α7 nAChRs while maintaining the fluorescent properties of the label. Pharmacological characterization of the fluorescent probes was conducted at human nAChRs expressed in *Xenopus* oocytes. Both antagonists and agonists were identified and characterized at different receptor subtypes to demonstrate the selectivity of these probes. Fluorescent measurements were conducted in cells expressing the α7 receptors and under primary culture conditions, and compared with results obtained with fluorescent α-Bgt.
The data generated suggest that the specificity of small molecules can be maintained allowing the design of new tools to investigate the functional properties of nAChRs. Illustrating the importance of careful design in small molecule labeling, these data reveal new strategies that will find important applications in the localization and characterization of receptors as well as in drug design.

Title: T cell receptor activation decreases excitability of neocortical interneurons by inhibiting α7 nicotinic receptors

Authors: *P. KOMAL[1], G. GUDAVICIUS[2], C. NELSON[2], R. NASHMI[1];
[1]Dept. of Biol., [2]Dept. of Biochem. and Microbiology, Univ. of Victoria, Victoria, BC, Canada

Abstract: T cell receptors (TCR) are expressed on the surface of T lymphocytes where its role in adaptive immunity is well described. Recently, immune proteins have also been found to be expressed in the brain. One such class of proteins are TCRs, which are expressed in the cerebrel cortex of the CNS, though their function remains largely unknown. α7 nicotinic acetylcholine receptors (nAChRs) are a major class of ligand-gated ion channels in the brain, implicated to play an important role in cognition, attention, working memory and synaptic plasticity. Since α7 receptors are expressed in the same brain region where TCR expression is localized, we investigated whether TCRs may potentially functionally interact with α7 nAChRs. Whole-cell recordings were performed in Jurkat cells transfected with α7 nAChRs and from layer 1 neurons of prefrontal cortical brain slices. Concanavillin A (ConA, TCR agonist) incubation significantly attenuated α7 mediated nicotinic receptor currents both in Jurkat cells and in layer 1 cortical interneurons. Genistein (a tyrosine kinase inhibitor) pre-incubation rescued the effects of ConA on acetylcholine (ACh) mediated responses. We then examined if src family kinases directly phosphorylate the tyrosine (Y442) residue located in the M3-M4 cytoplasmic loop of α7 receptors by using mutant α7(Y442A) nAChRs. ConA stimulation did not have any effect on α7(Y442A) mediated nAChR currents. Immunoprecipitation experiments showed that TCR activation significantly increased tyrosine phosphorylation of α7 nAChRs. To examine the mechanism of action of TCRs, Alexa-647 α-bungarotoxin surface labelling of α7 receptors in Jurkat cells showed that TCR activation reduced α7 receptor surface expression. Furthermore, current fluctuation analysis revealed that TCR stimulation decreased single-channel conductance of α7 nAChRs without altering gating kinetics. Current-clamp recordings on layer 1 cortical interneurons showed that TCR activation with ConA or α7 nAChR inhibition with the antagonist MLA both reduced the excitability of layer 1 neurons of the cortex. Our study provides evidence that TCRs do have a neuronal function in the CNS. Activation of TCRs attenuate neuronal excitability by negatively modulating α7 nAChR activity.

Title: A minimal pharmacophore for a nicotinic alpha7 silent agonist, relevance for the therapeutic development of treatments for asthma

Authors: *C. STOKES[1], E. ISRAËL-ASSAYAG[2], R. L. PAPKE[1];
[1]Pharmacol & Therapeut., Univ. Florida, GAINESVILLE, FL; [2]Asmacure Ltée, Quebec City, QC, Canada

Abstract: ASM-024 (1,1 di-ethyl-4-phenylhomopiperazinium), a compound in Phase 2 trials for the treatment of asthma and COPD, has been shown to be active at inhibiting methacholine as well as histamine-induced contraction of tracheal and bronchial smooth muscle and at inhibiting the LPS-evoked release of proinflammatory cytokines by cultured monocytes. We demonstrated that ASM-024 decreases muscarinic responses to acetylcholine of M1, M2, and M3 mAChR expressed in *Xenopus* oocytes. Due to the structural relationship between ASM-024 and the ganglionic nAChR agonist 1,1-dimethyl-4-phenyl-piperazinium iodide (DMPP), we evaluated the effects of ASM-024 on human nAChR subtypes expressed in *Xenopus* oocytes. ASM-024 inhibited the ACh-evoked responses of α3β4 and α7 receptors in co-application experiments. Competition studies indicated that antagonism of α3β4 was noncompetitive while a significant component of the α7 antagonism was competitive. A new type of α7 ligand has recently come to light: molecules which on their own produce little or no channel activation but effectively activate the ion channel when combined with a Type II positive allosteric modulator (PAM). Such "silent agonists" have been implicated as potential mediators of α7-dependent anti-inflammatory effects, and we confirmed that ASM-024 is an α7 silent agonist, since it activated α7 ion channels when co-applied with PNU-120596. DMPP is an efficacious agonist of α7, and one of the structural features distinguishing DMPP from ASM-024 is the presence of additional methyl groups on the quaternary ammonium. While tetramethylammonium is an efficacious α7 agonist, tetraethylammonium (TEA) is a competitive antagonist of α7 ACh-evoked responses. TEA was also confirmed to be a silent agonist, since it produced ion-channel activation when co-applied with PNU-120596. Triethylmethylammonium produced direct α7 channel activation, while TEA does not, defining TEA as the minimal structure required for PAM-dependent α7 activation. ASM-024 shows that the rudimentary silent agonist element of TEA may be incorporated in other more complex structures, suggesting that the TEA portion of ASM-024 prevents activation of ganglionic nAChR while permitting activation of α7-mediated anti-inflammatory pathways.

Title: Mutations of alpha7 nAChR W55 enhance the allosteric agonism of GAT107, the active isomer of 4BP-TQS, and decouple interactions between orthosteric and allosteric sites

Authors: *R. L. PAPKE[1], N. A. HORENSTEIN[2], C. STOKES[3], C.-Y. MAENG[4], A. R. KULKARNI[5], G. A. THAKUR[6];
[1]Dept Pharmacol & Therapeut, Univ. Florida, GAINESVILLE, FL; [2]Chem., [3]Pharmacol. & Therapeut., Univ. of Florida, Gainesville, FL; [4]SK Biopharmaceuticals, Daejeon, Korea, Republic of; [5]Pharmacol. & Therapeut., [6]Pharmacol., Northeastern Univ., Boston, MA

Abstract: GAT107, the (+)-enantiomer of racemic 4BP-TQS with 3aR, 4S, 9bS absolute stereochemistry, is a strong positive allosteric modulator (PAM) of α7 nAChR with intrinsic agonist (IA) activity, while GAT106, the (-)- enantiomer with 3aS, 4R, 9bR stereochemistry, is inactive and does not compete with GAT107. There are two fundamental modes for the positive allosteric modulation of α7 nAChR: one mode, barrier modulation (BM), which affects the energy barriers between conducting and nonconducting states but not absolute free energy of the states, will operate on a population of receptors responding synchronously to agonist application to produce a transient increase in channel opening. The other mode, equilibrium modulation (EM), which affects the relative stability of conducting and nonconducting (i.e. desensitized) states, will produce protracted increases in current and may reverse some forms desensitization (Ds states) induced by agonist, while other nonconducting states are insensitive (Di states). Like PNU-120596, GAT107 has both BM and EM effects. The IA activity of racemic 4BP-TQS was hypothesized to be due solely to binding at the same allosteric site. However, it is unclear if this is the case since the IA effects are only manifested when GAT107 is in the external solution,

while the PAM effects persist long after the free drug is washed away. Prolonged application of GAT107 alone produced primarily IA and EM effects with protracted activation. Addition of the orthosteric agonist (OA) ACh resulted in transient activation followed by PAM-insensitive desensitization. We have previously characterized W55 as a fulcrum within the extended orthosteric ligand binding domain such that mutations of this residue have varying effects depending on specific ligands and receptor subunit composition. We determined that a range of amino acid substitutions at W55 in α7 had the common effect of increasing the IA activity of GAT107 and imbuing the PAMs TQS and PNU-12596 with IA activity. For the W55A mutant the IA activity was decoupled from the effects of OAs. The IA effects of PNU-120596 were additive with OAs, while for TQS OA effects depended on the PAM concentration. While the IA effects of GAT107 in the wild-type α7 nAChR were sensitive to the orthosteric antagonist/inverse agonist MLA, the IA activity of GAT107 for the W55A mutant was MLA insensitive. Our data suggest that a further fulcrum effect of W55 is a containment/limitation of positive modulation produced by allosteric ligands. Homology modeling suggests that Y93 on the primary face of the LBD may be a partner to W55 on the complementary side in providing this containment, a hypothesis we have confirmed with mutation of Y93.

Title: Silent agonists of alpha7 nicotinic acetylcholine receptors require positive allosteric modulators for channel activation

Authors: *K. CHOJNACKA[1], R. L. PAPKE[2], N. A. HORENSTEIN[1];
[1]Chem. Dept., [2]Pharmacol. & Therapeut., Univ. of Florida, Gainesville, FL

Abstract: The α7 nicotinic acetylcholine receptor (nAChR) is a homopentameric ligand-gated ion channel that is considered to play an important role in cognition, sensory gating, and neuroprotection in the CNS. There is also growing appreciation that α7 nAChRs are able to modulate inflammatory responses mediated by non-neuronal cells and do so in a way that may not involve ionotropic behavior. There are at least two different desensitized states of α7 nAChR:

D_s, which is sensitive to type II positive allosteric modulators (PAMs) such as PNU-120596, and D_i, which is insensitive to type II PAMs. We introduce new non-traditional ligands, "silent agonists", that bind to the conventional acetylcholine binding site with little or no probability of ion channel activation, but that place the receptor selectively into the D_s state. We have classified three structurally unique groups of molecules that act as silent agonists. One group is exemplified by benzylidene anabaseine-type molecules such as 3-pyridinylmethylene anabaseine (3PAB). The second group features compounds that contain a positively charged ring, a central ring with hydrogen bonding capability, and a flanking aryl group. The third group is represented by bulky quaternary alkyl ammonium compounds (see Stokes et al. presentation this session). To explore the molecular features of PAM-dependent activators from group 2, we designed and synthesized a series of compounds (KC-1 to KC-9). 5'-Phenylanabaseine (KC-1) was made in three steps by Suzuki coupling and organolithium addition to N-Boc-2-piperidinone, and we identified it as a new silent agonist. KC-1 showed essentially no conventional agonism when tested at 100 μM on human α7 nAChR expressed in *Xenopus* oocytes (net charge 0.083 ± 0.009 of ACh control responses), it reduced responses of α7 to acetylcholine (IC_{50} = 41 ± 5 μM), and when co-applied at 100 μM with type II PAMs, it produced greatly potentiated currents when compared to 60 μM control ACh applications (21-fold higher with 10 μM PNU-120596 and 4-fold higher with 30 μM TQS). The data indicate that KC-1 is likely to bind to the same site as traditional α7 agonists because 100 nM of the nAChR competitive antagonist MLA was 100 % effective at blocking responses to 100 μM KC-1 co-applied with 10 μM PNU-120596. Two of the compounds in the series of close KC-1 analogs (KC-5 and KC-7) were also identified as new silent agonists. Type II PAM–dependent activators of α7 may find use as tools to study functions of the receptor that do not involve ion channel opening and may also constitute a new class of α7 therapeutics.

Title: Effects of positive allosteric modulators (PAMs) of nicotinic receptors on intracellular Ca2+ concentration [Ca2+]i in mouse embryonic mesencephalic neurons in primary culture

Authors: *C. COSI[1], F. MARTY[1], P. MAILLOS[2], P. C. MOSER[1];
[1]Neuropsychopharm. Res., [2]Medicinal chemistry, Inst. De Recherche Pierre Fabre, Castres, France

Abstract: PAMs of centrally expressed nicotinic acetylcholine receptors (nAChRs) have therapeutic potential in areas of cognition, motor function and addiction. Nicotine (NIC) addiction is thought to operate through nAChR located primarily on dopaminergic (but also GABAergic) neurons in the mesencephalic ventral tegmental area. Mouse embryonic neurons from the ventral mesencephalon in culture have functional α7 and non-α7 nAChRs (Neurosci 109, 275-285, 2002 ; FASEB J. fj.11-182824, 2011) and contain dopaminergic neurons. In the present study we investigated the effects of PAMs at α7 and α4β2* nAChR on ACh- and NIC-induced changes in [Ca2+]i in mouse embryonic (E18) mesencephalic neurons in primary culture. These cultures contained about 10% tyrosine hydroxylase positive neurons. Atropine (1 µM) was present in the experiments that included ACh. NIC (100 µM) had a small effect on [Ca2+]i (17 % increase vs. basal, one neuron out of 35 tested). A higher concentration of NIC (300 µM) was able to recruit more neurons (57%) and to increase the average [Ca2+]i response to 50% over basal. The effect of ACh (100 µM) was greater than that of NIC (100 µM). The PAM α7 PNU 120596 concentration-dependently amplified the effect of NIC 100 µM, by recruiting more neurons and increasing the amplitude of the [Ca2+]i response. The PNU 120596-induced potentiation of NIC was antagonized by the α7 nAChR antagonist methyllycaconitine (MLA, 10-100 nM). Desfomylflustrabromine (dFBr), a PAM α4β2* (1 µM), increased the number of ACh responding neurons and the amplitude of the [Ca2+]i increase, but had little effect on the response to NIC. The α4β2 nAChR antagonist dihydro-β-erythroidine (DHβE, 1 µM) partially antagonized the effect of the high concentration of NIC (300 µM) but did not antagonize ACh even at 10 µM. MLA (30 nM) partially inhibited the effect of NIC. PNU 120596, dFBr, MLA and DHβE by themselves had little or no effect on [Ca2+]i. These data show that nAChR PAMs α7 and α4β2* are able to modulate the activity of embryonic mesencephalic neurons in culture in response to ACh and NIC.

Title: Does the β2 C loop of the neuronal nicotinic acetylcholine receptor dictate the type of allosteric modulation?

Authors: *M. M. LEVANDOSKI, C. A. SHORT, C. A. SIBBALD, T. KLJAIC;
Grinnell Col., GRINNELL, IA

Abstract: Numerous compounds allosterically modulate neuronal nicotinic acetylcholine receptors (nAChRs). Studying nicotinic receptors heterologously expressed in *Xenopus* oocytes primarily by electrophysiology, we identified a novel binding site for the anthelmintics morantel and oxantel in mammalian nAChRs. The site is in the β(+)/α(–) interface of α3β2 receptors, in a pocket homologous to the canonical ACh/competitive antagonist site. We have elucidated the residues necessary for constituting this binding site and the determinants of its specificity; in particular, the anthelmintics generally potentiate α3-containing receptors but inhibit α4-containing receptors. We hypothesize that flexibility or concerted movement of the C loop of the β2 subunit is important in allosteric modulation from this site, as well as for receptor activation by agonist. Co-expressing mutant β2 subunits with a cysteine substitution in the C loop and a paired α3(–) cysteine mutant yields receptors susceptible to modification by oxidation and reduction. The effects of these chemical treatments on receptor activation depend on the location of the residue pairs. For example, oxidation of α3T115Cβ2D190C receptors significantly reduced evoked currents compared to control, whereas oxidation of α3T115Cβ2S192C significantly enhanced them. In ongoing studies, we aim to determine the extent to which the putative motion in the β2 C loop is analogous to that of the canonical α subunit C loop for agonist activation of nAChRs, and whether contacts made from the β2 C loop dictate the nature of the modulation.

Title: Transmembrane structural models of human neuronal nicotinic acetylcholine receptors in unbound, agonist and antagonist bound complexes optimized by extensive molecular dynamics simulations

Authors: *D. XU[1], P. W. TAYLOR[3], H. J. D. MILLER[4], A. TAO[5], T. T. TALLEY[2];
[1]Idaho State Univ. Col. of Pharm., Meridian, ; [2]Biomed. and Pharmaceut. Sci., Idaho State Univ. Col. of Pharm., Meridian, ID; [3]Skaggs Sch. of Pharm. and Pharmaceut. Sci., Univ. of California at San Diego, La Jolla, CA; [4]Meridian Med. Arts Charter High Sch., Meridian, ID; [5]Univ. High Sch., Irvine, CA

Abstract: Past efforts in modeling human neuronal nicotinic acetylcholine receptors (nAChRs) have been primarily focused on combining structural information from two sources: the X-ray structures of water soluble acetylcholine binding proteins (AChBPs) of snails, and the electron microscopy (EM) derived structures of the transmembrane domain of the Torpedo nAChR. However, this approach has several inherent deficiencies: The structures of Torpedo nAChR and many snail AChBPs, published nearly a decade ago, have less than 30% sequence identities to human nAChRs. Compared to x-ray structures, the quality of EM derived structures suffers from low atomic resolution. On the other hand, AChBP structures do not provide any information about transmembrane domain and might be considered as a distinct subtype of receptor ectodomain.

In recent years, structural biology of the pentameric ligand-gated ion channel family (Cys-loop receptors) has experienced remarkable progress. Based on the recently available X-ray structure determination of C. elegans glutamate-gated chloride channel (GluCl), we constructed three-dimensional models of the extracellular and transmembrane domains embedded within lipid bilayers of three major types of human nAChRs, α7, α4β2, and α3β4, in unbound and complex forms bound to a variety of agonists and antagonists. Large-scale all-atom explicit solvent molecular dynamics (MD) simulations are employed to allow full equilibration and energy minimization. To the best our knowledge, this is a first attempt to present a complete nAChR structure with extracellular and transmembrane domains with annular lipid bilayers. The model employs crystallographic structural resolution and is optimized via extensive MD simulations. We anticipate that such nAChR models will provide an improved structural base for understanding the molecular determinants of conformational states accompanying ligand binding to nAChRs.

Sci., Idaho State University, Col. of Pharm., Meridian, ID

Abstract: 3,7-diazabicyclo[3.3.1]nonane is a naturally occurring scaffold (known as bispidine), which is a moiety found e.g. in the nicotinic acetylcholine receptor (nAChR) ligand cytisine and the sodium ion channel blocker sparteine. Bispidine derivatives have been investigated as novel nAChR compounds, but have also been examined as the base of potential antiarrhythmic drugs, opioid receptor ligands, antiviral agents, for BIOS, and as multidentate ligands for organometallic agents. We used bispidine in development of two nicotinic compound series based on the 1) template, and 2) hybrid approach. The template approach involved the examination of linker/spacer motifs, whereas the hybrid approach was based on the overlap mode of two identical or distinct pharmacological entities. Compounds were evaluated for their affinities for diverse nAChR subtypes by competition with the radioligands [3H]epibatidine (a4/b2*, a3/b4* and muscle type) and [3H]methyllycaconitine (a7*), in membrane fractions from

rat brain, pig adrenal, and Torpedo californica electroplax. In addition, [3H]epibatidine was used in radioligand competition assays for testing selected candidates of the compound series at three different acetylcholine binding proteins (Lymnaea stagnalis, Aplysia californica (Ac) and a single Ac mutant) as structural surrogates for nAChRs. A broad spectrum of affinities (Ki values: < 1 nM to > 10,000 nM) was obtained providing important insights into structure-affinity relationships for these nAChR targets. High resolution X-ray crystal structures of the compounds in complex with both WT and mutant AChBPs allows a detailed examination of the molecular features contributing to specificity and potency. Both drug design approaches are successful strategies for the development of novel nAChR ligands, including low-efficacy partial agonists at a4/b2* nAChRs with reduced off-target (a3/b4*, a7) and 5-HT3 activity.

[3]Pharmacol., UC San Diego, LA JOLLA, CA

Abstract: We have employed the AChBP as a template lead into studying the molecular recognition properties of the pentameric ligand-gated ion channels. The approach encompasses direct measures ligand association with AChBP, delineating agonist and antagonist activity at subtypes of nAChR on intact cells, and in limited cases, crystallographic structures complexes of

the ligands with AChBP to ascertain the binding poses of the associated ligand. Responses for human α7 and α4β2 nAChRs as well as mouse 5-HT3 A pLGICs were characterized using an in vitro fluorescent functional assay using a genetically encoded Ca2+ indicator. Compounds were identified and characterized as agonists or antagonists on the basis of peak Förster resonance energy transfer responses mediated through Ca2+ flux through the pLGICs. This three pronged approach has enabled us to use structure to design and define molecular determinants of selectivity. For example, the binding poses and determinants of selectivity distinguish quaternary nicotinic ligands stabilized in an aromatic nest of side chains can be distinguished from imines and secondary and tertiary amines where a hydrogen bond from a protonated nitrogen to a backbone carbonyl oxygen becomes the critical orientation of the bound ligand. In turn, positions of the less basic amines are defined within the subunit interfaces through the association with polar residues and water. In turn the binding protein serves as a template for synthesis and characterization of unique ligands that achieve receptor subtype selectivity.

Title: Development of heteromeric human nicotinic receptor/AChBP chimeras

Authors: D. HENDRICKSON[1], M. WILSON[1], P. TAYLOR[2], *T. T. TALLEY[1];
[1]Dept. of Biomed. and Pharmaceut. Sci., Idaho State Univ. Col. of Pharm., Meridian, ID;
[2]Skaggs Sch. of Pharm. & Pharmaceut. Sciences, Univ. of California, San Diego, La Jolla, CA

Abstract: The acetylcholine binding proteins (AChBPs) have provided a wealth of information on structure of the extracellular domain of the Cys-loop ligand-gated ion channels since their initial report by Sixma and colleagues. The availability of high resolution X-ray crystal structures of these proteins in complex with various nicotinic ligands has provided an atomic resolution view of the determinants of ligand recognition. In turn, this has provided opportunities for structure-guided drug design, target “template” synthesis and computational analyses of ligand recognition. However, these efforts had been hampered by the fact that the binding proteins, while homologous with human nicotinic receptors, have a pharmacology that is dissimilar to human drug targets. In addressing this shortcoming we have successfully designed a sires chimeric AChBP constructs. The initial set of constructs replaced the amino acids in the C-loop of the ligand binding site with those corresponding to each of the human alpha subunits. With the successful expression, characterization and co-crystallization of the initial chimeric entities we have expanded our efforts to include non-alpha mutations with the goal of developing constructs that better mimic heteromeric binding environments. The new series of human nicotinic receptor/AChBP chimeras allow for detailed examination of the molecular determinants of ligand recognition and selectivity. Using these insights we are developing new ligands targeting specific receptor subtypes.

Title: Differential modulation of brain nAChR function by cytisine and bispidine compounds and emergent properties of a hybrid molecule

Authors: *C. PENG[1], I. TOMASSOLI[2], C. EIBL[2], D. GUENDISCH[2], R. L. PAPKE[1]; [1]Dept. of Pharmacol. and Therapeut., Col. of Medicine, Univ. of Florida, Gainesville, FL; [2]Dept. of Pharmaceut. Sci., Col. of Pharmacy, Univ. of Hawaii, Hilo, HI

Abstract: Partial agonist therapies for the treatment of nicotine addiction and dependence depend on both agonistic and antagonistic effects of the ligands, and side effects associated with other nAChRs greatly limit the efficacy of nicotinic partial agonists. Here, we evaluated the *in vitro* pharmacological properties of four partial agonists, two current smoking cessation drugs varenicline and cytisine, as well as two novel bispidine compounds BPC and BMSP, by using defined nAChR subtypes expressed in *Xenopus* oocytes. All four agents showed relatively little activity for mouse muscle α1β1εδ nAChR, although 30 μM BPC produced a small inhibition when co-applied with control ACh. Like varenicline and cytisine, BPC was a partial agonist of α4β2 nAChRs, especially of the HS form. However, BMSP produced very little activation of these α4β2 receptors. The partial agonist activity of BPC for α4β2α5 was comparable to cytisine, while BMSP was the least efficacious among the four agents on this receptor as well as β3α4β2α6β2. Unlike varenicline and cytisine, BPC and BMSP showed desired low activity for the two off-target subtypes, α7 and α3β4. In acute co-application experiments, HS α4β2 receptors were the most sensitive to all four agents, although least sensitive to BPC. All four agents inhibited α4β2α5 and β3α4β2α6β2 receptors which were most sensitive to varenicline and cytisine. Several α4* subtypes were sensitive to all four agents when pre-applied for 5 minutes prior to ACh application, with the greatest effects obtained with the HS α4β2. In addition, bath applications of BMSP at submicromolar concentrations effectively down-regulated the responses of all α4* receptors other than the α6* subtype. All α4* receptors were also functionally down-regulated by bath-applied 100 nM BPC, which produced mecamylamine-sensitive steady-state activation that was not evident with BMSP. Modulation of α4*- and α7-mediated responses in rat lateral geniculate nucleus (LGN) neurons and hippocampal stratum radiatum (SR) interneurons by the four partial agonists were also investigated. The LGN neurons were sensitive to a very low concentration of varenicline, and the SR interneuron responses were also sensitive to varenicline at a submicromolar concentration. Both types of neurons were approximately 10-fold less sensitive to bath applications of cytisine. While 300 nM BPC strongly inhibited the ACh-

evoked responses of LGN neurons, it didn't suppress the α7 currents of SR interneurons. Similar results were observed with 300 nM BMSP. Our data indicate that BPC and BMSP are promising α4β2* partial agonists for pharmacotherapeutics.

Title: Positive allosteric modulation of $(\alpha4)3(\beta2)_2$ nicotinic acetylcholine receptors by NS9283 *In vitro* and *In vivo*

Authors: *M. GRUNNET[1], J. BASTLUND[1], M. SARTER[2], A. JENSEN[3], M. GRUPE[1]; [1]Lundbeck A/S, Valby, Denmark; [2]3Department of Psychology and Neurosci. Program, Univ. of Michigan, Ann Arbor, MI, USA, Ann Arbor, MI; [3]Dept. of drug design and pharmacology, Copenhagen, Denmark

Abstract: Disturbance of cholinergic transmission is implicated in a series of neurological conditions such as ADHD, schizophrenia, Parkinson's Disease and Alzheimer's Disease. The nicotinic acetylcholine receptors (nAChRs) are important players in cholinergic transmission. nAChRs are cation-selective ligand-gated ion channels belonging to the superfamily of Cys-loop receptors. Among many different subtypes α4β2 nAChR is believed to be a key player in neuronal synaptic communication. Within the field of drug development targeting nAChRs it has been proposed that positive allosteric modulators (PAMs) possess several pharmacological advantages over agonists. These include higher subtype selectivity as well as maintenance of endogenous spatiotemporal patterns of cholinergic signaling due to lack of desensitizing effects as observed with agonists. The compound NS9283, represent a potent and selective PAM of α4β2 nAChRs. Previous patch-clamp studies have demonstrated how NS9283 increase agonist-induced activity of α4β2 nAChRs by left-shifting the concentration-response curve ~60-fold through a decrease in the rate of deactivation but without major effect on desensitization parameters. Furthermore, systemic administration of NS9283 potentiates nicotine-evoked glutamate release in rat medial prefontal cortex *in vivo*. In the present study we have investigated the impact of nicotinic allosteric modulation on auditory evoked potentials in rats performing a two-tone auditory discrimination task using NS9283. This was addressed with EEG electrodes

implanted into secondary auditory cortex, mediodorsal thalamus, hippocampus and prefrontal cortex. Especially the latter two are key brain regions for higher cognitive executive functions, such as working memory and attention.

Title: A walk in the chemical space to discover new molecules active at nAChRs

Authors: J. BÜRGI[1], *S. BERTRAND[2], E. NEVEU[3], T. SCHAER[3], J.-L. REYMOND[1], D. BERTRAND[3];
[1]Chem. and Biochem., Bern Univ., Bern, Switzerland; [2]Hiqscreen, Vesenaz - GE, Switzerland; [3]HiQScreen, Geneva, Switzerland

Abstract: The chemical space can be seen as an almost infinite universe in which each point represents one possible combination of atoms forming a defined molecule. Based on the observation that compounds comprising a quinuclidine moiety, such as the PNU-282987 are potent agonists at the neuronal nicotinic acetylcholine receptors (nAChRs) a strategy of virtual screening was developed to identify interesting analogues. Herein we report N-(2-halobenzyl)-(S)-3-aminoquinuclidine (S)-6a-c as a new class of α3β2 nAChR PAM, identified by surveying nearest neighbours of 1 within the chemical space of the public database ChEMBL using a web-browser available at www.gdb.unibe.ch. We term this approach "chemical space walking" because the vicinity of most compounds comprises at most a few hundred nearest neighbours when focusing on known molecules, allowing one to perform the selection without the aid of a machine. Identified compounds were screened for functional effects with automated two electrode voltage clamp on approach on human recombinant nicotinic acetylcholine receptors expressed in Xenopus oocytes using HiClamp (Multichannel system). Pharmacological characterization further highlighted the properties of the molecules of interest and confirmed that ligands (S)-6a-c are the strongest α3β2 nAChR PAM to date. This approach confirms that chemical space walking should be generally useful to identify bioactive drug analogues.

Title: Desensitization of presynaptic alpha4beta2- and alpha4alpha5beta2-nAChR

Authors: *S. R. GRADY, C. R. WAGEMAN, M. J. MARKS;
Inst. Behav Genet., Univ. Colorado, BOULDER, CO

Abstract: Previously we have shown that presynaptic nicotinic acetylcholine receptors (AChR) of different subtypes on dopaminergic terminals differ in desensitization. The alpha4alpha5beta2-nAChR subtype requires higher concentrations of nicotine than the alpha4beta2-subtype for an equivalent amount of desensitization with a 10 min exposure. Experiments were conducted to compare the 10 min exposure with 60 min exposures. No additional increase in desensitization was seen with the longer exposure for either subtype. Recovery kinetics and amount of recovery were also unchanged.
To model longer term exposure more equivalent to smoking exposures, we treated mice with drinking water containing nicotine (dose) for several weeks. We compared these mice to mice given tap water. One striatum from each mouse was prepared in the normal fashion and the other side in buffers containing 300 nM nicotine for all steps of crude synaptosome preparation and [3H]-dopamine uptake. This protocol results in about 90 min of nicotine exposure. Aliquots were superfused with buffer with or without 300 nM nicotine, followed by release stimulation using acetylcholine. The procedure results in 8 groups of samples: two treatment groups X two preparation groups X two superfusion groups. Results indicated that the longterm treatment did not significantly affect subsequent desensitization in this assay.
Because the alpha4alpha5beta2-nAChR subtype appears to be significantly more active than the alpha4beta2-nAChR subtype, there is some possibility that this higher activity could create a spare receptor population. We investigated this possibility by using subunit null mutant

heterozygous mice that have been shown to express about half as much receptor as wildtype mice. The beta2 heterozygous mice exhibited about a 40% decrease in activity measured by [3H]-dopamine release, while the alpha4 heterozygous mice had approximately 20% decrease. Results with the beta2 or the alpha4 heterozygous mice with the 10 min desensitization protocol were not different from wildtype, suggesting a lack of spare receptors.

Abstract: The pentameric acetylcholine-binding protein (AChBP) from marine and freshwater snails is a soluble surrogate of the extracellular, ligand-binding domain of the nicotinic acetylcholine receptor. Nicotinic agonists and competitive antagonists bind primarily within a nest of aromatic side chains contributed by loops C and F on opposing faces of each subunit interface. We have solved a range of crystal structures of Lymnaea and Aplysia AChBP in complexes with peptidic and organic antagonists, including the emergent marine phycotoxins, and with organic full and partial agonists of various plant, animal and synthetic origins. We show

that common AChBP determinants are involved into conferring high affinity binding whereas distinctive determinants, located within the nest or extending outside the nest towards apical, radial or “membrane” subsites of the interface, and associated with positional/conformational changes in loop C, appear to be associated with agonist/antagonist-elicited modulation of channel opening in the full-length receptor. These studies also point to the respective contributions of loops C and F in AChBP and determinants in the ligand in dictating either broad or narrow selectivity for muscle-type or neuronal receptor subtypes. A comparative overview of binding (kinetic and equilibrium approaches), functional (voltage-clamp recordings), and structural (x-ray crystallography) data will be presented.

Title: Pharmacological properties of novel 2,5-disubsituted-pyridinyl compounds as highly selective nicotinic acetylcholine receptor desensitizers

Authors: *Y. XIAO[1], Y. LIU[2], E. TUAN[1], N. SAHIBZADA[1], N. AL-MUHTASIB[1], T. TRAN[1], T. XIE[1], M. PAIGE[2], M. L. BROWN[2], A. H. REZVANI[3], E. D. LEVIN[3], K. J. KELLAR[1]; [1]Dept Pharmacol and Physiol, [2]Ctr. for Drug Discovery, Georgetown Univ., WASHINGTON, DC; [3]Psychiatry and Behavioral Sci., Duke Univ. Med. Ctr., Durham, NC

Abstract: Neuronal nicotinic acetylcholine receptors (nAChRs) are essential for a wide range of physiological and behavioral functions. They are implicated in a number of pathological processes and are the targets of nicotinic drugs. It is widely accepted that there are three functional states of nAChRs: closed, open and desensitized. We reported previously that Sazetidine-A potently and selectively desensitizes α4β2 nAChRs. It was proposed that selective ligands causing long lasting nAChR desensitization might be used as therapeutics for treating CNS disorders. Since then, studies have demonstrated significant behavioral effects of Sazetidine-A in several animal models including reducing nicotine and alcohol self-administration. Recently, we reported on the chemistry and pharmacology of 2,5-disubsituted-pyridinyl analogs of Sazetidine-A (Yong Liu et al., 2013, JMC), which selectively desensitize α4β2 nAChRs in cell models and significantly reduce alcohol intake in alcohol preferring rats. Importantly, preliminary results from studies in a ferret model indicate that the novel analogs have an improved adverse side-effect profile in comparison with that of varenicline. More recently, we have completed in vitro pharmacological studies of a new compound, YL-2-203, which is a member of this novel class of selective α4β2 nAChR ligands. YL-2-203 binds to human α4β2 nAChRs with much higher affinity (Ki = 0.2 nM) than to human α3β4 nAChRs (Ki = 97 nM). It shows very low agonist activity at both receptor subtypes. It potently and selectively desensitizes human α4β2 nAChRs (IC50(10') = 44 nM). This new nicotinic compound is currently being studied in a rat model of nicotine self-administration as well as in other animal behavioral models.

Title: Destabilization of a desensitized state contributes to potentiation of low-sensitivity α4β2 nicotinic receptors by desformylflustrabromine

Authors: A. DEMMERLY, *B. W. EDMONDS;
Dept. of Chem. & Biochem., Univ. of Alaska Fairbanks, Fairbanks, AK

Abstract: Neuronal nicotinic acetylcholine receptors (nnAChRs) are promising drug targets for therapy of Alzheimer's disease, nicotine addiction, and other disorders of cholinergic transmission. In comparison to partial agonists, noncompetitive (allosteric) modulators of nicotinic receptors may preserve the normal pattern of receptor activation by endogenous ligand (ACh), and therefore be well suited to correct errors in cholinergic signaling. Desformulflustrabromine (dFBr) is a selective, noncompetitive modulator of the α4β2 class of nAChRs. α4 and β2 subunits assemble to form receptors with two, alternate stoichiometries that exhibit high- and low-sensitivity to agonist, respectively. The heterogeneity of α4β2 nAChRs creates challenges for investigations of receptor mechanisms using whole-cell recording methods. We now use the cell-attached patch-clamp method to examine the effects of dFBr on gating of isolated low-sensitivity (30 pS) receptors expressed in HEK-293 cells. Open and closed duration distributions obtained with 1 μM ACh were fitted (QuB Software) using a 7-state model that includes two binding steps, mono- and di-liganded open states (O1 and O2, respectively), and two long-lived closed (desensitized) states, D1 and D2, that communicate with the di-liganded closed and open states, respectively. In 1 μM dFBr (and 1 μM ACh) we observe two noteworthy effects. First, the mean lifetime of D1 is decreased by a factor of 53 (mean lifetime in control = 390 ms; mean lifetime in dFBr = 7.4 ms). Second, the relative frequency of short (mean lifetime ≈ 1 ms), mono-liganded to long (mean lifetime ≈ 10 ms), di-liganded openings shifts from 30% in control to 80% in dFBr. This shift arises primarily from an apparent 45-fold

increase in the rate of entry into the mono-liganded open state. Simulations of macroscopic currents yield potentiated currents at all ligand concentrations, and the expected EC_{50} values were 49 μM for control, and 10.5 μM for dFBr. For very low concentrations of ACh (~ 100 nM), simulations are consistent with the view that potentiation is primarily due to the increased rate of entry into O1. For agonist concentrations above 100 nM, potentiation arises almost exclusively from destabilization of D1.

Title: Assessing alternate stoichiometries of the α4β2 neuronal nicotinic acetylcholine receptor

Authors: *K. DEDOMINICIS, N. SAHIBZADA, T. TRAN, Y. XIAO, B. WOLFE, K. KELLAR, R. YASUDA;
Pharmacol., Dept. of Pharmacology/Georgetown Univ., Washington, DC

Abstract: The nicotinic acetylcholine receptor (nAChR) plays a key role in nicotine addiction. One of the most important nAChRs related to nicotine addiction and withdrawal symptoms is the α4β2 nAChR. In heterologous expression systems, α4β2 nAChRs exist in one of two stoichiometries: (α4)3(β2)2 or (α4)2(β2)3. These different stoichiometric forms have been termed low-sensitivity (LS) or high-sensitivity (HS) α4β2 nAChRs, respectively, due to observed differences in potency in response to acetylcholine (ACh). Based on the literature, full concentration-response curves to ACh can indicate whether α4β2 nAChRs expressed heterologously are HS, LS, or a mixture of both stoichiometries. In this work, we altered transfection ratios of α4:β2 cDNA from 1:6 to 4:1 to favor assembly of HS or LS nAChRs. We present two new methods to predict which stoichiometric form(s) of rat α4β2 nAChRs is/are expressed in these cells. The first method uses whole-cell voltage clamp electrophysiology to predict the predominance of HS or LS α4β2 nAChRs based on peak current amplitude responses to discrete concentrations of ACh. We demonstrate that the HS stoichiometry has similar responses to 10 and 1000 μM ACh. In contrast, in the LS stoichiometry the response to 10 μM ACh is only 10% that of 1000 μM ACh. This is consistent with the complete concentration-response curves of the two stoichiometric forms. The second method uses immunoblotting

techniques to directly quantify and compare the ratio of α4 to β2 nAChR subunits in harvested tissue using an α4-β2 dimer construct as a standard. We use immunoprecipitation and/or chromatographic methods to remove subunit assemblies that are smaller than pentamers. By developing these assays to determine the stoichiometry of α4β2 nAChRs in HEK cells, we plan to assess the native stoichiometry of the α4β2 nAChR in brain from both naïve and nicotine treated animals.

Title: Contribution of the two binding sites in gating nicotinic receptor channels

Authors: *M. HECKMANN[1], P. STOCK[1], D. LJASCHENKO[1], J. DUDEL[2];
[1]Univ. Wuerzburg - Physiologisches Inst., Wuerzburg, Germany; [2]Friedrich-Schiedel-Institute for Neurosci., Tech. Univ. Munich, Munich, Germany

Abstract: Muscle type nicotinic acetylcholine receptor/channels (nAChRs) bind ligands at interfaces of α- and neighbouring γ- or δ-subunits. αγ- and αδ-sites differ in affinity but their contributions in opening the channel remain elusive. We compared high resolution patch-clamp currents evoked by epibatidine (Ebd), carbamylcholine (CCh) and acetylcholine (ACh). Ebd binds with higher affinity at αγ- than at αδ-sites whereas CCh and ACh prefer αδ-sites. Short (τ_{O1}), intermediate (τ_{O2}) and long types of openings (τ_{O3}) were observed with all three agonists. Below 10 nM Ebd preferentially τ_{O2} openings occurred from binding at αγ-sites. Vice versa, τ_{O1} openings appear to be generated at αδ-sites. In addition two types of bursts appeared: Short bursts of on average 0.75 ms (τ_{B1}) that should also arise from the αγ-site, and long bursts of 12 to 25 ms (τ_{B2}) durations arising from double liganded receptors. The duration of the about 180 µs openings within these bursts depended on the agonist, but with further improved time resolution may approach the shorter τ_{O2}. The 3 µs closings within bursts appeared to be agonist independent, and like the types of openings to be inherent properties of the channel opening

mechanism. Blocking αδ-sites with α-conotoxin M1 (CTx) eliminated both τ_{O1} and τ_{B2} and left only the longer single τ_{O2} openings and the short τ_{B1} bursts, as expected. When CTx was applied to `embryonic´ mouse endplates, monoquantal current amplitude and decay time constants were reduced and rise times increased, as expected.

Title: Functional properties of classic and novel nicotinic ligands: A patch clamp study using DynaFlow rapid solution exchange system

Authors: *E. TUAN[1], Y. LIU[2], T. XIE[1], N. AL-MUHTASIB[1], T. TRAN[1], M. PAIGE[1], M. BROWN[2], N. SAHIBZADA[1], K. J. KELLAR[1], Y. XIAO[1];
[1]Pharmacol., [2]Drug Discovery Program, Georgetown Univ., Washington, DC

Abstract: Neuronal nicotinic acetylcholine receptors (nAChRs) are cys-looped, pentameric ligand-gated ion channels that open in response to acetylcholine. These receptors are assembled in both homomeric and heteromeric fashions from a range of subunits, including nine α subunits and three β subunits. To study pharmacological properties of human nAChRs, we have established two stable HEK293 cell lines: YXα4β2H1, which expresses the human α4β2 subtype, and YXα3β4H1, which expresses the human α3β4 subtype. In $^{86}Rb^{+}$ efflux assays, acetylcholine potently activates nAChRs expressed in the cells. Compared to acetylcholine, nicotine elicits 85% agonist efficacy at the human α4β2 nAChRs and 100% efficacy at the human α3β4 nAChRs. To further explore the function of these two nAChR subtypes, we used the Dynaflow rapid solution exchange system to administer drugs to single cells while measuring elicited whole cell currents with patch clamp electrophysiology. Consistent with results from $^{86}Rb^{+}$ efflux assays, nicotine showed 100% agonist efficacy at the human α4β2 nAChRs and 97% efficacy at the human α3β4 nAChRs when determined using patch clamp. In the whole cell

current measurements, Sazetidine-A shows only 3.5% agonist efficacy at rat α3β4 nAChRs, consistent with our previous reports that Sazetidine-A has little efficacy in activating rat α3β4 nAChRs. Interestingly, in contrast to the effects at rat α3β4 nAChRs, Sazetidine-A showed 82% agonist efficacy at human α3β4 nAChRs, indicating a significant interspecies difference between rat α3β4 nAChRs and their human counterparts. We then studied agonist activities of two novel selective α4β2 nAChR ligands, YL-1-127 (Yong Liu et al., 2013, JMC) and YL-2-203 (Xiao et al., this meeting) using the Dynaflow system. The two new ligands have very low efficacy at human α3β4 nAChRs: 1.3% by YL-1-127 and 5.7% by YL-2-203. These novel ligands should be further studied for developing new CNS therapeutics.

Title: Positional-scanning analysis of α-conotoxin residues that confer selectivity for α3β2 nicotinic acetylcholine receptors

Authors: *A. J. HONE[1,3], S. EBERHARD[2], M. RUIZ[2], M. SCADDEN[2], J. GAJEWIAK[2], A. ALBILLOS[3], J. MCINTOSH[2,4];
[1]Neurosci., [2]Biol., Univ. Utah, SALT LAKE CTY, UT; [3]Pharmacol. and Exptl. Therapeut., Univ. Autonoma de Madrid, Madrid, Spain; [4]Psychiatry, George E. Whalen Veterans Affairs Med. Ctr., Salt Lake City, UT

Abstract: Nicotinic acetylcholine receptors (nAChR) containing α3 subunits mediate fast synaptic transmission between neurons of the parasympathetic, sympathetic, and enteric nervous systems; the receptors subtypes expressed are primarily of the α3β2 and α3β4 subtypes. In the

central nervous system, α3β2 receptors may be expressed in brain regions where the closely related α6β2 subtype is also expressed. Some of these areas include the superior colliculus, interpeduncular nucleus, and the striatum. Distinguishing α3β2 from α6β2 receptors using pharmacological probes has been hampered by the scarcity of ligands that selectively target α3β2 vs α6β2 receptors. Several α-conotoxins (α-Ctx) and their analogs selectively inhibit α6β2 receptors over α3β2 receptors but only a few show a preference for α3β2 over α6β2 receptors and include, for example, OmIA and LtIA. However, these α-Ctxs are only marginally selective for the α3β2 subtype and thus have limited utility for distinguishing α3β2 from α6β2 receptors. We used positional-scanning mutagenesis of α-Ctx PeIA, a peptide that targets both α3β2 and α6β2 with equal potencies, and substituted non conserved residues from α3β2-selective α-Ctxs into the sequence of PeIA in order to identify residues that are important for conferring selectivity for α3β2 receptors over α6β2 receptors. Successive substitution of several residues generated analogs of PeIA with improved selectivity. The results of this study should be useful for guiding the synthesis of ligands that selectively target α3β2 nAChRs.

Title: AT-1001: Pharmacological profile at rat and human α3β4 and α4β2 nicotinic receptors

Authors: *C. BOWMAN DALLEY[1], A. LEWIN[1], E. TUAN[1], N. AL-MUHTASIB[1], T. TRAN[1], Y. GAO[2], A. G. HORTI[2], K. J. KELLAR[1];
[1]Dept. of Pharmacol. and Physiol., Georgetown Univ., Washington, DC; [2]Div. of Nuclear Med., Johns Hopkins Univ., Baltimore, MD

Abstract: The predominant nicotinic acetylcholine receptor (nAChR) in major sympathetic ganglia and the pineal gland is the α3β4*subtype. In addition, this nAChR subtype is found in important areas of the CNS, where it has been associated with nicotine addiction and withdrawal. A major impediment to studying α3β4*nAChRs has been the lack of a highly selective drug/ligand for use in pharmacological and radioligand binding studies; however, in 2012, AT-1001 was introduced as a highly selective, high affinity α3β4 nAChR antagonist (Toll, Zaveri et

al., 2012). Because of its high selectivity, AT-1001 might be a powerful tool to study the pharmacology and physiology α3β4* nAChRs. Moreover, AT-1001 potently blocked nicotine self-administration in rats (Toll, Zaveri et al. 2012), suggesting that the drug may have clinical applications in the treatment of addiction. There are certain differences between the rat and human β4 subunit that can result in some pharmacological differences (Young, Broad et al., 2007); therefore, we further characterized AT-1001 by measuring the pharmacologic properties of this drug at both the rat and human receptor subtypes expressed in stably transfected HEK cells. Consistent with the previous study (Toll, Zaveri et al. 2012), in our radioligand binding studies AT-1001 displayed ~30-fold selectivity for rat α3β4 over rat α4β2 nAChRs. However, in studies with human receptors AT-1001 displayed ~1800-fold selectivity. This higher selectivity was due primarily to a much higher affinity for human compared to rat α3β4 nAChRs (K_i 0.12 nM vs 7.6 nM), with virtually no difference in the affinities at the α4β2 nAChRs (K_i 217 nM vs 232 nM). Consistent with the previous report (Toll, Zaveri et al., 2012), saturation binding curves with [^{3}H]-epibatidine in the presence and absence of AT-1001 indicated a mixed type of binding inhibition, with both a rightward shift and an apparent decrease in binding maximum of the curves in the presence of AT-1001 in both rat and human receptors. In $^{86}Rb^+$ efflux assays, AT-1001 was ~8-times more potent in inhibiting the response to co-applied nicotine at human compared with rat α3β4 nAChRs (IC_{50} 0.36 μM vs 2.7 μM). Surprisingly, AT-1001 showed 33% - 50% partial agonist activity at α3β4 nAChRs in both $^{86}Rb^+$ efflux assays and patch clamp measurements. Furthermore, in patch clamp measurements with rapid application, AT-1001 showed partial agonist activity (~12%) at α4β2 nAChRs. Preliminary studies indicate that AT-1001 can also desensitize nAChRs.

Title: Differential agonist desensitization of HS vs. LS nicotinic receptors

Authors: *P. WHITEAKER[1], J. B. EATON[1], L. M. LUCERO[1], H. STRATTON[1], Y. CHANG[1], J. F. COOPER[2], J. M. LINDSTROM[2], R. J. LUKAS[1];
[1]Div. Neurobiol, St. Joseph's Hosp, PHOENIX, AZ; [2]Dept. of Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: α4β2 nAChRs are the predominant subtype in the central nervous system, and exist in two pentameric isoforms, with $(\alpha4)_2(\beta2)_3$ and $(\alpha4)_3(\beta2)_2$ stoichiometries. These have high and low sensitivity (HS/LS) agonist activation affinities, respectively. Both isoforms share two orthosteric agonist-binding α4/β2 interfaces, but the $(\alpha4)_3(\beta2)_2$ isoform contains an additional agonist binding site at a unique α4/α4 interface. At low agonist concentrations, $(\alpha4)_3(\beta2)_2$ nAChRs produce a small amount of "HS" function mediated by the α4/β2 interfaces. At higher agonist concentrations the distinctive, and much larger, LS response is seen. For most agonists, desensitization concentration dependence is indistinguishable between HS and LS α4β2 nAChRs. However, using both $^{86}Rb^+$ efflux and two-electrode voltage-clamp (TEVC) electrophysiology, we show that it is possible to preferentially pre-desensitize the HS isoform by extended exposure to a low concentration (3 nM) of the highly HS- vs. LS-preferring agonists AMOP-H-OH and A85380. This also abolishes the small "HS" response from $(\alpha4)_3(\beta2)_2$ nAChRs, while leaving the typical LS response relatively intact. To demonstrate the role of the α4/α4 site in this phenomenon, we mutated aromatic amino-acids in the A-D conserved agonist binding loops to alanine. A concatameric construct was used to enforce LS stoichiometry, and to ensure only the LS interface was mutated. Constructs were expressed in *Xenopus* oocytes, and function assessed using TEVC. In all cases, acute stimulation of the mutant receptors showed an increase in the HS:LS function ratio, as expected if LS function is uniquely dependent on the α4/α4 site. Most mutations did not change EC_{50} values of the LS phase, although those in the C-loop resulted in even lower agonist sensitivity. Maximum function of the A- and C-loop LS concatemer mutants was significantly lower, while that of B- and D-loop mutants was similar to the un-mutated construct. Surface expression of the w.t. and mutant constructs was assessed using [^{125}I]mAb295 binding to intact oocytes, and showed no significant differences. Increased absolute HS-phase function per receptor was seen in two cases (α4/α4 W88A, Loop D; W182A, Loop B); this suggests functional interdependence between the α4/β2 and α4/α4 agonist sites. Occupation of the α4/β2 sites following 5 min exposure to 3 nM AMOP-H-OH also causes changes α4/α4 site-mediated function; LS-phase EC_{50} values were consistently right-shifted. These findings will guide further pharmacological and drug-discovery studies.

Title: Novel nicotinic agonist TI-299423 potently elicits conditioned-place preference in wild-type mice

Authors: *T. WALL[1], B. N. COHEN[1], C. R. WAGEMAN[2], S. R. GRADY[2], M. J. MARKS[2], B. H. HENDERSON[1], S. MCKINNEY[1], P. DESHPANDE[1], D. YOHANNES[3], H. A. LESTER[1]; [1]Caltech, Pasadena, CA; [2]Inst. Behav. Genet., UC, Boulder, CO; [3]Targacept, Inc., Winston-Salem, NC

Abstract: Because they are selectively expressed in dopaminergic neurons, nicotinic acetylcholine receptors (nAChRs) containing α6 subunits (α6*) play a key role in nicotine reward and nicotine neuroprotection in Parkinson's disease. Activation of the locomotor response in transgenic mice expressing hypersensitive α6* (α6L9'S*) nAChRs provides a way to test whether nicotinic ligands activate α6* nAChRs. We measured the locomotor response to three novel ligands (TI-299423,TI-165179,TI-186079) to determine whether they activate α6L9'S* nAChRs as potently as nicotine or varenicline. At 500 nmol/Kg, none of the drugs induced locomotor activity in WT mice. In α6L9'S* mice, however, nicotine, varenicline, and TI-299423 (but not TI-165179 or TI-186079) significantly ($P < 0.05$) increased locomotion. Varenicline and TI-299429 had nearly equal effects that were significantly greater than nicotine. Thus, TI-299423 and varenicline potently activated α6L9'S* nAChRs. The nicotinic antagonist mecamylamine (1 mg/Kg) and the dopamine D1 antagonist SCH-23390 blocked (2 mg/Kg) the α6L9'S* locomotor response to TI-299423 (500 mg/Kg). Transgenic mice expressing hypersensitive α4* (α4L9'A*) nAChRs (but not α6L9'S* mice) are hypersensitive to nicotine-induced hypothermia, suggesting that non-α6* nAChRs mediate this effect. To determine whether TI-299423 could selectively activate α6* nAChRs, we compared its potency in inducing hypothermia in α4L9'A*mice with nicotine. At 100 nmol/Kg, nicotine induced a 2 °C drop in core body temperature. TI-299423 did not significantly affect core temperature. At 500 nmol/Kg, TI-299423 significantly reduced core temperature. Thus, TI-299423 appeared to show some selectivity for α6* nAChRs. Conditioned-place preference (CPP) measures drug reward in mice. To determine whether TI-299423 was rewarding in mice, we asked if a low dose of TI-299423 (12 ng/Kg) could induce CPP in WT or α6L9'S* nAChR mice. Unexpectedly, TI-299423 induced significant CPP in WT, but not α6L9'S* mice, suggesting that TI-299423 had a more potent rewarding effect on WT mice than α6L9'S* mice. Measurements of TI-299423-induced [3H]dopamine release from midbrain synaptosomes confirmed that TI-299423 elicits more MII-

conotoxin-resistant (non-α6-mediated) , than MII-conotoxin-sensitive (α6-mediated), release from synaptosomes a this dose, suggesting that TI-299423 activation of the non-α6*nAChRs on dopaminergic neurons mediates its potent rewarding effects in WT mice. TI-299423 also potently and robustly activates α4β2 nAChRs expressed in N2A cells.

Abstract: Receptor heteromers are becoming the focus of extensive research in the field of G-protein-coupled receptors. Recent studies have shown evidence for the existence of heteromers between dopamine D_1 and D_3 receptors, which could have implications for basal ganglia disorders and drug addiction. In the present study we wanted to address the molecular interactions involved in D_1-D_3 receptor heteromerization, in particular, the role of transmembrane (TM) domains, by using synthetic peptides containing the amino acid sequence of TM domains of the D_1 receptor. Stably transfected cell lines (HEK293) expressing either the D_1 receptor fused to Rluc or the D_3 receptor fused to YFP or both were created. BRET analysis in D_1Rluc-D_3YFP cells (using D_1Rluc cells as controls) provided evidence for D_1-D_3 heteromerization. Unfortunately, and at odds with previously published studies, BRET analysis could not be used to study a possible destabilazing effect of TM peptides on D_1-D_3 heteromerization, due to a strong functional interference with Rluc. Nevertheless, using transient transfection of D_1 and D_3 receptors fused to potentially complementing moieties of YFP, TM5

and TM6 but not TM7 peptides were able to significantly decrease YFP-induced fluorescence. Importantly, TM5 and TM6 but not TM7 peptides counteracted D_1-D_3 cross-talk and cross-antagonism at the level of MAPK signaling in D_1Rluc-D_3YFP cells. These results indicate the selective involvement of TM5 and TM6 of D_1 receptor in the intermolecular and functional interactions between D_1 and D_3 receptors in the D_1-D_3 receptor heteromer. Looking for receptor-heteromer selective compounds, we also analyzed the ability of TM5 and TM6 peptides to selectively counteract ligand binding properties of D_3 receptor that depend on D_1-D_3 receptor heteromerization. This type of studies could clarify the role of the overexpression of the D_3 receptor described in several neuropsychiatric disorders, including drug addiction.

Title: Varying agonist efficacies of novel dopamine D3-selective ligands studied in the GTP-shift radioligand binding assay

Authors: J. ZHEN[1], M. E. A. REITH[1,2], *A. K. DUTTA, Dr[3];

[3]Wayne State Univ., Detroit, MI

Abstract: Dopamine (DA) D2 and D3 receptors belong to the superfamily of G-protein-coupled-receptors (GPCRs). Agonist binding introduces conformational changes, compacting the extracellular agonist binding pocket and collapsing the central binding site of sodium. This provides a structural context for the well-known allosteric effect of Na^+ and GTP in shifting agonist potency in inhibiting the binding of a labeled antagonist towards lower affinity (GTP-shift assay). We hypothesized that this phenomenon represents the capability of agonists to convert and stabilize the intermediate or active states of DA D_2 or D_3 receptors, which is correlated with their potencies and efficacies to activate G protein in functional assays. The current study focused on the full agonists DA, quinpirole, and D-296, and on the partial agonists with varying efficacies (-)3PPP, D-301, D-303, and D-313 (for our novel D_3-selective D-ligands

aimed against PD see Biorg. Med. Chem. 2009: 17, 3923 and 2010: 18, 5661; J. Med. Chem. 2010: 53, 1023). Their potencies in inhibiting the binding of [^{3}H]spiperone to DA D_2 or D_3 receptors stably expressed in HEK293 and CHO cells were assessed under two different assay conditions (Mg^{2+} only – giving $K_{i\text{-}Mg}$, versus Na^+ and GTP_YS – giving $K_{i\text{-}Na}$). There was no difference between the two cell lines in the $K_{i\text{-}Na}$ values, but the $K_{i\text{-}Mg}$ values were significantly increased in CHO-D_3R ($P<0.001$). The affinity ratio $K_{i\text{-}Na}/K_{i\text{-}Mg}$, expressed as % of the ratio for DA, was strongly correlated between HEK-D_3R and CHO-D_3R ($Y=0.97*X+0.21$, $R^2=0.88$, $P<0.005$). This suggests that G protein coupling helped stabilize the active receptors (in absolute terms more in CHO-D_3R than in HEK- D_3R), but was not required for receptor activation. Thus, significant agonist-stimulated GTPγ^{35}S binding to cell membranes was not detected in HEK-D_3R. Interestingly, for both DA D_2 and D_3 Rs, $K_{i\text{-}Mg}$ in the [^{3}H]spiperone binding assay was highly correlated with EC_{50} in the functional [^{35}S]GTP_YS binding assay ($Y=1.05*X-0.03$, $R^2=0.91$, $P<0.0001$); the relative affinity ratio was also strongly linked with efficacy ($Y=0.80*X+0.27$, $R^2=0.68$, $P<0.01$). Thus, the capability of agonists to promote a more active state of DA D_2 or D_3 receptors is correlated with both their potency and efficacy to activate G protein. Additionally, the present results indicate that GTP-shift binding assays can be used for approximating partial D_2 and D_3 agonist properties.

Title: Evidence for limited D1 and D2 receptor co-expression and co-localization within striatal patch neurons of the neonatal mouse

Authors: *D. BIEZONSKI, P. TRIFILIEFF, J. JAVITCH, C. KELLENDONK;
Columbia Univ., New York, NY

Abstract: The striatum is the major input nucleus of the basal ganglia involved in reward processing, goal-directed behaviors, habit learning, and motor control. The striatum projects to the basal ganglia output nuclei via the “direct” and “indirect” pathways which can be distinguished on the basis of their projection fields and their opposing effects on behavior. In adult animals, the functional opposition is modulated by the differential actions of D1 and D2

dopamine receptors (D1R, D2R) whose expressions are largely separated between these pathways. Although extensively studied in the adult, little research exists on the relative expression patterns of D1 and D2 receptors early post-natally. To address this issue, we have used dual-label immunohistochemistry to map striatal D1 and D2R expression at the promoter level in post-natal day 1 (PD1) Drd1a-tdTomato/Drd2-eGFP BAC transgenic mice, and at the receptor level by co-staining for native D1 and D2Rs in wild-type P1 animals. We confirmed our observations with a recently developed proximity-ligation assay. In contrast to the limited overlap of both receptors in adults, our results demonstrate that shortly after birth some D1 and D2 receptors are co-expressed in the same neurons of the striatal patch - but not the matrix - compartment, the matrix exhibiting low levels of D1R expression. Moreover, we found that D1 and D2R proteins co-localize at a distance less than 16 nm suggesting that these receptors may have the potential to heterodimerize early post-natally. These novel findings pave the way for future research on the role dopamine receptors may play in early striatal ontogeny and function, and the significance this may have for proper development of striatally-mediated behaviors.

Abstract: The D_2 dopamine receptor (DAR) is a highly validated drug target in neurology and psychiatry. For instance, receptor-based antiparkinsonian drugs primarily work via stimulating the D_2 DAR. However, most drugs targeting the D_2 DAR are problematic as they are either less

efficacious than desired or possess adverse side effects due to either cross reactivity or activation of inappropriate signaling pathways. A novel approach for attaining greater selectivity of therapeutic agents targeting the D_2 DAR is to identify and develop ligands that exhibit functional selectivity, or biased agonism. In contrast to most agonists, which activate all signaling pathways in parallel with equal efficacy, functionally biased agonists favor one transduction pathway over another. Here we report the discovery of a novel D_2 DAR agonist that is fully biased for G-protein-linked signaling while having no ability to activate β-arrestin-based signaling. We have also generated preliminary structure-activity relationship (SAR) data for this compound. We initially performed a high throughput-screening (HTS) campaign to interrogate a 380,000+ small molecule library to identify novel D_2 DAR agonists. The primary HTS assay utilized a cell line expressing the D_2 DAR coupled to a chimeric Gqi5 protein, thereby linking receptor activation to robust Ca^{2+} mobilization. We also conducted secondary assays to measure orthogonal D_2 DAR signaling activities including cAMP modulation and β-arrestin recruitment. The primary HTS screen resulted in the identification of 2,288 compounds with agonist activity. While the majority of the subsequently confirmed agonist hits activated all signaling pathways tested, some compounds showed a diminished ability to stimulate β-arrestin recruitment. One such compound, reported here, (MLS1547) is a full agonist at D_2 DAR mediated G-protein-linked signaling (Ca^{2+} and cAMP), but demonstrates no ability to activate β-arrestin recruitment (enzyme-complementation as well as BRET-based assays). The compound does, however, antagonize dopamine-stimulated β-arrestin recruitment to the D_2 DAR. Furthermore, the compound does not stimulate β-arrestin recruitment from any other DAR subtype (D_1-D_5). In an effort to further interrogate the chemical scaffold and identify a preliminary SAR that imparts this unique pharmacological profile; 20 analogs of MLS1547 were obtained or synthesized and analyzed in our assays. Interestingly, some of these analogs gain the ability to stimulate β-arrestin recruitment without losing the G-protein activating response. In summary, we have identified the first known compound that is a G-protein biased agonist of the D_2 DAR.

Title: Functional recruitment of g protein beta5 to d2 dopamine receptors

Authors: *J. OCTEAU[1], J. CELVER[1], M. SHARMA[1], J. SCHRADER[1], C. COLVIN[1], C. AIUDI[2], K. SUN[2], C.-K. CHEN[3], A. KOVOOR[1];
[1]Biomed. & Pharmaceut. Sci., [2]Univ. of Rhode Island, Kingston, RI; [3]Dept. of Biochem. and Mol. Biol., Virginia Commonwealth Univ. Sch. of Med., Richmond, VA

Abstract: G beta 5 (Gbeta5) is a G protein subunit that is thought to exist as obligate heterodimer with R7 RGS proteins. We found that while the majority of Gβ5 found in the cortex segregates into the detergent-soluble biochemical fraction, the majority of Gβ5 expressed in the striatum, a brain region that expresses high concentrations of D2R, segregates instead into the detergent-resistant biochemical fraction. We have previously shown that the vast majority of D2R either expressed endogenously in the brain or exogenously in cell lines segregates into detergent-resistant membrane (DRM) fractions. Therefore we asked if the detergent-insolubility of striatal Gβ5 was produced as a result of an interaction with D2R. When expressed in HEK293 cells Gβ5 is predominantly detergent-soluble but is re-targeted to the DRM after D2R co-expression. Furthermore, an in-cell proximity biotin-transfer assay indicated that D2R and Gβ5 interact in DRM and coexpression of D2R enhances the both the expression levels and stability of Gβ5. Gβ5 coexpression suppressed phosphorylation of MAP kinase (MAPK) elicited by dopamine-bound D2R and also altered the effects of D2R expression in a cellular adherence assay. Our data suggest that Gβ5 can exist as a complex with D2R in DRM independently of R7 RGS proteins since HEK293 cells do not endogenously express these proteins.

Title: D2 receptor overexpression in accumbal indirect pathway medium spiny neurons leads to hyperexcitability and alterations in behavioral sensitization to cocaine

Authors: *E. F. GALLO[1], B. FENG[1], J. A. MORON CONCEPCION[2], J. A. JAVITCH[1], C. KELLENDONK[1];
[1]Psychiatry, [2]Anesthesiol., Columbia Univ., NEW YORK, NY

Abstract: The nucleus accumbens (NAc) is implicated in the neuroadaptations underlying drug addiction. Medium spiny neurons (MSNs), the main cellular output of the NAc, typically belong to either the direct or indirect projection pathways, which differ in their respective enrichment of D1 and D2 receptors (D1Rs and D2Rs). D2Rs play a key role in drug reinforcement, as demonstrated with pharmacological and gene knockout approaches. Moreover, neuroimaging studies indicate that chronic drug use in humans is associated with decreased D2R availability in the striatum. However, it is unknown whether selectively increasing D2R levels in the indirect pathway protects against the reinforcing effects of drugs of abuse, and if so, through which cellular mechanisms. Our previous work indicates that transgenic mice that overexpress striatal D2R (D2R-OE) since early development display increased MSN excitability, yet the consequences of inducing D2R overexpression in adult MSNs on excitability and drug-related behaviors is unknown.

To address these questions, we restricted D2R overexpression to indirect D2-expressing MSNs (D2-MSNs) by injecting a conditional adeno-associated virus encoding D2R into the NAc of Drd2-Cre transgenic mice. Using whole-cell patch clamp recordings in acute slices, we found that D2-MSNs overexpressing D2Rs show increased excitability compared to MSNs expressing EGFP. We also found a reduction in inwardly-rectifying K+ channel (Kir) currents, suggesting that, as in D2R-OE mice, D2R upregulation in adult MSNs may lead to hyperexcitability through downregulation of Kir function.

To begin to examine the behavioral effects of indirect pathway-specific D2R upregulation, we tested whether Drd2-Cre mice overexpressing D2R display alterations in cocaine-induced locomotor sensitization. We found that while D2R-overexpressing mice have a significantly higher basal locomotor activity compared to EGFP-expressing controls, both groups display a similar relative response to the first cocaine injection (15mg/kg, i.p.). However, unlike EGFP-expressing mice which progressively developed sensitization to daily cocaine injections, mice overexpressing D2R maintained the same locomotor response following repeated cocaine exposure. Together, these results suggest that indirect pathway-specific D2R upregulation in adult NAc leads to increased MSN excitability, which may be related to the observed alterations in locomotor activity and cocaine sensitization.

Title: Presynaptic dopamine D1 receptor regulation of the striatonigral GABA transmission

Authors: S. DING, *F.-M. ZHOU;
Univ. Tennessee, MEMPHIS, TN

Abstract: The GABAergic projection neurons (GABA neurons) are the main cell type in the substantia nigra pars reticulata (SNr), a key basal ganglia output nucleus that influences the thalamocortical motor circuit. The high frequency spontaneous firing in these GABA neurons is sculpted by excitatory and inhibitory synaptic inputs. SNr GABA neurons receive a robust GABA input from the direct pathway medium spiny neurons in the striatum (striatonigral pathway). Dopamine D1 receptors are abundantly expressed on the striatonigral axon terminals. Activated by endogenously released dopamine from the dendrites of nigral dopamine neurons, these D1 receptors may play an important role in regulating the striatonigral pathway. We hypothesize that D1 receptors facilitate the striatonigral GABA transmission at the axon terminal level and consequently reduces the output from the SNr. To test this idea, we have performed preliminary experiments in an angular sagittal brain slice preparation that enables the activation of the striatonigral projection without any apparent contamination from antidromically activated pallidonigral neurons. To avoid activating the potential presynaptic D2 receptors on other GABA afferents, we use the selective D1-like full agonist SKF81297. Our preliminary results indicate that SKF81297 facilitates striatonigral IPSCs in SNr GABA neurons. This facilitatory effect is blocked by the D1 receptor antagonist SKF83566. SKF81297 also increases the frequency but not the amplitude of miniature IPSCs in SNr GABA neurons. Taken together, these results indicate that dopamine D1 receptors on the striatonigral axon terminals promote the transmission of the inhibitory signal from the direct pathway medium spiny neurons to SNr GABA neurons. This facilitation may be important in normal movement control and also in Parkinson's disease.

Title: Haloperidol-induced Nur77 expression depends on Thr34 DARPP-32 phosphorylation in striatopallidal medium spiny neurons of mice

Authors: *N. SANCHEZ[1], R. COURA[2], O. ENGMANN[2], L. MARION-POLL[2], S. LONGUEVILLE[2], D. HERVÉ[2], J.-A. GIRAULT[2], M. E. ANDRES[1];
[1]Pontificia Univ. Catolica De Chile, Santiago, Chile; [2]Inserm, UMR-S 839, Paris, France

Abstract: Unbalanced signaling in striatopallidal and striatonigral striatal neurons impairs movements and may participate in diseases such as addiction and schizophrenia. Nur77 is an orphan nuclear receptor closely associated to dopamine signaling in these neurons. Classical antipsychotic drugs, such as haloperidol, are known to increase Nur77 expression in the striatum. However, little is known about the neuronal population in which Nur77 is induced by haloperidol and the intracellular signaling pathways involved. The striatal projecting GABA medium spiny neurons (MSN) are characterized by the segregated expression of D1 (striatonigral pathway) or D2 (striatopallidal pathway) dopamine receptors. Here, using pharmacological approaches and a variety of transgenic mice models, we investigated the mechanisms underlying the upregulation of Nur77 protein expression in the dorsal striatum after haloperidol injection. Our data show that Nur77 upregulation induced by haloperidol occurs preferentially in the D2 striatopallidal (MSN) cells and depends on Thr34 DARPP-32 phosphorylation. In addition, we showed that haloperidol-dependent Nur77 upregulation is mediated by A_{2a} signaling. Understanding the regulatory mechanisms of Nur77 expression in the striatum may help deciphering the molecular mechanisms underlying the extrapyramidal symptoms produced by haloperidol treatment.

Title: Cellular mechanisms for dopaminergic modulation of axon initial segment calcium channels

Authors: *S. YANG[1], R. M. VAN RIJN[2], J. L. WHISTLER[2], K. J. BENDER[2];
[2]Neurol., [1]Univ. of California at San Francisco, San Francisco, CA

Abstract: The axon initial segment (AIS) is a specialized neuronal subcompartment that supports action potential initiation. Recently, we found that low-voltage activated calcium channels enriched at the AIS are regulated by type 3 dopamine receptors (D_3R), and that this modulation strongly suppresses high frequency spike burst output. The cellular mechanisms by which dopamine modulates AIS calcium channels, and the identity of the channels modulated, has been unclear. We utilized 2-photon calcium imaging and electrophysiology in acute slice and cell culture preparations to probe the molecular pathway that underlies modulation of AIS calcium. In contrast to traditional G-protein mediated modulation, we found that D_3R signaling requires beta-arrestin and ERK1/2 to downregulate AIS calcium, suggesting that modulation of AIS channels is a novel example of biased signal transduction in neurons.
In previous experiments in dorsal cochlear nucleus cartwheel cells, we found that spike-evoked AIS calcium transients were sensitive to nickel and ascorbate, suggesting that the T-type isoform $Ca_V3.2$ is localized to the AIS. Consistent with these results, D_3R activation did not modulate residual AIS calcium transients in $Ca_V3.2$ knockout mice. Because neuronal voltage clamp of T-type currents is dominated by dendritic currents (Bender et al., 2011), the manner in which AIS $Ca_V3.2$ channels are modulated remains unknown. We therefore have transfected HEK cells with D_3R and $Ca_V3.2$ constructs. In isolated cells, D_3R activation reduced peak calcium currents 30 ± 1.5% (voltage steps from -100 to -40 mV, n = 8). We are currently utilizing this system to determine both the activity dependence of this modulation by D_3Rs and the molecular determinants in the receptor necessary for arrestin-dependent modulation.

Title: Impaired dopamine signaling in dorsal striatum of Wfs1 deficient mice

Authors: *A. TERASMAA, T. VISNAPUU, C. A. HUNDAHL, E. VASAR;
Inst. of Physiol., Univ. of Tartu, Tartu, Estonia

Abstract: Loss of function of the Wolframin (Wfs1) gene causes Wolfram syndrome, a rare multisystem degenerative disorder. Wfs1 gene is widely expressed in the brain and our previous work demonstrated that lack of Wfs1 protein leads to impaired function of dopaminergic system. Thus Wfs1 knock-out animals show diminished amphetamine induced locomotion. Also, the homozygous Wfs1 mutant mice show significantly
decreased striatal dopamine output in response to high-concentration K^+ challenge. The aim of this study is to further characterize the function of intracellular signaling in dopaminoceptive neurons of Wfs1-deficient mice. Acute administration of direct dopamine agonist apomorphine (3mg/kg, i.p.) induced an increase (163±11 % of baseline, $p<0.05$, n=5) in phosphorylation of the dopamine- and cAMP-regulated phosphoprotein of 32 kDa (DARPP-32) at Thr34 in dorsal striatum of the wild type mice. Such effect of apomorphine was absent in Wfs1 knock-out mice (102±9 % of baseline, n=5). These results suggest that intracellular signaling downstream of dopamine receptor is altered in the dorsal striatum of Wfs1 deficient mice.

Title: Modulation of canonical dopamine signaling system in hippocampus via formation of ghrelin and dopamine 1 receptor heteromers

Authors: *A. KERN, C. ULLRICH, R. ALBARRAN-ZECKLER, R. G. SMITH;
Metabolism & Aging, The Scripps Res. Inst., Jupiter, FL

Abstract: The orphan growth hormone secretagogue receptor (GHSR1a) first identified by reverse pharmacology and was subsequently de-orphanized by the discovery of the ghrelin. This cognate receptor for ghrelin belongs to the class A family of GPCRs. In the brain, GHSR1a is expressed mainly in hippocampal structures, hypothalamus and midbrain. Paradoxically, despite the broad expression of GHSR1a, other than trace amounts in the hypothalamus, endogenous ghrelin is undetectable in the brain; hence, we asked what the function of apo-GHSR1a might be. Using GHSR-IRES-GFP mice we identified subsets of neurons in the hippocampus that coexpress GHSR1a and DRD1. We speculated that apo-GHSR1a modifies DRD1 signaling. In a neuronal cell line coexpressing GHSR1a and DRD1, and in primary cultures of hippocampal neurons, we show that canonical DRD1 signaling is modified by GHSR1a such that dopamine (DA) treatment causes mobilization of intracellular Ca^{2+} ($[Ca^{2+}]_i$). Using pharmacological inhibitors, genetically encoded PLC and Ca^{2+} sensors, and BRET assays we dissected the signal transduction pathway. In the presence of GHSR1a, DRD1 couples to $G\alpha_q$ and DA activates the PLC and IP_3 signaling cascade. Furthermore, using Tr-FRET with SNAP and CLIP-tagged receptors, and inducible receptor homomerization assays, we found that non-canonical DA signaling is a consequence of formation of GHSR1a:DRD1 heteromers. The neutral GHSR1a antagonist (JMV2959) blocks DA-induced $[Ca^{2+}]_i$ release indicating that within the heteromer, one protomer allosterically modifies function of the other. The possibility of a mechanism involving receptor crosstalk, caused by basal activity of GHSR1a, was ruled out by experiments with: GHSR1a point mutants, selective Gα-protein knockdown, specific pharmacological inhibition of components of the $G\alpha_s$ signaling pathway. In mouse hippocampal brain slices we confirmed the presence of functional GHSR1a:DRD1 heteromers by FRET confocal microscopy and Ca^{2+} imaging. *In vivo* relevance was demonstrated by comparing DRD1 agonist-induced behavioral responses in mice treated with a neutral GHSR1a antagonist (JMV2959). The JMV2959 treated mice were resistant to DRD1 agonist-induced behaviors. Therefore, pharmacological intervention with a GHSR1a antagonist is a selective way to block DA signaling in neurons expressing GHSR1a:DRD1 heteromers, without affecting neurons expressing DRD1 alone. These results show the potential of designing new drugs for targeting psychiatric disorders associated with abnormal DA signaling by selectively targeting subsets of neurons expressing GHSR1a:DRD1.

Title: Activation of G(s/olf) heterotrimers in living cells: Development of novel G(s/olf) biosensors

Authors: *H. YANO[1], D. PROVASI[2], M. FILIZOLA[2], S. FERRE[1], J. JAVITCH[3];

Abstract: G protein-coupled receptors (GPCRs) mediate neurotransmission of numerous molecules. Their structure-function relationship is the key to better development of neuropharmacological agents. Conformational changes associated with GPCR activation have been revealed in remarkable details by the crystal structure of agonist-bound β2 adrenergic receptor (β2AR) coupled to G(s) as well as by complementary spectroscopy and imaging studies. However, the extent to which conformational changes in G protein are conserved in living cells as well as across different receptors and different G protein species, particularly G(olf), which shares 89% sequence homology, remains to be determined.
We first investigated conformational changes in the G(s) heterotrimer after activation of β2AR in intact cells. Using bioluminescence resonance energy transfer, we made observations on movements both within the G protein as well as between the receptor and the G protein. Using a library of novel G(s) biosensors with either luciferase or GFP inserted at various positions throughout the structure, we studied conformational changes in cells and compared the results to

the crystal structures of the inactive and active conformations. We also studied conformational changes in G(s) protein induced by the D1 dopamine receptor and A2A adenosine receptor. Finally, taking advantage of the significant homology, G(olf) biosensor constructs were made at the same ten positions used for G(s) and subsequently validated for measuring ligand activation. Our analysis using these G(s) biosensors suggests that conformational changes within the G(s) heterotrimer are very similar for different G(s)-coupling receptors. Comparison between the G(s) and G(olf) sensor readouts gives us a perspective on possible differences in the regulation of activation. Using this set of G(s) and G(olf) biosensors, partiality of agonists can be studied in relation to structural changes and subsequent effector activation. Further, activation preference between G(s) and G(olf) can be addressed. Thus, these biosensors represent a novel pharmacological tool to study structure-function relationships.

Title: Differential role of α2-adrenoceptor subtypes in the inhibition of the vasopressor sympathetic outflow in diabetic pithed rats

Authors: *A. H. ALTAMIRANO-ESPINOZA, G. MANRIQUE-MALDONADO, I. I. RUIZ-SALINAS, B. VILLANUEVA-CASTILLO, C. M. VILLALÓN;
Farmacobiología, Dept. De Farmacobiología Cinvestav Sede Sur, Mexico DF, Mexico

Abstract: Several lines of evidence suggest a link between diabetes and disturbances on the modulation of blood pressure, related with pre/post-junctional α2-adrenoceptors on blood vessels from different species including humans. Hence, we hypothesize that the expression of different α2-adrenoceptor subtypes mediating sympatho-inhibition and/or systemic vasoconstriction (i.e. vasopressor responses) could be altered in diabetic subjects, probably as a compensatory mechanism. On this basis, the present study identified the pharmacological profile of the α2-adrenoceptor subtypes mediating inhibition of the sympathetic vasopressor outflow in diabetic pithed rats. For this purpose, 125 male Wistar rats (95 pretreated i.p. with 50 mg/kg streptozotocin and 30 pretreated i.p. with vehicle) were anaesthetized, pithed and artificially

respired with room air (56 strokes/min; stroke volume: 20 ml/kg). Under these conditions, electrical stimulation (0.03, 0.1, 0.3, 1 and 3 Hz; 50 V and 2 ms) of the thoracic (T7-T9) preganglionic sympathetic vasopressor outflow or i.v. bolus injections of exogenous noradrenaline (0.03, 0.1, 0.3, 1 and 3 μg/kg) resulted in frequency dependent (n=105) and dose-dependent (n=20) vasopressor responses, respectively. Furthermore, i.v. continuous infusions of the α2-adrenoceptor agonist, BHT 933 (10 and 30 μg/kg.min), inhibited the sympathetically-induced, but not the noradrenaline-induced, vasopressor responses. Interestingly, in euglycemic (vehicle-treated) rats, lower doses of BHT 9333 (1 and 3 μg/kg.min), which were inactive in diabetic rats, dose-dependently inhibited the sympathetic vasopressor outflow. Furthermore, after i.v. administration of selective antagonists, the BHT 933-induced sympatho-inhibition in diabetic rats was: (i) abolished after BRL-44408 (α2A; 100 μg/kg); (ii) dose-dependently, but not completely, blocked by imiloxan (α2B; 300 and 1000 μg/kg); and (iii) unchanged after JP 1302 (α2C; 1000 μg/kg). These doses of antagonists, which did not affect per se the sympathetically-induced vasopressor responses, were high enough to completely block their respective receptors. In conclusion, these results in diabetic rats suggest that the inhibition of the sympathetic vasopressor outflow produced by 10 μg/kg.min BHT 933 is predominantly mediated by the α2A- and, to a lesser extent, by the α2B-adrenoceptor subtypes, with no evidence for the role of the α2C subtype. This pharmacological profile contrasts with that of the α2 adrenoceptors mediating sympatho-inhibition in euglycemic rats, in which mainly α2A/2C- but not α2B-, adrenoceptors are involved.

Title: Lasting activity of alpha1-AR during postnatal development alters membrane properties of LC in SHR

Authors: S. IGATA[1,2], T. HAYASHI[3], M. ITOH[2], M. TAKANO[2], *M. ISHIMATSU[4,2]; [1]Dept. Healt. Sci., Kyushu Univ., Fukuoka, Japan; [2]Dept. Physiol, [3]Urol, Kurume Univ. Sch. Med., Kurume, Japan; [4]Nishikyushu Univ., Kanzaki, Japan

Abstract: Attention Deficit Hyperactivity Disorder (ADHD) is a developmental disorder commonly found in childhood. Several lines of evidence indicate that locus coeruleus (LC) is the brain region involved in attention, vigilance, and cognitive functions, key clinical features of ADHD. Using a spontaneously hypertensive rat (SHR), a widely used ADHD animal model displaying ADHD like behaviors starting from 3 to 4 weeks old, we characterized synaptic transmission in LC neurons during the course of postnatal development. In particular, we analyzed membrane properties by whole cell patch clamp technique at two developmental time points, postnatal day (P) 3-5 (neonates) and P21-28 (juveniles). The data measured in SHR LC neurons were compared to those in age matched Wistar rats as normotensive controls. So far, our data showed no statistical changes in resting membrane potential (RMP) and spontaneous firing frequency (SFR) in the neonatal Wistar and SHR. However, we found age specific alterations in the juvenile SHR LC neurons; significantly depolarized RMP and significantly higher SFR. Noradrenaline is a prominent neurotransmitter in LC, and induces an outward current through an inwardly rectifier potassium channel coupled to alpha2-adrenergic receptor (AR) activation. Since previous study demonstrated the expression of functional alpha1-AR in the neonatal rats, we asked whether alpha1-AR contributes to altered membrane properties in the LC neurons of SHR in a postnatal development dependent manner. The neonatal LC neurons of both SHR and Wistar produced Phenylephrine (PE), an alpha1-AR-agonist, induced inward currents. In contrast, the juvenile LC neurons of SHR, but not Wistar, produced the PE induced inward currents, which were abolished by TRP channel blockers. Furthermore in the presence of yohimbine, application of an alpha1-AR antagonist, Prazosin, to the juvenile SHR LC neurons resulted in an outward current, indicating that basal activity of alpha1-AR modulates the resting membrane potential of the juvenile SHR LC neurons. Importantly, neither PE nor prazosin affected the RMP of the juvenile LC neurons of Wistar. These results indicates the loss of alpha1-AR function during normal rodent development. In contrast, the LC neurons of SHR persistently display the basal activity of alpha1-AR throughout the postnatal development, possibly leading to the depolarized membrane potential and increased spontaneous firing. In summary, our study highlights the alterations in the membrane properties in the LC neurons of SHR, which occur in the postnatal development dependent manner, may underlie pathophysiology of ADHD.

Title: Heterologous signaling via Src regulates sequence-dependent recycling of signaling receptors via modification of cortactin

Authors: *R. VISTEIN, M. PUTHENVEEDU;
Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Post-endocytic recycling of neurotransmitter receptors from endosomes is a critical step that determines the resensitization of neurons to signals. While some proteins can recycle without apparent requirements, many signaling proteins recycle through a highly defined actin- and sequence-dependent pathway. Why signaling receptors have these additional requirements is not clear. Here, using high resolution Total internal reflection fluorescence (TIRF) and spinning disk confocal microscopy to visualize the recycling of the beta-2 adrenergic receptor (B2AR) in live cells, we show that B2AR recycling through the sequence-dependent pathway is regulated by the Src Kinase. This regulation is restricted to proteins that recycle via the sequence-dependent pathway. Src kinase regulates the recycling rate of B2AR via phosphorylation of cortactin, an actin nucleation promotion factor, which controls the rate of generation of vesicles in this pathway. Together, our results suggest that the restriction of signaling receptors to a sequence-dependent recycling pathway allows for heterologous signaling pathways to control receptor recycling and neuronal resensitization to signals.

Genet., [4]Dept. of Neurol., Univ. Med. Ctr. Maastricht, Maastricht, Netherlands; [5]Dept. of Neurol., Spaarne Hosp., Hoofddorp, Netherlands

Abstract: Painful small-fiber neuropathy represents a significant public health problem. In approximately one-half of cases (termed idiopathic) a cause cannot be identified. Gain-of-function mutations of the sodium channel $Na_V1.7$ have recently been identified in nearly 30% of patients with biopsy confirmed idiopathic small-fiber neuropathy. More recently, gain-of-function mutations of sodium channel $Na_V1.8$ have been found in a smaller percentage of patients with small-fiber neuropathy. Previously described mutations of $Na_V1.8$ associated with painful neuropathy accelerate recovery from inactivation (repriming), enhance the response to slow depolarizations, and enhance activation at the channel level, and produce hyperexcitability of small DRG neurons, which include nociceptors, at the cellular level. We have now identified a new $Na_V1.8$ mutation from two patients with painful small-fiber neuropathy, and our preliminary studies suggest a previously unreported mode of gain-of-function of $Na_V1.8$, i.e. impaired fast-inactivation. We also show that the mutant channel causes DRG neuron hyperexcitability. Together with our earlier results, our observations support the conclusion that an array of Nav1.8 mutations, which affect channel function in multiple ways, can contribute to the pathophysiology of painful peripheral neuropathy.

Title: The role of 'neonatal' form of $Na_V1.2$ in neuronal function and brain development

Authors: *E. GAZINA, B. LEAW, K. RICHARDS, C. REID, S. PETROU;
The Florey Inst., Melbourne, Australia

Abstract: Four Na^+-channel α subunits are expressed at high levels in human brain. Each of them has a 'neonatal' and an 'adult' form due to developmentally regulated alternative splicing of coding exons 5N and 5A. This splicing event is largely conserved between humans and mice, suggesting that it has an important biological function which is currently unknown. The Na^+-channel α subunit $Na_V1.2$ undergoes the largest 'neonatal' to 'adult' transition in postnatal mouse cortex: from 2:1 'neonatal' to 'adult' ratio at birth to 1:13 at 15 days of age. When expressed in HEK293 cells, the 'neonatal' form of human $Na_V1.2$ is less excitable than the 'adult' form, suggesting that alternative splicing may regulate neuronal excitability during brain development. To examine the functional role of the 'neonatal' $Na_V1.2$, we mutated the 5N exon, thus creating a mouse line that expresses 'adult' $Na_V1.2$ regardless of the splicing pattern. Electrophysiological properties of L2/3 cortical pyramidal neurons of the wild-type and homozygous 'adult $Na_V1.2$' mice were then compared using whole-cell patch-clamp. At P3 the 'adult $Na_V1.2$' mice had an excitable phenotype with an increase in action potential firing. Furthermore, the 'adult $Na_V1.2$' cortices contained a population of fast-firing neurons (23% of total) that were not present in the wild-type mice. At P15 the action potential firing in neurons of the mutant and the wild-type mice became identical, consistent with the dominance of 'adult' $Na_V1.2$ in the wild-type cortex at this age. Nevertheless, adult mutant mice (P45-90) had a significantly reduced threshold for proconvulsant-induced seizures compared to the wild-type. They also exhibited behavioural differences from their wild-type siblings. For example, the 'adult $Na_V1.2$' mice spent significantly more time on the open arms of the elevated plus maze than the wild-type.
In summary, these results demonstrated that expression of the 'neonatal' $Na_V1.2$ reduces excitability of pyramidal cortical neurons in neonatal wild-type mice. Moreover, the expression of the 'neonatal' $Na_V1.2$ at young age has long-term effects on behaviour and seizure susceptibility, likely due to its role in development of neuronal networks.

Title: Functional characterization of a novel Nav1.6 mutation in a patient with infantile epilepsy

Authors: *M. R. ESTACION[1,2], J. E. O'BRIEN[3], D. TALWAR[4], S. D. DIB-HAJJ[1,2], M. F. HAMMER[4], M. H. MEISLER[3], S. G. WAXMAN[1];
[1]Neurol, Yale Univ. Sch. of Med., New Haven, CT; [2]The Rehabil. Res. Ctr., VA Connecticut Healthcare Syst., West Haven, CT; [3]Dept. of Human Genet., Univ. of Michigan, Ann Arbor, MI; [4]Div. of Biotech., Univ. of Arizona, Tuscon, AZ

Abstract: The etiology of neurodevelopmental disorders such as epilepsy represent a considerable challenge for molecular genetic analysis because of marked genetic heterogeneity, but it has been hypothesized that rare or novel point mutations may contribute to a substantial number of these cases. When the observed phenotype is particularly severe and there is no prior family history of the disorder, it is reasonable to consider a disease model that involves a dominant de novo mutation. Support for this model comes from studies of epileptic encephalopathies, where de novo mutations of several genes have been observed, including many mutations in the voltage-gated sodium channel gene SCN1A in individuals with Dravet Syndrome (MIM 607208). The etiology for many cases of epileptic encephalopathy remains unknown, suggesting that there may be causal mutations in additional genes. Using a whole genome sequencing approach and electrophysiological recordings, we previously identified the first mutation of SCN8A (sodium channel Nav1.6) in a patient with infantile epileptic encephalopathy and SUDEP (Veeramah et al, AJHG 2012). The de novo mutation hNav1.6-N1768D resulted in a distinctive 5-fold increase of persistent current. Current-clamp analysis in hippocampal neurons transfected with N1768D channels revealed increased spontaneous firing, paroxysmal depolarizing shift (PDS)-like complexes, and increased firing frequency, consistent with a dominant gain-of-function phenotype in the heterozygous proband. We now report a second heterozygous de novo SCN8A mutation in another patient with infantile epilepsy. Using voltage-clamp recording in the neuronal cell line ND7/23 we observed a significant hyperpolarizing shift of the voltage-dependence of activation for the mutant channel as well as an enhancement of ramp current. Both properties are predicted to make neurons hyperexcitable, consistent with the clinical phenotype. Functional characterization of this second Nav1.6 channel

mutation provides further evidence supporting the inclusion of SCN8A as a causative gene in infantile epilepsy.

Title: Inactivation properties of Na^+ channels in the axonal spike trigger zone of cortical pyramidal neurons

Authors: *I. A. FLEIDERVISH, G. BARANAUSKAS;
Dept. of Physiol., Ben Gurion Univ., Beer Sheva, Israel

Abstract: In cortical pyramidal cells, as in many CNS neurons, action potentials (APs) initiate in the axon initial segment (AIS) - the proximal part of the axon where the neuronal membrane is not covered with a myelin sheath and which possesses a distinctive, specialized assembly of voltage gated channels and associated proteins. Preferable AIS spike initiation is explained, at least partially, by lower activation voltage of local Na^+ channels. To what extent the inactivation properties of these channels differ from those in soma and dendrites? Molecular studies suggest that inactivation is voltage independent process that derives all of its apparent voltage-dependence from activation. Thus, hyperpolarizing shift in channel steady state activation characteristics should lead to an equivalent shift in its steady state inactivation curve. This theoretically expected shift, if it exists, could cause reduction in channels availability in the subthreshold range of voltages and, paradoxically, to render the AIS less excitable.
Here, we probed the voltage dependence of the axonal Na^+ channel inactivation by measuring changes in fluorescence of Na^+ -sensitive dye, SBFI, elicited by single AP in layer 5 pyramidal neurons in neocortical slices. As with conventional Na^+ current recordings, we assumed that the amplitude of Na^+ flux could provide us with an estimate of Na^+ channel availability before an AP was fired. We found that axonal Na^+ channel availability was nearly maximal at resting potential, as stepping the membrane even to very negative potentials caused no significant increase in Na^+ flux. By applying slow depolarizing current ramps to the soma, we found that availability of the AIS Na^+ channels changes very little (<20 %) by depolarization to voltages of up to -55 mV.

Our data indicate that voltage dependence of inactivation of the AIS Na^+ channels is rightward shifted as compared with somatic channels, making them fully available even at very depolarizing voltages.

Title: Exploring the obscure profiles of pharmacological binding sites on voltage-gated sodium channels by bmk neurotoxins

Authors: Z. LIU[1,2], *Y.-H. JI[1];
[1]Shanghai Univ., Shanghai, China; [2]Dept. of Pharmacology, Inst. of Med. Science, Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China

Abstract: Diverse subtypes of voltage-gated sodium channels (VGSCs) have been found throughout tissues of the brain, muscles and the heart. Neurotoxins extracted from the venom of the Asian scorpion *Buthus martensi* Karsch (BmK) act as sodium channel-specific modulators and have therefore been widely used to study VGSCs. α-type neurotoxins, named BmK I, BmK αIV and BmK abT, bind to receptor site 3 on VGSCs and can strongly prolong the inactivation phase of VGSCs. In contrast, β-type neurotoxins, named BmK AS, BmK AS-1, BmK IT and BmK IT2, occupy receptor site 4 on VGSCs and can suppress peak currents and hyperpolarize the activation kinetics of sodium channels. Accumulating evidences from binding assays of scorpion neurotoxins on VGSCs however indicate that pharmacological sensitivity of VGSC subtypes to different modulators is much more complex than that suggested by the simple α-type and β-type neurotoxin distinction. Exploring the mechanisms of possible dynamic interactions

between site 3- / 4-specific modulators and region- and/or species-specific subtypes of VGSCs would therefore greatly expand our understanding of the physiological and pharmacological properties of diverse VGSCs. In this review, we discuss the pharmacological and structural diversity of VGSCs as revealed by studies exploring the binding properties and cross-competitive binding of site 3- or site 4-specific modulators on VGSC subtypes in synaptosomes from distinct tissues of diverse species.

Title: Effect of selective Nav1.7 blockers on action potential generation of cultured mouse DRGs, human DRGs and hESC-derived sensory neurons

Authors: *E. B. STEVENS[1], A. R. BROWN[1], L. CAO[1], P.-P. SAINTOT[1], G. T. YOUNG[1], M. L. CHAPMAN[2], A. NITZSCHE[1], J. G. BILSLAND[1], R. P. BUTT[1], C. E. PAYNE[1];

Abstract: Evidence from clinical pain genetics , transgenic mouse models and detailed channel biophysics suggest that Nav1.7 has a key role in action potential electrogenesis in sensory neurons (Dib-Hajj et al., 2013).
The specific role of Nav1.7 in action potential generation was studied using highly selective small molecule blockers of Nav1.7. Effects of Nav1.7 currents were measured in 3 different cultured sensory neuron models: small diameter mouse DRG neurons, small diameter human DRG neurons and human embryonic stem cell (hESC)-derived sensory neurones using whole-cell patch clamp recordings. We have previously demonstrated that Nav1.7 is the major component underlying the TTX-S current in mouse and human DRGs (Alexandrou et al., 2012), in contrast Nav1.7 constitutes approximately 30% of the TTX-S current in hESC-derived sensory neurons. Using current-clamp recordings single action potentials were evoked using current injections just above threshold for firing. Selective Nav1.7 blockers caused either a change in action potential waveform parameters or a complete ablation of action potential firing in all three sensory neuron preparations. In particular, there was a significant decrease in both rate of rise of the upstroke and amplitude of action potentials. These data provide further evidence that Nav1.7 has an important role in controlling sensory neuron action potential propagation through its

contribution to electrogenesis at threshold of firing.

Title: Analysis of inward excitatory currents during an action potential from suprachiasmatic nucleus neurons

Authors: *J. R. CLAY;
Physiol., NIH, ROCKVILLE, MD

Abstract: The ionic currents underlying excitability in suprachiasmatic nucleus (SCN) neurons have been analyzed in voltage clamp conditions using both voltage steps and the action potential (AP) clamp method (AC Jackson, GL Yao, BP Bean, J. Neurosci. 24:7985, 2004). In this study one of the APs in their report was digitized and applied to models of the excitatory sodium current, I_{Na}, and the calcium current, I_{Ca}, in voltage-clamp, i.e., a computational method of implementing the AP clamp technique. The Hodgkin-Huxley m^3h model was used in the I_{Na} analysis. Initially, rate parameters similar to theirs were also used. That analysis yielded a significant I_{Na} during AP repolarization, as occurs in squid giant axons but not in mammalian neurons. Using I_{Na} rate constants from an analysis of this component in hippocampal mossy fibers as the starting point for the SCN I_{Na} results was successful. The model predicts maximum

I_{Na} during the latter part of the upstroke of the AP followed by a rapid decline to near-zero during the remainder of the AP, as observed experimentally. A d^2f model was used in the I_{Ca} analysis. Initially, voltage-dependent inactivation was used for the f parameter. This was replaced by calcium current dependent inactivation. The model successfully describes I_{Ca} results obtained from SCN neurons both with voltage steps and action potential clamp. These results provide building blocks for a full model of the AP from SCN neurons. They also demonstrate a general method for building models of the AP for other excitable cells.

Title: Inhibition of excitatory synaptic transmission in mouse spinal cord by a $Na_v1.7$ selective sodium channel antagonist

Authors: *M. K. PATEL[1], M. CHAPMAN[2], E. B. STEVENS[3], D. GRYDER[1];
[1]Anesthesiol., Univ. Virginia Hlth. Sys, CHARLOTTESVLE, VA; [2]Neusentis, Raleigh, NC;
[3]Pfizer Neusentis, Cambridge, United Kingdom

Abstract: In view of the importance of Na channels in cellular excitability, pharmacological modulation of their activity has proved beneficial in the treatment of many disorders including pain. In this study, we have examined the effects of a sodium channel antagonist selective for the Nav1.7 isoform (Compound A), on synaptic transmission onto substantia gelatinosa (SG) neurons of the mouse dorsal horn.
Spinal cord slices (350 μm) were superfused with solution comprising (mM) 125.0 NaCl, 25.0 $NaHCO_3$, 10.0 glucose, 2.5 KCl, 1.25 NaH_2PO_4, 2.0 $CaCl_2$, 1.0 $MgCl_2$ bubbled with 95%, 5% O_2/CO_2. Electrophysiological recordings were made from visually identified lamina II SG neurons using electrodes filled with (mM) 120.0 Kgluconate, 10.0 NaCl, 2.0 $MgCl_2$, 0.5 K_2EGTA, 10.0 HEPES, 4.0 Na_2ATP, 0.3 Na_2GTP, 5 μM QX314, pH 7.2 and held at –60 mV. Stimulation of the dorsal root using a suction electrode evoked both Aδ and C fiber excitatory post synaptic currents (EPSC). All EPSC's were recorded in the presence of 50 μM picrotoxin and strychnine. Values are mean ± SE. All animal experiments were approved by the Institute of Animal Care and Use Committee.

Evoked EPSC's were completely abolished by NBQX (5μM) and TTX (500 nM). Bath application of Compound A at 30 nM (20-30 mins) inhibited Aδ fiber responses by 46.9 ± 5.4% (n=4) and C fiber responses by 53.7 ± 10.1% (n=8). At 100 nM Compound A, the effects on EPSC's were more pronounced. Aδ fiber responses were inhibited by 90.2 ± 7.0% (n=5) while C fiber responses were inhibited by 88.2 ± 5.9% (n=10). Prolonged washout (>30 mins) resulted in only partial recovery of EPSC amplitudes in a few neurons. Under current clamp conditions, stimulation of the dorsal root evoked a single action potential from SG neurons. In the presence of 30 nM Compound A, evoked action potentials were abolished in 7 out of 13 neurons tested. The effects of Compound A were compared with the clinically available sodium channel antagonist mexilitine (100μM). Mexilitine reduced Aδ fiber amplitudes by 71.8 ± 13.9% (n=5) and C fiber responses by 83.4 ± 14.5% (n=5). In summary, we have shown that Compound A, a sodium channel antagonist with selectivity against Nav1.7, is capable of modulating excitatory synaptic transmission within the dorsal horn.

Title: Sodium channel β4 auxiliary subunit (Scn4b) controls spike-timing-dependent plasticity in core nucleus accumbens medium spiny neurons

Authors: X. JI[1], *G. E. MARTIN[2];
[1]Psychiatry, UMass Med. Sch., Worcester, MA; [2]UMass Med. Sch., WORCESTER, MA

Abstract: Alcoholism is the most widespread and costly form of drug addiction in the world. A number of studies have identified genes whose expression is associated with a greater propensity to drink alcohol in mice and rats. However, there is currently very little information regarding their functional role in brain regions that are directly responsible for dependence to the drug. In the core nucleus accumbens, known for its key role in drug addiction and reward, we

investigated the role of Scn4b, one of the four currently known sodium channel auxiliary subunits. Recent works reported that Scn4b expression is correlated with high alcohol-drinking intake in mice and rats. In a previous study in the same brain region, we explored spike-timing-dependent plasticity (STDP), a stimulation paradigm widely used to study synaptic plasticity and to evoke both long-term potentiation (tLTP) and long-term depression (tLTD). Surprisingly, we showed that tLTP depended on NMDA receptors, while tLTD relied on action potentials only. Indeed, blockade or alterations of action potential properties selectively and robustly inhibited LTD, but left LTP intact. Therefore, we hypothesized that alterations of Scn4b expression similarly and specifically targeted tLTD. In C57Bl/6 mice accumbens medium spiny neurons, we knocked down Scn4b expression using lentivirus Scn4b shRNA injected bilaterally. Two weeks after injections, we compared synaptic plasticity in these mice with those injected with the virus only, or with control (non-injected) animals. We found that injection of the virus alone had little effects on both tLTP and tLTD as amplitude and ratio were similar to that of control mice. In contrast, in neurons transfected with shRNA, tLTD amplitude was strongly reduced. Importantly, we showed that the ratio tLTP/tLTD was markedly shifted towards tLTP. Our study shows for the first time the selective role of sodium channel auxiliary subunit in synaptic plasticity and tLTD. Additional studies are needed to further establish the relationship between Scn4b expression, tLTD, and excessive drinking.

Title: Nav1.7 inhibitory peptide from tarantula venom

Authors: *B. D. MOYER[1], D. LIU[1], J. LIGUTTI[1], A. ZOU[1], J. K. MURRAY[2], L. P. MIRANDA[2], S. I. MCDONOUGH[3];
[1]Neurosci., [2]Peptide Chem., Amgen, Thousand Oaks, CA; [3]Amgen, San Francisco, CA

Abstract: Peptides isolated from animal venom have been useful tools for determining ion channel function, structure, and gating. In screening for novel inhibitors of the voltage-gated sodium channel Nav1.7, venom collected from the Chilean rose tarantula (*Grammastola porteri*) was fractionated and an active peptide, termed GpTx-1, was identified. GpTx-1 is a member of the inhibitory cysteine knot family of peptide toxins that includes HwTx-IV and ProTx-II.

Characterized with patch-clamp electrophysiology, GpTx-1 rapidly and reversibly inhibited human Nav1.7 with an IC50 ~ 10 nM. GpTx-1 inhibition was partially relieved by strong depolarizations delivered at high frequency, suggesting that GpTx-1 binding reduces Nav1.7 sensitivity to voltage and that GpTx-1 has lower affinity for channel open states. GpTx-1 was not more potent when tested on channels with 20% fractional inactivation, suggesting most prominent binding to closed channels. GpTx-1 also inhibited human Nav1.3 (IC50 ~ 40 nM) and human Nav1.4 (IC50 ~200 nM) but was more selective over human Nav1.5 (IC50 > 5 uM). GpTx-1 rapidly and reversibly inhibited endogenous tetrodotoxin-sensitive (TTX-S) sodium channel currents recorded from acutely dissociated mouse dorsal root ganglion sensory neurons with an IC50 ~ 5 nM. In summary, GpTx-1 peptide, identified from tarantula venom, is a potent human Nav1.7 inhibitor that is selective over the cardiac (Nav1.5) Nav isoform.

Title: Co-expression of β-subunits with α-subunits modify the conotoxin-susceptibilities of voltage-gated sodium channels

Authors: M.-M. ZHANG[1], L. AZAM[1], J. GAJEWIAK[1], J. IMPERIAL[1], G. BULAJ[2], B. M. OLIVERA[1], *D. YOSHIKAMI[1];
[1]Biol., [2]Medicinal Chem., Univ. Utah, Salt Lake City, UT

Abstract: Four families of conotoxins have been identified thus far that target voltage-gated sodium channels. Each family has a distinct mechanism of action: μ-conotoxins are pore blockers, μO-conotoxins block channel activation, ι-conotoxins promote channel activation, and δ-conotoxins block channel inactivation. We are examining the influence of Na_Vβ-subunits on the activities of conotoxins by seeing how co-expression of rat Na_Vβ1- through β4-subunits affect the conotoxin-susceptibilites of various rat Na_V1- (or α-) subunits exogenously expressed in *X. laevis* oocytes. We previously reported that co-expression of β-subunits modified the kinetics and voltage-sensitivity of the block of Na_V1.8 by μO-conotoxin MrVIB (Wilson, M. J., et al. 2011. J Pharmacol Exp Ther, 338, 687). More recently, we reported that co-expression of β-subunits altered the kinetics of the block of Na_V1.1, 1.2, 1.6 and 1.7 by μ-conotoxins (principally, μ-TIIIA, μ-PIIIA and μ-SmIIIA); in general, co-expression with either β1 or β3 increased the k_{on} of block whereas co-expression of either β2 or β4 decreased the k_{on} (Zhang, M.-M., et al. 2013 Brit J Pharmacol 168, 1597). We used these results, in part, to help identify the likely Na_V1-isoforms that are functionally expressed on the soma of small and large neurons acutely dissociated from adult rat dorsal root ganglia (DRG) (Zhang, M.-M., et al. 2013 Brit J Pharmacol 169, 102). A major distinguishing feature between β1 or β3 and β2 or β4 is that β2 and β4 are each covalently linked with its associated α-subunit via a disulfide bond, whereas β1and β3 are non-covalently associated with their α-subunit counterparts (Catterall, W. A. 2012 J Physiol 590**,** 2577; Chen, C., et al. 2012 J Biol Chem 287, 39061). Preliminary analyses suggest that the kinetics of the onset of block by μ-SmIIIA of putative Na_V1.7 currents in large DRG neurons are slower than those in small DRG neurons; we are examining this further and suggest that the disparity in kinetics reflects differences in the β-subunits associated with Na_V1.7. Our experience suggests that it should be rewarding to study the effects of β-subunit co-expression on other Na channel ligands; appropriate ones may help in assessing the β-subunit composition of Na channels as well as interactions between α- and β-subunits. Furthermore, knowledge of the pharmacological consequences of β-subunit co-expression may aid in the design of drugs that target Na channels.

Title: Use dependent spike shape changes in peripheral cutaneous unmyelinated fibers do not rely on Nav1.8 or Nav1.9

Authors: T. HOFFMANN, K. KISTNER, S. K. SAUER, P. REEH, *C. WEIDNER;
Dept. of Physiol. 1, Univ. of Erlangen, Erlangen, Germany

Abstract: Ionic currents produced during the course of action potential (AP) propagation can be translated into measurable voltage differences, to yield specific waveforms. The shape and size of these waveforms represent biophysical qualities of the cell membrane. It has previously been shown that in rodent DRGs, various voltage dependent currents such as potassium, Ih, TTXs and TTXr sodium currents contribute to the shaping of an AP. Accordingly, both a depolarized membrane potential as well as maintained cell stimulation result in reduction of the AP amplitude and a parallel decrease in conduction velocity (Harty TP et al. 2007, Soleng AF et al. 2003, Blair NT et al. 2003), presumably due to use dependence depletion of sodium influx. Using electrophysiological recordings of single unmyelinated (C) cutaneous fibers and C-fiber compound action potential (CAP) measurements, we evaluated the use dependent waveform changes in mouse peripheral nerves, and the contribution of the TTXr sodium channels Nav1.8 and Nav1.9 to these changes. Nerves from C57Bl6, Nav1.8 KO and Nav1.9 KO mice were electrically stimulated using a single pulse at 2Hz (for CAP experiments) or double pulses at 2Hz (20ms intrastimulus intervals; for single fiber experiments).The induced AP waveforms were divided into several rise/fall sections and for each section, amplitude (i.e., height) as well as duration (i.e., width) were determined.
In all three mice strains, iterative electrical stimulation led to prominent changes in spike waveform. After 120 seconds, the amplitude in both single fibers- and CAP-experiments diminished.
In addition to a reduction in spike amplitudes, waveforms also showed activity dependent increase in spike duration. Waveform changes for all sections were comparable in all three mouse strains.
Upon repetitive electrical stimulation of nerve fibers, slowing of conduction velocity is encountered. This translates into latency shifts and is presumably due to slow inactivation of sodium channels (Carr RW et al. 2008). Accordingly, the electrical protocol used in our study

lead to progressive latency shifts which were comparable in all three mouse strains.
We conclude that in peripheral unmyelinated nerves use dependent waveform changes are neither Nav1.8 nor Nav1.9 dependent.

Maastricht, Maastricht, Netherlands; [5]Dept. of Neurol., Spaarne Hosp., Hoofddorp, Netherlands

Abstract: Idiopathic small-fiber neuropathy (I-SFN), clinically characterized by burning pain in distal extremities and autonomic dysfunction, is a disorder of small caliber nerve fibers, unknown etiology with limited treatment options. Recently, functional variants of the peripheral voltage-gated sodium channel $Na_v1.7$, encoded by *SCN9A*, were identified in about one-third of I-SFN patients. These variants were shown to render dorsal root ganglion (DRG) neurons hyperexcitable. Like $Na_v1.7$, sodium channel $Na_v1.8$, encoded by *SCN10A*, is preferentially expressed in small-diameter DRG neurons, and has been shown to be responsible for most of the transmembrane current underlying the upstroke of action potentials in these neurons. We previously demonstrated functional variants of $Na_v1.8$ that either enhance ramp current or shift

activation in a hyperpolarizing direction, and render DRG neurons hyperexcitable in several I-SFN patients with no mutations of *SCN9A*. We have now evaluated additional I-SFN patients with no mutations in *SCN9A*, by sequencing *SCN10A*. We have identified a novel I-SFN related $Na_v1.8$ mutant and tested it functionally using whole-cell voltage-clamp and current-clamp recordings in small DRG neurons. Compared to the wild-type, mutant channels show a significant hyperpolarizing shift in $V_{1/2}$ of activation and in the voltage for the peak ramp current. The mutation does not affect the $V_{1/2}$ or slope factor of steady-state fast inactivation, but it decreases the percentage of non-inactivating channels, probably associated with a smaller persistent current. Current-clamp studies reveal that the mutation negatively shifts the voltage threshold of action potential and depolarizes the resting membrane potential, and reduces the current threshold and increases the firing frequency of evoked action potentials. These observations suggest that the effects on activation and ramp current are dominant over the reduced persistent current amplitude, and these pro-excitatory gating changes confer hyperexcitability on peripheral sensory neurons, which may contribute to pain in this individual with I-SFN.

Title: Lacosamide modulation of the voltage-gated sodium channel $Na_v1.1$

Authors: D. H. FELDMAN[1], S. S. SHAHANGIAN[1], S. HIROSE[2], M. A. ROGAWSKI[1], *C. LOSSIN[1];
[1]Neurol., UC Davis - Sch. of Med., Sacramento, CA; [2]Pediatrics, Fukuoka Univ. – Sch. of Med., Fukuoka, Japan

Abstract: Lacosamide is a new generation anticonvulsant drug targeting voltage-gated sodium (Na_v) channels. Its mode of action is unique in that it primarily blocks Nav channels under high-frequency firing conditions while maintaining the normal physiological activity of the channels. This is possible through selective enhancement of Na_v channel slow inactivation, a state entered

mainly when the channels are stimulated for prolonged periods of time. Biophysical characterizations of lacosamide blockade are now available for several Na_v channel isoforms. However, the effects on one particularly important player in epilepsy, $Na_v1.1$, remain unknown. Variations in the $Na_v1.1$ gene, *SCN1A*, lead to several types of febrile seizures, including those where status epilepticus is a hallmark component of the presentation. To get a more complete understanding of lacosamide's mechanism of action, we subjected heterologously expressed $Na_v1.1$ to various lacosamide concentrations. Consistent with previous reports, we found a hyperpolarizing shift in the voltage-dependence of slow inactivation, reducing $Na_v1.1$ activity at less depolarized potentials compared to when the drug is absent. We furthermore observed a shift in the onset of slow inactivation, which makes $Na_v1.1$ enter slow inactivation more readily when lacosamide is present. Use dependence of the channel was clearly enhanced, particularly at higher frequencies.

Title: Tctx2 and Tctx3 : Tityus caripitensis toxins with effect over Nav1.4 channels

Authors: *Y. D. HERNANDEZ ESTEVEZ[1,2], C. CASTILLO[1];
[1]Fundacion Inst. De Estudios Avanzados, Caracas, Venezuela, Bolivarian Republic of;
[2]Postgrado en Ciencias Biologicas, Univ. Simon Bolivar, Caracas, Venezuela, Bolivarian Republic of

Abstract: Scorpion venoms are a rich mixture of compounds and had been broadly studied as a source of peptides known as toxins. These toxins have effect over sodium, potassium, calcium

and chloride voltage gated channels. Toxins that affect sodium channels have 60-76 amino acids and are stabilized by four disulfide bridges. They have been traditionally classified in two groups: alpha-toxins and beta-toxins, both are structural and functionally different. In one hand, alpha-toxins bind to site 3 of sodium channel and modify the inactivation kinetic of sodium channels maintaining the channels open. On the other hand, beta-toxins bind to site 4 and modified activation kinetic by shifting the voltage dependence of activation to more negative potentials, induce repetitive and spurious firing of action potentials and reduce the peak conductance. One of the species related with scorpionism accidents in Northeastern Venezuela is *Tityus caripitensis*. The venom of *Tityus caripitensis* was fractionated using SE-HPLC on a Protein Pak 60 column. The most abundant fraction was further separated by RP-HPLC on an analytical C18 column and the fractions named Tctx2 and Tctx3 were upon a refined RP-HPLC yielded pure peptides. We determined their molecular weight by MALDI-TOF (mode reflector) of 7702 and 7683 Da respectively. Finally, we use whole cell clamp to evaluate the effect of both toxins over Nav1.4 channels expressed in HEK293 cells. We found that in the presence of 130nM of Tctx2 the conductance of the Nav1.4 channel decreased 45% while in presence of 130nM of Tctx3 the conductance is decreased by 69%. The midpoint potential of the steady state activation curve were shifted to the left by 10mV ± 1.4 in presence of Tctx2 (n=3) and by 8mV ± 1.2 in presence of Tctx3 (n=3). Tctx2 and Tctx3 are the first beta-toxins isolated from *Tityus caripitensis* venom.

Title: Functional regulation of the Nav1.2 channel by glycogen synthase kinase 3

Authors: *T. F. JAMES[1], J. LUISI[2], M. N. NENOV[2], N. PANOVA[2], F. LAEZZA[2];
[2]Pharmacol. and Toxicology, [1]Univ. of Texas Med. Br., Galveston, TX

Abstract: Dysregulation of glycogen synthase kinase 3β (GSK3β) has been associated with several disorders, including Alzheimer's disease, addiction, and mood disorders and may be fundamentally linked to disorders of excitability in brain circuits. We hypothesized that a critical link between GSK3β and brain disorders may arise from regulation of voltage-gated sodium

(Na_v) channels that are critical molecular determinants of neuronal excitability. To test this hypothesis, we used patch clamp electrophysiology to record sodium currents from $Na_v1.2$ channels stably expressed in HEK293 cells. We found that pharmacological inhibition of GSK3 with GSK3 inhibitor XIII potentiated the peak current density of $Na_v1.2$ from -56.91 ± 10.60 pA/pF (0.05% DMSO; n=10) to -115.44 ± 17.51 pA/pF (10 µM GSK3 inhibitor XIII; n=14, p=0.01) and shifted V1/2 of the voltage dependence of steady-state inactivation from -63.79 ± 2.05 mV (n=9) to -54.14 ± 0.67 mV (n=15, p=0.001). To explore the notion that GSK3 may modulate the expression level of these channels, we used confocal microscopy to analyze the $Na_v1.2$ protein expression within the cell. Our results indicate that exposure to GSK3 inhibitor XIII induced a significant increase in $Na_v1.2$ channel expression when compared to findings following DMSO treatment (n>80 cells, p<0.0001). Additional confocal studies were performed to analyze the cell surface expression of a CD4 chimeric construct expressing the C-terminal tail of the $Na_v1.2$ channel (CD4-$Na_v1.2$-C-tail) in DMSO versus GSK3 inhibitor XIII. Phenotypic changes in fluorescence intensity distributions relative to surface labeling between the two groups indicate that inhibition of GSK3 might affect membrane trafficking of the $Na_v1.2$ channel through its C-terminal tail. Taken together, these findings indicate that GSK3 modulates pathways affecting Na_v channel expression and function, broadening the repertoire of possible targets for future therapeutic interventions against its associated disorders.

Title: Regulation of the Nav1.6 channel by glycogen synthase kinase 3 (GSK3)

Authors: *M. N. NENOV, N. I. PANOVA, F. LAEZZA;
Dept. of Pharmacol. and Toxicology, The Univ. of Texas Med. Br., Galveston, TX

Abstract: GSK3 is an evolutionarily conserved ubiquitous kinase known to control normal brain function through an intricate network of intracellular signaling pathways. Evidence indicates that dysfunctional activity of this kinase correlates with psychiatric disorders, addictive behaviors, and neurodegenerative diseases. However, the detailed mechanisms of GSK3 action on neuronal

functioning are still poorly understood. Exciting new evidence indicates that neuronal ion channels are new promising targets of this enzyme. In support of this, we recently demonstrated that inhibition of GSK3 reduces the assembly of the voltage-gated sodium channel Nav1.6 with its regulatory protein, the fibroblast growth factor 14 (FGF14), modifying FGF14-dependent regulation of Nav1.6 currents (Shavkunov et al., J Biol Chem., 2013 in press). Building on these results, we posited that GSK3 might also exert a direct action on the Nav1.6 channel in the absence of any regulatory proteins. To test this hypothesis we applied whole-cell patch-clamp to record sodium currents from HEK293 cells stably expressing human Nav1.6 channels. Our results indicate that pharmacological inhibition of GSK3 (GSK3 inhibitor XIII, 30 uM) induces a significant reduction ($p<0.05$) of Nav1.6 peak current density (-29.3±3.9 pA/pF, n=8) compared to control (-47.2± 6.5 pA/pF, n=8). Furthermore, we show that inhibition of GSK3 produces a significant shift ($P<0,005$) in the steady-state inactivation of the Nav1.6 channel (-68.9±1.7, n=6) compared to control (-58.8±1.6, n=7,) without apparent changes in the voltage-dependence of activation. Taken together, these findings provide evidence for a complex role of GSK3 on neuronal Nav channels which is expected to greatly impact neuronal excitability in brain circuits.

Title: Lacosamide inhibition of Nav1.7 voltage-gated sodium channels: Binding to fast-inactivated versus slow-inactivated states

Authors: *S. JO, B. BEAN;
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Lacosamide (Vimpat) is an anti-epileptic agent that appears to be targeted to voltage-dependent sodium channels. Previous experiments suggested that lacosamide is unusual in having selective binding to the slow-inactivated state of sodium channels, in contrast to other anti-epileptic drugs that bind tightly to fast-inactivated states of the channel. We examined the

state-dependent effects of lacosamide on human Nav1.7 sodium channels, studied in a stable cell line. In agreement with previous results, inhibition by lacosamide was highly voltage-dependent. 100 μM lacosamide inhibited sodium current elicited from a holding potential of -120 mV by 3 ± 1%, current elicited from -80 mV by 43 ± 4%, and current elicited from -70 mV by 61 ± 1%. However, in contrast to previous results, we found that lacosamide induced a reversible shift in the voltage-dependence of fast-inactivation studied with 100 ms prepulses, suggesting that the compound can bind tightly to fast-inactivated as well as slow-inactivated states. To explore this issue further, we used a protocol examining the rate of entry of channels into slowly-recovering states at either -40 mV, where fast-inactivation is complete but slow-inactivation is not, or 0 mV, where slow-inactivation is maximal. At -40 mV, in control 24 ± 4% of channels entered slowly-recovering states after 16 seconds, and this was increased substantially to 49 ± 5% of channels in the presence of 100 μM lacosamide. At 0 mV, in control 48 ± 4% of channels entered slowly-recovering states after 16 seconds, and this was increased relatively little, to 52 ± 7% of channels, in the presence of 100 μM lacosamide. The results of these and other experiments seem more compatible with lacosamide binding slowly to fast-inactivated states (and possibly also to slow-inactivated states) than with exclusive binding to slow-inactivated states. Comparisons to carbamazepine (fast binding to fast-inactivated states), phenytoin (slow binding to fast-inactivated states) and brilliant blue G (binding to both fast-and slow-inactivated states) will be presented.

Title: Conserved functional impact of alternative splicing in domain 1 of neuronal sodium channels

Authors: A. LIAVAS, *S. SCHORGE;
Clin. and Exptl. Epilepsy, UCL Inst. of Neurol., London, United Kingdom

Abstract: A conserved splicing event in sodium channel genes gives rise to two alternative splice variants, the so-called neonatal (N) and adult (A) forms. This splicing may have clinical impact, as a polymorphism in the SCN1A gene that modifies the consensus sequence of the neonatal exon (5N) has been linked to altered seizure predisposition or to altered anti-epileptic drug (AED) dosage in epileptic patients; however these associations have not been replicated in all populations. The functional impact of the splicing has not been systematically compared in different channel backgrounds. We asked whether the functional effects seen in NaV1.1 channels, which are thought to dominate in interneurons of the CNS, can be replicated by splice variants of NaV1.7 channels, which are important in peripheral pain-sensing neurons.
Previously we reported that heterologously expressed NaV1.1-5N channels in HEK cells recover more quickly from fast inactivation than NaV1.1-5A channels. Here, we use similar whole cell patch clamp recordings to characterize the conditions that maximise this difference. Recovery rate is influenced by temperature, voltage, duration of the gap between the first (P1) and recovery (P2) depolarizing steps, and by the length of the first depolarising step (P1). The difference between splice variants seems to be most robust at physiological temperature, with short P1 intervals, and short gap durations. Furthermore, the difference is augmented by consecutive rapid pulse protocols that are consistent with the sort of fast neuronal activity that might occur during epileptic events. In contrast, the difference between splice variants is masked by prolonged depolarizing P1 steps or by recovery intervals longer than 200ms. To test whether the functional impact of the conserved splicing event is also conserved, we expressed the closely-related NaV1.7-5A and NaV1.7-5N splice variants. We found that although NaV1.7 shows a more depolarised voltage-dependence of inactivation than NaV1.1, the splice variants of NaV1.7 preserved the difference in recovery from inactivation seen for variants of NaV1.1, with the neonatal variant recovering more quickly in these channels after a range of depolarizing pre-pulses.
Our data indicate that, in NaV channels, a molecular conservation of splicing between channel subtypes may lead to a conserved functional change across channel subtypes. Moreover, splicing may have its biggest impact on inactivation in conditions that could mimic rapid firing patterns, such as fast activity during a seizure or in interneurons.

Title: Inhibitory excitability effect by terpinen-4-ol is related to both blocked sodium and potassium voltage-gated channels in small dissociated dorsal root ganglia neurons

Authors: *T. SANTOS-NASCIMENTO, K. MORAIS VERAS, L. MOREIRA-JUNIOR, J. LEAL-CARDOSO;
State Univ. of Ceara, Fortaleza, Brazil

Abstract: Terpinen-4-ol (4TERP) is a monoterpenoid with extensive commercial use, with several pharmacological activities and with potential therapeutic interest, including depressant effects on the nervous system. The present study investigated whether 4TERP alters neuronal excitability through effects on both Na+ (INa) and K+ (IK) voltage-gated currents in neurossoma of dorsal root ganglia (DRG). We used preparations of intact and dissociated neurons of rat DRG for intracellular and patch-clamp recordings. At 6 mM, 4TERP blocked the generation of action potentials (AP) and depolarized ≈ 6 mV (n=7) of resting potential (control -59.09 ± 2.27 mV; 4TERP -53.19 ± 2.28 mV) of neurons of intact DRG. At 1 mM, 4TERP decreased rising (dV/dt)max and increased AP duration. In dissociated neurons, 4TERP inhibited ≈ 50% total INa (IC50 was 0.8 ± 0.3 mM) and ≈ 20% TTX resistant INa (IC50 was 300 ± 300 μM). 4TERP also inhibited ≈ 60% of two 4-aminopiridin sensitive K+ current: the transient (Ia, IC50 was 3.2 ± 0.0 mM) and steady (Id, IC50 was 700 ± 100 μM). 4TERP also inhibited ≈ 85% of steady TEA sensitive K+ current (Ik, IC50 was 1.6 ± 0.7 mM). 4TERP shift to the right the activation curve and did not alter inactivation curve of the all currents tested. In conclusion, we demonstrated that 4TERP blocks neuronal excitation and its effect on Na+ and K+ currents is coherent with its activity on nervous excitability. This effect of 4TERP on currents is relevant to the explanation of several other effects of 4TERP reported on the literature.

Title: A-type fibroblast growth factor homologous factors function as open channel blockers to modulate voltage-gated sodium channel availability

Authors: *Y. LIU, M. GOLDFARB;
Hunter College, City Univ. of New York, New York, NY

Abstract: Action potential generation is controlled by the opening, inactivation, and recovery of voltage-gated sodium channels (Na_V). A-type fibroblast growth factor homologous factors (A-type FHFs), which are cytosolic Na_V binding proteins, mediate rapid-onset, long-term inactivation (LTI) of Na_V by contributing an independent inactivation particle that competes with the Na_V intrinsic fast inactivation mechanism (Dover et al., J. Physiol. 588:3695; 2010). To further explore the structural mechanism of A-type FHF induced LTI of Na_V, we have performed cotransfection of wild-type and mutant FHF2A expression plasmids together with wild-type and mutagenized TTX-resistant Nav1.6 and Nav1.5 expression plasmids into Neuro2A cells, and have analyzed TTX-resistant sodium currents through various whole cell voltage clamp protocols. Our results demonstrate that LTI induced by FHF2A only occurs when the channels reach the open state. FHF2A can compete for binding to channels with another open channel blocking protein, Na_V[[Unsupported Character - Symbol Font ]]4, which is responsible for resurgent sodium current due to its rapid dissociation from channel upon repolarization. Both FHF2A and Na_V[[Unsupported Character - Symbol Font ]]4 blocking particles rely upon hydrophobic and basic residues, suggesting they may share a common binding surface within Na_V's cytoplasmic cavern exposed in the open state. However, FHF2A dissociates much more slowly from channels than does Na_V[[Unsupported Character - Symbol Font ]]4, accounting for their functional dissimilarity. Ongoing channel mutagenesis seeks to reveal channel binding sites for each of these blocking particles. In summary, our studies show that A-type FHFs serve as open sodium channel blockers, in competition with both the Na_V intrinsic fast inactivation mechanism and the accessory subunit Na_V[[Unsupported Character - Symbol Font ]]4, to drive channels into a long-term refractory state.

Title: Gating properties of somatic voltage-gated sodium currents in layer 4 primary cells and interneurons of the somatosensory cortex

Authors: *Y. MA[1], M. GUTNICK[2], D. PRINCE[1], J. HUGUENARD[1];
[1]Stanford Univ., Stanford, CA; [2]The Hebrew Univ. of Jerusalem, Rehovot, Israel

Abstract: In somatosensory cortex, neurons of Layer 4 are the primary recipients of thalamocortical input. Because somatic Na^+ channels play a pivotal role in regulating membrane and cellular excitability, study of their kinetic properties and functions is important for understanding thalamocortical information processing. Using the nucleated patch clamp recording technique in acute cortical slices, we have quantified the kinetics of somatic Na^+ channels in identified regular-spiking excitatory (RS) cells, fast-spiking (FS) inhibitory cells, and somatostatin-containing (SOM) inhibitory cells. We now describe our data in terms of the classical Hodgkin-Huxley formalism. Because voltage-dependence of transfer rates for channel opening (α) and closing (β) are the two fundamental factors determining the channel behavior as a function of voltage and time, we optimized the equations to describe α and β as a function of voltage for each of the cell types, and constructed steady state activation (m_∞) and inactivation (h_∞) curves. curves. Activation kinetics were similar for all three cell types, while the h_∞ curve was slightly right-shifted in FS interneurons, and markedly right shifted in SOM cells. Thus, the SOM cells had a significantly greater window current ($m_\infty^3 * h_\infty$). The higher steady state Na^+ channel open probability near resting potential suggests that the excitability of layer 4 SOM cells at subthreshold voltages is tightly regulated by voltage-gated Na^+ currents.

Title: Acid-sensing ion channels in NS20Y cells - potential role in neuronal differentiation

Authors: Z. O'BRYANT, T. LENG, K. INOUE, Z. ZENG, *Z.-G. XIONG;
Neurosci. Inst., Morehouse Sch. of Med., Atlanta, GA

Abstract: Cultured neuronal cell lines can express many properties of mature neurons if properly differentiated. Although the precise mechanisms underlying neuronal differentiation are not fully understood, expression and activation of ion channels, particularly Ca^{2+}-permeable channels, have been suggested to play an important role in the process. NS20Y, a neuronal cell line derived from the mouse neuroblastoma, has been used as an *in vitro* model for the study of neuronal differentiation. However, there has been a lack of extensive characterization of the expression and properties of various ion channels in these cells. Using patch-clamp recording and RT-PCR technique, we explored the existence of acid-sensing ion channels (ASICs), a novel family of proton-gated cation channels, in NS20Y cells. Fast drops of extracellular pH activated transient inward currents with a $pH_{0.5}$ at ~6.0. Currents in NS20Y cells were blocked by amiloride, a non-selective ASIC blocker, and PcTX1, a specific inhibitor for homomeric ASIC1a and heteromeric ASIC1a/2b channels. RT-PCR demonstrated the existence of ASIC1a transcript in these cells. Other pharmacological characteristic such as potentiation by zinc chelation also supports the presence of functional homomeric ASIC1a channels. Potential function of ASIC1a channels in the growth and differentiation of NS20Y cells is under investigation.

Title: Bace 1 regulates the voltage gated sodium channel Nav 1.7

Authors: X. REZAI, V. CURTO-REYES, *I. DECOSTERD;
CHUV and Lausanne Univ., Lausanne, Switzerland

Abstract: Voltage gated sodium channels (Nav) are responsible for the generation and transmission of action potential. In dorsal root ganglion neurons, the alpha subunit Nav 1.7 is crucial for the transmission of nociceptive information. Following nerve injury, Nav 1.7 expression is altered, a process that has been associated with the development of neuropathic pain. We demonstrated previously an important regulatory role the auxiliary beta subunits in the dysregulation of Nav channel expression during neuropathic pain. In addition, it has been shown that beta subunits can be cleaved by BACE1, a beta-secretase best known for cleaving APP in the context of Alzheimer's disease, thereby regulating the amount of channel expressed and stabilized at the plasma membrane but also directly modulating Nav channel properties.
Here, we co-expressed human BACE1, Nav 1.7 and different beta subunits in HEK cells. BACE1 mutants with and without catalytic site have also been used. Western blots and whole cell electrophysiological recording of sodium currents were performed to study modification of Nav 1.7 expression and current carrying properties induced by the presence of BACE1, alone or in presence of beta subunits.
Results show that Nav 1.7 current carrying properties are modified in the presence of BACE1, a process that seems to be independent from the ability of the enzyme to cleave the beta subunits. Nav 1.7 total protein level was not modified in the presence of BACE1 alone or co-expressed with the Beta2 subunit. We are carrying now cell biotinylation in order to quantify Nav1.7 expression at the plasma membrane.
Overall our results suggest that Nav 1.7 properties are regulated by BACE1. Our future experiments will determine if this regulation is relevant in the context of neuropathic pain. This highlights a potential therapeutical interest in parallel to the tremendous effort spent to develop specific sodium channel blockers.

Title: Resolving the transport kinetics of the corticosterone-sensitive organic cation transporter 3 (OCT3/Slc22a3) in the male rat brain

Authors: *J. S. TALBOOM[1,2], J. MOLINARO[1], C. A. LOWRY[3], K. J. RENNER[4], M. ORCHINIK1[1];
[1]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [2]Arizona Alzheimer's Consortium, Phoenix, AZ; [3]Dept. of Integrative Physiol., Univ. of Colorado Boulder, Boulder, CO; [4]Dept. of Biol., Univ. of South Dakota, Vermillion, SD

Abstract: The organic cation transporter 3 (OCT3/Slc22a3) is a low affinity and high capacity polyspecific monoamine transporter found in the human and rodent brain. OCT3 is thought to clear monoamines (e.g., serotonin, norepinephrine, & dopamine) from extracellular fluid in the brain, thereby helping to terminate their signal after release. OCT3 may complement other specific (e.g., SERT, DAT, & NET) or polyspecific (e.g., PMAT, OCT1, & OCT2) transporters in regions of the brain that are innervated by monoaminergic terminals. OCT3 is a unique transporter in that it is the only known monoamine transporter inhibited by physiological levels of corticosterone (CORT) in the rat. Among other stress-related neural processes, CORT-mediated inhibition of OCT3 may modulate the hypothalamic-pituitary-adrenocortical (HPA) axis via alterations in monoaminergic neurotransmission. We hypothesize that OCT3 functions in brain regions regulating the HPA axis to increase extracellular monoamine concentrations during the acute stress response. Previous studies determining the transport kinetics of OCT3 have been contradictory. Data collected from a cell line expressing OCT3, as compared to tissue minces of the rat hypothalamus, suggested a several fold difference in the potency of CORT to inhibit OCT3-mediated transport. We set out to resolve these conflicting reports and confirm that physiological levels of CORT can inhibit OCT3-mediated transport in intact brain sections. To accomplish this, we quantified the uptake of 4-(4-dimethylaminostyryl)-N-methylpyridinium (ASP^+), a fluorescent organic cation, in live ciliated ependymal cells lining the ventral third cerebral ventricle (V3V). Three hundred μm live brain sections from male Sprague Dawley® rats (~250 g), containing the V3V (adjacent to the dorsomedial hypothalamus), were collected in artificial cerebrospinal fluid equilibrated with O_2 and CO_2. Sections were placed in a perfusion chamber under the laser scan head of an Olympus confocal microscope equipped with a water immersion objective. ASP^+ was excited by a 488 nm Ar laser and optical sections were acquired; our dependent measure was the relative fluorescent intensity of the V3V ependymal cells across time. Separate brain sections from multiple animals were treated with different transporter inhibitor solutions in order to determine OCT3-mediated ASP^+ uptake. Iterative curve-fitting techniques were used to determine the transport kinetics of OCT3 as well as the IC_{50}s of the inhibitors. The results indicated a CORT-induced inhibition of OCT3-mediated ASP^+ uptake. Studies of this nature may lead to a better understanding of the function of OCT3 in the brain.

Title: The vesicular monoamine transporter 2 (VMAT2) as a mediator of vesicular function, neurotoxicity and behavior

Authors: *K. M. LOHR[1], A. I. BERNSTEIN[1], K. A. STOUT[1], A. R. LUCE[1], T. S. GUILLOT[1], M. WANG[1], Y. LI[1], A. SALAHPOUR[2], G. W. MILLER[1];
[1]Envrn. Hlth., Emory Univ., Atlanta, GA; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: The vesicular monoamine transporter 2 (VMAT2) is responsible for packaging monoamines into vesicles for rapid release at the synapse. In addition to its role in neurotransmission, VMAT2 is also responsible for sequestering toxicants away from their sites of action in the cell. Our lab has previously characterized mice with reduced vesicular capacity, which results in progressive degeneration of monoaminergic neurons and both motor and non-motor deficits (Caudle et al., JNS 27:8138, 2007; Taylor et al., JNS 29:8103, 2009). Despite ample evidence suggesting that decreased VMAT2 levels results in neuronal dysfunction, it was not known if an increase in VMAT2 level would result in increased function in an animal model. We created a BAC transgenic VMAT2 overexpressing (VMAT2HI) mouse line to determine the effects of increased vesicular monoamine filling on associated neurochemical, behavioral, and toxicological outcomes. Our findings using these VMAT2HI mice suggest that the increased vesicular storage mediated by increased VMAT2 levels can alter both the neurochemical and behavioral output of the monoaminergic system. In addition to increased vesicular uptake, VMAT2HI mice also show a 75% increase in locomotor activity during the active period and improved outcomes on measures of anxiety and depressive-like behaviors, including a 42% reduction in marble burying and a 22% decrease in immobility time on the forced swim test. Further, since VMAT2 serves as a neuroprotective mechanism in monoaminergic systems, our VMAT2 overexpressing mice also serve as a valuable tool to investigate resistance to both endogenous and exogenous toxicant exposure. Preliminary evidence suggests that VMAT2HI mice have reduced indices of cytosolic dopamine turnover in the striatum and cortex (as

indicated by the metabolite/transmitter ratio of DOPAC to DA by HPLC). Supported by NIEHS P01 ES016731, T32 ES012870, and T32 ND015040.

Title: Genetic manipulation of vesicular transport machinery mediates dopamine neurochemistry and release dynamics

Authors: *A. LUCE[1], K. M. LOHR[1], K. A. STOUT[1], A. I. BERNSTEIN[1], T. S. GUILLOT, III[1], T. S. GUILLOT, III[1], M. WANG[1], Y. LI[1], A. SALAHPOUR[3], G. W. MILLER[1,2]; [1]Envrn. Hlth., [2]Ctr. for Neurodegenerative Dis., Emory Univ., Atlanta, GA; [3]Pharmacol. and Toxicology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Proper vesicular function is critical for dopamine neuron health and integrity. The vesicular monoamine transporter 2 (VMAT2) is responsible for packaging monoamines such as dopamine into synaptic vesicles. This readies the synapse for rapid dopaminergic neurotransmission. Impairing function of the vesicle by reducing VMAT2 levels leads to an excess of cytosolic dopamine, which is toxic to the cell. This leads to dopaminergic degeneration and motor and nonmotor deficits in mouse models of VMAT2 underexpression, as characterized previously by our lab. These characteristics are similar to human Parkinson's disease, of which dopamine neurodegeneration and motor and nonmotor deficits are key components. Although there is ample evidence that impaired vesicular function resulting from VMAT2 deficiency leads to dopamine mishandling and cell death, the converse_enhanced vesicular function_had been previously unexplored. The current investigation explores the protective potential of overexpressing VMAT2. We utilize a bacterial artificial chromosome (BAC) transgenic mouse

model to overexpress VMAT2 (VMAT2HIs) and various outcome measures including radioactive vesicular uptake, ex vivo fast scan cyclic voltammetry and analysis of vesicular morphology by electron microscopy to determine the effect of VMAT2 overexpression on dopamine handling characteristics and neurochemistry. Results from these experiments indicate that enhanced vesicular function resulting from VMAT2 overexpression increases vesicular capacity for dopamine. First, we observed a 12% increase in average vesicular diameter in VMAT2HI animals, which corresponds to a 50% increase in vesicular volume. This larger vesicular capacity for dopamine is thought to underlie observed neurochemical changes. We found a two-fold increase in vesicular uptake of dopamine that is reversible by reserpine, as well as an increase in stimulated dopamine release by voltammetry. We hypothesize that this enhanced vesicular function confers resistance to endogenous and exogenous toxic insults.

Title: Dextroamphetamine induces reanimation from sevoflurane general anesthesia by enhancing dopaminergic neurotransmission

Authors: J. D. KENNY, E. N. BROWN, *K. SOLT;
Anesthesia, Critical Care and Pain Med., Massachusetts Gen. Hosp., Boston, MA

Abstract: BACKGROUND
Previous studies show that methylphenidate induces reanimation (i.e. active emergence) from general anesthesia in rodents. The objective of this study was to probe the relative contributions of dopaminergic vs. noradrenergic neurotransmission to reanimation from general anesthesia.
METHODS
Male Sprague-Dawley rats were anesthetized with sevoflurane, and an IV catheter was placed in

a lateral tail vein. The animals were placed supine in an anesthetizing chamber with a port for IV access. The dose of sevoflurane sufficient to maintain loss of righting was established and fixed prior to the administration of dextroamphetamine (n=6) or the selective norepinephrine transporter inhibitor atomoxetine (n=6). An additional group of rats with extradural EEG electrodes (n=3) received dextroamphetamine or atomoxetine during continuous sevoflurane general anesthesia, and spectrograms were computed from the EEG recordings.

RESULTS

During continuous sevoflurane general anesthesia, dextroamphetamine restored conscious behaviors including the righting reflex in a dose-dependent manner, whereas atomoxetine did not induce an arousal response. Pretreatment with the D1 dopamine receptor antagonist SCH-23390 greatly attenuated dextroamphetamine-induced arousal, and inhibited the return of righting in 5/6 rats. Spectrograms computed from EEG recordings revealed a prompt shift in peak power from delta (<4 Hz) to theta (4-8 Hz) after intravenous administration of dextroamphetamine or atomoxetine (Fig. 1).

CONCLUSIONS

Dextroamphetamine restores conscious behaviors including the righting reflex during continuous sevoflurane anesthesia. The primary mechanism of action is likely via activation of dopaminergic (rather than noradrenergic) arousal circuits. However, similar EEG changes were induced by dextroamphetamine and atomoxetine, suggesting that the shift in EEG power from delta to theta is mainly driven by noradrenergic stimulation. These findings suggest that dextroamphetamine may be clinically useful to restore consciousness in surgical patients.

Title: Regulation of noradrenaline transporter gene expression by nicotine

Authors: *N. SOGAWA, C. SOGAWA, K. OHYAMA, X.-F. WEN, D. YI, S. KITAYAMA; Dent. Pharmacol., Okayama Univ. Grad. Sch. Med. Dent. Pharmaceut. Sci., Okayama, Japan

Abstract: Nicotine, a major alkaloid constituent in tobacco, is a potent sympathomimetic stimulant, and is believed to be responsible for the pathogenesis of cardiovascular diseases associated with cigarette smoking. Nicotine increases sympathetic nerve and adrenomedullary activity, which underlies the pathogenesis of cardiovascular diseases associated with cigarette smoking. One possible target of nicotine is the reuptake system for catecholamines, such as noradrenaline transporter (NET). Uptake through the plasma membrane NET is the primary mechanism for regulating extracellular noradrenaline concentrations, and is, thus, a key player in controlling sympathetic nerve activity. NET belongs to the Na^+ and Cl^--dependent neurotransmitter transporter gene family, and is a target of various drugs acting on the central nervous system, including psychostimulants. However, there is little evidence for nicotinic modulation of the uptake system including NET. We investigated the effects of nicotine on NET expression in PC12 cells derived from rat pheochromocytoma, human neuroblastoma SK-N-SH cells, and rat tissues. Nicotine had no influence on the transcriptional activity of human NET gene constructs transiently transfected in SK-N-SH and PC12 cells. However, nicotine decreased NET mRNA levels within several hours in SK-N-SH cells. In contrast, nicotine up-regulated the mRNA and protein of NET in PC12 cells. A single administration of nicotine increased NET mRNA levels in the adrenal medulla and brain stem of the rat, whereas chronic nicotine treatment for 2 weeks decreased NET mRNA levels. These results suggest that nicotine up- and down-regulates the expression of NET through a posttranscriptional mechanism. The decrease in NET expression induced by nicotine may be of particular clinical relevance to the pharmacological action of nicotine.

Title: Noradrenergic axon terminals in the prefrontal cortex of mice heterozygous for the norepinephrine transporter show limited differences when compared to wild-type mice in plasmalemmal and cytoplasmic transporter localization and content of tyrosine hydroxylase

Authors: K. M. MARKLE[1], S. L. ERICKSON[1], *J. BALCITA-PEDICINO[1], M. K. HAHN[2], S. R. SESACK[1];
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Med. and Pharmacol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract:
Brainstem norepinephrine (NE) neurons that innervate the prefrontal cortex (PFC) modulate cognitive functions and attention. Malfunction of this NE projection contributes to depression and other disorders that are treated by blocking the NE transporter (NET). Interestingly, a mutation that fully knocks out the gene for NET results in neurochemical effects that mimic antidepressants. An important question is whether a heterozygous knockout (NET-het) similarly boosts NE levels by reducing NET protein on axonal membranes. The present study explored the ultrastructure of NE axons within the PFC of transgenic NET-het versus wild type (WT) mice. We hypothesized that NET-het mice would exhibit fewer NET-immunoreactive axons in the PFC as well as less total NET per profile. We expected these reductions to be accompanied by a redistribution of NET that preserved normal amounts of protein on the plasma membrane by drawing from the cytoplasm. We further hypothesized that detection of the rate-limiting synthetic enzyme tyrosine hydroxylase (TH) would increase in NE axons, particularly if normal plasmalemmal NET levels were not maintained. In a single cohort of 5 het and 5 WT mice, we examined PFC sections labeled by immunogold-silver for NET and found surprisingly no change in the density of labeled axons and no change in the distribution of NET to the membrane or cytoplasm. In adjacent sections double labeled for NET by gold and TH by immunoperoxidase, we similarly found no difference in the density of dually-labeled profiles. Within these axons, however, we found a significant reduction in the density of cytoplasmic gold for NET-het versus WT mice. There was no difference in the density of membrane gold, and so taken together, the proportion of total gold found on the plasma membrane was significantly increased for the NET-

het group. Finally, the percentage of NET-labeled axons that also exhibited TH was not different between NET-het and WT mice. These data suggest that PFC NE axons use homeostatic mechanisms (e.g. reduced NET degradation) to maintain normal levels of plasmalemmal NET regardless of whether total NET declines in each axon. The findings have important implications for understanding the capacity of the PFC NE system to adjust to partial loss of NET.

Title: Effects of serotonin transporter deletion on microglial function

Authors: *C. G. ALVARADO[1], Y. LIU[2], J. F. NEUMAIER[2], T. J. MONTINE[2], C. E. HAGAN[1];
[1]Univ. of Missouri, Columbia, MO; [2]Univ. of Washington, Seattle, WA

Abstract: The past several decades have seen an emergence of studies providing evidence that the pathogenesis of depression cannot be solely explained by the monoamine theory, which holds that this devastating disorder is the result of a deficit of brain monoamine neurotransmission. Inflammation has been raised as an alternate theory. Recent studies have demonstrated that antidepressants have an anti-inflammatory effect on some immune cells, suggesting a possible alternate mechanism of action for antidepressants. Specifically, studies have shown that selective serotonin reuptake inhibitors (SSRIs), which target the serotonin transporter (SERT), have anti-inflammatory effects on microglia, the primary innate immune cells of the central nervous system. While a microglial cell line has been reported to express SERT, studies exploring whether this expression occurs *in vivo* are lacking. Determining whether SERT expression occurs in microglia and its possible role in the anti-inflammatory effects of SSRIs would further our understanding of how inflammatory processes may be involved in the pathogenesis of depression and/or the mechanism of action of antidepressants.
To this end, a mouse line expressing yellow fluorescent protein under the SERT promoter was

used to investigate expression of SERT in microglia. Primary microglia from SERT knockout (KO) mice and wild type (WT) mice were also used to explore the role of SERT deletion and pharmacologic blockade on microglial inflammatory responses.
Preliminary findings include evidence of SERT expression *in vitro* by the co-expression of SERT and the microglial marker Iba1 in primary microglial cell cultures. Studies are currently underway to further evaluate under which conditions, if any, *in vivo* SERT expression occurs. In addition, pharmacologic studies evaluating multiple SSRIs are ongoing to determine whether the anti-inflammatory effects seen thus far are due to action at SERT, which may be expressed on microglia, or due to off-target effects.

Abstract: Compromised serotonin (5-HT, 5-hydroxytryptamine) signaling has been implicated in multiple neuropsychiatric and neurodevelopmental disorders including depression, obsessive-compulsive disorder (OCD), anxiety and autism. The presynaptic 5-HT transporter (SERT) is the primary mechanism of extracellular 5-HT inactivation and is a major target of antidepressant medications. In an effort to identify novel regulators of 5-HT signaling, we implemented proteomic and genetic paradigms, efforts that converged on the synaptic cell adhesion gene neuroligin 2 (Nlgn2). Whereas NLGN2 protein appears to coordinate GABA signaling in the

forebrain, our profiling of midbrain RNA expression in recombinant inbred mice revealed that Nlgn2 gene expression strongly correlated with the expression of multiple genes required for 5-HT identity and signaling, including Fev (PET-1), Tph2, and Slc6a4 (SERT). These results converged with proteomic and co-immunoprecipitation studies which showed that NLGN2 forms stable, midbrain-specific protein associations with SERT. These findings have led us to hypothesize that NLGN2 makes critical contributions to both 5-HT and GABA mediated regulation of raphe neurons via a somato-dendritic SERT/5-HT1A/NLGN2/GABAA receptor complex. Our preliminary data using constitutive NLGN2 KO mice demonstrate that NLGN2 is required to maintain normal 5-HT levels, normal SERT protein expression, and performance on tasks sensitive to antidepressants. NLGN2 KO mice also displayed social avoidance as they backed away more frequently when confronted by another mouse in tube test. Our findings on the essential roles of NLGN2 in 5-HT signaling may relate to the rare gene variants in NLGN2 identified from subjects with neuropsychiatric disorders and raises the possibility that psychiatric disorders traditionally associated with altered 5-HT signaling may in some cases originate from perturbation of cell-adhesion mechanisms linking 5-HT and GABA signaling in the midbrain.

Title: The role of ongoing versus early-life IL-1R/p38 MAPK signaling in raphe neurons in the enduring effects of early-life stress

Authors: *N. L. BAGANZ[1,2], L. J. HARBOM[1], J. T. SMITH[1], R. D. BLAKELY[1,2,3];
[1]Dept Pharmacol., [2]Silvio O. Conte Ctr. for Neurosci. Res., [3]Dept Psychiatry, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Depression is the primary cause of disability worldwide and has long been linked to alterations in serotonin (5-HT) signaling, as well as perturbed immune system function. We are pursuing the hypothesis that depression may represent an inappropriate expression of basic physiological processes normally organized to modulate behavior in the context of immune system activation. Supporting this concept, patients diagnosed with depression often display higher levels of proinflammatory cytokines, such as interleukin-1β (IL-1β). Moreover, peripheral administration of IL-1β and other inflammatory agents produces depressive-like effects on behavior in rodents and humans, effects that can be attenuated or eliminated with antidepressant medications. Despite these long-standing observations, the cellular and molecular pathways by which immune system activation alters behavior remain ill defined. We propose that one of these pathways involves immune system signaling to, and through, regulatory pathways that insure proper 5-HT signaling. A prominent control point for 5-HT signaling is the presynaptic, antidepressant-sensitive 5-HT transporter (SERT, *SLC64A*). SERT activity can be rapidly increased by IL-1 receptor (IL-1R) activation *in vitro* by IL-1β through a p38 MAPK-dependent pathway. Additionally, i.p. injection of lipopolysaccharide (LPS) rapidly enhances synaptosomal 5-HT transport and 5-HT clearance. Finally, LPS also produces a depressive-like effect on behavior as assessed in the tail suspension (TST) and forced swim tests (FST), effects that are absent in IL-1R KO mice. Since early-life stress is a risk factor for the development of mood disorders in adults, and in animal models produces changes in adult immune system activation, we have implemented a maternal separation (MS) model to investigate whether the ensuing anxiety and depressive behavior of adult animals is dependent on IL-1R function and also whether such signaling involves early or later life (or both) modulation of CNS 5-HT signaling. Here we provide evidence that the anxiety- and depressive-like effects of MS observed in older animals are lost in IL-1R KO mice. Ongoing studies with conditional, raphe-specific elimination of IL-1R and p38 MAPK seek to determine whether CNS 5-HT neurons provide a critical link between early-life stress, the immune system and risk for depression.

Title: Discovery of monoamine transporter ligands via virtual screening with the S1 substrate pocket of the serotonin transporter

Authors: L. M. GEFFERT[1], R. R. ROSS[1], T. L. NOLAN[1], B. J. KOLBER[2], J. D. MADURA[3], *C. K. SURRATT[1];
[1]Div. Pharmaceut. Sci., [2]Dept. Biol. Sci., [3]Dept. Chem. Biochem., Duquesne Univ., PITTSBURGH, PA

Abstract: The relatively recent elucidation of an x-ray crystal structure for LeuT, a leucine transporter and bacterial homolog of the mammalian solute carrier 6 (SLC6) family, was a major advance toward understanding the 3-D structure of plasmalemmal monoamine transporter (MAT) proteins. Using LeuT as a template, a credible 3D computational model of the human serotonin transporter (SERT) has been developed using Molecular Operating Environment (MOE) software. Ligand docking simulations with the model identified binding pockets consistent with the SERT S1 and S2 sites known to bind both substrates and inhibitors. Structure-based virtual screening (VS) of the PubChem small molecule structural database using MOE and the primary substrate (S1) SERT pocket yielded 19 “hit” compounds. In vitro pharmacologic testing of the VS hits revealed four structurally unique compounds that inhibited substrate transport and displayed nanomolar binding affinity K_i values for at least one of the three plasma membrane MATs. The four compounds were characterized in vivo using C57/BL mice via the tail suspension test (TST), a measure of acute depression/anxiety. Two of the compounds significantly decreased mouse TST immobility times at moderate doses, an outcome that suggests antidepressant/anxiolytic effects in humans. It is hoped that the approach outlined above will provide a new avenue toward discovery of medications for treating depression, anxiety, chronic pain, addiction and other CNS-related disorders. By focusing on compounds of unique structural scaffold, the VS hit compounds may lead to drugs carrying fewer adverse effects. This study suggests that MAT computational models are useful for identification or development of lead compound pharmacotherapies, and to our knowledge is the first report of MAT inhibitor discovery using the S1 pocket as a VS tool.

Title: Are the acute and chronic behavioral actions of serotonin selective reuptake inhibitors mediated solely by the serotonin transporter? Studies of drug action with the SERT M172 mouse

Authors: *A. G. NACKENOFF[1,2], A. B. MOUSSA-TOOKS[1], R. D. BLAKELY[1,3];
[1]Dept. of Pharmacol., [2]Grad. Program in Pharmacol., [3]Dept. of Psychiatry, Vanderbilt Univ., Nashville, TN

Abstract: Depression is one of the most common and burdensome disorders worldwide. The most widely prescribed antidepressants are serotonin (5-HT) selective reuptake inhibitors (SSRIs), believed to provide therapeutic benefit by antagonizing the 5-HT transporter (SERT) and elevating extracellular 5-HT levels. Significant, indirect evidence supports this conclusion, although multiple SSRIs have been found to interact with a sizable number of non-trivial targets at physiologically relevant concentrations. Several of these targets, when manipulated pharmacologically or genetically, can induce some of the same biochemical and behavioral effects associated with SSRI administration, raising the question whether all of the effects of SSRIs are 5-HT mediated. In order to separate the 5-HT/SERT dependent effects from the non-SERT effects of SSRI administration, we developed a transgenic mouse line that expresses a point mutation in the SERT SSRI binding site, converting an Ile at amino acid 172 to Met (SERT M172) (Thompson et al, PNAS 2011). The M172 substitution is benign with respect to SERT protein expression and 5-HT transport activity in vitro and in vivo, but confers a marked reduction in sensitivity (10-1000 fold) to many SERT antagonists. In our prior studies, where SERT M172 was expressed on a 129S6/S4 background, WT mice on the same background demonstrated either meager or anomalous responses to SSRIs in classical, acute tests of antidepressant action (tail suspension test and forced swim test). Although insensitivity was documented for citalopram and fluoxetine in biochemical, physiological, and behavioral assays, deeper analyses of SSRI action, particularly with chronic administration, required moving the M172 variant to a more favorable genetic background. After producing SERT M172 mice congenic on a C57BL/6J background, we repeated our initial characterization studies, validating prior observations that the variant supports normal synaptosomal 5-HT uptake kinetics but disrupts the ability of multiple SSRIs to inhibit 5-HT uptake. Moreover, these SERT M172 mice permitted a clear demonstration that SERT, and enhanced extracellular 5-HT, is essential for the immobility reducing behavioral actions of acute administration of citalopram and fluoxetine. Our ongoing studies aim to evaluate the requirement of SERT interactions for the effects of chronic antidepressant action, as assessed in behavioral, biochemical and stem cell analyses. Additionally, RNA profiling of SSRI-treated SERT M172 animals will provide an opportunity to elucidate gene and protein expression networks dependent and independent of SSRI-modulated 5-HT signaling.

Title: Mechanisms contributing to lack of antidepressant efficacy in juveniles and adolescents

Authors: *N. MITCHELL[1], W. OWENS[1], R. HORTON[1], M. VITELA[1], G. GOULD[1], W. KOEK[2,3], L. DAWS[1,3];
[1]Physiol., [2]Psychiatry, [3]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstract: Depression is a major health problem for which most patients are not effectively treated. This problem is further compounded in children and adolescents where only two antidepressant drugs are currently approved for clinical use. Both are selective serotonin reuptake inhibitors (SSRIs), which are often less therapeutically efficacious in this young population compared to adults. Consistent with clinical literature, we found that antidepressant-like effects of SSRIs in mice aged 21 days post-partum (P21, juvenile) was reduced relative to adult mice. The increase in extracellular 5-HT following SSRI administration is thought to trigger downstream events required for therapeutic efficacy. Thus, our data raise the possibility that transporters capable of 5-HT uptake other than SERT may be present in disproportionately higher levels than SERT during juvenile and adolescent periods thereby preventing extracellular 5-HT from climbing to therapeutically relevant levels. We found that SERT expression in hippocampus of juvenile and adolescent (P28) mice is lower compared to adult mice. Conversely, in juveniles and adolescents, the density of [^{3}H]decynium-22 (D22) binding sites, which include organic cation transporters (OCTs) and the plasma membrane monoamine transporter (PMAT), was greater than that of binding sites for the SERT ligand, [^{3}H]citalopram. Western blot analysis using specific antibodies revealed that increased [^{3}H]D22 binding was

most likely driven by increased PMAT expression in young mice relative to adults.
Studies are underway to assess the antidepressant-like effects of blocking PMAT (and/or OCTs) in juvenile and adolescent mice, as well as the ability of D22 to inhibit 5-HT clearance in these young mice. Because PMAT and OCTs can take up serotonin from extracellular fluid, these transporters may limit the therapeutic efficacy of SSRIs, providing a mechanistic basis for poor treatment response to SSRIs particularly
in juveniles and adolescents.

Title: Unique neuro-adaptations of the dopaminergic synapse in DAT mutant mice with altered cocaine-, food-, and sugar-reinforced operant behavior

Authors: *G. SORENSEN[1,2], P. H. HANSEN[1,2], P. WEIKOP[2], M. RICKHAG[1], D. LEO[3], R. R. GAINETDINOV[3], A. FINK-JENSEN[2], G. WÖRTWEIN[2,4], U. GETHER[1];

Abstract: Dopamine has an important modulatory role in the central nervous system controlling motor activity, cognition and reward mechanisms. Impairment of dopaminergic function is associated with several neuropsychiatric diseases. Re-uptake from the extracellular compartment by the dopamine transporter (DAT) is crucial for homeostatic transmitter levels. In the basal ganglia, dopaminergic modulation of the direct striatonigral and the indirect striatopallidal pathways are critical in reward learning and drug addiction.

This unique mouse model was originally generated as an in vivo model in which DAT contains a substitution in the extreme C-terminus that promotes a higher constitutive internalization of an otherwise functional transporter. This subtle mutation in DAT reduces DAT levels.
In order to analyze the mutant mice for in vivo neuro-adaptations of the dopaminergic synapse, we measured total striatal dopamine levels and clearance from the extracellular space. In addition, we assessed striatal D1 receptor, and D2 receptor distribution as well as D2 autoreceptor function. Behaviorally, we investigated the operant self -administration of the mutant mice when reinforced by cocaine, food, and sugar.
We found a decreased level of total striatal DA, and a decrease in D2 receptors but no change in D1 receptor levels in mutant mice. In addition, in voltammetry experiments mutant mice had a prolonged clearance time of extracellular DA than wild-type mice.
Mutant mice learned cocaine-reinforced operant behavior similar to wild-type mice during naïve acquisition but earned significantly less cocaine reinforcers than their wild-type littermates in a dose-response FR1 schedule of reinforcement. In contrast to this, mutant mice showed significantly higher response rates for liquid food and sugar under FR1 and for liquid food under PR schedules.
Our results suggest that disruption of PDZ-protein interactions has profound influence on the role of DAT in regards to cocaine-, food, and sugar-induced reinforcing behaviour and underlines the importance of DAT in the regulation of dopaminergic homeostasis.

Title: Increases in rapid nucleus accumbens dopamine signaling, and cocaine and methylphenidate potency in social isolation reared rats

Authors: *J. T. YORGASON, E. S. CALIPARI, M. FERRIS, N. J. ALEXANDER, B. A. MCCOOL, J. L. WEINER, S. R. JONES;
Neurosci. Program, Wake Forest Sch. of Med., WINSTON SALEM, NC

Abstract: Social isolation rearing (SI) is a model of early life stress that results in neurobiological alterations that lead to increased vulnerability to addiction-like behaviors. Striatal dopamine circuitry is a key mediator of behavioral changes that occur due to long-term stressors. These changes are characterized by increased dopamine metabolite tissue content, midbrain dopamine neuron burst firing, and increased dopamine overflow to psychostimulants in SI versus group reared (GH) animals. Because of the documented increase in psychostimulant effects in SI animals relative to GH, we aimed to assess the potency of two structurally dissimilar dopamine uptake inhibitors, cocaine and methylphenidate (MPH). Long-Evans rats were either group housed (GH; 4/cage) or SI (1/cage) from weaning into early adulthood [postnatal day (PD) 28-77] and neurochemical changes were assessed at PD 77 using fast scan cyclic voltammetry in brain slices. Voltammetric detection of dopamine allows for the assessment of release and uptake kinetics as well as assessing shifts in drug potency at the dopamine transporter (DAT). We show that SI rats, relative to GH, show marked increases in electrically-evoked dopamine release and uptake. Increases in uptake rates are mediated by increases in DAT levels in SI animals, which have been confirmed with western blot hybridization. Surprisingly, the ability of MPH, but not cocaine, to inhibit DA uptake is significantly greater in SI animals relative to GH. Although cocaine effects on uptake were not greater in isolates, we did observe larger increases in cocaine, but not MPH induced release after SI rearing.
The differential effects of MPH and cocaine could be due to structural differences between the two compounds. MPH is structurally similar to the releaser AMPH, which has previously been demonstrated to be more behaviorally potent in the DAT transgenic overexpressing mice as well as SI animals. Further, these data indicate that the potency of cocaine at the DAT is likely not involved in the increased cocaine-induced dopamine overflow that has been shown previously in SI animals, but rather due to the increased releasing effects of cocaine, possibly through interactions at release related machinery.

Abstract: Amphetamine (AMPH) abuse is a major societal problem with severe psychological and physiological consequences for the abusing individual. The major molecular target of AMPH is the dopamine (DA) transporter (DAT), a member of the Na^+/neurotransmitter symporter family. AMPH's addictive properties are mediated by its ability to increase extracellular concentrations of DA by reversing DAT function and, as a consequence, causing DA efflux into the synaptic cleft. Here, we show that the N-terminus of the human DAT (hDAT) interacts electrostatically with phosphoinositol-4,5-bisphosphate (PIP_2; a key signaling molecule known to interact with and regulate ion channels and transporters) and that this interaction regulates AMPH-induced DA efflux, while hDAT uptake and DA clearance functions are unaffected. Using computational modeling of the hDAT N-terminus/plasma membrane interaction to guide our experiments, we have identified key residues on the N-terminus that directly interact with PIP_2, Lys3 and Lys5. Mutation of these residues to either Ala or Asn disrupts the interaction between the hDAT N-terminus and PIP_2 *in silico*, and *in vitro*, severely impairing the ability of the hDAT to efflux DA in response to AMPH. Importantly, DA uptake is unaffected in these mutants, suggesting an asymmetric mechanism for selectively regulating one aspect of the hDAT transport cycle. Finally, using a behavioral model we developed in *Drosophila melanogaster* (namely, locomotion), we determined that the N-terminus interaction with PIP_2 regulates the ability of AMPH to induce behaviors. These findings have implications for developing efflux-selective therapies for AMPH abuse, while preserving endogenous DA uptake function. To our knowledge, this is the first demonstration that the interaction of hDAT with membrane lipids regulates AMPH-induced DA efflux, and that this interaction has profound effects on organismal behavior. **These authors contributed equally to this work.

Title: Intracellular S(+)-Methamphetamine decreases dopamine-dependent inward current via dopamine transporter

Authors: *K. SAHA[1], S. GOODWIN[2], D. ANGOLI[1], P. DAVARI[1], L. VILLARROEL[1], H. KHOSHBOUEI[1];

Abstract: Dopamine (DA) transporter (DAT) regulates the spatial and temporal dimensions of brain dopaminergic neurotransmission. DAT is implicated in neuropsychiatric conditions such as schizophrenia, Attention-deficit hyperactivity disorder, Parkinsonism and drug addiction. Drugs of abuse like amphetamine (AMPH) and methamphetamine (METH) are DAT substrates. They increase DA levels in the synapse by competing with DA for uptake as well as by inducing reverse transport of DA via DAT albeit by poorly understood mechanism. Although DA's chemical structure is similar to that of AMPH and METH enantiomers, DAT responses to these drugs are fundamentally different. We have shown that as compared to AMPH, systemic METH increases the amplitudes and duration of extracellular dopamine 200 times more than AMPH in the nucleus accumbens. In the present study we will examine the underlying molecular mechanism of these differences. We used voltage-clamp electrophysiology in mammalian cells expressing Yellow fluorescent-tagged DAT to examine the hypothesis that differences in chemical structure or chirality of substrates influence the nature of DAT-mediated inward currents via a use-dependent mechanism. Our data suggest that S(+)-METH elicits a DAT-mediated inward current larger than that of DA, S(+)-AMPH, racemic mixture of METH (S(+), R(-) isomers) or R(-)-METH alone. Thus, R(-)-METH may be a DAT partial agonist which decrease DAT current elicited by S(+)-METH, the more effective stereoisomer. Next, we

determined DAT-mediated inward current when the drugs are individually dialyzed into the cell via the patch pipette. In the absence of extracellular substrate, the intracellular drug application via the patch-pipettes produced lesser inward current that was not significantly different amongst the tested compounds. Lastly we studied the nature of DA-induced inward current (a measure of DA uptake) when either S(+)-METH or S(+)-AMPH are dialyzed into the cells via the patch pipette. Compared to S(+)-AMPH, the intracellular S(+)-METH reduced the magnitude of DA-induced inward current when DA is applied extracellularly. Ongoing experiments will examine the effects of these compounds in DA neurons and their effect on the firing activity of DA neurons. Findings from our experiments will provide new research tools to study DAT and potentially determine the mechanistic differences between structurally similar DAT substrates required for the development of effective and economically viable therapeutic approaches for psychostimulant addiction.

Title: Methamphetamine affects the plasma membrane mobility of the dopamine transporter via a calcium-dependent mechanism

Authors: *J. S. GOODWIN[1], K. SAHA[2], P. DAVARI[2], L. VILLARROEL[2], H. KHOSHBOUEI[2];

Abstract: Neurotransmitter reuptake by transporters is a major mechanism for terminating synaptic transmission. The human dopamine transporter (hDAT) is one of the main targets for psychostimulants, and is critical to DA homeostasis in the brain. We previously reported that at maximally effective concentrations, METH released significantly more calcium from internal stores compared with AMPH. The effect of AMPH and METH on intracellular calcium mobilization was thapsigargin-sensitive and hDAT-dependent. Pretreatment of the cells with hDAT antagonist blocked the response. Our current findings implicate elevated levels of calcium in regulating DAT diffusion and membrane microdomain association. Using fluorescence recovery after photobleaching (FRAP) we found that METH decreased the diffusion rate (D) and mobile fraction (Mf) of hDAT. Treatment with thapsigargin, which releases and prevents reuptake of calcium from the ER, mimics the METH mediated decrease in D and Mf of hDAT. Treatment with BAPTA, a calcium chelator, restores DAT diffusion and Mf in the presence of METH. Additionally, treatment with cytochalasin D, which inhibits actin polymerization and induces depolymerization of actin filaments, not only restores hDAT diffusion and mobile fraction in the presence of METH but also increases DAT diffusion in control conditions. These preliminary data are consistent with the interpretation that METH-induced, DAT-mediated elevation in intracellular calcium in DAT-expressing cells affects the actin cytoskeleton, decreasing the mobility of hDAT.

Title: σ-1 receptor regulates methamphetamine inhibition of substrate uptake via dopamine transporter

Authors: *D. O. SAMBO[1], M. LIN[1], B. BLOUGH[2], D. ANGOLI[1], H. KHOSHBOUEI[1]; [1]Univ. of Florida, Gainesville, FL; [2]RTI Intl., Research Triangle Park, NC

Abstract: The principle mechanism for terminating dopaminergic signaling is the reuptake of dopamine via the dopamine transporter (DAT). The activity of this Na^+/Cl^- symporter determines the intensity and duration of dopamine neurotransmission in the brain. The transporter is implicated in a variety of neurological disorders and is one of the primary targets for psychostimulants such as cocaine and methamphetamine (METH). METH is a highly addictive drug that competes with dopamine at the transporter and induces dopamine efflux via DAT. Past studies indicate that self-administration of METH causes upregulation of the σ-1 receptor, a chaperone protein at the endoplasmic reticulum-mitochondria interface, in midbrain regions. Upon activation, this non-opioid receptor translocates to the plasma membrane where it has been shown to modulate the activity of various receptors and channels. Using co-immunoprecipitation and fluorescence resonance energy transfer (FRET) we have found that the DAT and σ-1 receptor interact at the plasma membrane, and that this interaction is potentiated by treatment with METH. In this study, we investigated the functional consequence of the DAT/σ-1 receptor interaction on the activity of the transporter. Through live cell imaging in DAT-expressing cells, we monitored uptake of a fluorescent substrate of DAT, ASP^+, when the σ-1 receptor is overexpressed. Our preliminary data suggests that overexpression of σ-1 receptor increases the rate of DAT-mediated substrate uptake both at baseline and when treated with METH. Consistent with the literature, METH treatment decreased DAT-mediated substrate uptake. In this study we found that overexpression of σ-1 receptor in DAT cells blocked the METH induced inhibition of substrate uptake. These results suggest that the upregulation of the σ-1 receptor can modulate the activity of the transporter both at baseline and when exposed to METH. Ongoing experiments examine the underling mechanism of σ-1 receptor regulation of DAT activity in dopaminergic neurons. Because METH self-administration increases σ-1 receptor levels in brain regions with the highest number of DAT positive terminals, understanding the mechanism of σ-1 receptor regulation of DAT activity may reveal novel therapeutic approaches for the treatment of METH addiction.

NIDA Intramural Research

Title: Exploring the association of the dopamine transporter with the sigma-1 receptor

Authors: *W. C. HONG[1], S. G. AMARA[2];
[1]Intramural Res. Program, Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The dopamine transporter (DAT) clears dopamine (DA) released from presynaptic terminals and plays an important role in regulating DA neurotransmission. The sigma receptor was initially proposed as a subtype of opioid receptors, and sigma ligands were shown to inhibit midbrain dopamine neuronal firing and modulate dopamine release in earlier pharmacological studies (Walker et al., Pharmacol Rev 1990). Recent progress has demonstrated that the sigma-1 receptor (Sig-1R) is a ligand-modulated molecular chaperone (Hayashi and Su, Cell, 2007) capable of interacting with a variety of membrane channels and receptors (Kourrich et al., Trends Neurosci, 2012). To explore the potential association between Sig-1R and plasmalemmal neurotransmitter transporters, we performed co-immunoprecipitation studies in transfected cells. Sig-1R co-immunoprecipitated with DAT, but not with the excitatory amino acid transporter EAAT2. We then generated truncation mutants of Sig-1R to dissect the necessary domains involved in this association. Deletion of the short N-terminus or a major portion of the C-terminus of Sig-1R did not abolish its co-immunoprecipitation with DAT, suggesting that the two transmembrane domains of Sig-1R are likely crucial in mediating its association with DAT. Intriguingly, a splice variant of Sig-1R which lacks the C-terminus exhibited enhanced association with DAT, compared with the full-length Sig-1R. Preliminary data also showed that the association of Sig-1R and DAT could be regulated by Sig-1R ligands, as treatment with the agonist (+)pentazocine reduced the amount of Sig-1R associated DAT. Whether the dynamic association of the DAT with Sig-1R can affect transporter surface expression and modulate DA neurotransmission is currently under investigation.

Title: Electrophysiological and amperometric evidence that modafinil blocks the dopamine uptake transporter to induce behavioral activation

Authors: *N. B. MERCURI, M. FEDERICI, C. LATAGLIATA, F. RIZZO, R. NISTICÒ, S. PUGLISI-ALLEGRA;
IRCCS -SANTA LUCIA FOUNDATION, Roma, Italy

Abstract: Although the wake-promoting drug modafinil has been shown to bind quite exclusively to the dopamine transporter (DAT), its action in the brain has been thought to be partially independent from the facilitation of the dopaminergic signals.
Here we used electrophysiological and amperometric techniques to investigate the effects of modafinil on the dopaminergic neurons of the substantia nigra *pars compacta* (SNpc) and on the synaptic release of dopamine in the dorsal striatum from sliced tissue of wild-type and cocaine-insensitive genetically modified mice (DAT-CI). Moreover, we examined the consequences of modafinil administration on the locomotor behavior of wild-type and DAT-CI mice.
In *in vitro* experiments, modafinil inhibited the spontaneous firing discharge of the dopaminergic neurons. More consistently, it potentiated firing inhibition and the membrane responses caused by exogenously applied dopamine on these cells. Furthermore, it augmented the stimulus-evoked outflow of DA in the striatum. Noteworthy, modafinil caused locomotor activation in wild-type mice. On the other hand, neither the electrophysiological nor the behavioral effects of modafinil were detected in DAT-CI animals.
These results demonstrate that modafinil potentiates brain dopaminergic signals via DAT inhibition by acting at the same binding site of cocaine. Therefore, this mechanism of action explains most of the pharmacological properties of this compound in the clinical setting.

Title: Dopamine transporter coding variant Ala559Val associated with attention deficit hyperactivity disorder impairs dopamine transporter trafficking and function

Authors: E. A. BOWTON[1], C. SAUNDERS[2], D. SAKRIKAR[2], R. D. BLAKELY[2], H. J. G. MATTHIES[1], A. GALLI[1], *K. ERREGER[1];
[1]Dept. of Mol. Physiol. & Biophysics, [2]Dept. of Pharmacol., Vanderbilt Univ., NASHVILLE, TN

Abstract: Alterations in components of brain dopamine (DA) signaling and homeostasis have been implicated in the pathophysiology of neuropsychiatric disorders including attention deficit hyperactivity disorder (ADHD). The human dopamine transporter (DAT) variant with the nonsynonymous single nucleotide polymorphism Ala559Val ("hDAT A559V") was found in two male siblings with ADHD and had previously been reported in one female with bipolar disorder. When heterologously expressed, hDAT A559V exhibits anomalous non-vesicular DA release (DA efflux) that mimics the actions of amphetamine (AMPH)-like psychostimulants. AMPH acts by promoting DA efflux through DAT and recruiting signaling pathways that regulate DAT function, including protein kinase C (PKC) activation and increased phosphorylation of DAT. Importantly, AMPH has also been shown to cause trafficking leading to internalization of DAT. Previous data suggest that intracellular AMPH accumulation is required for AMPH-induced DAT trafficking, possibly due to the ability of AMPH to increase intracellular Ca2+ levels and stimulate Ca2+-dependent kinases including PKC.
Here, we show that while AMPH induces DAT internalization in hDAT-expressing cells, AMPH has no effect on DAT trafficking in hDAT A559V cells. Moreover, AMPH fails to elicit DA efflux in hDAT A559V cells. However, both AMPH-induced internalization and AMPH-induced DA efflux are restored by 1) mutating N-terminal serines of hDAT A559V to alanine prevent phosphorylation or 2) pharmacologically inhibiting PKCβ activity, suggesting that phosphorylation of hDAT A559V N-terminal serines by PKCβ may support anomalous DA efflux activity of hDAT A559V. AMPH uptake was investigated at 10 nM AMPH (a concentration sufficient to induce AMPH uptake and DA efflux in hDAT cells) to avoid high nonspecific signals observed at larger AMPH concentrations. Under these conditions, AMPH is not transported by hDAT A559V, indicating that hDAT A559V is either unable to uptake AMPH or has a shifted apparent affinity for AMPH uptake compared with hDAT. Importantly, direct intracellular delivery of AMPH in hDAT A559V cells restores DAT internalization to levels similar to that seen in hDAT cells treated with AMPH. These data suggest that PKCβ-dependent phosphorylation of the hDAT A559V N-terminus impairs transport of AMPH, thereby preventing AMPH from eliciting its intracellular effects that subsequently result in DA efflux and in DAT internalization.
These results demonstrate how genetic variation in DAT coding regions can impact transporter trafficking and function, as well as potentially contribute to altered DA neurotransmission in disease states.

Abstract: De novo genetic variation is an important class of risk factors for autism spectrum disorder (ASD). Recently, whole exome sequencing of ASD families has identified a novel de novo missense mutation in the human dopamine (DA) transporter (hDAT) gene, which results in a Thr to Met substitution at site 356 (hDAT T356M). The DAT is a presynaptic transmembrane protein that regulates dopaminergic tone in the central nervous system by mediating the high-affinity re-uptake of synaptically released DA, making it a crucial regulator of DA homeostasis. Here, we report the first functional, structural, and behavioral characterization of an ASD-associated de novo mutation in the hDAT. We demonstrate that the hDAT T356M displays anomalous function, characterized as a persistent reverse transport of DA (substrate efflux). Importantly, in the bacterial homolog leucine transporter, substitution of A289 (the homologous site to T356) with a Met promotes an outward-facing conformation upon substrate binding. In the substrate-bound state, an outward-facing transporter conformation is a required for substrate efflux. In Drosophila melanogaster, expression of hDAT T356M in DA neurons lacking Drosophila DAT leads to hyperlocomotion, a trait associated with DA dysfunction and ASD. Taken together, our findings demonstrate that alterations in DA homeostasis, mediated by aberrant DAT function, may confer risk for ASD and related neuropsychiatric conditions.

Title: Identification and characterization of recognition binding sites on human dopamine transporter involved in HIV-1 Tat-mediated disruption of dopamine transport

Authors: *N. M. MIDDE[1], X. HUANG[2], A. M. GOMEZ[1], C.-G. ZHAN[2], J. ZHU[1];
[1]Dept. of Drug Discovery and Biomed. Sci., Univ. of South Carolina, Columbia, SC; [2]Dept. of Pharmaceut. Sci., Univ. of Kentucky, Lexington, KY

Abstract: HIV-1 Tat protein impairs dopamine (DA) neurotransmission through inhibiting DA transporter (DAT) function. Based on the predictions of computational modeling and simulations, we have recently demonstrated that mutation (Y470H) of human DAT (hDAT) attenuates Tat-induced inhibition of DA transport. In the present study, we characterized the pharmacological profiles of two other mutations (Y88F and K92M) in hDAT for Tat binding. Compared to wild type hDAT (WT hDAT), the Vmax for DA uptake in CHO cells transfected with these mutants was differentially decreased: Y470H > K92M > Y88F without changes in Km values. Further, Y88F and K92M displayed decreased potency of DA substrate and increased potency of cocaine, WIN35,428, and GBR12909 for inhibition of DA uptake. These results suggest that the identified residues may not overlap with the binding sites in hDAT for

DA substrate but are critical for the interaction of these inhibitors with DAT. In addition, exposure to recombinant Tat1-86 decreased Vmax by 38% and 18% in WT hDAT and both Y88F and K92M, respectively, suggesting that these residues are important for HIV-1 Tat-induced inhibition of dopamine transport. Furthermore, Y88F and K92M altered zinc-mediated modulation of WIN35,428 binding and enhanced basal DA efflux compared to WT hDAT. Determining this potential mechanism underlying Tat-induced transporter conformational transitions is an important ongoing study. Collectively, these results provide additional information to understand the functional relevance of identified residues for Tat binding on hDAT and aid in developing compounds that can specifically block the functional binding of Tat to hDAT.

Title: GDNF/Ret signaling regulates dopamine transporter trafficking via guanine nuclear exchange factor Vav2

Authors: *C. ZHAO, S. ZHU, J. ZHOU;
Inst. of Neuroscience, Chinese Acad. of Sci., Shanghai, China

Abstract: The dopamine transporter (DAT) plays a key role in controlling the dopaminergic signaling and dopamine homeostasis via its dopamine reuptake activity. Here we found that glial cell line-derived neurotrophic factor (GDNF) reduced DAT activity in the nucleus accumbens by inducing the DAT endocytosis. In this process the association between GDNF receptor Ret and a Rho family GEF Vav2 is critical. GDNF-dependent phosphorylation of Vav2 modulated the internalization of Ret and DAT, thereby regulating the dopamine homeostasis. Moreover, Vav2 KO mice showed delayed response to cocaine in the addictive behavior. These results suggest that GDNF modulates the dopamine transmission via regulating DAT internalization.

Title: Gβγ protein activation promotes dopamine efflux trough the Dopamine Transporter

Authors: *J. GARCIA-OLIVARES[1], S. G. AMARA[1], G. E. TORRES[2];
[1]Natl. Inst. of Mental Health/NIH, Bethesda, MD; [2]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Proper function of reward circuitries in the brain requires that the presynaptic dopamine transporter (DAT) efficiently recaptures dopamine (DA). DAT function can be regulated by many intracellular mechanisms including phosphorylation, ubiquitination, and protein-protein interactions. Recently, our laboratory reported a novel mechanism describing the regulation of DAT by G-proteins. Gβγ subunits bind DAT, and upon activation decrease DA uptake. We are now exploring whether activation of Gβγ subunits also affect DA efflux in an amphetamine-dependent or -independent manner. Using a radiolabeled efflux assay, we measured DA efflux in HEK-293 cells stably expressing DAT that were preloaded with [H3]-DA. Activation of Gβγ with the cell permeant peptide mSIRK resulted in a dose-dependent release of DA. This effect was blocked by cocaine and GBR12935 demonstrating that Gβγ activation promotes DA efflux through DAT. Similarly, amperometric recordings demonstrated that mSIRK activation of Gβγ also induced DA release in HEK-293-DAT cells. Taken together, our results suggest that DA efflux through DAT occurs by a G protein-dependent process and this novel mechanism might have important implications in the actions of amphetamine.

Title: Sumoylation modulates Alpha synuclein interaction with the Dopamine Transporter

Authors: *E. CARTIER[1], H. KHOSHBOUEI[2];
[2]Neurosci., [1]Univ. of Florida, Gainesville, FL

Abstract: Sumoylation is a posttranslational modification by which small ubiquitin-like modifiers (SUMO) are covalently conjugated to target proteins. Sumoylation is highly dynamic and reversible as SUMO specific proteases can rapidly remove SUMO from their substrates. The specific SUMO conjugase, UBC9, sumoylates target proteins. Conversely, the SUMO Interacting Domains (SIM) of non-sumoylated proteins can recognize conjugated SUMO. SUMO modification of a given protein has been shown to create or abolish binding interfaces that can regulate trafficking, protein-protein interactions, protein aggregation and solubility. Recent reports suggest that alpha-synuclein, a synaptic protein implicated in multiple neurodegenerative diseases and drug addiction, is sumoylated in two specific residues. Alpha-synuclein is one of DAT's interacting partners that directly associate with the C-terminus of the transporter. Confocal microscopy and biochemical data from our lab have demonstrated that alpha-synuclein and dopamine transporter interact at the plasma membrane. Whole-cell patch clamp electrophysiology results suggest that alpha-synuclein over-expression induces a transporter mediated inward chloride current and decreases DAT-mediated substrate uptake. DAT molecule contains a number of putative SIMs that might be critical in order to regulate DAT interaction with sumoylated alpha-synuclein. In this study we used co-immunoprecipitation (Co-IP) and biotinylation assays to examine whether DAT interacts with SUMO (SUMO-1 and/or 2), and whether sumoylation affects DAT/alpha-synuclein interaction. Our preliminary data suggest that DAT associates with the SUMO conjugase UBC9 and appears to be sumoylated. In addition, in the striatum, HEK and MN9D cells expressing DAT, we found a strong interaction between DAT and SUMO-1 which is consistent with the existence of one or more SIM in the DAT structure. Moreover, sumoylation appears to reduce the association between DAT and alpha-synuclein, increasing the expression of DAT at the plasma membrane. Our ongoing confocal microscopy will examine whether sumoylation regulates DAT/alpha-synuclein interaction in living cells. The functional assays will demonstrate the functional significance of these observations.

Title: Alpha-synuclein regulates trafficking of dopamine transporter

Authors: *B. R. BUTLER[1], E. CARTIER[2], D. ANGOLI[2], H. KHOSHBOUEI[2];
[1]Univ. Of Florida, Gainesville, FL; [2]Neurosci., Univ. of Florida, Gainesville, FL

Abstract: The dopaminergic system regulates several brain functions including motor, behavior and reward. The dopamine transporter (DAT) is a 12 multi-pass transmembrane protein, which regulates the magnitude and timing of dopaminergic signaling by re-uptake of excess dopamine from the synapse as well as efflux of dopamine into the synapse. Dysregulation of DAT function has been implicated in neurodegenerative, neuropsychiatric disorders and drug addiction. DAT directly or indirectly interacts with multiple proteins. These protein partners have shown to alter the DAT-mediated substrate uptake, efflux and/or the trafficking of the transporter. Alpha-synuclein is one of DAT's binding partners that directly interact with the C-terminus of the transporter. Confocal Microscopy and molecular biochemistry data from our lab have demonstrated that alpha-synuclein and dopamine transporter interact at the plasma membrane. Whole-cell patch clamp electrophysiology results suggest that alpha-synuclein over-expression induces a transporter mediated inward chloride current and decreases DAT-mediated substrate uptake. In the current studies we examined whether alpha-synuclein influences DAT trafficking and when the transporter is exposed to 10 uM amphetamine or 1 uM phorbol ester (PMA). We used live-cell confocal microscopy and biotinylation assay to examine the relative level of DAT at the surface membrane when alpha-synuclein is over-expressed, as compared to the absence of intracellular alpha-synuclein. Our preliminary results show that alpha-synuclein stabilizes the transporter at the surface membrane and decreases amphetamine-induced DAT internalization. Currently, we are examining these findings in alpha-synuclein wild-type, knockout and overexpressing neurons. These preliminary findings support the hypothesis that pathological levels of alpha-synuclein can alter the biology of DAT and thus dopamine transmission in the brain. Title: Protein-kinase c mediated internalization of the dopamine transporter

Authors: *S. M. UNDERHILL, S. G. AMARA;
Lab. of Mol. and Cell. Neurobio., NIH/NIMH, Bethesda, MD

Abstract: The dopamine transporter (DAT) clears neurotransmitter from the extracellular space and serves as an important regulator of signal amplitude and duration at sites of dopamine release. In both DA neurons and transfected cell lines, the activation of several different intracellular signaling pathways has been observed to modulate DAT activity by regulating the trafficking of carriers to and from the cell surface. PKC signaling has been the most extensively studied of these mechanisms for regulating transporter cell surface density, and it has been well-established that acute activation of PKC by phorbol esters facilitates internalization of the transporter in a variety of model systems. However, the physiological stimuli and cell-surface receptor systems that activate PKC and potentially regulate the DAT in dopamine neurons within the mammalian brain remain elusive. In studies presented here we sought to identify the endogenous GPCRs coupled to PKC-activation that regulate DAT internalization in DA neurons. Because three of the five muscarinic acetylcholine receptor isoforms are coupled to PKC activation and one of these, M1, is found in dopamine neurons, we hypothesized that DAT internalization could be mediated by PKC-coupled M1 muscarinic acetylcholine receptor stimulation in dopamine neurons.
We found that stimulation of M1 receptors with carbachol in midbrain cultures decreased the ability of these cells to transport dopamine through DAT. The M1-specific antagonist, pirenzepine, blocked these effects while the M3 antagonist, DAU 5884, had no effect, indicating the receptor subtype responsible for modulation in dopamine neurons is most likely the M1 isoform. A PKC inhibitor, bisindolylmaleimide, blocked the effects of carbachol stimulation on dopamine uptake supporting a role for PKC in DAT internalization. Furthermore, as shown previously for PKC-induced internalization, downregulation of the DAT was clathrin- and dynamin-dependent. In acute midbrain slices, biotinylation of cell-surface proteins revealed the loss of dopamine transport mediated by M1 receptor stimulation was, indeed, due to loss of membrane expression of the DAT. These data indicate that stimulation of cholinergic pathways can lead to modulation of dopamine through internalization of the DAT.

Title: Voltage-dependent regulation of dopamine transporter trafficking

Authors: *B. D. RICHARDSON[1], E. CARTIER[1], J. SWANT[1], K. SAHA[1], D. ANGOLI[1], M.-F. ZOU[2], A. H. NEWMAN[2], H. KHOSHBOUEI[1];
[1]Dept. of Neurosci., Univ. of Florida, Gainesville, FL; [2]Medicinal Chem. Section, Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: The dopaminergic system is essential for the function of the brain's reward, motor coordination, attention and cognitive processes whereas aberrations in dopamine (DA) neurotransmission contributes to neuropsychiatric disorders; including addiction, attention deficit/hyperactivity disorder (ADHD), Schizophrenia, and Parkinson's. DA neurotransmission timing and magnitude is dependent on how DAT regulates extracellular DA levels, but membrane surface expression of DAT is plastic. Regulation of DAT trafficking to and from the cell surface is sensitive to changes in multiple protein-protein interactions and substrate binding. However, many of the substrates and DA-related disease states linked to altered DAT trafficking also effect neural excitability. Since some cell signaling mechanisms known to alter DAT trafficking are also sensitive to changes in membrane conductance or excitability (e.g. CaMKII) themselves, their voltage-dependent activation/inhibition may change the cytosolic/membrane distribution of proteins like DAT.
Data in heterologous expression systems suggest that change in cellular resting membrane potential (RMP) is a regulator of DAT trafficking to and from the cell membrane. Here, we examine the regulation of DAT trafficking by a novel factor: membrane voltage/resting membrane potential (RMP). Using Total Internal Reflection Fluorescence (TIRF), confocal microscopy, whole-cell patch-clamp and cell surface biotinylation, we examined the effect of changes in the membrane voltage on the density of cell surface YFP-DAT and internalization of DAT in CHO and HEK293 cells. It was found that depolarization of the cell's RMP reduces membrane surface TIRF YFP-DAT signal and increases DAT and DAT-JHC1-064 complex

internalization. Conversely, membrane potential hyperpolarization increases membrane surface TIRF YFP-DAT density. These voltage-dependent changes in membrane surface DAT were also sensitive to CaMKII inhibition. Results indicate the sensitivity of protein trafficking to cellular electrophysiological state; providing a new mechanism dynamically regulating protein function through changes in cell surface density. Ongoing experiments using specific tools (e.g. optogenetics) to control the neuronal RMP in DAT overexpressing CHO and HEK cell lines and DAergic neurons will further determine the impact of membrane potential state on DAT density and DA uptake capacity.

Title: Investigating microdomain localization of the dopamine transporter using super-resolution microscopy

Authors: T. RAHBEK-CLEMMENSEN[1,2], J. ERIKSEN[1,2], S. ERLENDSSON[1,2], *T. N. JORGENSEN[1,2], U. GETHER[1,2];
[1]Dept. Neurosci. and Pharmacol., Univ. of Copenhagen, Copenhagen, Denmark; [2]The Lundbeck Fndn. Ctr. for Biomembranes in Nanomedicine, Copenhagen, Denmark

Abstract: The dopamine system is highly important for cognition, motivation, and motor functions. Dysfunctions of dopaminergic neurotransmission is coupled to neuropsychiatric disorders such as Parkinson's disease, schizophrenia, attention deficit/hyperactive disorder, and drug addiction. The dopamine transporter (DAT) is present on the presynaptic membrane of the dopaminergic neuron and mediates reuptake of released dopamine. Furthermore, DAT is a major target for psychostimulants such as cocaine and amphetamine. By conventional confocal and widefield imaging we have previously shown a homogenous distribution of DAT at the plasma membrane of cultured dopaminergic neurons [1]. Based on work with transiently transfected heterologous cells, others and we have suggested a microdomain localization of DAT through co-localization with cholera toxin beta; a known marker for lipid rafts [2, 3]. These imaging studies, however, are all limited by the physical barriers of conventional light microscopy, reaching a spatial resolution of 250 nm and above in the XY plane and 500 nm in the Z plane.

Here, we use 2 dimensional stochastic optimization reconstruction microscopy (STORM), to reach sub-diffraction limit resolution (17 nm) and show that DAT is distributed into membrane microdomains in transiently transfected CAD cells as well as primary cultures of dopaminergic neurons from the ventral tegmental area. We verified a segregated membrane distribution of mature DAT through continuous sucrose gradients from lysates of transiently transfected CAD cells as well as striatal slices. Furthermore, cholesterol depletion using methyl-beta-cyclodextrin show that for transiently transfected CAD cells this segregation is cholesterol dependent. Similar cholesterol depletion in dopaminergic neurons indicates that the microdomain clustering of DAT observed by STORM is cholesterol dependent. Finally, by combining total internal reflection microscopy with STORM and a fluorophore-conjugated monoclonal, primary antibody-only setup we will investigate the clustering nature of DAT at the plasma membrane of CAD cells.

Title: Protomers in a dopamine transporter oligomer can influence each other

Authors: T. ANTONIO[1], S.-Y. CHENG[3], J. ZHEN[1], S. ALI[2], K. T. JONES[1], *M. E. REITH[1,4]; [1]Psychiatry, [2]Physiol. and Neurosci. Mol. Neurobiol. Progr., New York Univ. Schl Med., NEW YORK, NY; [3]Sci., John Jay Col. of Criminal Justice, New York, NY; [4]Biochem. and Mol. Pharmacol., New York Univ. Sch. Med., New York, NY

Abstract: Previous studies point to quaternary assembly of dopamine transporters (DATs) in oligomers. However, the functional role of DAT oligomers is not clear. As a first step in establishing whether protomers in an oligomeric DAT assembly can function independently, we co-transfected HEK 293 cells with DAT constructs possessing differential binding affinity for the phenyltropane analog of cocaine, [^{3}H]CFT. The goal was to determine whether the binding properties in co-transfected cells (where oligomers containing the two constructs can occur) differ from those in preparations obtained by simply mixing cells that had been separately transfected (where such oligomers cannot occur). For example, single transfection with WT DAT gave a high-affinity K_d of 16 $\pm$ 3 nM, whereas single transfection with D436N DAT resulted in a low-affinity K_d of 129 $\pm$ 16 nM. Co-transfection of these two constructs yielded a K_d of 103 $\pm$ 5 nM, which differed ($P<0.005$) from the higher-affinity value of K_d of 25 $\pm$ 2 nM to be predicted for non-interacting protomers. The latter was calculated from simulating an analysis of results obtained in silico by mixing the separate binding components of high and low affinities incorporating classical Rosenthal analysis. This method for predicting resultant K_d (and B_{max}) values was validated by mixing cell lines stably transfected with either WT or D436N, and comparing predicted with "mixed" binding values. Dominance of the K_d value of a low-affinity protomer co-present with WT was also found for D345N co-transfected with WT, suggesting interaction among the protomers. In contrast, affinity values consonant with independently functioning protomers (simply mixing the two binding components) were found upon co-transfection with the following pairs of constructs with differential K_d: W84L-WT, and W84L-D345N. The results obtained so far indicate that, under some, but not all, circumstances one protomer can influence the properties of another protomer. It will be important to establish how protomers with sufficiently different DA *transport* properties influence each other.

Title: L-DOPA induces non-vesicular dopamine release

Authors: *D. XU[1], W.-X. SHI[2];
[1]Dept. of Pharmaceut. Sci., Loma Linda Univ. Sch. of Pharm., Loma Linda, CA; [2]Depts of Pharmaceut. and Basic Sic., Loma Linda Univ. Schs of Pharm. and Med., Loma Linda, CA

Abstract: L-DOPA is a precursor of dopamine (DA) and the gold-standard treatment of Parkinson's disease. L-DOPA increases DA release in both the terminal regions and somatodendritic area of DA cells in the substantia nigra (SN). SN DA release regulates both the activity of DA neurons and GABA release from striatonigral terminals. In this study, we tested whether L-DOPA still induces DA release in the SN after vesicular release is blocked by a combined inhibition of the vesicular monoamine transporter (VMAT), Ca^{2+} influx, and TTX-sensitive Na^{+} channels. We indirectly measured DA release by measuring L-DOPA-induced membrane hyperpolarization of DA neurons using whole-cell recording in rat brain slices. Under control conditions, L-DOPA-induced hyperpolarization was completely reversed by the D2 receptor antagonist raclopride and enhanced by the DA transporter (DAT) inhibitor cocaine, confirming that it is mediated by DA release and subsequent activation of DA autoreceptors. To block vesicular release, slices were first incubated with the VMAT blocker reserpine (2 μM) for at least 1 hour and then perfused with a Ca^{2+}-free medium containing TTX (1 μM) in addition to reserpine. Under such conditions, L-DOPA (100 μM) still induced a hyperpolarization of DA cells, though the amplitude (4.61 ± 0.56 mV, n=7) was significantly reduced compared to controls (7.94 ± 0.42 mV, n=6, $p<0.05$, ANCOVA). Additionally, the time between 20% and 80% of the maximal response was prolonged from 1.02 ± 0.25 min in controls to 2.57 ± 0.78 ($p=0.05$) after blockade of vesicular release, suggesting a decrease in not only the amount, but also the speed of DA release. The observation that the hyperpolarization induced by L-DOPA in the presence of blockade of vesicular release was still enhanced by cocaine (10 μM, 11.70 ± 1.61 mV, n=8, $p<0.01$, ANCOVA) and reversed by raclopride confirms that the effect is due to DA release induced by L-DOPA. Based on these results, we conclude that a large portion of DA release induced by L-DOPA is not mediated by Ca^{2+}-dependent exocytosis.
While the exact mechanism underlying the observed non-vesicular DA release remains to be determined, it is possible that L-DOPA, by increasing the DA concentration inside DA neurons, induces a reverse transport of DA through the DAT. If true, our results with cocaine would suggest that the DAT-mediated reverse transport is not blocked by cocaine or is less sensitive to cocaine than the DAT-mediated reuptake.

Title: Slc6a3-GFP: A novel transgenic mouse strain to obtain high purity isolation of dopaminergic neurons

Authors: *M. RICKHAG[1], S. STILLING[1], J. ERIKSEN[1], G. SØRENSEN[1], T. RAHBEK-CLEMMENSEN[1], J. PRAVSGAARD CHRISTENSEN[2], U. GETHER[1];
[1]Molecular. Neuropharm Lab, Dept. of Neurosci & Pharmacol, Univ. of Copenhag, Copenhagen, Denmark; [2]Dept. of Intl. Health, Immunol. and Microbiology, Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Dopamine (DA) plays a fundamental role in the central nervous system as a modulatory neurotransmitter, controlling different brain functions including locomotor activity, reward mechanisms, cognition and neuroendocrine functions. Dopaminergic neurons are primarily localized in substantia nigra (SN) and ventral tegmental area (VTA) of the midbrain and project to areas in the basal ganglia, prefrontal cortex and the limbic system. However, only a fraction of the cells in the VTA and SN are dopaminergic, therefore, markers permitting specific visualization and identification of dopaminergic neurons in this area are highly desirable. We have obtained a BAC transgenic mouse strain from GENSAT, which expresses enhanced green fluorescent protein (GFP) under control of the dopamine transporter (DAT) promoter (Slc6a3-GFP). The presynaptic DAT is responsible for sequestering released dopamine from the synaptic cleft and is selectively expressed in DA neurons. Immunohistochemical analysis showed robust endogenous GFP expression in both ventral midbrain and striatal terminals that co-localized with dopaminergic markers. Antibody labelling of GFP also showed extensive overlay with DAT in both cell soma and extensions of DA neurons in midbrain validating that GFP is a reliable marker of dopaminergic neurons in Slc6a3-GFP mice. Furthermore, we did not observe any functional or behavioural abnormalities in these mice compared to non-transgenic wildtype mice when assessing striatal dopamine uptake, basal locomotion and psychostimulant-induced hyperactivity. Using fluorescence activated cell sorting, we demonstrate that a pure dopaminergic cell population can be obtained from Slc6a3-GFP mice as evidenced by enrichment of gene transcripts highly expressed in dopaminergic cells. Furthermore, the GFP expression in *Slc6a3*-GFP mice will in combination with fluorescent cocaine analogues allow direct visualization of DAT trafficking in live striatal slices. We believe that Slc6a3-GFP mice represent a novel tool for high-purity isolation of dopaminergic neurons

that can be used in transcriptomic and epigenetic analyses as well as for high-yield dopaminergic primary cultures.

Title: Dopamine signaling in *C. elegans* is regulated presynaptically by a highly conserved ortholog of the atypical MAP Kinase ERK7/8

Authors: *D. BERMINGHAM[1], J. A. HARDAWAY[1], S. M. WHITAKER[1], S. L. HARDIE[1], L. CARVELLI[2], R. D. BLAKELY[1];
[1]Vanderbilt Univ., Nashville, TN; [2]UND Sch. of Med. and Hlth. Sci., Grand Forks, ND

Abstract: The neurotransmitter dopamine (DA) acts across phylogeny to modulate fundamental aspects of physiology and behavior, including movement, appetite, reward and attention. The model system *Caenorhabditis elegans* is a powerful platform for the discovery and manipulation of genes controlling synaptic function, including genes that control DA production, secretion, inactivation and response. We have observed a phenotype that occurs in late larval animals where loss of the DA transporter, DAT-1, results in animals that paralyze over a course of 10 minutes when placed in water, whereas wild-type animals swim at a relatively constant rate for up to an hour. "Swimming-induced paralysis", or Swip, can be reversed pharmacologically by treatment with reserpine, which prevents vesicular DA packaging and release, as well as by genetic ablation of the DA biosynthetic enzyme tyrosine hydroxylase (*cat-2*) or the D2-like DA receptor *dop-3*. Using the Swip phenotype, we have performed a forward genetics screen to identify mutants that exhibit *dat-1* like paralysis that can be rescued by reserpine treatment as well as by mutation of genes supporting DA synthesis and response. One such mutant, *vt32*, was

localized by SNP mapping and whole genome sequencing to an uncharacterized gene, here referred to as *swip-13*. We find that *swip-13* mutations result in significantly reduced sensitivity to the neurotoxic *dat-1* substrate 6-OHDA, supporting a role for *swip-13* in sustaining DAT-1 protein expression, surface trafficking and/or activity. Consistent with these findings, transport studies in primary *C. elegans* cultures reveals a significant reduction in DA uptake. We observe that *swip-13* mutants also possess reduced DA levels, suggesting that they may either fail to recycle DA as seen in DAT knockout mice, or that the mutation has more pleiotropic actions on DA synthesis, packaging or release. Importantly, DA neuron-specific, transgenic expression of the wild-type *swip-13* gene restores normal swimming behavior of *swip-13* mutants, establishing expression by DA neurons as the key site of SWIP-13 expression to modulate DA signaling . Fluorescently-tagged, functional *swip-13* protein localizes to DA terminals, consistent with a presynaptic role for SWIP-13. SWIP-13 protein is highly conserved, likely representing the nematode homolog of the atypical MAP kinase ERK7/8. Further efforts to uncover the mechanisms by which SWIP-13 and ERK7/8 modulate DA signaling may provide novel insights into disorders associated with perturbed DA signaling and their treatment.

Title: Loss of α4-laminin results in aberrant neurotransmission in multiple skeletal muscle fiber types

Authors: *K. K. CHAND[1], K. LEE[1], P. G. NOAKES[1,2], N. A. LAVIDIS[1];
[1]Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia; [2]Queensland Brain Inst., Brisbane, Australia

Abstract: Synaptic basal lamina such as laminin-9 (α4β2γ1), have been shown to play an integral role in the organization of the neuromuscular junction (NMJ). Formation of active zones and junctional folds occur normally in α4-laminin knockout mice (α4 $^{-/-}$) as in wild-type (WT) mice. However, the precise apposition of active zones and postsynaptic folds fails to develop at α4 $^{-/-}$ NMJs. The α4-laminin chain, is found in highest concentration between the postsynaptic

folds rather than in the folds themselves, suggesting it plays an instructive role in the placement of postsynaptic specializations such as acetylcholine receptors (AChRs). Here, we compare neurotransmission at postnatal day 18 (P18) and 60 (P60) in wild type and $\alpha4^{-/-}$ NMJs. We functionally examined the consequence of α4-laminin knockout in muscles composed of predominantly three fiber types; type I, soleus; type IIB, extensor digitorum longus (EDL); and mixed type I and type IIA, diaphragm, utilising intracellular electrophysiological recordings of end-plate potentials (EPPs) and miniature end-plate potentials (MEPPs). Mice were bred and maintained on a C57BL/6-129SvJ genetic background. Soleus, EDL and diaphragm along with associated innervating nerves were dissected from WT (n=6) and $\alpha4^{-/-}$ (n=6) mice at both P18 and P60. Immunofluorescence staining was conducted to investigate the presence of presynaptic active zone markers in relation to postsynaptic AChRs. Our results demonstrate clear aberrations in neurotransmission at $\alpha4^{-/-}$ NMJs. At P18, both MEPP and EPP amplitude increased significantly in $\alpha4^{-/-}$ NMJs compared to WT ($p<0.05$) in all fiber types. Analysis of spontaneous release displayed a two-fold increase in rise time ($p<0.05$) and a decrease in frequency ($p<0.05$) at $\alpha4^{-/-}$ NMJs across each fiber type. P18 $\alpha4^{-/-}$ NMJs displayed an increase in the frequency of evoked stimuli that failed to illicit a response in each fiber type compared to WT. At P60 increased MEPP and EPP amplitudes were observed at $\alpha4^{-/-}$ NMJs in comparison to WT ($p<0.05$). Rise time of spontaneous release also increased for each fiber type at $\alpha4^{-/-}$ NMJs compared to WT ($p<0.05$). Immunohistochemical studies demonstrated normal presence of presynaptic components in relation to postsynaptic AChRs, suggesting the necessary release machinery is present at $\alpha4^{-/-}$ NMJs but may not be organized for optimal neurotransmission. Our present findings suggest a decrease in the number of active release sites at $\alpha4^{-/-}$ NMJs across each fiber type investigated. Given the large safety factor associated with synaptic transmission at the NMJ these aberrations are not sufficiently significant to compromise the survival of the animal even at P60.

Title: Organization of the presynaptic filamentous matrix in glutamatergic hippocampal synapses analyzed by EM tomography

Authors: *A. A. COLE, X. CHEN, T. S. REESE;
Structural Neurobio. Section, NINDS, Bethesda, MD

Abstract: Diffusion has been thought to facilitate the transfer of synaptic vesicles to the presynaptic active zone where they dock prior to fusion. However, it is difficult to see how diffusion would work in synapses like those in squid, where synaptic vesicles cluster in vesicle clouds not restrained by the membrane of the bouton. Recently, electron microscopy (EM) tomography has shown an abundance of filamentous material between vesicles (Burette et al. 2012, Fernàndez-Busnadiego et al. 2011, Siksou et al. 2007, Szule et al. 2012), confirming that vesicles may not generally be free to diffuse. Here, we use EM tomography on thin sections of freeze-substituted, dissociated hippocampal neurons (Chen et al. 2008) to study in more detail the filamentous connections between vesicles. By freezing in lieu of initial fixation, we avoid fixation induced synaptic activity and present a picture of synaptic vesicle distribution and filament connectivity that is close to a synapse at rest. We show that vesicles in the glutamatergic boutons are constrained by two distinct clustering systems. One system consists of short filaments that connect a vesicle with up to eight neighboring vesicles. These connections show little directional bias and appear to tether the vesicles into a relatively evenly spaced, symmetrical network. The other system consists of larger, more complex, branched filaments that contact up to eight vesicles. This complex-branched system includes ~80% of vesicles, which are also cohesive with the vesicles tethered by the short-filament system. In contrast to the short-filament system, the complex-branched system is notably oriented towards the active zones and therefore positioned to move vesicles in that direction in response to tensions in the filament system - for instance, as vesicles at the active zone disappear by complete exocytosis. These two cohesive systems, working together, may represent a mechanism for both maintaining a vesicle cloud and for moving them to the active zone, in glutamatergic synapses. A comparable complex system of filaments constraining vesicle mobility is present at the active zone of the neuromuscular junction (Szule et al. 2012).

Title: An ATP binding site regulates synapsin IIa function

Authors: *D. GITLER, Y. SHULMAN;
Fac. of Hlth. Sciences, Ben-Gurion Univ., Beer-Sheva, Israel

Abstract: The synapsins are neuron-specific proteins mostly known for their capability to cluster synaptic vesicles and to control the movement of vesicles between adjacent en-passant synapses. All members of the synapsin family bind ATP at a well-conserved site in their central "C" domain. ATP binding in different synapsin isoforms is differentially regulated by calcium ions, suggesting a physiological function. However, the significance of ATP binding has not been investigated in the context of neurotransmission. We studied the effect of ATP binding on the clustering of vesicles and on their mobilization by reintroducing wildtype and mutant synapsin IIa into cultured mouse neurons lacking all synapsins. We used mutations that render synapsin IIa incapable of binding ATP (K270Q) or which alter its calcium-dependence (K374E). Using electrophysiological recordings from hippocampal autaptic neurons we found that both synIIa-K270Q and synIIa-K374E are defective in rescuing synaptic depression. In contrast, quantification of synaptobrevin 2 immunofluorescence revealed that the K270Q mutation significantly enhanced vesicle clustering, while the K374E mutation had no effect. These observations suggest that interfering with ATP binding by synapsin IIa results in hoarding of vesicles in a manner that is under-responsive to activity patterns. Consequently, we hypothesize that under normal resting conditions ATP-binding by synapsin IIa plays a significant role in organizing the vesicles into clusters close to the synaptic active zone. In addition, calcium-dependent regulation of ATP binding during intense neuronal activity may couple activity to vesicle recruitment and mobilization.

Title: Novel ligands of the synaptic organizer neurexin 1alpha

Authors: *G. RUDENKO[1], Y. WANG[1], L. ZHANG[2], Z. LU[2], F. CHEN[1], A. M. CRAIG[3], G. REN[2];

Abstract: Alpha-neurexins are essential synaptic adhesion molecules implicated in neuropsychiatric diseases such as autism spectrum disorder and schizophrenia. Neurexins play a role in synapse maturation and synaptic transmission. In mammals, thousands of neurexin splice forms are generated. Alternative splicing to neurexin mRNA transcripts typically results in small stretches of amino acids being inserted at evolutionarily conserved regions in the protein; the presence or absence of specific splice inserts is known to regulate binding of certain protein partners. The extracellular domains of alpha-neurexins interact with many different endogenous proteins in the synaptic cleft, including neuroligins, LRRTM family members, alpha-dystroglycan, latrophilin, cerebellins, neurexophilin and the GABAA-receptor. Unlike the much smaller beta-neurexins that contain a single LNS domain in their extracellular domain, the extracellular domains of alpha-neurexins are comprised of 9 modules, i.e. 6 LNS domains interspersed by 3 EGF-like repeats (over 1300 residues). Our structure of the neurexin 1alpha extracellular domain determined to 2.65 Å reveals that putative protein partner binding sites, also known as 'hyper-variable surfaces', map to one side of the L-shaped extracellular domain. Mapping the sequence conservation between alpha-neurexins onto the surface of the neurexin 1alpha ectodomain reveals a characteristic distribution and suggests that novel partners are likely. We describe our approaches to identify novel partners for neurexin 1alpha and the identification of calsyntenin-3 as a novel alpha-neurexin specific protein partner. Our data provide insight into how alpha-neurexins can use the architecture of their extracellular domains to recruit multiple different synaptic protein partners and organize them into large macromolecular complexes in the synaptic cleft promoting synapse function.

Title: Trans-synaptic regulation of presynaptic organization and function by postsynaptic N-Cadherin

Authors: *T. SHINOE, Y. GODA;
RIKEN Brain Sci. Inst., Wako, SAITAMA, Japan

Abstract: N-cadherin is the most widely expressed classic cadherin family member in the CNS. Localized to the pre- and the postsynaptic sites, homophilic interaction of N-cadherins across the synaptic cleft plays important roles in the brain. Previous studies have shown that interfering with N-cadherin-dependent adhesion results in fewer synapses, more spines with immature properties, and attenuation of long-term synaptic plasticity. Compromising N-cadherin activity selectively in postsynaptic neurons decreases the expression level of presynaptic proteins, the number of synaptic vesicles, and the basal release probability. Moreover, this trans-synaptic impairment is accompanied by delayed vesicle endocytosis. In contrast, presynaptic disruption of N-cadherin activity does not cause similar presynaptic impairments. These results strongly suggest that postsynaptic N-cadherin activity can regulate presynaptic function without cooperating with presynaptic N-cadherin. We sought to clarify this novel trans-synaptic regulatory mechanism in cultured hippocampal neurons using optical and electrophysiological approaches. Total vesicle pool size, recycling pool size, and exo/endocytic properties were investigated in the VGLUT1-pHluorin expressing-presynaptic terminals forming synapses with the postsynaptic neuron overexpressing either mCherry-tagged wild-type N-cadherin, a dominant-negative N-cadherin, or a mCherry control. We also addressed the role of GluA2 extracellular domain that directly binds to N-cadherin extracellular region. Overexpressing GluA2 extracellular domain-deletion mutant, GluA2ΔN showed the same effects as impairing postsynaptic N-cadherin activity where it significantly decreased miniature EPSC frequency and the number of presynaptic terminals received by the GluA2ΔN-expressing neurons and their expression level of VGLUT1. Our findings suggest that GluA2 extracellular region is part of a novel regulatory mechanism that could cooperate with postsynaptic N-cadherin to control presynaptic organization and function in *trans*.

Title: Transsynaptic modulation of the synaptic vesicle cycle by synaptic adhesion molecules

Authors: B. VAN STEGEN, *K. GOTTMANN;
Neurophysiol, Univ. Duesseldorf, Duesseldorf, Germany

Abstract: Synaptic adhesion molecules are well known to mediate transsynaptic signaling that controls the formation, maturation, and function of synapses in the brain. The adhesion molecule N-cadherin is present at excitatory glutamatergic synapses and interacts homophilically across the synaptic cleft thus forming the N-cadherin/catenin adhesion complex. In immature mouse cortical neurons, N-cadherin has been described to indirectly control presynaptic vesicle accumulation by targeting and activating postsynaptic Neuroligin1, which in turn induces presynaptic vesicle clustering via Neurexin binding. The N-cadherin and Neuroligin1 adhesion systems have further been proposed to be molecularly linked by postsynaptic scaffolding proteins.

We have now studied the functional role of N-cadherin and Neuroligin1 at mature glutamatergic synapses by postsynaptically overexpressing these adhesion molecules in long-term cultured cortical neurons. The vesicle cluster-inducing, synaptogenic activity of Neuroligin1 was absent after intrinsic synaptogenesis had ceased as demonstrated by VAMP2 immunocytochemistry. However, staining cycling vesicle clusters with FM dye revealed an enhanced vesicle cycling upon Neuroligin1 overexpression. Intriguingly, overexpression of N-cadherin also resulted in a similar enhancement of synaptic vesicle cycling. This suggests that the molecular cooperation of the N-cadherin and Neuroligin1 adhesion systems may be also of functional importance at mature glutamatergic synapses.

To further study the role of synaptic adhesion molecules at mature synapses, we have performed fluorescence imaging of exo- and endocytosis of synaptic vesicles using Synaptophysin-pHluorin (SypHy). This high-resolution technique will enable us to study the functional role of N-cadherin, Neuroligin1, and their cooperation in the retrograde modulation of the synaptic vesicle cycle.

Title: Analysis of synapsin III function at the squid giant synapse

Authors: *S.-H. SONG[1,2], G. J. AUGUSTINE[1,3,4];
[1]Ctr. for Functional Connectomics, Korea Inst. of Sci. and Technology(KIST), Seoul, Seongbuk-Gu, Korea, Republic of; [2]Marine Biologucal Lab., Woods Hole, MA; [3]Program in Neurosci. and Behavioral Disorders, Duke-NUS Grad. Med. Sch., Singapore, Singapore; [4]Marine Biol. Lab., Woods Hole, MA

Abstract: Among the 3 synapsin genes, synapsin III is unique because of its J domain. This domain contains a MAPK phosphorylation site, S470, that is mutated in some schizophrenia patients (Biol. Psych. 55: 118). To examine the function of the J domain, we injected J domain peptides into squid giant presynaptic terminals. One J domain peptide (J2) reversibly inhibited synaptic transmission. A scrambled version of this peptide did not cause any inhibition, showing that the effect of the J2 peptide is sequence-specific. Estimation of intraterminal peptide concentration indicated that half-maximal inhibition of synaptic transmission was achieved at a J2 concentration of 0.8 mM. To determine the site of inhibition, we examined synaptic depression kinetics during peptide injection. J2 accelerated the time constant of depression, indicating that the peptide inhibits synaptic transmission by disrupting the synaptic vesicle reserve pool. Thus, like the C and E domains of synapsins, the J domain is involved in maintaining vesicles in the reserve pool. To examine the function of MAPK phosphorylation, the MAPK phosphorylation site within J2 was mutated by replacing a serine residue with aspartate (J2D). This pseudophosphorylated J2D peptide was capable of inhibiting synaptic transmission, while a non-phosphorylatable version (J2N) did not. The half-maximal concentration of J2D required to inhibit synaptic transmission (0.4 mM) was lower than that required for J2, suggesting that J2 peptide must be phosphorylated before it can block synaptic transmission. Consistent with this hypothesis, the time required for J2 to inhibit synaptic transmission was significantly longer than that required for J2D to act. Differences in latency indicate that J2 requires 7 min to be phosphorylated within the presynaptic terminal. In summary, our results indicate that interactions mediated by the J domain of synapsin IIIa can regulate reserve pool size and that this function is controlled by MAPK phosphorylation.

Title: Amygdala intercalated cells provide presynaptically - modulated sensory feed-forward and feedback inhibition to the basolateral amygdala

Authors: *D. T. ASEDE[1,2], D. BOSCH[1], F. FERRAGUTI[3], I. EHRLICH[1];
[1]HIH / CIN, Univ. of Tuebingen, Tübingen, Germany; [2]Grad. Sch. of Neural & Behavioural Sciences, IMPRS, University of Tuebingen, Germany; [3]Dept. of Pharmacology, Innsbruck Med. Univ., Innsbruck, Austria

Abstract: During classical fear conditioning, sensory information is relayed from specific thalamic and cortical regions and converges in the lateral amygdala (LA). Properties and plasticity of these inputs onto glutamatergic neurons is well studied, but recruitment of inhibitory neurons is still poorly understood. GABAergic intercalated neurons (ITCs) surrounding the BLA in distinct clusters have recently been shown to be activated differentially during high and low fear states. Particularly, cells in the medial paracapsular cluster (mpITCs) appear to have additional outputs apart from the canonical view that they inhibit the central amygdala. Here, we address two questions: (1) Are mpITCs innervated by sensory inputs and what are their properties? (2) Are there novel targets of mpITCs within the amygdala?
Using tracing, electrical and optogenetic stimulation, and patch clamp recordings in brain slices of adult mice, we show that mpITCs receive monosynaptic sensory inputs from the same thalamic and cortical regions that innervate the LA. These inputs are glutamatergic, and mediated by AMPA- and NMDA-receptors. Both thalamic and cortical inputs express functional GABA(B) receptors, and activation leads to a presynaptic depression. Strong activation of the mpITC network by priming either thalamic or cortical afferents with high frequency stimulation, resulted in presynaptic inhibition of the other pathway, which was blocked by a GABA(B)-receptor antagonist. This suggests that sensory inputs to mpITC cells are under presynaptic modulatory control via GABA(B) heteroreceptors that can be physiologically activated by recruitment of the mpITC intrinsic GABAergic network.
To identify outputs of recorded mpITCs, we filled cells and reconstructed their axonal arbors. We identify mpITCs with axonal patterns in accordance with three published cell-types and a population with significant axonal arbors in the BLA that establishes inhibitory synaptic contacts with dendrites of BLA neurons. In keeping, retrograde tracing from the BLA labels a subpopulation of mpITCs, indicating that mpITCs provide sensory-driven feed-forward inhibition to the BLA. Furthermore, retrogradely labeled mpITCs receive monosynaptic excitatory inputs from optogenetically activated BLA principal cells in their target region. This suggests that mpITCs can also participate in feedback inhibitory control of the BLA.

Taken together, we describe novel sensory inputs to mpITCs and provide evidence that mpITCs are part of feed-forward and feedback inhibitory circuits controlling the BLA. These findings extend and challenge the classical view of ITC function in amygdala networks.

Title: The conserved isoforms of Miro may have different roles for mitochondrial biology in axons of *Drosophila*

Authors: *M. BABIC[1], T. M. KUHN[2], K. E. ZINSMAIER[2];
[1]Grad. Interdisciplinary Program in Neurosci., Univ. of Arizona, TUCSON, AZ; [2]Dept. of Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Neuronal function critically depends on the prolonged presence of mitochondria in axons and dendrites. However, the molecular mechanisms underlying the specialized biology of axonal mitochondria remain poorly understood.
Previous work suggested that the mitochondrial GTPase Miro is critical for mitochondrial transport in axons and dendrites by coupling mitochondria to kinesin motors via the adaptor protein Milton (OIP98/106/TRAK1/2). In addition, Miro may play a critical role for the organization and health of mitochondria, possibly by coordinating transport with mitochondrial fusion and fission, degradation and mitochondria-ER interactions.
The *Drosophila miro* gene expresses three protein isoforms that differ in length by only 21 amino acids, termed Miro-long, -medium and -short (Miro-L, -M, -S). The precise location of this variable domain (VD) within the Miro protein sequence (~15 aa from the TM domain) is conserved from flies to humans but the length and sequence is not, not even between mouse and human. Hence, the VD has no discernible function other than possibly affecting the distance of the GTPase and EF-hand domains from the OMM, which could have functional consequences. To test whether Miro-L, -M, and -S are functionally equivalent, we expressed each isoform in *miro* null mutant *Drosophila*. Surprisingly, neuronal expression of Miro-M restored a normal viability, but expression of Miro-L or -S did not. Moreover, neuronal overexpression of Miro-L or -S (but not -M) caused premature death during development with a few escapers surviving to

adulthood that failed to inflate their wings and died prematurely within several hours. Further analyses revealed differential effects on mitochondrial transport, distribution, structure and health in larval motor axons. Most prominently, Miro-L (and to a lesser degree -S) expression induces the formation of 2 very different abnormal subpopulation of mitochondria: severely enlarged mitochondria with an extremely increased density of cristae and severely thin, highly elongated mitochondrial structures that are interconnected in a complex network. Interestingly, overexpression (OE) of Parkin or Pink 1 suppresses the effects on lethality induced by Miro-S expression but not that of Miro-L. Hence, the different phenotypes induced by Miro-L, -M, and -S and different genetic interactions support the notion that they are functionally different.

Title: Glutamatergic and GABAergic projections from the medial amygdala to the posterior bed nucleus of the stria terminalis

Authors: *A. R. BURNS[1], D. SHUKLA[2], L. A. MARTINEZ[2], B. M. COOKE[2], A. PETRULIS[2];
[2]Neurosci. Inst., [1]Georgia State Univ., Atlanta, GA

Abstract: The perception and processing of socially relevant odors is critical to the execution of reproductive behavior in rodents. The bed nucleus of the stria terminalis (BNST), in conjunction with the medial amygdala (MeA), plays an important role in the integration of hormonal and chemosensory cues. The posteromedial BNST (BNSTpm) has numerous steroid-sensitive cells and receives projections from the posterodorsal medial amygdala (MePD) whereas the posterointermediate BNST (BNSTpi) receives a large input from the chemosensory anterodorsal medial amygdala (MeAD). However, the neurotransmitter phenotype of the connections from the different subnuclei of the MeA to the BNST has yet to be characterized. Consequently, we investigated the phenotype of these projections with injections of the anterograde tracer biotinylated dextran amine (BDA) into the MeAD and MePD. Presynaptic boutons were labeled with a marker of glutamatergic terminals, vGlut2, and a marker of GABAergic terminals, GAD65. The extent of colocalization between the BDA-labeled axons and the presynaptic

markers was then quantified. The colocalization of vGlut2 with BDA in the BNST indicates that the proportion of glutamatergic terminals is independent of the injection site (MeAD or MePD) and BNST subnucleus (BNSTpi or BNSTpm). Similarly, colocalization of GAD65 with BDA in the BNST does not vary with injection site or subnuclei. Our preliminary analysis confirms that projections from the MeAD and MePD project selectively to the rostral BNSTpi and BNSTpm, respectively. In contrast, both caudal BNSTpi and BNSTpm appear to be innervated by projections from the MePD. This pattern was not seen in projections from the MeAD, where fibers were most abundant in the BNSTpi throughout the rostral-caudal axis.

Title: Increased post-tetanic asynchronous neurotransmitter release at parasympathetic major pelvic ganglion neurons of type 2 diabetic mice may involve altered mitochondrial regulation of Ca2+ homeostasis

Authors: *J. D. TOMPKINS, R. PARSONS;
Dept. of Neurolog. Sci., Univ. of Vermont, Burlington, VT

Abstract: We previously determined that the frequency of tetanic stimulation-induced miniature excitatory postsynaptic potentials (mEPSPs) is substantially greater in parasympathetic major pelvic ganglion (MPG) neurons of type 2 diabetic mice. Recently we sought to determine, 1) if post-tetanic mEPSP activity correlates with the severity of hyperglycemia and hyperlipidemia in multiple strains of type 2 diabetic mice and 2) if the increased mEPSP activity is associated with impaired mitochondrial regulation of nerve terminal Ca2+. Post-tetanic mEPSP activity, after 5, 10 and 20 Hz (5 sec duration) of preganglionic nerve stimulation, was significantly increased in BKS-db+/+ (leptin receptor deficient) mice as early as 6 wks of age. mEPSP activity was greatest in BKS-db+/+ mice at 12 wks of age. In BL6-ob+/+ (leptin deficient), post-tetanic mEPSP frequency was greater than controls at 6 and 12 wks of age. The number of post-tetanic mEPSPs correlated with the degree of hyperglycemia and body weight in both models, with the greatest number of mEPSPs observed in severely hyperglycemic and obese BKS-db+/+ mice. To

test if the increased post-tetanic mEPSP activity was associated with [Ca2+]o, we determined the frequency of post-tetanic mEPSPs at multiple extracellular concentrations of Ca2+ . Increasing [Ca2+]o significantly increased post-tetanic mEPSP number. Mitochondrial depolarization also significantly increased post-tetanic mEPSP activity in both control and BKS-db+/+ mice. There was a smaller increment in mEPSP activity before and after mitochondrial depolarization in BKS-db+/+ mice indicating a possible involvement of mitochondrial Ca2+ uptake in the pathogenesis of nerve terminal dysfunction with diabetes. Ongoing experiments test the hypothesis that impaired intraterminal Ca2+ homeostasis with type 2 diabetes alters presynaptic regulation of neurotransmitter release.

Title: Functions of nuclear distribution proteins in axonal mitochondrial transport

Authors: *Y. SHEN[1], C.-Y. SHAO[2], J. ZHU[2], Y.-J. XIE[2], T.-H. ZHOU[3];
[1]Neurobio., Zhejiang Univ. Sch. Med., Hangzhou, China; [2]Neurobio., [3]Zhejiang Univ. Sch. of Med., Hangzhou, China

Abstract: Neurons critically depend on the long-distance transport of mitochondria. Motor proteins kinesin and dynein control anterograde and retrograde mitochondrial transport respectively in axons. The adaptor molecules that link them to mitochondria need to be better characterized. Nuclear distribution (Nud) family proteins LIS1, Ndel1 and NudCL are critical components of cytoplasmic dynein complex. Roles of these Nud proteins in neuronal mitochondrial transport are unknown. Here we report distinct functions of LIS1, Ndel1 and

NudCL on axonal mitochondrial transport in cultured hippocampal neurons. We found that LIS1 interacted with kinsein family protein KIF5b. Depletion of LIS1 enormously suppressed mitochondrial motility in both anterograde and retrograde directions. Inhibition of either Ndel1 or NudCL only partially reduced retrograde mitochondrial motility. However, knocking down both Ndel1 and NudCL almost blocked retrograde mitochondrial transport, suggesting these proteins may work together to regulate retrograde mitochondrial transport through linking dynein-LIS1 complex. Taken together, our results uncover novel roles of LIS1, Ndel1 and NudCL in axonal mitochondrial transport.

Title: Excitation by GABA spillover in a sound localization circuit

Authors: *C. J. WEISZ, K. KANDLER;
Otolaryngology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: The lateral superior olive (LSO), an auditory nucleus involved in horizontal sound localization, receives tonotopically organized inhibitory glycinergic inputs from the medial nucleus of the trapezoid body (MNTB). The MNTB-LSO pathway undergoes refinement before hearing onset through synaptic strengthening and silencing. In addition to glycine, developing MNTB neurons also release glutamate and GABA, but their function is poorly understood. Here, we investigate a possible role for GABA. Whole-cell voltage-clamp recordings were performed from LSO neurons in brain slices from P3-P14 C57BL/6J mice. Electrical stimulation of MNTB axons elicited post-synaptic currents (PSC) in LSO neurons. In about half of recordings an unusual PSC occurred characterized by two distinct components following a single stimulus. We term these responses “doublets”. In doublets, the second component did not occur without the first, but the first could occur without the second. Both components of a doublet reversed at -20

mV (60 mM Cl- internal, n=4), suggesting that both components are chloride currents most likely due to inhibitory neurotransmitter release from MNTB neurons. The short latency from the first to the second component (~3 ms) is faster than MNTB neurons can release neurotransmitter at these ages (300 Hz stimulation), suggesting that the two components are elicited by different populations of axons. Our results suggest that doublets are the result of GABA spillover between nearby MNTB axons: 1) The probability of recording a doublet increased with stimulus strength (increased neurotransmitter release). 2) The second component in a doublet was blocked by the GABAAR antagonist gabazine (30 µM), without loss of the first PSC (n = 9 of 17 cells). 3) Doublet occurrence was enhanced by the GABA reuptake blocker guvacine (30 µM, 3 of 9 cells). 4) Higher frequency stimulation increased the occurrence of doublets in about 20% of cells. To test the presynaptic excitatory action of GABA on MNTB axons, current clamp recordings were performed from MNTB somata and axons were filled with dye to visualize terminals in the LSO with 2-photon imaging. Focal RuBi-GABA (100 µM) uncaging at the MNTB axon depolarized the soma up to 15 mV (>500 microns distant) indicating direct axonal excitation by GABA. We suggest that GABA spillover excitation of neighboring MNTB axons may play a role in the refinement of tonotopic projections from the MNTB to the LSO.

Title: Human α-synuclein mutants E46K and A53T cause vesicle trafficking defects at the lamprey giant synapse

Authors: *R. B. WALSH[1], D. J. BUSCH[2], P. A. OLIPHINT[2], W. S. WOODS[3], J. M. GEORGE[4], J. R. MORGAN[1];
[1]Marine Biol. Lab., Falmouth, MA; [2]Dept. of Mol. Cell and Developmental Biol., The Univ. of Texas at Austin, Austin, TX; [3]Mol. and Integrative Physiol. and Neurosci., The Univ. of Illinois, Urbana, IL; [4]Div. of Biol. and Exptl. Psychology, Sch. of Biol. and Chem. Sci., Queen Mary Univ. of London, London, United Kingdom

Abstract: Parkinson's Disease (PD) is pathologically characterized by death of dopaminergic neurons and the presence of Lewy bodies, which contain aggregates of the synaptic vesicle-

associate protein α-synuclein. Multiplication of the α-synuclein gene, as well as A53T and E46K missense mutations, has been linked to familial PD. While a great deal is known about the biochemical properties of WT synuclein and the disease-related mutants, how they affect synapse structure and function is unclear. Dynamic imaging studies have revealed that overexpression of WT α-synuclein, A53T, and E46K cause general defects in synaptic vesicle trafficking. However, the specific stages of the synaptic vesicle trafficking pathway that are affected, and the underlying mechanisms, remain unknown. To address this, we took advantage of the experimental accessibility of the giant reticulospinal axons of the lamprey (Petromyzon marinus), which enables us to acutely microinject excess α-synuclein or the mutants and examine the ultrastructural effects at synapses. We have previously shown that excess WT human α-synuclein causes defects in synaptic vesicle endocytosis at stimulated synapses, characterized by a depletion of synaptic vesicles (SV) and an expansion of the plasma membrane (PM). Excess synuclein also increases the amount of large atypical internal membrane structures with only a modest increase in clathrin-coated pits and vesicles. In this study, we similarly examined the effects of A53T and E46K on synaptic vesicle trafficking. A53T and E46K are mutations in the highly conserved, alpha-helical N-terminal domain of α-synuclein. A53T possesses an alpha helical structure that is similar to WT α-synuclein, while E46K has a disrupted helix. Accordingly, A53T induced severe defects in synaptic vesicle endocytosis that were similar to those observed for WT: a 50% decrease in SVs, >33% increase in PM evaginations, >10-fold increase in total internal membrane (TIM), and a modest increase in clathrin-coated structures. In contrast, the E46K mutant caused a marked decrease in SVs and a modest increase in the TIM. However, with E46K, the PM and number of clathrin coats did not differ significantly from controls. Taken together, these data indicate that A53T and E46K cause severe, but distinct, vesicle trafficking defects at the lamprey synapse. Through these and future experiments we aim to gain a deeper understanding of the mechanisms underlying α-synuclein's pathogenic role in PD.

Title: Super resolution imaging reveals high amounts of BDNF in granules within presynaptic glutamatergic synapses of hippocampal neurons *In vitro*

Authors: *R. BLUM[1], T. ANDRESKA[1], S. AUFMKOLK[2], S. VAN DE LINDE[2], M. SAUER[2]; [1]Inst. for Clin. Neurobio., [2]Dept. of Biotech. and Biophysics, Univ. of Wuerzburg, Wuerzburg, Germany

Abstract: In the mammalian brain in brain-derived neurotrophic factor (BDNF) has emerged as a key factor involved in synaptic plasticity. Defects in hippocampal BDNF signaling are associated with reduced episodic memory, emotional disorders and misbalanced regulation of learned fear. Although BDNF-induced signaling cascades are beginning to be well appreciated, the spatial aspects of synaptic BDNF release are purely understood. Recent data provide evidence for an exclusive presynaptic location and anterograde secretion of BDNF in synapses of the hippocampal circuit. In contrast many studies using cultured neurons support the idea that synaptic BDNF acts retrogradely and is preferentially released from postsynaptic sites. Here we used rigorously tested anti-BDNF antibodies to achieve a dense labeling of BDNF at synaptic sites of long-term cultures of hippocampal neurons. High-resolution confocal microscopy revealed strong BDNF labels close to glutamatergic synapses. GABAergic synapses or postsynaptic neuronal structures showed only minor BDNF immunoreactivity. To ultimately resolve the BDNF distribution within the fine structure of synapses we implemented super-resolution imaging by *direct* stochastic optical reconstruction microscopy (*d*STORM) for colocalization studies with a spatial resolution of ~ 20 nm. Two-color *d*STORM images identify BDNF present mainly in small granule-like vesicles within presynaptic glutamatergic terminals (see Figure). Quantification of localization points in *d*STORM images of peripheral neurites shows that ~ 50% of all BDNF molecules in are found on the presynaptic side within glutamatergic synapses. Only about 5% of all BDNF molecules detected close to postsynaptic bars. In conclusion, super resolution imaging of endogenous BDNF reveals the principle capability of in vitro hippocampal neurons to enrich and store high amounts of BDNF within glutamatergic presynapses.

Title: Electron microscope tomography of synaptic cell adhesion proteins

Authors: *B. HIGH[1], X. CHEN[2], T. REESE[2];
[1]NIH, Rockville, MD; [2]Natl. Inst. of Neurolog. Disorders and Strokes, NIH, Bethesda, MD

Abstract: Traditional electron microscopy reveals myriad organized structures, thought to represent cell adhesion proteins, which span the synaptic cleft. Several of these cell adhesion proteins-neurexin, neuroligin, cadherin, SynCAM, ephrin, and ephB-are localized to the synaptic cleft of excitatory synapses, where some of their functions have been characterized. Although electron microscopy (EM) provides the resolution to see individual molecules in the cleft, extensive overlap in a typical section makes it difficult to resolve individual proteins (Chen et al., 2008). Here we utilize EM tomography to visualize distinct individual structures in the synaptic clefts. Segmentation and rendering of these structures from 1.4 nm thick virtual sections calculated from the tomograms reveals several types of structure bridging the cleft between the

pre- and post synaptic membranes. The three most abundant types of transynaptic structure are distributed throughout the ~120 nm slice of postsynaptic density in the sample. The first type, represented by 34 copies in the sample, exhibits large, oblong pre- and postsynaptic attachments connected by a thin filament with a characteristic central nodule, while the other two types lack central nodules. The first of these, represented by 42 copies, is a filament ~4 nm in diameter within the cleft, while the other type, represented by 28 copies, is a filament ~10 nm in diameter. The two least abundant proteins spanning the cleft have distinct distributions-15 vertically oriented, doughnut-shaped complexes reside in the center of the PSD, and 9 deeply curved, filamentous structures with large presynaptic attachments and small postsynaptic attachments reside around the periphery. When the entire population of cleft structures was overlaid with renderings of presynaptic vesicles attached to the presynaptic membrane, it became apparent that transynaptic cleft structures avoid synaptic vesicle release sites. It would be premature to identify any of the cleft structures at this point, but we expect that each type corresponds to a known class of transynaptic proteins, and that eventually identifying them will provide new insights into synaptic transmission and connectivity.

Title: Using tetanus toxin (TNT) to blast the SNARE machinery

Authors: K. NEUSER[1], N. EHMANN[1], T. MARTINI[1], M. SAUER[2], M. HECKMANN[1], *M. PAULI[1];
[1]Dept. of Neurophysiol., Inst. of Physiology, Julius-Maximilians Univ., Wuerzburg, Germany;
[2]Dept. of Biotech. and Biophysics, Biocenter, Julius-Maximilians Univ., Wuerzburg, Germany

Abstract: Tetanus toxin (TNT) causes paralysis by blocking synaptic neurotransmission through proteolysis of the v-SNARE protein synaptobrevin (VAMP2). Electrophysiological recordings at the Calyx of Held revealed that TNT leads to a decrease of evoked vesicle release, loss of the fast release component and to slowed recovery of the fast release component (Sakaba et al. 2005). These kinetic changes can be interpreted as a TNT mediated block of vesicle release sites. To examine spatial molecular reorganizations and functional alterations, TNT was conditionally expressed in *Drosophila melanogaster* larvae in a spatially and temporally restricted manner.

This allows to target a specific set of neurons and to determine the onset of TNT expression. Assessing third instar larval locomotion, we found that induction of TNT expression in motoneurons for 1200 min is sufficient to alter behaviour. Therefore this time-regime was used to induce sub-maximal TNT expression. At neuromuscular junctions amplitudes of spontaneous miniature excitatory postsynaptic currents (mEPSCs) and action potential evoked excitatory postsynaptic currents (eEPSCs) (paired-pulse stimulation, 0.2 Hz) were reduced after TNT expression in two-electrode voltage clamp (TEVC) recordings. Furthermore rise and decay times of mEPSCs were reduced and synaptic delays of eEPSCs increased by TNT.
For further analysis the organization of the filamentous active zone component Bruchpilot (Brp; Wagh et al. 2006; Kittel et al. 2006) was evaluated using a monoclonal antibody, Brp^{NC82}, directed against a C-terminal epitope of Brp (Fouquet et al. 2009). Super-resolution light microscopy of wildtype w^{1118} and TNT expressing larvae showed altered Brp-distributions in line with a reorganization of active zones (AZs). The sub-maximal blast of the SNARE machinery thus altered synaptic transmission and induced AZ growth or clustering.

Title: Syntaxin Habc domain is required for synaptic function

Authors: *L. A. PARRA[1,2], J. M. WHIPPEN[1,2], C. Y. DY[1,2], E. JORGENSEN[2,3];
[1]Univ. of Utah, Salt Lake City, UT; [2]Howard Hughes Med. Inst., [3]Univ. of Utah, Salt lake city, UT

Abstract: Intracellular membrane fusion is mediated by the assembly of specific SNARE complexes. These interactions are believed to provide the driving force for bilayer fusion. The neuronal SNARE protein syntaxin (UNC-64) contains a highly conserved three-helix bundle known as the Habc domain. The Habc domain folds back to interact with its own SNARE motif, rendering syntaxin ‘’closed’’ in solution and preventing SNARE complex formation. However, it is not clear whether the Habc domain performs additional functions in synaptic transmission beside self-inhibition. In vitro studies suggest that the Habc domain is dispensable for liposome fusion. However, to date, no one has tested the role of syntaxin’s Habc domain in regulating synaptic vesicle dynamics in vivo.

To test the role of the Habc domain in vivo, we have performed rescue experiments in C. elegans. When the Habc domain of syntaxin is replaced with the homologous yeast Habc domain from Sso1, transgenes no longer rescue the unc-64 null animals. Similarly, when the SNARE motif of syntaxin is replaced with the yeast SNARE motif of Sso1, the transgene is incapable of rescuing unc-64. However, when the two chimeric proteins are expressed together, they rescue the syntaxin null. We find that this paired chimera-rescue occurs independent of the N-peptide, which has previously been shown to be important for fusion. These preliminary observations suggest that the Habc domain may facilitate fusion by a mechanism independent of self-inhibition and transport.

Since C. elegans unc-64 nulls are lethal, we are currently generating a single copy insert expressing unc-64(+) in the acetylcholine neurons to restore viability of the unc-64 null mutants. This mosaic strain will be used to express the yeast Habc domain chimera in GABA neurons to examine the role of the Habc domain in neurotransmission. Furthermore, in an effort to explore novel functions of the Habc domain, we propose to identify interacting proteins using proteomics.

Title: The α-neurexin ligand neurexophilin 3 modulate important properties of excitatory synapses

Authors: S. WANG, G. BORN, A. BLANQUÉ, A. ROHLMANN, *M. MISSLER;
Inst. of Anat. & Mol. Neurobio., Westfaelische Wilhelms Univ. of Muenster, Muenster, Germany

Abstract: The mostly presynaptic cell-adhesion molecules neurexins (Nrxns) play an essential role in synaptic transmission. However, the role of their extracellular, α-Nrxn-specific ligand neurexophilin 3 (Nxph3), a small glycoprotein that binds tightly to the second LNS domain, is unknown. Although α-Nrxn variants are expressed in virtually all excitatory and inhibitory neurons throughout the brain, Nxph3 expression is restricted to subpopulations of excitatory neurons, mostly in cerebral cortex layer 6b and in the vestibulocerebellum. To test the hypothesis that Nxph3 is a modulator of α-Nrxn function in neurotransmission, we generated a transgenic (TG) mouse model which overexpresses GFP-tagged Nxph3 under control of the Thy1.2 promoter. Morphological analysis confirmed that Nxph3-GFP in TG mice is ubiquitously expressed in many cortical neurons, and localized to the synaptic cleft, for example, of excitatory synapses in cortical layer 5 pyramidal cells which normally do not contain this molecule. Using whole-cell patch clamp recordings from these pyramidal cells in the primary somatosensory cortex, we compared synaptic transmission in Nxph3 TG and wild-type (WT) mice. While the ultrastructure of transgenic asymmetric synapses was intact, frequencies of miniature excitatory postsynaptic currents (EPSCs) were decreased in Nxph3 TG mice. Since these decreased frequencies could be rescued to normal levels by applying the $GABA_B$ receptor (R) antagonist CGP-55845, our data indicate that $GABA_BR$ are involved in the altered spontaneous neurotransmitter release. Moreover, amplitudes of electrically evoked EPSCs were also diminished in Nxph3 TG mice, which could in turn be restored to normal levels by extracellular treatment of TG neurons with the NMDAR antagonist APV. Similar rescue results could be obtained with the NMDAR antagonist MK-801 in the recording pipette, implying that postsynaptic NMDAR are involved in the altered activity-dependent neurotransmission at excitatory Nxph3 TG synapses. In support, we observed that NMDAR contributed more to EPCSs at TG synapses because NMDA/AMPA ratios were increased. As control and consistent with our immunolabeling data that showed Nxph3-GFP at excitatory synapses only, inhibitory transmission remained unchanged in TG mice. In summary, our results show that ectopic expression of the α-Nrxn-ligand Nxph3 influences basal synaptic transmission of excitatory synapses, presumably through $GABA_B$ and NMDA receptor-dependent mechanisms.

Title: α4-laminin is not involved in the developmental switch of voltage-gated calcium channel subtypes

Authors: *K. LEE[1], K. K. CHAND[1], N. A. LAVIDIS[1], P. G. NOAKES[1,2];
[1]Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia; [2]Queensland Brain Inst., Brisbane, Australia

Abstract: α4-laminin has a role in aligning pre- to postsynaptic components of the neuromuscular junction (NMJ). β2-laminin that forms the laminin heterotrimer 9, with α4- and γ1-laminin is involved in organizing the presynaptic components of the developing NMJ. *In vitro* studies showed that β2-laminin binds directly to P/Q-type voltage-gated calcium channels (VGCCs) at the active zone. At postnatal day 8 (P8), neurotransmission is predominantly mediated by activation of N-type VGCCs. By postnatal day 18 (P18) there is a switch to P/Q-type VGCC dominance. As α4-laminin forms laminin-9 with β2-laminin, it is postulated that it may also be involved in this switching of VGCCs at the NMJ. In the present study we investigated the role of α4-laminin in the switch from N- to P/Q-type VGCCs at the active zones of developing P8 and matured P18 NMJs. We functionally determined the neurotransmission properties of α4-laminin-deficient mice ($\alpha4^{-/-}$) and wild types (WT) using intra- and extracellular electrophysiological recordings of evoked and spontaneous transmitter release. Mice were bred and maintained on a C57BL/6-129SvJ genetic background. Mice were sacrificed by cervical fracture with diaphragm and innervating nerve dissected free. The phrenic nerve was stimulated while recording end-plate potentials (EPPs) and miniature end-plate potentials (MEPPs) using intracellular recordings from hemi-diaphragm muscle fibres. End-plate currents (EPCs) and miniature end-plate currents (MEPCs) were recorded using focal extracellular electrodes. Immunofluorescence staining was performed using primary antibodies against N- and P/Q-type VGCCs and compared with α-bungarotoxin staining for $\alpha4^{-/-}$, β2-laminin-deficient mice and WT at P8 and P18. Electrophysiological analysis of MEPPs amplitude in $\alpha4^{-/-}$ displayed a significant increase at P8 ($n=6$, $p<0.01$) and P18 ($n=6$, $p<0.05$) compared to WT. Analysis of EPPs amplitude at P18 ($n=6$) of $\alpha4^{-/-}$ showed a significant increase ($p<0.05$) for evoked transmitter release. Intermittence in transmitter release was significantly increased in $\alpha4^{-/-}$ at P8 ($n=6$,

p<0.001) and P18 (n=6, p<0.05) compared to WT. Morphologically the distribution of N- and P/Q- type VGCCs was not changed in the $\alpha4^{-/-}$ when compared with WT at both ages examined. The present results indicate that, $\alpha4^{-/-}$ resulted in a greater intermittence which may suggest fewer active release sites. $\alpha4^{-/-}$ also showed increased MEPP and EPP amplitudes suggesting possible increased acetylcholine receptor density or decreased acetylcholinesterase activity. There was no alteration in the developmental switch from N- to P/Q-type VGCCs or the density and distribution of VGCCs at $\alpha4^{-/-}$ NMJs.

Title: Functional role of the ATP-binding site of Synapsin I in synaptic vesicle trafficking and release dynamics

Authors: *G. LIGNANI[1], M. ORLANDO[1], L. MARAGLIANO[1], S. GIOVEDI`[3], S. GALIANI[2], A. FASSIO[3], P. BIANCHINI[2], A. DIASPRO[2], P. BALDELLI[1,3], F. BENFENATI[1,3]; [1]Neurosci. and Brain Technol., [2]Nanophysics, Inst. Italiano Di Tecnologia, GENOVA, Italy; [3]Dept. of Exptl. Med., Univ. of Genova, Genova, Italy

Abstract: The effect of energy metabolism on synaptic transmission and plasticity is a poorly explored topic. Our aim was to investigate whether presynaptic ATP concentration can be altered by intense synaptic activity and if this could affect synaptic vesicle (SV) mobilization. Synapsins (Syns) are SV−associated phosphoproteins implicated in the regulation of neurotransmitter release and synapse formation. Synapsins display a major and highly conserved ATP binding site in the central C-domain, shared by all Syn isoforms. Moreover, Syn I binds Ca2+ and Ca2+-binding regulates ATP binding. This suggests that Syn I functions, such as its capability to induce SV mobilization and trafficking, could be modulated by the Ca2+-dependent binding of ATP. To elucidate the structural basis of ATP binding to Syn I we performed Molecular Dynamics Simulations of the native protein with and without ATP and Ca2+ bound, as well as of the mutant SynI-K269Q, unable to bind ATP. To analyze the functional consequences of an alteration in ATP binding, we reintroduced either native Syn I or Syn I- K269Q mutant in Syn I knockout hippocampal neurons via lentiviral vectors. Inhibitory synaptic transmission was studied by patch-clamp coupled with genetically encoded fluorescent reporters of exocytosis

(synaptophysin-pHluorin) to evaluate SV cycling, number of active synapses, and synaptic vesicle fusion. We also used STED and electron microscopy to analyze how SVs and Syn I distribution are modified in neurons infected with native Syn I or with its mutated form both under resting conditions and upon electrical stimulation. Analysis of the ultrastructure of inhibitory synapses revealed variations in SV density and distribution in SynI-K269Q. Infection of primary neurons with Syn I-K269Q increased the strength of inhibitory transmission, altered release dynamics and impaired SV reorganization in pools. The application of sustained stimulation trains showed that the ATP mutant induced a stronger depression and a slower recovery, suggesting an altered SV supply to the readily releasable pool. Taken together these results suggest that ATP binding to Syn I plays a fundamental role in the modulation of synaptic transmission and plasticity of inhibitory synapses. Furthermore, we demonstrated that incubation of purified SVs in vitro with ATP in the absence of Ca2+ was able to increase Syn I binding to SVs and Syn I oligomerization with respect to control conditions, suggesting that Syn I might be also able to bind ATP in a Ca2+-independent manner; under these conditions SVs result more clustered, suggesting a possible direct role for ATP binding in the Syn I-induced SV clustering.

Title: Mechanisms of kHz-transmission at a central synapse

Authors: *A. RITZAU-JOST[1,2], I. DELVENDAHL[1,2], A. WEYHERSMÜLLER[1,2], J. HIRRLINGER[1,3], H. SCHMIDT[1], J. EILERS[1], S. HALLERMANN[1,2];
[1]Carl-Ludwig-Institute for Physiology, Med. Fac., Leipzig Univ., Leipzig, Germany; [2]European Neurosci. Inst., Univ. Med. Center, Göttingen Univ., Göttingen, Germany; [3]Dept. for Neurogenetics, Max-Planck-Institute for Exptl. Med., Göttingen, Germany

Abstract: The rate at which signals can be transmitted between single neurons limits the speed of information processing in the central nervous system. Cerebellar mossy fiber boutons display rates of action potentials up to 1 kHz *in vivo* [1,2]. While rapid reloading of vesicles at the release site likely sustains reliable transmission [3,4], a mechanistic analysis with presynaptic

recordings has not been performed. Here, we established paired patch-clamp recordings between cerebellar mossy fiber boutons and granule cells, presynaptic capacitance measurements, deconvolution of postsynaptic currents and quantitative presynaptic two-photon Ca^{2+}-imaging. We show that presynaptic action potentials are ultrafast (half-width 107 ± 4 μs, n = 44) and can be elicited and reliably transmitted at frequencies of at least 1 kHz. We analyze the kinetics and the Ca^{2+}-dependence of transmitter release during trains of action potentials and prolonged depolarization. The findings suggest that heterogeneous vesicle populations with Ca^{2+}-independent reloading contribute to release. Our results show that Ca^{2+}-independent reloading and heterogeneity among vesicles allow kHz transmission at a central synapse.

Title: Adrenergic C1 neurons drive central noradrenergic (NE) neurons via monosynaptic glutamatergic synapses

Authors: *B. B. HOLLOWAY, R. L. STORNETTA, G. BOCHORISHVILI, K. E. VIAR, P. G. GUYENET;
Pharmacol., Univ. of Virginia, Charlottesville, VA

Abstract: C1 neurons, located in the rostral ventrolateral medulla (RVLM), are activated by hypotension, hypoglycemia, hypoxia, infection, pain and psychological stress. C1 activation increases sympathetic tone and peripheral norepi- and epi-nephrine via direct excitation

sympathetic preganglionic neurons in the intermediolateral column. C1 neurons also target the locus coeruleus (LC) and other noradrenergic brainstem regions such as the A2 neurons located in the nucleus of the solitary tract and the A1 neurons located in the caudal VLM. In this study we examined whether the C1 cells establish synapses with these three groups of CNS noradrenergic neurons, and we test whether these synapses are excitatory. C1 neurons and projections were identified by microinjecting DIO-ChR2-eYFP(or mCherry)-AAV2 into the RVLM of dopamine-β hydroxylase-Cre (DβHCre/0) mice. We showed by immunohistochemistry that >98% of the ChR2-expressing neurons were also tyrosine-hydroxylase- (TH-)-ir and that most contained PNMT. Plentiful synaptic contacts between mCherry-ir boutons and noradrenergic neurons were identified as close appositions by light microscopy (LC, A1 A2 neurons) and ultrastructurally confirmed as synapses via immunogold-silver labeling of tyrosine-hydroxylase (TH) using electron microscopy (A1 and A2 neurons). Synaptic transmission between C1 neurons and brainstem NE neurons was studied electrophysiologically in coronal brain slices from adult mice (whole cell voltage and current clamp at 23°C). ChR2-containing C1 axons were photoactivated (1 ms, 5 mW, 473nm laser light). LC neurons were identified using landmarks and cell properties and the NE phenotype of the recorded neurons was verified posthoc by histology. A1 and A2 neurons were recorded in DβHCre/0/ROSA26-tdTomato mice after verification that tdTomato red fluorescence was specifically expressed by TH-ir neurons. Photostimulation evoked 5.5±0.4ms latency EPSCs (34.8±5.0 pA at VH= -74 mV) in 53% (42/79) of LC neurons and activated these cells from 1.9±0.4 Hz to 3.1±0.7 Hz (N= 4; current clamp). The EPSCs were eliminated by tetrodotoxin, reinstated by the K-channel blocker, 4-aminopyridine and eliminated again by adding CNQX and AP5, thus demonstrating the existence of a monosynaptic glutamatergic excitatory input from the C1 cells to LC neurons. Virtually identical results were obtained in 8 A2 neurons and 5 A1 neurons. We conclude that the C1 cells have the potential of activating the release of NE throughout the CNS via their monosynaptic excitatory input to the LC and other brainstem noradrenergic neurons.

Title: Synaptic analysis of neurexin 2 (nrxn2) function in conditional nrxn2 knockout mice

Authors: *L. Y. CHEN[1], T. C. SUDHOF[1,2];
[1]Stanford Inst. for Neuro-innovation & Translational Neurosciences, [2]Mol. and Cell. Physiol., Stanford Univ., Stanford, CA

Abstract: Increasing evidence suggests that neurexins (Nrxns) are presynaptic cell adhesion molecules that are critical for maintaining synaptic function. NRXN genes have been linked toautism spectrum disorders (ASD) and schizophrenia. In particular, recent studies identified patients with ASDs that have a truncating mutation of NRXN2. However, due to the lacking of fundamental understanding of Nrxn2 function, it remains unknown why Nrxn2 is associated with these disorders. Here, we made, characterized, and used conditional knockout (cKO) mice in which both the α- and β-forms of NRXN2 can be deleted by Cre recombinase. These mice allow us to investigate the synaptic function and requirements for NRXN2. The design and creation of this cKO NRXN2 mouse was confirmed by genotyping and quantitative reverse transcriptase polymerase chain reaction (qRT-PCR) to measure mRNA levels. Analysis of spontaneous miniature postsynaptic currents, evoked responses and synaptic morphology will address the precise contributions of specific NRXN isoforms to synaptic transmission and identify pathways relevant to synapse development that give rise to cognition and brain function.

Title: Nanoscale organization of readily-releasable vesicles in native hippocampal terminals

Authors: *F. CRAWFORD[1], V. MARRA[3], K. STARAS[2];
[1]Life Sci., [2]Univ. of Sussex, Brighton, United Kingdom; [3]Univ. of Leicester, Leicester, United Kingdom

Abstract: Small central nerve terminals rely on the efficient turnover of neurotransmitter-containing synaptic vesicles. How these recycling vesicles are organized in the terminal, what factors influence this organization, and how their structural characteristics contribute to synaptic function remain key questions in neuroscience. Here we used FM-dye labelling methods combined with ultrastructural imaging approaches to examine principles of organization of functional vesicle pools in acute rat hippocampal slices. Specifically, we stimulated Schaffer-collaterals (40 APs, 20 Hz) while FM1-43 was applied to the stratum radiatum to drive the labelling of readily-releasable vesicles in CA3-CA1 terminals. Following rapid chemical-microwave fixation, target synapses were photoconverted in the presence of diaminobenzidine, generating an electron-dense precipitate in recycling FM-dye-positive vesicles that can be readily observed in electron micrographs. We demonstrate that the readily releasable pool is 5-10% of the total vesicle pool, comparable with previous studies. We also characterize the spatial distribution of this pool, showing that it exhibits a preferential bias towards the active zone that becomes more pronounced with increasing time after the end of stimulation. The nanoscale organization of the preferentially releasable pool offers important insights into key structure-function relationships which contribute to synaptic signalling.

Title: *In vitro* monosynaptic circuits of Helix neurons as an experimental model to study synapsin knock-down

Authors: O. BRENES[1], C. N. G. GIACHELLO[3], M. GHIRARDI[2], *P. MONTAROLO[4]; [1]Dept. of Neurosci., [2]Deptament of Neurosci., Univ. of Turín, Turin, Italy; [3]Fac. of Life Sci., Univ. of Manchester, Mancheter, United Kingdom; [4]Dept Neurosci., Univ. Turin, Turin, Italy

Abstract: Synapsins (Syn) are a conserved family of presynaptic proteins, involved in the fine-tuning of synaptic transmission. In addition, they have been related to neurite outgrowth, synapse formation and plasticity, with emerging post-docking roles.
Syn mutations or deletions have been associated with epileptogenesis. Studies in mammalian models have clarified in some degree their role in this process. However, the presence of

different genes and the possible development of compensatory mechanisms hinder an accurate data interpretation. Consequently, the aim of this project is to develop an in vitro monosynaptic connection, as a reliable experimental model, in order to better investigate the effects of Syn down regulation and employ it to analyze epilepsy-related forms of Syn.
First, we cloned two antisense RNAs (asRNA) against Helix synapsin (helSyn) into a plasmid able to constitutively overexpress them. In the asRNA expressing cells we observed a time-dependent decrease of helSyn immunostaining levels, confirming protein loss. Afterward, we investigated the effect of synapsin knock-down on neuronal morphology. In this sense, asRNA expressing cells displayed a significant reduction of neurite linear outgrowth, a decrease in the branching of newly sprouting neurites and a diminution in size and number of the synaptic varicosities.
Given that Syn are also involved in the organization of synaptic vesicle pools, we measured 5-HT release. When cultured in isolation or coupled to their physiological target, helSyn knock-down cells presented an increased release, following a short tetanic stimulation, probably related to an enhanced synchronous readily realizable pool. Furthermore, in asRNA expressing cells, presynaptic long tetanic stimulations generated synaptic depression.
Since Syn deletions have been associated to epilepsy, a pathology linked to highly excitable neuronal circuits, we characterized the cellular activity. The analyses revealed no changes in resting potential or voltage threshold. However, asRNA expressing cells presented a smaller rheobase and a higher firing response to depolarizing stimulus (higher Mean Firing Frequency), suggesting a higher intrinsic excitability. In addition, when cells were exposed to a epileptogenic drug as pentylenetretazol we observed a higher percentage of cells developing abnormal discharges and longer periods of activity (especially bursting) in helSyn-depleted cells.
Taken together, these data suggest that the lack of synapsin may affect not only neurotransmitter release and neuronal connectivity, but also cell intrinsic excitability, thus leading to an altered circuitry activity.

Title: Glutamatergic and cholinergic miniature synaptic currents at the motoneuron-Renshaw cell synapse

Authors: B. LAMOTTE D'INCAMPS[1], *P. ASCHER[2];
[1]Neurophysique et Physiologie, Univ. Paris Descartes, Paris, France; [2]Univ. Paris Descartes, CNRS, Paris, France

Abstract: In newborn mice, excitation of Renshaw cells (RCs) by motoneurons (MNs) involves the co-release of glutamate and acetylcholine (ACh) and the activation of AMPA and NMDA receptors as well as of homomeric and heteromeric nicotinic receptors (nAChRs). We have previously shown that the synaptic currents mediated by these four receptors differ in both their rise times (RTs) and their decay times (DTs) (Lamotte d'Incamps and Ascher, 2008; Lamotte d'Incamps et al., 2012). We have used these differences to examine if co-release leads to "mixed " miniature synaptic currents (mEPSCs), which would indicate that ACh and glutamate are stored in the same vesicles.
The experiments were conducted on slices of neonate mice (P5-P10). The mEPSCs were recorded in the presence of TTX at -45 mV and -60 mV. We first applied 3 antagonists out of a set of 4 (APV, NBQX, MLA, DHßE) to block selectively 3 of the 4 excitatory receptors. The experiments were then repeated in the presence of only 2 of the 4 antagonists. The results, displayed on diagrams relating RT and DT of the mEPSCs, showed that:
- if the two nAChRs are available, the diagram shows a region which is not present in either of the two diagrams for single receptors, and corresponds to "mixed" mEPSCs with the very short RT characteristic of homomeric nAChRs and the long DT characteristic of heteromeric nAChRS.
- if the two glutamate receptors are available, the diagram shows a region corresponding to "mixed" mEPSCs with the short RT characteristic of AMPA GluRs and the long DT characteristic of NMDARs
- when one glutamate receptor and one nAChR are available, the diagram does not show evidence for the presence of mixed mEPSCs
We thus find evidence for co-activation by a single vesicle of either AMPA and NMDA receptors or homomeric and heteromeric nAChRs, but not of nAChRs and glutamate receptors. This situation is thus very different from that described in the tadpole spinal cord by Li et al. (2004). The simplest explanation of our results is that ACh and glutamate are stored in and released by distinct vesicles. However, one cannot exclude that the two transmitters be stored in the same vesicles and that the separation of cholinergic and glutamatergic mEPSCs be due to a postsynaptic segregation of receptors (see Dugué et al. 2005).

Title: Developmental regulation of GABAb-mediated modulation of sensory inputs to lateral amygdala principal neurons

Authors: D. BOSCH, *I. D. EHRLICH;
HIH / CIN Tuebingen Univ., Tübingen, Germany

Abstract: In adult animals, the lateral amygdala (LA) is a major site for acquisition and storage of the CS-US association during pavlovian fear leaning. Sensory thalamic and cortical pathways converge onto LA principal neurons and are under tight control of local GABAergic interneurons. Furthermore, GABAergic inhibition (mediated by GABAa and GABAb receptors) plays a critical role in synaptic plasticity and fear and extinction learning. Behavioral experiments show that fear learning in rodents first appears at the infant to juvenile transition, and differences in fear and extinction learning continue into adulthood. Here the most striking change occurs at the juvenile to adolescence transition. While adolescent mice show learning behavior similar to adults, juveniles display fear memory erasure like behavior after extinction training. Additionally, extinction only requires activity in the amygdala and is not influenced by modulators of GABAa receptor activity, which suggests developmental changes in GABAergic inhibition in the LA. However, the development of excitatory and inhibitory networks in amygdala that may underlie changes in fear and extinction learning have been largely unexplored.
Using patch clamp recordings in acute slices from infant, juvenile, adolescent and adult mice, we investigate changes in synaptic properties of excitation and feed-forward inhibition onto LA principal neurons during the critical time windows when behavioral learning changes. Our results show a significant increase in global inhibitory drive and an upregulation of sensory feed-forward inhibition onto LA principal neurons at the juvenile to adolescent transition. Furthermore, the effect of the GABAb antagonist CGP 55845 suggests an age-dependent influence of GABAergic modulation on excitatory and feed-forward inhibitory sensory inputs including effects on amplitude, paired-pulse ratios and heterosynaptic inhibition. Taken together, our data suggest a developmentally regulated change in basic synaptic properties of sensory synapses onto LA principal neurons and an increasing influence of GABAergic modulation via

GABAb receptors in mouse lateral amygdala. These changes occur at the same time when fear memory extinction switches from erasure like mechanisms to fear memory suppression.

Title: Physiologically evoked DA release from LC terminals mediates long term hippocampal, CA1 synaptic enhancement

Authors: *C. C. SMITH[1], M. S. GOLDBERG[2], R. W. GREENE[1];
[1]Psychiatry, [2]Neurol. and Neurotherapeutics; Psychiatry, UT Southwestern Med. Ctr., Dallas, TX

Abstract: The pre-synaptic source of dopamine (DA) in the CA1 field of dorsal hippocampus was previously thought to originate from the ventral tegmental area (VTA), even though little DA transporter (DAT) positive staining is observed. We have shown that either a knockdown of TH expression in the locus coeruleus (LC) or blockade of the norepinephrine (NE) transporter (NET) in hippocampus prevents an amphetamine induced enhancement in glutamate synaptic transmission at hippocampal CA3-CA1 synapses. Importantly, this same treatment reliably induces an increase in glutamate transmission under control conditions. Whether LC terminals readily release DA under physiological conditions was unclear. Optogenetic stimulation of LC terminals from transgenic mice expressing Cre recombinase under the TH promoter (TH-Cre), induced a DA dependent increase in glutamate transmission at CA3-CA1 synapses. Moreover, this same stimulation induced a significant increase in DA release, which was blocked by the NET inhibitor nisoxetine as determined by HPLC analysis. Future work will elucidate the dynamics of DA vs. NE release from LC terminals. These findings will direct our understanding of the particular patterns of LC neuronal activity that underlie the DA mediated reward and/or salience to experience.

Title: Neurotensin and its analog, D-Tyr[11]neurotensin, differentially modulate excitatory post-synaptic currents in different populations of ventral midbrain neurons

Authors: *P. BOSE[1], P.-P. ROMPRÉ[2,3], R. A. WARREN[2];
[1]Psychiatrie, Univ. De Montréal, Montreal, QC, Canada; [2]Psychiatry, Univ. de Montréal, Montreal, QC, Canada; [3]FRQS Res. Group in Behavioral Neurobio., Concordia Univ., Montreal, QC, Canada

Abstract: Neurotensin(NT) is a potent modulator of limbic neurotransmission. Ventral midbrain (VM) injection of NT or its analog, D-Tyr[11]NT1-13, for instance, produces pro-dopamine-like effects; it stimulates locomotor activity and produces lasting sensitization to the locomotor stimulant effect of systemic amphetamine. The induction of amphetamine sensitization by D-Tyr[11]NT1-13 is dependent upon activation of VM NMDA receptors, hence suggesting that the analog stimulates glutamate release in this region. This study was aimed at comparing the effects of different concentrations of NT1-13, NT8-13 and D-Tyr[11]NT1-13 on excitatory post-synaptic current (EPSC) generated in different populations of VM neurons by electrical stimulation of the afferent pathways. Horizontal VM slices (250 um) preserving afferent inputs were obtained from male Long Evans rats aged 14 to 21 days. The action potential, Ih current and membrane conductance parameters were measured after achieving whole cell configuration. Neurons were grouped according to the presence (+) or absence (-) of the Ih current. Excitatory post-synaptic current was evoked by delivering an electrical stimulation through a monopolar tungsten microelectrode placed rostral to the recording site. Bicuculline methochloride (10 uM) was included into the ACSF to block the $GABA_a$ mediated synaptic current and isolate glutamatergic EPSCs. Five minutes of baseline EPSC activity was recorded before application of NT1-13, NT8-13 and D-Tyr[11]NT1-13 (0.01uM, 0.1uM and 0.5uM) for 7 min. Only one concentration of each peptide was tested per recorded neuron. In some experiments with D-Tyr[11]NT1-13, SR142948A (0.5 uM) and SR48692 (0.5 uM) were first added to the superfusing medium before the peptide. Results show that NT1-13 and NT8-13 both produced a concentration dependent increase in EPSC amplitude in Ih(+) and Ih(-) neurons. D-Tyr[11]NT1-13 also increased EPSC amplitude in Ih(-) but decreased it in Ih(+) neurons. The NT receptor antagonists, SR142948A and SR48692, were both effective at blocking both effects of D-

Tyr[11]NT1-13, hence suggesting they are mediated by NT receptors. The higher affinity of SR48692 for NTS1 suggests that the differential effects of D-Tyr[11]NT1-13 on each population of neurons are mediated by activation this receptor. However, this can hardly account for the similar effects of NT1-13 and NT8-13, two peptides that have a higher affinity for NTS1. A possible explanation is that one of the effects of D-Tyr[11]NT1-13 is mediated by NTS2 and that at the concentration used, SR48692 also blocked this receptor sub-type; this hypothesis is currently being investigated.

Title: Wnt-5a acts through Gαi/0 to regulate dendritic spine formation in hippocampal neurons

Authors: *V. T. RAMIREZ, D. ORDENES, F. G. SERRANO, N. C. INESTROSA;
Pontifical Catholic Univ., Santiago, Chile

Abstract: Recently, several synaptic roles have been report for Wnt signaling pathway. Particularly, Wnt-5a activates non-canonical Wnt signaling cascade in hippocampal neurons and stimulates the development of the postsynaptic region. We have demonstrated that Wnt-5a promotes the formation of dendritic spines and increases the clustering of postsynaptic proteins as PSD-95 and modulates glutamatergic transmission, however, the molecular mechanism involved in these processes it is not fully understood. There is evidence in several models that heterotrimeric G-proteins might play a key role in the transduction of Wnt signaling, but this has not been demonstrated at least in neurons. Here, we characterized the role of G-protein in Wnt-5a signaling in a neuronal cell context and we established that the activation Gαi/0 is upstream of the Wnt-5a-induced effects in hippocampal neurons.
To address this question we first investigated the effect of pertussis toxin (PTX), an inhibitor of Gαi/0 proteins, over the Wnt-5a signaling. Neurons were stimulated with recombinant Wnt-5a

and they were pretreated or not with PTX. We observed that PTX prevents the Wnt-5a-induced activation of CaMKII and JNK. Also, pre-treatment with PTX inhibits the increase in dendritic spine number in GFP-transfected neurons and inhibits in a significantive manner the PSD-95 clustering induced by Wnt-5a.
Interesting, Mastoparan-7 (Mas-7) a specific Gαi/0 agonist, enlarges the clustering of PSD-95 and augments the number of dendritic spines. Moreover, Mas-7 activated CaMKII and JNK as Wnt-5a does. Mas-7 increases the glutamatergic transmission in mice hippocampal slices, in a similar way as Wnt-5a does. Additionally, we test if Wnt-5a promotes the activation of G protein. We used a specific antibody that recognizes the active form of Gαi/0 and we found that Wnt-5a promoted the binding of GTP to Gαi/0 at hippocampal neurons.

Title: Modulatory role of t-cadherin in hippocampal synaptic functions

Authors: *H. BADIE-MAHDAVI[1], A. J. ROBERTS[2], B. RANSCHT[1];
[1]Neurobio., Sanford-Burnham Med. Res. Inst., San Diego, CA; [2]Neuropharm., The Scripps Res. Inst., San Diego, CA

Abstract: A growing body of evidence indicates the importance of cell adhesion molecules in regulating synapse formation, stability and function in the central nervous system (CNS). T-cadherin (Cadherin-13; Cdh13), a glycosylphosphatidylinositol-linked cadherin-type cell adhesion molecule, is prominent in diverse structures of the CNS. Mutations in the human CDH13 gene have been linked to neuropsychiatric disorders, including addiction, autism spectrum- and Attention Deficit Hyperactivity Disorder. We here report the behavioral phenotype of T-cadherin null (Tcad-KO) mice and link gene function to modulations in spine morphology and synaptic functions in the hippocampus. Tcad-KO mice show no overt phenotypes under normal housing conditions and live a normal life span. No significant

differences from wildtype (WT) controls were evident in baseline vision, hearing or locomotor activity, or spatial learning performance in the Barnes maze. However, challenge in fear conditioning tests revealed reduced freezing responses of Tcad-KO mice in both the contextual and cued paradigms that are associated with hippocampal- and amygdalar activity. Moreover, Tcad-KO mice exhibited a lower threshold for Kainic acid-induced seizure compared to WT mice consistent with modifications in hippocampal synaptic function. Polyclonal antibodies revealed strong punctate T-cadherin immunoreactivity in the hippocampus and amygdala of WT mice that was absent in the KO condition. The expression of T-cadherin in specific neuron populations in the hippocampus was confirmed by expression of Red-Fluorescent Protein (RFP) from the Rosa26 locus in Tcad-Cre mice. Compared to their WT counterparts, hippocampal slices prepared acutely from Tcad-KO mice displayed significant reductions in synaptic transmission and CA1 long-term potentiation. Spine densities of Tcad-KO CA1 hippocampal pyramidal dendrites were reduced by 28 percent, and 30 percent fewer spines showed the mature mushroom-shaped morphology in the KO than in the WT condition. Synaptic loss was confirmed by reduced expression of Synapsin I in the CA1 region of Tcad-KO mice. Our data implicate a modulatory role of T-cadherin expressed by select neuron populations in the regulation of hippocampal synaptic functions that affect behaviors encoded in components of the limbic system. **Support:** NIH HD025938 (BR); P30 NS057096 (AR).We acknowledge Ann DInh for performing some of the behavioral experiments.

Title: An amphipatic alpha-helix in Corticotrophin Releasing Factor Binding Protein determines its sorting to the regulated secretory pathway

Authors: C. P. BASTIAS[1], E. H. BLANCO[1], *K. GYSLING[2,1];
[1]Millenium Sci. Nucleus Stress and Addiction, Santiago, Chile; [2]Dept Cell & Mol. Biol., Pontificia Univ. Catolica de Chile, Santiago, Chile

Abstract: Corticotrophin Releasing Factor Binding Protein (CRF-BP) is a secreted glycoprotein with high affinity for both CRF and urocortin-1 peptides. Initially, it was shown that CRF-BP binds CRF and/or urocortin-1, decreasing their activity. However, more recently, is has been proposed that CRF-BP could also facilitate CRF and/or urocortin-1 actions. Previously, we have shown that CRF-BP readily enters to the regulated secretory pathway and that its release depends on depolarizing stimuli. The purpose of the present work was to identify the sorting domain of CRF-BP necessary to enter the regulated secretory pathway. Thus, we used *in silico* prediction software of secondary structure (NPS@ Consensus Secondary Structure Prediction) to reveal CRF-BP cis-elements that could serve as the sorting signal. We found an alpha-helical structure at the N- terminal of CRF-BP. The helical wheel projection of this CRF-BP alpha-helix structure showed that it has an amphipathic configuration. Thereafter, we studied the subcellular localization and release behavior of truncated and mutated forms of CRF-BP expressed in PC12 cells. The results showed that the mutations at the level of the amphipatic alpha-helix resulted in the loss of CRF-BP sorting toward the regulated secretory pathway. Thus, our results suggest that an amphipatic alpha-helix in the N-terminal of CRF-BP is critical for its sorting to the regulated secretory pathway.

Title: Neurotensinergic modulation of synaptic transmission in the oval Bed Nucleus of the Stria Terminalis

Authors: *C. P. NORMANDEAU[1], C. DI PROSPERO[2], E. HAWKEN[2], E. C. DUMONT[2]; [1]Biol., [2]Queen's Univ., Kingston, ON, Canada

Abstract: Anxiety is both an adaptive and pathological behavioural state that is coordinated by different neuronal pathways. The Bed nucleus of the Stria Terminalis (BNST) seems critical in anxiety behaviours and responses to contextual stimuli. More specifically, activation of the oval subregion of the BNST (ovBNST) increases anxiety-like behaviours. However, the underlying cellular mechanism remains unknown. Neurotensin (NT) is a neuropeptide involved in anxiety and is found both in ovBNST neuronal cell bodies and synaptic terminals. Yet, the

neurophysiological role of NT in the ovBNST remains largely unclear. The objective of this project was to determine whether and how NT modulates synaptic transmission in the ovBNST using whole-cell patch clamp recordings in brain slices prepared from male Long-Evans rats. We report that exogenous application or endogenous NT release potentiated GABAergic inhibitory synaptic transmission in the ovBNST. Paired-pulse ratio analyses revealed that NT mostly acted pre-synaptically to increase the probability of GABA release. Conversely, NT had no measurable effects on glutamate release or synaptic transmission through AMPA channels. These results suggest that NT powerfully modulates inhibitory synaptic transmission in the ovBNST, a mechanism which may contribute to anxiety-like behaviours.

Title: Serotonergic excitation of amygdala projection neurons in the mouse medial prefrontal cortex

Authors: *D. AVESAR, A. T. GULLEDGE;
Physiol. and Neurobio., Geisel Sch. of Med. at Dartmouth, LEBANON, NH

Abstract: Pyramidal neurons in the rodent medial prefrontal cortex (mPFC) project to a variety of subcortical structures. We recently revealed that serotonin (5-HT) selectively excites commissural/callosal (COM) projection neurons in the mouse mPFC via 5-HT_{2A} (2A) receptor stimulation, while most other pyramidal neurons, including all corticopontine projection neurons, are functionally inhibited by 5-HT via 5-HT_{1A} (1A) receptor activation. Here we have investigated the functional impact of 5-HT on the excitability of retrograde-labeled corticoamydalar (CAm) neurons in brain slices of the mPFC from 7- to 12-week-old C57/BL6 mice. Focal application of 5-HT (100 µM; 1 second) elicited excitatory (2A-mediated) or biphasic (short 1A-dependent inhibition followed by 2A-dependent excitation) responses in CAm neurons located in both the ispilateral (n = 14) and contralateral (n = 23) hemispheres. The proportion of serotonergic responses in contralateral CAm neurons was 66% excited, 30% biphasic, and 4% having no response. In ipsilateral CAm neurons, 43% of neurons were excited

by 5-HT, and 57% exhibited biphasic responses. No CAm neurons in either hemisphere displayed a purely inhibitory response to 5-HT. Given that both COM and CAm neurons are preferentially excited by 5-HT, we tested whether these populations overlap by injecting retrograde traces of different colors into both the contralateral amygdala and contralateral mPFC. Double-labeled COM /CAm neurons (n = 11) displayed excitatory (64%) or biphasic (27%) responses, or were unresponsive (9%) to 5-HT. Finally, we found that CAm neurons had physiological properties similar, but not identical, to COM neurons. Overall, our findings reveal that CAm neurons partially overlap with COM neurons, and that both neuron types preferentially exhibit 2A-dependent excitatory or biphasic responses to 5-HT. Since CAm neurons from the mPFC participate in fear conditioning and extinction of conditioned fear, our results suggest that cortical release of 5-HT may contribute to fear responses by activation of 2A receptors.

Title: Inhibitory effect of pregabalin on excitatory synaptic transmission in the spinal dorsal horn after nerve injury

Authors: R. MATSUZAWA[1], *S. YAMAGUCHI[2], T. TAKASUSUKI[2], T. OHTSUBO[3], Y. HORI[3];

Abstract: It is well known that pregabalin can be of value for the relief of neuropathic pain. In this study, we investigated the effects of pregabalin on synaptic transmission in the spinal cord dorsal horn after sciatic nerve ligation in mice. Tight-seal whole-cell recordings were obtained from neurons in the superficial dorsal horn of the spinal cord slices. Electrical stimulus-evoked excitatory postsynaptic currents (eEPSCs) and spontaneously occurring miniature EPSCs (mEPSCs) in the presence of tetrodotoxin were analyzed. The properties of eEPSCs and mEPSCs were observed before and after sciatic nerve ligation (Seltzer model). In sham-operated control mice, pregabalin showed a dose-dependent inhibition of amplitude of eEPSCs with EC50 of 65μM. The frequency of mEPSCs was inhibited by the bath application of pregabalin, but their amplitudes were not affected. Inhibitory effect on the frequency of mEPSCs was

significantly larger in ligated mice than in sham-operated control mice. Real-time RT-PCR analysis showed that the expression of calcium channel α2δ subunit increased in the spinal dorsal horn of sciatic nerve ligated mice, compared with sham-operated mice. Calcium channel α2δ subunit knockdown (KD) was induced by intrathecal injection of an antisense oligodeoxynucleotide. KD mice showed significant attenuation of mechanical allodynia as compared with non-sense oligodeoxynucleotide-injected control mice. In KD mice, there was no significant increase in α2δ subunit expression after nerve ligation. Our results suggest that relief of neuropathic pain by pregabalin may result from inhibition of voltage gated calcium channels containing α2δ subunits whose expression is increased after nerve injury.

Title: Presynaptically mediated effects of cholecystokinin on the excitability of area postrema neurons in rat brain slices

Authors: *S. SUGETA, M. FUNAHASHI;
KITA13 NISHI7, Hokkaido Univercity, Sapporo, Hokkaido, Japan

Abstract: Cholecystokinin (CCK) is one of the well-known gut hormones which show anorexigenic effects via the peripheral and central receptors. Previous studies have reported that CCK inhibited feeding behavior and gastric function by acting as a paracrine modulator of vagal afferents in the periphery. CCK is also widely distributed throughout the mammalian brain and appears to function as a neurotransmitter and neuromodulator. The area postrema is one of the circumventricular organs, located on the dorsal surface of the medulla oblongata at the caudal end of the fourth ventricle. Blood vessels in the area postrema lack a blood brain barrier, offering specific central neuron components unique access to circulating substances. Immunohistochemical studies have revealed a CCK-A receptor in the area postrema. Further the presence of CCK-sensitive neurons has been demonstrated in our previous study. However, the receptive mechanism of CCK in the area postrema neurons still remains unexplained. We investigated the responses of area postrema neurons to agonists and antagonists of CCK receptors using a patch-clamp technique in rat brain slices. We found CCK-induced excitatory

responses, such as increases in the frequency of mEPSCs (miniature excitatory postsynaptic currents) and changes in the amplitude distribution of mEPSCs. These changes were found in 24 cells not displaying the hyperpolarization-activated cation current (Ih) and only 2 cells displaying Ih. An inhibitory response to CCK was never seen. CCK-induced tonic inward currents were not observed in any cells. Analysis of the amplitude of mEPSCs before and after the application of CCK indicated the responses mediated via the presynaptic receptors. The effect of CCK was abolished in the presence of CNQX (AMPA type glutamate receptor antagonist). In the presence of lorglumide(a selective CCK-A receptor antagonist)CCK-induced excitatory responses were inhibited. We conclude that CCK-induced excitation of area postrema neurons not displaying Ih is due to the facilitation of the glutamate release mediated via the presynaptic CCK-A receptors.

Title: Functional interaction of Synapsin II and Rab3a at cultured hippocampal neurons

Authors: *H. Y. MATOS[1], R. ANDRADE[2], M. BYKHOVSKAIA[1];
[1]Neurosci., Univ. Central Del Caribe, Bayamon, Puerto Rico; [2]Dept. of Pharmacol., Wayne State University, Sch. of Med., Detroit, MI

Abstract: Synapsins are a family of phosphoproteins that have been shown to regulate the synaptic vesicle cycle and the preparatory steps for exocytosis. Synapsin gene deletion produces epileptic seizures in human patients and in animal models. Rab3a is a Synapsin binding partner, a GTP-binding protein that plays a role in the mobilization of synaptic vesicles to the active zone. Previous work has shown that Rab3a gene deletion rescues the epileptic seizures produced by Synapsin II gene deletion. We investigated excitatory and inhibitory synaptic activity in cultured dissociated hippocampal neurons of mice lacking Synapsin II (SynII(-)), Rab3a (Rab3a(-)), and both proteins (SynII(-)/Rab3a(-)) double knock out (DKO). We performed whole-cell patch clamp and paired recordings of spontaneous and evoked responses at excitatory and inhibitory synapses. Both spontaneous excitatory post-synaptic currents (sEPSCs) and miniature EPSCs (mEPSCs) frequency were increased at the SynII(-) synapses. Evoked EPSCs at SynII(-) neurons were not significantly different from those seen in wild type (WT) neurons.

In contrast, a decreased frequency was observed in both spontaneous inhibitory post-synaptic currents (sIPSCs) and miniature IPSCs (mIPSCs) at the SynII(-) neurons. These results suggest that Synapsin II deletion may disrupt the excitation/inhibition balance at hippocampal neurons. Importantly, Rab3a deletion balanced the effect of Synapsin II deletion on inhibitory transmission. More specifically, we did not observe a significant alteration in either sIPSC or mIPSC frequency at either SynII(-)/Rab3a(-) DKO or Rab3a(-) synapses compared to WT inhibitory synapses. This suggest that the deletion of Rab3a may compensate the over excitation observed at SynII(-) at inhibitory synapses.

Title: Promiscuous interactions of dopamine augment GABA release within rat entorhinal cortex

Authors: *N. I. CILZ, L. KURADA, B. HU, S. LEI;
Pharmacology, Physiology, & Therapeut., Univ. of North Dakota, Grand Forks, ND

Abstract: The entorhinal cortex (EC) acts as a gate for the majority of cortical input to the hippocampus and plays an important role in learning and memory. Dopamine (DA) is a neuromodulator known to influence learning and memory processes and the EC receives DAergic input from midbrain neurons. Whereas DA has a largely suppressive role on the excitability of the principle neurons within the EC, the relationship between DA and the GABAergic interneurons remains less clear. Using a whole-cell patch-clamp analysis, we investigated this relationship by making both postsynaptic and direct recordings from interneurons. Our results show that DA (10-100 μM) increases the frequency but not amplitude of spontaneous and miniature inhibitory postsynaptic currents (sIPSCs and mIPSCs), suggesting a pre-synaptic site of action for DA. Pharmacological interventions indicate that this effect is mediated by α-1 adrenergic receptors (α1ARs) and not DA receptors. The DA-induced increase in frequency of both sIPSCs and mIPSCs requires extracellular Ca2+ influx and involves T-type Ca2+ channels. Recordings from interneurons indicate that DA increases the intrinsic excitability and depolarizes the resting membrane potential by approximately 4 mV. This depolarization is independent of extracellular Ca2+ and Na+ influx. Substitution of intracellular K+ with N-

methyl-D-Glucamine prevented DA-induced depolarization. DA-induced currents generated with a voltage ramp show a reversal potential close to the calculated K+ reversal potential and exhibit inward rectification. Depolarization was blocked by both the selective α1ARs antagonist corynanthine and blockade of inward rectifying K+ channels (Kirs) by Ba+. Taken together, our results suggest a sequential mechanism by which DA enhances GABA release. DA activates α1ARs, which initially depolarizes interneurons via inhibition of Kirs, and permits secondary activation of T-type Ca2+ channels and Ca2+ influx, ultimately increasing GABA release.

Title: Exclusive glycine receptor-mediated inhibition to forelimb motoneurons in adult mouse spinal cord

Authors: *J. JIANG, B. ALSTERMARK;
Dept. of Integrative Med. Biology, Section of Physiol., Umeå, Sweden

Abstract: It is widely accepted that glycine and GABA mediate inhibitory synaptic transmission in the brain stem and spinal cord. The abundance of GABAergic and glycinergic terminals and postsynaptic clusters of their distinct receptors on motoneurons (MNs) suggests that both glycine and GABA exert important effects in controlling movement(1, 2). Since some of them are co-localized in the same terminals, they even can act as co-transmitters and mediate co-transmission(3). However, it also poses the question about their relative contribution to inhibition in MNs. Here, we used in vivo intracellular recordings from forelimb MNs in adult mouse to investigate the inhibitory transmission from the reticulospinal tracts, the propriospinal neurons and forelimb afferents. We found that the glycine receptors antagonist Strychnine can completely block inhibitory postsynaptic potentials (IPSPs), whereas the GABAA receptors antagonist Gabazine has no significant effect on postsynaptic potentials. Moreover, all IPSPs remaining after Gabazine disappeared after adding Strychnine. Our results show that, in the intact adult mouse, the inhibitory actions on MNs exerted by the reticulospinal tracts, the propriospinal

neurons and forelimb afferents are all exclusively glycinergic. The findings may help us understand neurodegenerative disease mechanism characterized by progressive loss of MNs, like amyotrophic lateral sclerosis (ALS) which shows abnormal synaptic inhibition resulting from dysfunction of Glycine receptors(4).

Title: Modulation of excitatory synaptic transmission by the somatodendritic release of glycine in the rat medial nucleus of the trapezoid body

Authors: *M. KRALIKOVA[1], R. TURECEK[2];
[1]Inst. of Exptl. Medicine, CAS CZ, Prague, Czech Republic; [2]Inst. of Exptl. Med. CAS, Prague, Czech Republic

Abstract: The somatodendritic release (SDR) of neurotransmitters fulfills a significant physiological role in the central nervous system. SDR can quickly deliver relatively high concentrations of neurotransmitters to extrasynaptic sites where they effectively modulate neuronal excitability. Glycine, the main inhibitory transmitter in the spinal cord and brainstem, is typically released from nerve terminals to mediate phasic synaptic communication. However, little is known about the SDR of glycine. We studied the mechanisms and relevance of the SDR of glycine in the glycinergic principal cells (PCs) forming the medial nucleus of the trapezoid body (MNTB), one of the brainstem auditory nuclei. In the MNTB, glycine is known to activate

both pre- and postsynaptic strychnine-sensitive chloride permeable receptors (GlyRs). Using patch-clamp recordings from the somata of PCs in MNTB slices, we observed tonic outwardly-rectifying and strychnine-sensitive currents. A detailed examination of the currents pharmacologically stimulated by filling the cells with a glycine-containing solution revealed their dependence on Na+ and their sensitivity to ALX1393. This indicated that glycine could be released from the PCs by a reverse action of glycine transporter 2 (GlyT2). The presence of GlyT2 proteins in MNTB principal cells was confirmed by immunohistochemistry. Our further experiments showed that SDR could be triggered by a Na+ influx during bursts of postsynaptic action potentials. In addition to postsynaptic GlyRs, extracellular glycine resulting from pharmacologically stimulated SDR also efficiently activated presynaptic GlyRs at giant nerve terminals, the calyces of Held. The activation resulted in a potentiation of the presynaptic release probability of glutamate from the calyx. Our results suggest a novel retrograde mechanism of modulation of excitatory synaptic transmission by glycine released by activity-dependent reverse uptake from postsynaptic cell compartments.

Title: Rapid membrane estrogen receptor activation increases the excitatory/inhibitory ratio in rat basal forebrain slices

Authors: *J. C. DAMBORSKY, D. W. DUBOIS, A. S. FINCHER, C. ROTH, W. H. GRIFFITH;
NExT, Texas A&M Univ. Syst. Hlth. Sci. Ctr., Bryan, TX

Abstract: Estrogen can exert rapid, non-genomic actions on cells in the brain via plasma membrane receptors, including ERα and β, and the G-protein coupled estrogen receptor (GPER). This rapid estrogenic signaling can have dramatic effects on calcium signaling and synaptic transmission, with varying effects observed in individual cell types and brain regions. Previously, our lab has shown that 17 β-estradiol (17βE) can reduce the frequency of spontaneous inhibitory synaptic transmission onto acutely dissociated basal forebrain (BF) neurons. Here, we extend these findings by looking at the effects of 17βE on excitatory and

inhibitory synaptic transmission in BF neurons in slices with more intact local circuits. We recorded spontaneous and evoked EPSCs and IPSCs from basal forebrain neurons in acute brain slices from young adult F344 female rats using whole-cell patch clamp recording techniques. We then bath applied either 17βE (100 nM), the ERβ agonist DPN (100 nM), or the GPER agonist G-1 (100 nM) to slices and recorded changes in synaptic activity. Similar to what was observed in the reduced synaptic preparation, we found that 17βE reduced sIPSC frequency in a majority of cells (6/10) with an average decrease in those cells of 23 ± 6% (n=6). Additionally, 17βE reduced the amplitude of evoked IPSCs and increased paired-pulse ratios (PPRs) in 6/10 cells, suggesting a decrease in GABA release probability. These effects may be at least partially mediated by activation of ERβ, as we found that in response to DPN, 3/5 cells showed a reduction in sIPSC frequency, and 4/5 cells had reduced evoked IPSC amplitudes or increased PPRs. Following bath application of G-1, 2/6 cells had a reduction in sIPSC frequency, and 3/6 cells showed a reduction in evoked IPSC amplitude or an increase in PPR. Interestingly, when we looked at excitatory synaptic transmission, we observed an estrogen-induced increase in synaptic transmission. Following bath application of 17βE, 8/11 cells exhibited an increase in sEPSC frequency (average increase of 47 ± 13%, n=8), 7/11 had an increase in evoked EPSC amplitude, and 7/11 had a decrease in PPR. These data from BF neurons suggest that in the presence of estrogen there is an overall increase in the excitation/inhibition ratio as a result of reduced inhibitory signaling and enhanced excitatory signaling. We observed a similar global increase in excitation in the CA1 hippocampus of adult female rats; in response to both 17β-E and G-1, we saw an increase in the slopes of field EPSPs in hippocampal slices. We conclude that estrogen has opposing rapid actions on excitatory and inhibitory signaling, and that the net effect is an increase in the excitatory/inhibitory ratio.

Title: Reciprocal regulation of inhibitory synaptic transmission by nicotinic and muscarinic receptors in rat nucleus accumbens shell

Authors: K. EBIHARA[1,2], K. YAMAMOTO[1], K. UEDA[2], N. KOSHIKAWA[1], *M. KOBAYASHI[1];
[1]Dept Pharmacol, [2]Dept. of Dysphagia Rehabil., Nihon Univ. Sch. Dent., Chiyoda-Ku, Japan

Abstract: Medium spiny neurons (MSNs) in the nucleus accumbens (NAc) are the principal neurons, whose neural activities are regulated by GABAergic inputs from MSN and fast-spiking interneurons (FSNs). Cholinergic interneurons play important roles in regulation of neural activities of MSNs; however, it is still unknown how acetylcholine modulates inhibitory synaptic transmission from MSNs/FSNs to MSNs. To clarify the cholinergic regulation of inhibitory synaptic transmission in the NAc comprehensively, it is necessary to discriminate the source of GABAergic inputs to the MSNs. In this study, we performed paired whole-cell patch-clamp recordings from MSNs and FSNs in rat NAc shell slice preparations and examined the nicotinic and muscarinic effects on unitary inhibitory postsynaptic currents (uIPSCs). Carbachol (1 μM) suppressed uIPSC amplitude by ~46% in MSN to MSN connections accompanying the increases in the paired-pulse ratio and failure rate, suggesting that acetylcholine reduces GABA release probability from synaptic terminals of MSNs. The carbachol-induced suppression of uIPSCs was antagonized by preapplication of atropine, and mimicked by pilocarpine (1 μM) but not by nicotine (1 μM). The analysis of coefficient of variation indicated that both carbachol and pilocarpine-induced uIPSC suppression were presumably mediated by presynaptic mechanisms. These results suggest that acetylcholine suppresses GABA release from MSNs via presynaptic muscarinic receptors. In contrast, FSN to MSN connections showed little effect of pilocarpine on uIPSC amplitude, whereas nicotine facilitated uIPSC amplitude by 30% with decreases in the failure rate and paired-pulse ratio suggesting that nicotine-induced uIPSC facilitation is mediated by presynaptic mechanisms. Miniature IPSC recordings suggest that muscarinic and nicotinic receptors reciprocally regulate the frequency of inhibitory inputs to the NAc MSNs. The present study suggests the contradictory role of presynaptic muscarinic and nicotinic receptors in modulating inhibitory synaptic transmission to MSNs in the NAc shell.

Title: GABAergic projection neurons gate odor-specific inputs to higher order neurons

Authors: *Y. LI[1,2], L. LIANG[3,5], C. POTTER[5,6,4], R. TSIEN[2,7], L. LUO[3,5];
[1]Peking Univ., Beijing, China; [2]Dept. of Mol. and Cell. Physiol., [3]Dept. of Biol., [4]Stanford Univ., Palo Alto, CA; [5]Howard Hughes Med. Inst., Palo Alto, CA; [6]Johns Hopkins Univ., Baltimore, MD; [7]New York Univ., New York, NY

Abstract: An understanding of how brains perceive external stimuli requires functional analysis of the interplay between excitatory and inhibitory neurons along the sensory projection pathway. Using Drosophila olfactory system as a model system, we here characterize a unique group of inhibitory projection neurons (iPNs) which receive direct input from antennal lobe glomeruli and send output to the lateral horn, a higher brain center involved in regulation of innate behavior. Taking advantage of the newly developed Q-driver system and the genetically encoded calcium sensor GCaMP3, we performed two-photon live imaging of iPNs and their putative postsynaptic target vlpr neurons. We found food-related odorant responses were selectively suppressed by iPNs, whereas pheromone related signals were spared. Co-application of food and pheromone odorants did not elicit additional responses in pheromone channels different than pheromone alone, suggesting that the food-specific inhibition likely result from specific connectivity of iPNs, rather than a generalized inhibitory tone. Calcium responses of the presynaptic excitatory input from antennal lobe to lateral horn did not show any detectable suppression by iPNs, suggesting that the inhibition is likely postsynaptic. Our experiments reveal functional important GABAergic neurons that may provide specificity in inhibition to funnel specific olfactory information, such as food and pheromone signals, into distinct downstream circuits.

Title: Imbalance of excitatory and inhibitory synaptic transmission lowers seizure threshold in RalBP1 hypomorphic mice

Authors: *S. H. YOON, Y.-S. BAE, K.-Y. PARK, M.-H. KIM;
Dept. of Physiol., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Idiopathic epilepsy is believed to be caused by genetic defects. Mutations in genes leading to neuronal hyperexcitability or an imbalance between excitatory and inhibitory synaptic transmission seem to increase susceptibility to seizures by lowering the seizure threshold. However, the identity of these genes is unclear. In addition, the underlying mechanisms that link genetic background and altered seizure threshold are still poorly understood. In the present study, we investigated the role of RalBP1, a downstream effector of the small GTPases RalA and RalB, in seizure threshold. Reduced RalBP1 expression itself was not sufficient for seizure induction. However, the intraperitoneal injection of pentylenetetrazol (PTZ) induced more severe seizures in RalBP1 hypomorphic mice. Electrophysiological studies on hippocampal CA1 pyramidal neurons revealed decreased inhibitory synaptic transmission with normal excitatory synaptic transmission in RalBP1 hypomorphic mice. However, reduced RalBP1 function had no effect on neuronal excitability. The excitatory/inhibitory imbalance was associated with the loss of GABAergic interneurons in the CA1 subfield of the hippocampus. These results suggest that RalBP1 is essential for normal excitatory/inhibitory synaptic balance and seizure threshold.

Title: Mechanisms of synaptic modulation by acetylcholine underlying acquisition and extinction of conditioned fear

Authors: *J. D. LEDERMAN, D. A. TALMAGE, L. W. ROLE;
Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Abnormal processing of sensory information underlies many cognitive disorders such attention deficit disorder, post-traumatic stress, and schizophrenia. The amygdala is especially important for integrating sensory information from many brain areas. In particular, afferents from cortical and thalamic sensory areas converge onto pyramidal neurons in the basolateral nucleus of the amygdala (BLA). In addition, the BLA is permeated by cholinergic fibers from the nucleus basalis of Meynert (NBM). These form few direct cholinergic synapses in the BLA and evidence suggests that acetylcholine primarily modulates other synapses in the BLA. Acetylcholine can dramatically alter glutamatergic transmission in the BLA and profoundly affects amygdala processing and behavior. This project asks how integration of convergent thalamic and cortical inputs to BLA is accomplished in the BLA and what role endogenous acetylcholine release plays in this integration.

To examine the behavioral role of endogenous ACh in the BLA, the nucleus basalis of Meynert is injected with an adeno-associated virus containing a double-inverted-floxed (DIO) oChIEF (an optimized version of channelrhodopsin 2), or a DIO-Halorhodopsin 3.0 construct in ChAT-Cre mice. The Cre/DIO system limits expression of the channel- or halo-rhodopsin to cholinergic cells while the afferents of these cells in BLA can be specifically stimulated or inhibited with high temporal precision by light of the appropriate wavelength. When these afferents are stimulated during training in a fear-conditioning paradigm, learned fear is enhanced and extinction of this fear is diminished. Conversely, inhibiting these afferents during training diminishes learned fear and enhances the extinction rate, supporting the role of ACh in memory acquisition and consolidation.

To understand the synaptic "rules" by which cholinergic modulation of glutamatergic synapses in the BLA occurs, patch-clamp electrophysiology is used in an acute slice preparation in conjunction with the optogenetic system described above. Stimulating electrodes are placed on the internal or external capsules to stimulate thalamic or cortical afferent fibers, respectively. Optogenetic stimulation of cholinergic afferents profoundly affects the magnitude and valence of plasticity at these glutamatergic synapses and suggests that endogenous ACh may differentially attune neurons to specific inputs. Moreover, ongoing experiments suggest that ACh may also influence the timing window in which these convergent inputs must coincide to induce plasticity.

Title: Presynaptic GABAb receptors silence excitatory synapses in neocortical networks

Authors: *J. URBAN CIECKO, E. FANSELOW, A. L. BARTH;
Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: In superficial layers of the neocortex, about 10% of neocortical pyramidal neurons are connected to each other with strong and reliable synapses, displaying near-zero failure rates. However, this analysis has typically been carried out under high extracellular Ca levels and low network activity. In vivo, Ca levels are close to 1 mM and many cells, including inhibitory neurons, exhibit elevated spontaneous firing activity. Here we investigated the effect of physiological Ca levels and network activity on connection probability, strength, and synapse reliability between layer 2/3 pyramidal neurons. Under these conditions, connection probability is decreased by half, and failure rates are two-fold higher. Although higher failure rates can in part be attributed to lower Ca levels, we find that presynaptic GABAb receptors are tonically active during spontaneous network activity and that these receptors profoundly influence release probability. Pharmacological GABAb activation can effectively silence synapses, resulting in failure rates that approach 100%. Conversely, pharmacological GABAb blockade can suppress failures below baseline levels. These data suggest that neocortical networks may be dynamically rewired based upon presynaptic GABAb activation, and that this phenomenon may be state-dependent.

Title: Nicotine disinhibits pyramidal cells via activation of oriens/alveus interneurons in rat hippocampal CA1 region

Authors: *K. SUMIKAWA, S. NAKAUCHI;
Univ. California Irvine, Irvine, CA

Abstract: Previous results show that nicotine facilitates the induction of long-term potentiation in the hippocampal CA1 region, and suggest that this facilitation involves circuitry-dependent disinhibition of pyramidal cells. Here, we investigated disinhibition mechanisms by performing dual whole-cell recordings in hippocampal slices and identified two possible disinhibition pathways. Most of the oriens/alveus (O/A) interneurons, which have their axons originating from a proximal dendrite and exhibit a significantly larger fast afterhyperpolarization, showed tonic action potential discharges by bath application of nicotine. We first examined whether activation of these O/A neurons leads to inhibition of feedforward interneurons in the radiatum, which is a possible pathway for disinhibition of pyramidal cells. In some pair recordings, we found that current injection in O/A interneurons evoked inhibitory postsynaptic currents (IPSCs) in radiatum interneurons, indicating that they are functionally connected. In these pairs, bath application of nicotine in the presence of glutamate receptor antagonists caused depolarization and increased action potential firing in O/A interneurons, and also increased spontaneous IPSC frequency in radiatum interneurons. These findings provide a potential disinhibition pathway of CA1 pyramidal neurons by nicotine. We next examined whether activation of nicotine-responding O/A interneurons, which are connected to pyramidal cells, influences excitatory postsynaptic currents (EPSCs) evoked in pyramidal cells by Schaffer collateral stimulation. We found that the excitation of these O/A interneurons by current injection reduced the amplitude of EPSCs in connected pyramidal cells, but the amplitude of EPSCs increased to levels above the basal EPSC amplitudes when O/A interneuron stimulation was stopped. Although the underlying mechanism remains to be determined, the finding provides a novel disinhibition mechanism by nicotine. Thus, our results show that nicotine causes circuitry-dependent disinhibition of pyramidal cells via two different pathways, both of which require the activation of O/A interneurons.

Title: Dual mechanisms diminishing tonic $GABA_A$ inhibition of dentate gyrus granule cells in Noda epileptic rats

Authors: S. PANDIT[1], D. KIM[2], H. KIM[1], *J. PARK[1];
[1]Dept. of Physiol., [2]Dept. of Anat., Sch. of Medicine, Chungnam Natl. Univ., Daejeon, Korea, Republic of

Abstract: The Noda epileptic rat (NER), a Wistar colony mutant, spontaneously has tonic-clonic convulsions with paroxysmal discharges. In the present study, we measured phasic (I_{phasic}) and tonic γ-aminobutyric acid A ($GABA_A$) current (I_{tonic}) in NER hippocampal dentate gyrus granule cells (DGGCs) and compared the results with those of normal parent strain Wistar rats (WIS). I_{tonic}, revealed by a bicuculline-induced outward shift in holding current, was significantly smaller in NER than in WIS ($p < 0.01$). The frequency of inhibitory postsynaptic currents (IPSCs) was also significantly lower in NER than in WIS ($p < 0.05$), without significant differences in the IPSC amplitude or decay time between WIS and NER. I_{tonic} attenuation in NER was further confirmed in the presence of GABA transporter blockers, NO-711 and nipecotic acid, with no difference in neuronal GABA transporter expression between WIS and NER. I_{tonic} responses to extrasynaptic $GABA_A$ receptor agonists (THIP and DS-2) were significantly reduced in NER compared with WIS ($p < 0.05$). Allopregnanolone caused less I_{tonic} increase in NER than in WIS, while it prolonged the IPSC decay time to a similar rate in the two groups. Expression of the $GABA_A$ receptor δ subunit was decreased in the dentate gyrus of NER relative to that of WIS. Taken together, our results showed that a combination of attenuated presynaptic GABA release and extrasynaptic $GABA_A$ receptor expression reduced I_{tonic} amplitude and its sensitivity to neurosteroids, which likely diminishes the gating function of DGGCs and renders NER more susceptible to seizure propagation.

Title: Cholinergic modulation of intact CA3 circuits *In vivo*

Authors: *M. GRIGUOLI, S. ZUCCA, C. MULLE;
IINS, Interdisciplinary Inst. For Neurosci., Bordeaux Cedex, France

Abstract:
Hippocampus receives extensive cholinergic innervation from fibers mainly originating in the medial septal nucleus of the basal forebrain. Acetylcholine (ACh), released by cholinergic fibers,

targets nicotinic and muscarinic receptors distributed in all hippocampal regions including CA3 neurons, which are particularly involved in new memory encoding. The relevance of the hippocampus and the CA3 region for memory processes and the well known importance of the cholinergic system for cognitive functions make it necessary to better understand how the activity of CA3 circuits is controlled by ACh in the intact network of a mammalian brain. To address this question we used an optogenetic approach, to selectively control the activity of cholinergic neurons, combined with *in vivo* recordings from CA3 pyramidal neurons. Double-floxed inverted open reading frame (DIO) viral vectors were used to target the expression of ChR2-EYFP to the cholinergic neurons of the *medial septum* in ChAT-Cre mice. To test the functionality of ChR2 we first performed whole cell recordings from EYFP positive cholinergic cells in acute brain slices. Brief pulses of blue light (0.5-1 ms; 470 nm) reliably induced action potentials at different frequencies of stimulation, indicating that this population of cholinergic neurons can be optically controlled. To study how the activation of the cholinergic neurons modulate CA3 network activity in the anesthetized mouse, an optical fiber was acutely implanted in the *medial septum* to deliver optical stimulation (1-5 ms, 470nm). We then recorded multi unit activity and oscillatory network activity (theta and gamma bands) in basal conditions and after light-mediated cholinergic stimulation. Activation of the cholinergic system increased the firing frequency of CA3 neurons and was associated with a consistent increase in the power of theta oscillations. Further studies at the single cell level will allow us to better characterize the effect of cholinergic activation on intrinsic membrane properties and synaptic inputs. This study will gain new insights on the functional role of ACh in modulating CA3 circuits involved in the rapid encoding of new information.

Title: Wiring principles in lateral subdivision of central amygdala

Authors: *W. S. HO, C.-C. LIEN;
Inst. of Neurosci., Natl. Yung-Ming Univ., Taipei, Taiwan

Abstract: Abstract
The amygdala is a key brain region for fear acquisition and expression. The lateral subdivision of the central amygdala (CeL), which comprises over 90% of GABAergic neurons, provides tonic inhibition onto the final output of the amygdala - the medial subdivision of the central amygdala (CeM) and thus controls fear expression. However, the CeL contains multiple neuronal subtypes and the functional connections between CeL neurons remain unclear. To answer this question, we performed whole-cell patch-clamp recordings from CeL neurons and found at least three different types of CeL neurons on the basis of their electrophysiology properties: late spiking (LS), regular spiking (RS) and low-threshold bursting (LTB) neurons. Among them, 90% of neurons were LS and RS neurons. Simultaneous pair- or triple-recordings from CeL neurons showed that temporal dynamics of GABA transmission within the CeL was target cell-specific. Specifically, synaptic transmission at LS-to-RS or RS-to-LS neuron output synapses exhibited activity-dependent depression, whereas the output synapses of LS-to-LS or RS-to-RS neurons were relatively insensitive to presynaptic activity or exhibited use-dependent facilitation. In addition to mutual inhibition, we also found that both LS and RS neurons exhibited autapses, which sent their axons back to modulate their own activity. Our preliminary results suggest that the diversity of GABAergic neurons and synapses may enable combinatorial inhibitory effects in the CeL and thus modulate fear expression.

Title: GABAergic dysfunction in anterior cingulate cortex of heterozygous BRD1 knockout mice

Authors: *I. V. VARDYA[1], J. H. CHRISTENSEN[1,2], P. QVIST[1,2], M. NYEGAARD[1,2], O. MORS[2,3], K. JENSEN[1], A. D. BØRGLUM[1,2,3];
[1]Dept. of Biomedicine, Aarhus Univ., Aarhus, Denmark; [2]The Lundbeck Fndn. Initiative for Integrative Psychiatric Res., iPSYCH, Denmark; [3]Ctr. for Psychiatric Research, Aarhus Univ. Hosp., Risskov, Denmark

Abstract: Anterior cingulate cortex (ACC) is a brain region that is critical for higher cognitive functions as attention, control of behavior and remote memory expression. Synchronization of pyramidal neurons of ACC is essential for the performance of neuronal circuits and dependent on activity of local GABAergic interneurons (Goldman-Rakic 1995). Alterations in GABA-mediated signaling in ACC were shown to be implicated in pathology of psychiatric disorders. Here, we investigated properties of GABA-mediated synaptic transmission in ACC in a new genetically modified mouse model of schizophrenia and bipolar disorder – heterozygous BRD1(R) knockout mice. The *BRD1 gene*, encoding a regulator of transcription - the bromodomain-containing protein1 (BRD1), was proposed to be susceptibility gene for schizophrenia and bipolar disorder (Severinsen et al. 2006; Nyegaard et al. 2010). Experiments were performed on adult male mice, BRD1(R) and BRD1(WT) littermates in the age range from 7 to 8 weeks. In acute coronal brain slices, whole-cell patch-clamp recordings from pyramidal neurons layers 2/3 of ACC were done. Pyramidal neurons were voltage-clamped at V_{hold} of -70mV and $GABA_A$ mediated inhibitory postsynaptic currents (IPSCs) were recorded in the presence of kynurenic acid, bloker of ionotropic glutamate receptors. We found 40% deficit in activity dependent GABAergic neurotransmission in ACC of BRD1(R) mice. Frequency of sIPSCs was 17.2 ± 1.6 Hz (n = 24) in BRD1(WT) and 10.1 ± 1.2 Hz (n = 21, $P < 0.01$) in BRD1(R) group. We repeated the experiments in the presence of the Na^+ channel blocker tetrodotoxin (1 μM) to isolate miniature IPSCs (mIPSCs). Frequency of mIPSCs was 8.2 ± 0.9 Hz (n = 8) in WT and 6.0 ± 0.7 Hz (n = 12) in R mice. There was no difference in mIPSCs mean amplitude, rise time or decay time between BRD1(WT) (39.9 ± 1.9 pA; 295.2 ± 15.0 μs; 4.1 ± 0.2 ms; n=8) and BRD1(R) mice (36.7 ± 2.0 pA; 298.7 ± 12.2 μs; 4.4 ± 0.2 ms; n = 12), indicating similar density and composition of synaptic $GABA_A$ receptors of pyramidal neurons of ACC. Interesting, a similar decrease in GABAergic inhibition was found in pyramidal neurons of somatosensory cortex, where significant reduction in GABA-mediated neurotransmission (from 12.5 ± 1.6 Hz (n = 11) in BRD1(WT) to 7.5 ± 0.9 Hz (n = 17 $P < 0.05$) in BRD1(R)) and in release probability of perisomatic GABAergic synapses was found. The data propose similar origin of GABAergic dysfunction throughout the cortical networks in the BRD1(R) mice. Deficit in GABA-mediated synaptic transmission in ACC of BRD1(R) mice may lead to altered synchronization of the cortical network and be involved in mechanisms, underlying behavior and cognitive alterations found in this model.

Title: Acetycholine reorganizes functional neocortical circuitry to favor feedforward thalamocortical information flow into superficial lamina

Authors: *M. J. RUNFELDT[1], J. N. MACLEAN[1,2];
[1]computational neuroscience, [2]Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Acetylcholine (ACh) has hetereogeneous effects on individual cortical neurons, yet has consistently been shown to increase intertrial reliability, enhance stimulus discriminability, and reduce pairwise activity correlations. These changes have been suggested to underlie to the attentional improvement of stimulus discriminability in awake behaving animals. However, it remains unclear how heterogeneous single cell changes driven by ACh receptor activation produce these changes in the population statistics. We address this question directly at the microcircuit level by sampling 600 +/- 165 neurons in a 1.1 mm diameter field of view using high speed multiphoton calcium imaging (15 +/-5 Hz sampling) in combination with patch clamp physiology.
We found that ACh (50μM) modifies spontaneous and thalamically-evoked activity differently. ACh causes a reduction in both the reliability and the numbers of recruited neurons in activity that spontaneously emerges intracortically. In contrast, more neurons are active in superficial lamina and demonstrate enhanced reliability when activity is thalamically evoked in the presence of ACh. We find that the majority of neuronal pairs, which have modest activity correlations and low joint probability of firing, are further reduced in the presence of ACh. In contrast, strong correlational structures, such as those activated by thalamic input, are strengthened. We also find that the neuronal pairs most correlated with ACh are further apart in temporal recruitment and geometric space. This places network dynamics within a regime that permits increased reliability of transmission of afferent input throughout local neocortical circuitry.

Title: Distribution of GAD65 and GAD67 immunoreactive somata in the mouse cortex: Classification using molecular markers

Authors: *H. MIWA[1,2], M. WATANABE[3], Y. YANAGAWA[1];
[1]Genet. & Behavioral Neurosci., Gunma Univ., Maebashi, Gunma, Japan; [2]JST, CREST, Tokyo, Japan; [3]Hokkaido Univ. Sch. of Med., Sapporo, Japan

Abstract: Inhibitory neurons play important roles in the regulation and stabilization for neural network activities and are essential for brain functions, including cognition, perception, movement, and emotion. γ-Aminobutyric acid (GABA) is a major inhibitory neurotransmitter in the central nervous system. GABA is synthesized from glutamate by two glutamate decarboxylase (GAD) isoforms, GAD65 and GAD67. The two GAD isoforms in somata are known to be heterogeneous among different subpopulations of GABAergic neurons. However, which subpopulation of GABAergic neurons exhibits somata labeling for the GADs remains unknown. Here, we examined the immunoreactivities against two GAD isoforms, GAD65 and GAD67, in somata of molecular markers [parvalbumin (PV), somatostatin (SST), vasoactive intestinal peptide (VIP), and reelin]-positve GABAergic neurons in the mouse cortex. The somata of GABAergic neurons containing PV and reelin showed more intense immunoreactivities against GAD67 than SST- and VIP-containing GABAergic neurons. These results indicate that different subpopulations of GABAergic neurons exhibit distinct expression levels of two GADs. In addition, they suggest that altered expression levels of GAD67 or GAD65, as reported in several psychiatric diseases including schizophrenia, would have GABAergic neuron subpopulation-specific consequences on the regulation of GABAergic neurotransmission.

Title: Carbachol induces a relative facilitation of intracellular EPSPs during short trains of theta- and gamma-frequency stimulation of the entorhinal cortex

Authors: *D. W. SPARKS, C. A. CHAPMAN;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: The superficial layers of the entorhinal cortex provide the hippocampus with much of its cortical sensory input, and the parasubiculum sends its single major output projection to layer II of the entorhinal cortex. The parasubiculum is therefore in a unique position to contribute to the modulation of entorhinal inputs to the hippocampal formation. Both the parasubiculum and entorhinal cortex receive cholinergic inputs that contribute to theta- and gamma-frequency EEG activities that are expressed as animals explore their environment. We previously found, using in vitro field potential recordings, that application of the cholinergic agonist carbachol, although suppressing the overall amplitude of evoked responses in parasubicular inputs to layer II of the medial entorhinal cortex, results in a relative facilitation of responses evoked during short 5-pulse trains of stimulation delivered at theta (10Hz) and gamma (33Hz) frequencies. This facilitation effect was dependent on M1 muscarinic receptors, was partially blocked by the NMDA receptor antagonist APV, and was completely blocked by ZD7288, which blocks the hyperpolarization-activated current Ih. The current study investigated the relative facilitation effect induced by carbachol in intracellularly recorded EPSPs during theta- and gamma-frequency stimulation at resting membrane potential and at hyperpolarized potentials. Whole-cell patch clamp recordings were obtained from layer II neurons of the medial entorhinal cortex in acute brain slices, and responses were evoked by stimulation of the parasubiculum using 5-pulse trains of stimulation at 10 or 33Hz. Hyperpolarization was associated with a large increase in EPSP amplitude despite no substantial change in input resistance, suggesting an effect of increased driving force on the EPSP. Similar to effects observed previously, intracellular responses during trains were reduced in normal ACSF (with a tendency for greater decline at hyperpolarized potentials), and carbachol led to a relative facilitation of the amplitude of later pulses in the trains for both theta- and gamma-frequency stimulation. Larger and more variable facilitation effects were observed at rest versus at hyperpolarized potentials. These results confirm that, even though carbachol suppresses the amplitude of single EPSPs in the parasubiculo-entorhinal pathway, carbachol also induces a relative facilitation of intracellular EPSPs evoked during short 5-pulse theta- and gamma-frequency trains. This novel finding suggests that repetitive synaptic inputs at these frequencies may be relatively well maintained as animals move about and explore their environment.

Title: Regulation of excitatory synaptic transmission at the hippocampal slices by synapsin II and Rab3a

Authors: *K. J. QUINONES, P. FELICIANO, M. BYKHOVSKAIA;
NEUROSCIENCE, Univ. Central Del Caribe, BAYAMON, Puerto Rico

Abstract: Synapsins are a family of synaptic vesicle phosphoproteins involved in the regulation of synaptic transmission. In humans, mutation on synapsin genes has been associated to the pathogenesis of epilepsy, while the deletion of synapsin genes has been implicated to induce epileptic seizures in mouse. The deletion of Rab3A, a synapsin binding partner involved in the vesicle mobilization, rescues the seizure activity observed at synapsin II deleted mice (SynII(-)). To understand how the interaction between these two proteins regulates synaptic activity, we investigated excitatory synaptic transmission at Syn II(-), Rab3a(-), and Syn II(-)/Rab3a(-) double knockout (DKO) mice. We have employed whole cell recordings from CA1 pyramidal neurons at hippocampal brain slices, while stimulating Schaffer collaterals at different current intensities. We detected a significantly increased synaptic activity at SynII(-) slices, and a significantly decreased synaptic activity at Rab3a(-) slices, while the activity at SynII(-)/Rab3A(-) DKO slices was not different from wild type (WT). Since reduced synaptic transmission is usually associated with an increase in pair-pulse facilitation (PPF), we investigated PPF in all the strains. The PPF at Rab3a(-) synapses was significantly increased, in agreement with the reduced synaptic activity. This result suggests that basal glutamatergic transmission at Rab3a(-) synapses may be diminished.

Title: Lethal phenotype of conditional VIAAT-knock-out in glycinergic neurons

Authors: J. RAHMAN[1], C. SCHNELL[1], *V. EULENBURG[2], S. M. WOJCIK[3], S. HÜLSMANN[1];
[1]Inst. for Neurophysiol. and cellular Biophysics, Goettingen, Germany; [2]Univ. of Erlangen, Inst. for Biochem. and Mol. Med., Erlangen, Germany; [3]Max-Planck-Institute of Exptl. Med., Göttingen, Germany

Abstract: The vesicular inhibitory amino acid transporter (VIAAT) is required for synaptic vesicle filling with GABA and/or glycine. To test the effect of a VIAAT knockout in glycinergic neurons we crossed floxed VIAAT mice to a BAC-transgenic GlyT2-Cre mouse line (Tg(Slc6a5-icre)121Veul). Knockout embryos (E18.5) delivered by caesarian section had a severe phenotype, with omphalocele, cleft palate, and respiratory failure. Electrophysiological recordings from hypoglossal neurons revealed the absence of spontaneous inhibitory postsynaptic currents (IPSCs), while evoked GABAergic inhibitory post-synaptic currents (eIPSCs) were unchanged and evoked glycinergic eIPSCs were decreased. The resting membrane potential of knockout neurons was slightly depolarized as compared to neurons from control littermates. Furthermore, immunohistochemical VIAAT-staining showed strongly reduced expression in the brainstems of knockout embryos. These results demonstrate that deletion of VIAAT in GlyT2-Cre-expressing neurons also strongly effects GABAergic transmission and suggest a large overlap of these two inhibitory neuron populations during embryonic development.

Title: Lactic acid modulates excitatory synaptic transmission at the calyx of Held

Authors: *O. D. UCHITEL[1], C. GONZALEZ INCHAUSPE[2], M. N. DI GUILMI[2];
[1]FBMC, IFIBYNE UBA CONICET, Buenos Aires 1428, Argentina; [2]IFIBYNE-CONICET, FCEyN, Univ. of Buenos Aires, Buenos Aires, Argentina

Abstract: Lactic acid is produced by anaerobic metabolism during physiological and pathological conditions in different sites: from muscle to brain. As a consequence, the pH in-vivo can fall as low as 6.5. The mechanism of action is still unclear but it was proposed an indirect role that would increase the activity of an acid-sensing ion channels (ASICs) and a direct role as a chelator of extracellular divalent ions (Immke and McCleskey, 2001). In this work we studied the effect of lactic acid on synaptic transmission using the calyx of Held-MNTB giant excitatory glutamatergic synapse in the mammalian central nervous system. Lactic acid (15 mM) enhanced ASIC currents evoked in postsynaptic MNTB neuron by a rapid drop in extracellular pH (reversible after washout). In addition, lactic acid decreased EPSC amplitudes as well the depression rate during high frequency trains at 100 and 300 Hz. The addition of extra calcium and magnesium to aCSF, reaching values of 2.35 Ca^{2+}/1.12 Mg^{+} (Immke and McCleskey, 2001), partially restored the original short term depression feature. These data suggest a direct role of lactic acid on synaptic transmission in addition to its role as a chelator of divalent ions and as modulator of postsynaptic ASIC channels.

Title: Network reponses to botulinum neurotoxin in synaptically coupled central nervous system neurons

Authors: *P. H. BESKE, K. S. HUBBARD, I. M. GUT, M. E. LYMAN, P. M. MCNUTT;
US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD

Abstract: Peripheral administration of *Clostridium botulinum* neurotoxins (BoNTs) is indicated for an increasing number of cosmetic and therapeutic applications. While much research effort has focused on BoNT intoxication of the neuromuscular junction, relatively little is known about the effect of BoNT on central synapses. In light of recent proposals suggesting therapeutic value for the central injection of BoNT, a functional determination of the consequences of intoxicating a networked population of central neurons remains a critical need. Therefore, to characterize the effect of BoNT intoxication on central synapses, we performed a multi-technique approach utilizing networked populations of murine embryonic stem cell-derived glutamatergic (90%) and GABAergic (10%) neurons (ESNs) as a central nervous system model. Whole-cell patch clamp electrophysiology revealed that ESNs develop mature electrical responses and form a complex synaptically coupled network after 18 days *in vitro* (DIV). Treatment of DIV 21+ ESNs with 2 pM of BoNT serotype A (BoNT/A) resulted in decreased synaptic signaling within 3 h, as determined by significant reductions in spontaneous action potentials (APs), excitatory post-synaptic potentials (EPSPs), and miniature excitatory post-synaptic currents (mEPSCs). ESNs were found to be highly sensitive to BoNT/A, with significant inhibition of APs, EPSPs, and mEPSCs at 24 h with doses as low as 0.1 mouse lethal units (0.067 pM). Given a calculated EC50 at 24 h of 0.81 pM using immunoblot detected cleavage of SNAP-25, measured inhibition of synaptic activity may provide a more sensitive metric of BoNT intoxication. Interestingly, early evidence suggests that treatment of ESNs with very low doses of BoNT/A perturbs the excitatory/inhibitory balance and elicits an epileptiform network response. Collectively, these studies functionally elucidate central network consequences of BoNT intoxication in a highly sensitive *in vitro* model system. This approach suggests that electrophysiological characterization of trans-synaptic activity may comprise a novel, rapid screen for the presence of functional toxin in forensic, pharmaceutical, environmental and/or food samples, as well as provide an *in vitro* model for central network research involving BoNT-induced synapse silencing. *Disclaimer: The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government.*

Title: Modulation of glutamate and dopamine levels in the prefrontal cortex by intra-cerebellar kynurenic acid infusion in the rat

Authors: *H.-Q. WU, R. SCHWARCZ;
Maryland Psych Res. Ctr, Univ. Maryland Sch. Med., Baltimore, MD

Abstract: Kynurenic acid (KYNA) is an astrocyte-derived, neuromodulatory tryptophan metabolite, which can act as an antagonist of both α7 nicotinic acetylcholine and NMDA receptors. KYNA levels are increased in several brain regions of individuals with schizophrenia (SZ) and may play a role in the cognitive impairments seen in the disease. A dysfunctional, cross-hemispheric connectivity between the cerebellum and the medial prefrontal cortex (mPFC) has been repeatedly proposed to be involved in the cognitive and affective deficits seen in SZ and other psychiatric diseases (Biol. Psychiatry, 64:81, 2008; Synapse, 65:1204, 2011). The present study was designed to examine the effects of cerebellar KYNA fluctuations both locally (i.e. within the cerebellum) and in the distant mPFC. To this end, extracellular levels of KYNA and glutamate in the cerebellum, and dopamine and glutamate in the contralateral mPFC, were determined in microdialysate samples obtained in freely moving rats. Locally, application of KYNA's bioprecursor kynurenine (0.5-10 µM) into the Purkinje cell layer by reverse dialysis produced the expected concentration-dependent increase in KYNA levels, and a corresponding reduction in glutamate, measured in the same microdialysate fraction. In contrast, intra-cerebellar infusion of (*S*)-4-(ethylsulfonyl)benzoylalanine (*S*-ESBA; 0.5-5 mM), a specific inhibitor of KYNA biosynthesis (ChemMedChem 1:528, 2006), induced a concentration-dependent reduction in KYNA and an increase in glutamate in same dialysate sample. Experimental manipulations of KYNA in the cerebellum resulted in qualitatively different consequences in the mPFC. Thus, an intra-cerebellar infusion of KYNA (10 µM, 10 µl for 2 hrs) induced significant peak increases in the extracellular levels of both dopamine (+50%) and glutamate (+75%) in the mPFC. This effect was duplicated by an intra-cerebellar infusion of kynurenine (5 µM, 10 µl for 2 hrs). In contrast, an intra-cerebellar infusion of *S*-ESBA (5 mM, 10 µl for 2 hrs) caused a decrease in extracellular dopamine (-20%) and glutamate (-30%) levels in the contralateral mPFC. Notably, an intra-cerebellar infusion of the specific glycine$_B$/NMDA receptor antagonist 7-Cl-kynurenic acid (10 µM, 10 µl for 2 hrs) affected neither extracellular dopamine nor glutamate levels in the mPFC, indicating that cerebellar NMDA receptors are not involved in the distant effects of KYNA described here. Current studies in the laboratory interrogate the characteristics of the polysynaptic connections that link fluctuations in cerebellar KYNA with prefrontally mediated behaviors, and the role of these phenomena in pathological conditions.

Title: Fluoxetine alters the mode of exocytosis in kinetically distinguished synaptic subtypes

Authors: *A. W. HENKEL[1], O. WELZEL[2];
[1]Physiol., Kuwait Univ., Safat, Kuwait; [2]Dept. of Psychiatry and Psychotherapy, Univ. of Erlangen-Nuremberg, Erlangen, Germany

Abstract: Neural transmission requires quantitative modulation of transmitter release and temporal coordination of information flow. Here we describe that the onset of synaptic exocytosis, monitored with FM1-43, can be significantly delayed. Hippocampal neurons from newborn rats were cultured in vitro until they obtained functionally mature synapses. Synaptic vesicles were fluorescently labeled, using 600 pulses at 30 Hz to label the whole recycling pool. After thorough wash-out, boutons were destained in two consecutive stimulation cycles, where the first served as internal control. Neurons were either treated with 1 µM fluoxtine or control solution during the second cycle and kinetic parameters from both cycles were compared. Mean exocytosis of FM followed roughly a single exponential decay curve during the stimulation period. Detailed analysis, however, revealed that the general synaptic population was composed of at least 4 kinetically distinguished exocytosis subtypes 1. single-exponential type, 2. delayed type, 3. two-component type and linear type. FM-exocytosis kinetics were significantly altered by application of fluoxetine during the second stimulation cycle, which decreased the number of delayed synapses by more than 50 % and increased the speed of synaptic exocytosis significantly by rising the percentage of fast two-component synapses. Synapses in control experiments showed the opposite effects when they were stimulated in a second stimulation cycle. Exocytosis in synapses, expressing synaptopHlourin as a reporter flurophore, was never delayed after start of stimulation. Considering earlier findings on synaptic release of FM1-43, our results suggest that the mode of exocytosis is switched between full vesicle fusion and “kiss-and-run” within the same synapse. The delay of FM release is due to “kiss-and-run” type of exocytosis, because the dye cannot leave a vesicle through a narrow fusion pore. Both, H+ ions and neurotransmitter molecules, however, can leave the vesicle lumen through a pore instantly, and therefore allow synaptopHlourin to monitor exocytosis.

Title: Role of a D2-like auto-receptor in modulating dopamine release in C.elegans and the potential co-transmission of dopamine with glutamate

Authors: *H. S. DHILLON[1], R. FORMISANO[1], M. MERSHA[2], R. KING[2], P. HAN[2], J. SINGH[2];
[1]Biol. Sci., [2]Delaware State Univ., DOVER, DE

Abstract: Dopamine is known to influence a wide range of neural processes including motor control, learning, memory and seeking behavior. Several neurological disorders are caused by dopamine imbalances, either due to low dopaminergic transmission (PD or attention deficit-hyperactive disorder, ADHD) or high dopamine levels (schizophrenia). At the cellular level there is degeneration of dopaminergic neurons in the ventral tegmental area of the midbrain of Parkinson's disease patients that leads to decreased levels of the monoamine neurotransmitter

dopamine that may involve D-2 like auto-receptors. We are using the *Caenorhabditis elegans* model to understand the auto-receptor functional component of the DOP-2 receptor in modulating dopamine levels in the synaptic cleft. In *C. elegans*, the D2-like dopamine receptor DOP-2 is expressed in all eight of its dopaminergic neurons and has been proposed to act as an auto-receptor that modulates dopamine release during the process of associative learning in the nematode. Four dopamine receptors have been identified in the *C. elegans* genome: DOP-1, DOP-2, DOP-3, and DOP-4. Their gene products are representative of two classes of dopamine receptors found in mammals: the D1-like and the D2-like receptors. Binding of dopamine to its G-protein coupled seven-transmembrane dopamine receptors can trigger antagonistic signal transduction cascade. Our interest is to understand the auto-receptor functional components of DOP-2 in regulating dopamine release. Recent work in our lab has shown that DOP-2 physically interacts with GPA-14, an inhibitory G-alpha subunit, and that both *dop-2* and *gpa-14* deletion mutants habituate at a significantly faster rate as compared to wild-type worms. Moreover, *gpa-14* deletion mutants have also shown associative learning deficits similar to those reported for *dop-2* in previous studies. In order to characterize the downstream molecular components of the DOP-2 auto-receptor function we are characterizing other mutants in TRP-N gene. In addition, we have quantified differential levels of alternatively spliced forms of the *dop-2* transcript in order to dissect function(s) of individual splice variants. Considering that the vulnerability of dopaminergic neurons in midbrain of PD patients is a likely function of excitotoxic death due to failure to regulate glutamate levels, we are also examining potential co-transmission of dopamine with glutamate and if D2 auto-receptors play a role in modulating co-release of the two neurotransmitters.

Title: Effects of action potential waveforms and the depolarizing afterpotential on calcium channel activity in the calyx of Held

Authors: *K. G. PARADISO, S. CLARKE, A. KISNER, B. CROWELL;
Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ

Abstract: At the calyx of Held nerve terminal, action potential waveforms can be used to activate calcium channels and trigger neurotransmitter release. Blockers for voltage-gated sodium and potassium channels are used to isolate calcium channel activity, and low resistance pipettes placed near the center of the calyx are used to optimize the ability to rapidly voltage-clamp the calyx. Using paired recordings, studies by others have clearly demonstrated that small changes in the kinetics or amplitude of the action potential can have large effects on the amount of neurotransmitter release. Following each action potential in the calyx, there is a depolarizing afterpotential (DAP) that affects the membrane potential reached by the repolarizing phase of the action potential. However, little is known about the effects of the DAP on calcium channel response. In order to test this, we have used a series of different action potential waveforms with and without this depolarizing afterpotential to activate calcium channels in the presynaptic terminal. At this time, the presence or absence of the DAP has not indicated any appreciable difference in the amount of calcium channel activity the action waveforms generate. However, since the presynaptic terminal is sensitive to very small changes in calcium, we are now investigating effects on exocytosis by using paired recordings or capacitance measurements to determine if the depolarizing afterpotential alters neurotransmitter release. In addition, to further determine how the shape of the action potential affects the calcium channel response, we have tested a series of different action potential waveforms that have the same total area, but vary in their rise and decay time. We started with a symmetrical waveform that has a rise time and decay time of 0.5 msec giving a total duration of 1 msec. Our results for a symmetrical waveform indicate that activation of calcium channels appears to begin during the peak of the action potential, continues during the repolarization phase and is largely complete by the end of the action potential. This finding agrees with similar experiments done by other labs. Of the waveforms we have tested that have identical areas, it is evident that a square waveform, although physiologically impossible, is the most efficient at activating calcium channels. Still, due to the short duration, even a square waveform will only activate ~50% of the peak calcium channel response. Finally, we are also investigating the extent to which various action potential waveforms affect the onset and recovery of calcium channel inactivation.

Title: Potentiation of adrenal catecholamine secretion by prostaglandin E_2: A novel role for "inhibitory" G proteins?

Authors: *R. L. BRINDLEY[1], M. L. JEWELL[2], K. P. M. CURRIE[3];
[1]Dept. of Anesthesiol., [2]Dept. of Pharmacol., [3]Departments of Anesthesiol. and Pharmacol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Adrenal chromaffin cells are an important neuroendocrine component of the sympathetic nervous system that release catecholamines, neuropeptides, and other hormones to help maintain homeostatic functions and appropriate responses to acute stress. G protein coupled receptors (GPCRs) integrate a variety of autocrine / paracrine signals to precisely control catecholamine exocytosis. Systemic immune challenge or inflammatory cytokines are thought to boost local production of prostaglandin E_2 (PGE_2) in the adrenal gland where mRNA for all four EP receptors (EP1 - EP4) is expressed. Previously we showed that PGE_2 inhibits Ca_v2 voltage-gated calcium channel currents (I_{Ca}) and exocytosis (changes in membrane capacitance) evoked by brief depolarizing stimuli in mouse chromaffin cells (*Mol. Pharm. 2011, 79: 987-996*). This pathway is mediated by G protein βγ subunits (Gβγ) liberated from $G_{i/o}$-type G proteins downstream of EP3 receptor activation by PGE_2. Here we show that during sustained stimulation to mimic acute stress, this canonical inhibition transitions to a novel potentiation of evoked catecholamine secretion. Catecholamine secretion was evoked by two rounds of stimulation with 30 mM KCl and detected using carbon fiber amperometry. In chromaffin cells isolated from wild-type mice, PGE_2 produced a robust potentiation of secretion evoked by KCl that was primarily due to a significant increase in the number of vesicular fusion events (amperometric spikes). The potentiation was abolished in cells treated with pertussis toxin indicating involvement of $G_{i/o}$-type G proteins. Further, two distinct antagonists of Gβγ signaling (gallein or anti-Gβγ phosducin-like C terminus peptide) blocked the PGE_2 mediated potentiation of catecholamine secretion. The potentiation was also prevented by a selective antagonist of the EP3 receptor (DG-041), and not seen in cells isolated from EP3 knockout mice. Thus, during brief stimuli, EP3 receptors suppress secretion through inhibition of I_{Ca}, but during sustained stimuli EP3 receptors potentiate evoked catecholamine secretion through a distinct pathway which also involves Gβγ subunits liberated from $G_{i/o}$-type G proteins. Taken together, our data reveal a rich, context-dependent modulation of catecholamine secretion by the inflammatory mediator PGE_2, and identify a novel signaling pathway through which "inhibitory" G-proteins can potentiate neuroendocrine hormone secretion.

Title: Mechanism of H_2O_2-induced facilitation on synaptic activity at developing neuromuscular synapse

Authors: *J.-C. LIOU;
Natl. Sun Yat-Sen Univ., Kaohsiung, Taiwan

Abstract: Although hydrogen peroxide (H2O2), a membrane-permeable reactive oxygen species, is better known for its cytotoxic effect, it has recently been suggested that it is released during neuromuscular activity and plays a negative feedback modulator on synaptic transmission. Here we test the role of H2O2 on synaptic transmission in developing Xenopus neuromuscular synapse by using whole-cell patch clamp recording. Bath application of H2O2 dose-dependently increases the spontaneous ACh secretion. Treatment the culture with either catalase or N-acetylcysteine has no significant on basal spontaneous synaptic neurotransmitter release, indicating H2O2 is not a retrograde factor, which might drive the machinery of neurotransmitter release. We next test the origin of H2O2-induced synaptic facilitation. The H2O2-induced synaptic facilitating effect was hampered while catalase was loading into myocyte through recording pipette, suggesting postsynaptic myocyte play crucial role in H2O2-induced facilitation on presynaptic neurotransmitter release. Surprisingly, H2O2 have no effect on neurotransmitter release from nerve terminal of a naïve motoneuron while an out-side-out patch of myocyte membrane was used as a probe to detect the ACh secretion. The Synaptic facilitation is occluded while IGF-1 antibody was added in the culture medium, suggesting IGF-1 is responsible for H2O2-induced synaptic facilitation. Overall, our current results provide evidences that H2O2 is important in developing neuromuscular synapse and further studies are needed to explore its role and underlying molecular mechanism in early synapse formation.

Title: Protein phosphatase 2A activation and GluR1 AMPA receptor dephosphorylation mediate adenosine A1 receptor-mediated synaptic depression in rat hippocampus

Authors: *J. A. STOCKWELL, Z. CHEN, M. NIAZI, N. SHU, F. S. CAYABYAB;
Dept. of Physiol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Therapeutic strategies aimed at decreasing the vulnerability of neuronal tissue after stroke have been successful in animal studies, but have yet to reveal a successful therapy in humans. During ischemic stroke, extracellular levels of adenosine increase due to the extracellular breakdown of ATP as well as transport of adenosine from ischemic cells. Adenosine is an inhibitory neurotransmitter that exerts some neuroprotective effects on ischemic tissue. Previously, we identified an interaction between adenosine receptors and glutamate receptors and showed that prolonged activation of adenosine A1 receptors (A1R) mimics stroke conditions, causing the induction of persistent synaptic inhibition. Recent evidence also suggests that p38 MAPK and JNK are involved in GluR2, but not GluR1, internalization by postsynaptic A1R stimulation. We hypothesized that protein phosphatase 2A (PP2A) activation and subsequent GluR1 dephosphorylation mediates the GluR1 reduction in surface expression after stimulation with the A1R agonist CPA (500 nM). Consistent with our hypothesis, we showed that in hippocampal membrane fractions GluR1 phosphorylation at S845 and S831, two known phosphorylation sites that influence GluR1 surface expression, was significantly reduced after CPA treatment. The selective PP2A inhibitors okadaic acid (3 and 20 nM) and fostriecin (20 nM) significantly blunted CPA-induced synaptic depression using fEPSP recordings from the CA1 region of the hippocampus. Recovery of synaptic depression following CPA washout was facilitated by both PP2A inhibitors. This was supported by biotinylation studies, in which CPA significantly reduced the surface expression of both GluR1 and GluR2, and this effect was prevented by both of the PP2A inhibitors, but not by the selective protein phosphatase 1 (PP1) inhibitor tautomycetin (20 nM). Based on these data, we conclude that prolonged adenosine A1 receptor stimulation during ischemic conditions causes A1R-mediated reductions in GluR1 surface expression and accompanying persistent synaptic depression, which depend on dephosphorylation of GluR1 by PP2A activation. This newly described interaction and its role in the increased vulnerability of neurons in ischemia will be further investigated in future studies.

Title: Dopaminergic agonists increase excitatory postsynaptic potentials in rat hippocampus in a region and input specific manner

Authors: *N. RIZVI, A. C. ARAI;
Pharmacol., Southern Illinois Univ. Sch. of Med., Springfield, IL

Abstract: The hippocampal-VTA dopaminergic network is implicated in motivated behavior and long term memory formation of novel and salient information. While many studies have focused on the effect of dopamine and synthetic dopaminergic agonists on CA1 pyramidal cell excitability, little attention has been given to their modulatory action in the dentate gyrus (DG). In the present study, we recorded extracellular excitatory postsynaptic potentials (EPSP) in response to perforant path (PP) stimulation in the dentate molecular layer. This was compared to recordings in CA1 stratum radiatum when Schaffer collaterals were stimulated. In both subregions, a concentration-dependent increase in EPSP amplitude was observed after application of the D1-like receptor agonist SKF38393. In the CA1 region, 20 µM drug produced a 25% increase in EPSP amplitude with no clear difference between dorsal and ventral portions of the hippocampus. In the dentate gyrus, higher concentrations were needed to produce comparable effects, but in this case the increase in EPSP amplitude showed major differences along the dorso-ventral axis and it differed between medial and lateral perforant path inputs. The largest effects of SKF38393 were observed at the medial perforant path (MPP) synapses in the dorsal DG (65%), the effect being twice as large as at ventral MPP synapses (30%). Amplitude changes at lateral perforant path (LPP) synapses were consistently smaller than those at MPP synapses. The effects of SKF38393 appeared to be irreversible and result in a long lasting increase in EPSP. In both hippocampal subregions, the SKF38393 mediated increase in EPSP amplitude was enhanced by the D1-like receptor antagonist SCH23390 and blocked by the D2 receptor antagonist sulpiride, and it was unexpectedly blocked by the phospholipase C inhibitor U73122, tentatively suggesting a role of D2 receptors in enhancing excitatory transmission through activation of Gαq signaling. Other dopaminergic agonists acting on D1-like receptors (SKF83959) and D2-like receptors (quinpirole) increased EPSP amplitude in a manner similar to

SKF38393. Our work shows that modulation of excitatory synaptic transmission in DG by dopamine exhibits gradients that may be important for hippocampal function.

Title: Anesthetic and ethanol enhancement of GABAA slow receptor-mediated synaptic inhibition

Authors: E. S. POSADAS[1], B. A. DAGNE[1], M. K. SUNAY[1], J. R. TRUDELL[1], B. H. BLAND[2], *B. MACIVER[3];
[1]Anesthesia, Stanford Univ., Stanford, CA; [2]Psychology, Univ. of Calgary, Calgary, AB, Canada; [3]Anesthesia, STANFORD, STANFORD, CA

Abstract: Despite widespread use and extensive research into the effects produced by anesthetics and ethanol, their mechanism(s) of action in the brain have yet to be elucidated. Recent research indicates that anesthetics and ethanol may act on extrasynaptic ‘delta’ subunit-containing GABAA receptors that generate ‘tonic’ chloride currents in neurons. We tested this hypothesis, and also asked if the drugs act on ‘non-tonic’ GABAA synaptic receptors, by measuring synaptic inhibition using field potential recordings from freely moving rats and from hippocampal brain slices, following institutional animal care approval. Stainless steel chronically implanted micro-electrodes were placed in Stratum Oriens of the CA1 region for in vivo recordings. Glass micro-electrodes were placed near the hippocampal CA1 cell body layer in brain slices prepared from 25 to 30 day old male rats. Population spikes were evoked by stimulating Schaffer-collateral fibers with bipolar electrodes in both preparations. Low concentrations of ethanol (1.0 g/kg IP or perfused: 0.10% = 22 mM), as well as higher concentrations, enhanced GABAA ‘slow’ receptor-mediated synaptic inhibition in hippocampus, seen as increased paired pulse inhibition of population spikes, at 100 ms, but not at earlier paired pulse time intervals. A similar effect was produced by isoflurane (0.2 to 1.5 vol % = 75 to 350 μM). This indicated selective enhancement of GABAA slow receptors by ethanol and isoflurane.

No evidence for effects on GABAA ‘tonic’ receptors was seen, but CA1 neurons only express delta subunit containing ‘tonic’ receptors at low levels. Thus, in this study we have shown an anesthetic and ethanol effect on GABA synapses at low concentrations associated with mild intoxication and at higher concentrations associated with loss of righting reflex.

Title: AAV2-agrin sciatic nerve delivery suppresses neuropathic pain induced by spinal cord injury

Authors: *J.-G. CUI[1], D. ERASSO[1], G. TENDER[2], R. LEVITT[1];
[1]Dept of Anesthesiol., Univ. of Miami, Miami, FL; [2]Neurosurg., Louisiana State Univ., New Orleans, LA

Abstract: Following spinal cord injury (SCI), up to 85% of patients may develop neuropathic pain (NP). SCI-NP is associated with pathological alterations of structure, biochemistry and genes in the peripheral and central nervous systems and is a most difficult disease to treat. Existent pharmacological and surgical therapies are ineffective overtime and produce side-effect results. Agrin, a single-gene-encoded heparin sulfate proteoglycan that acts as a neuromuscular junction inducer, has also been identified as a pain mediator in the dorsal horn (DH) of spinal cord. Our previous results showed that agrin up-regulation by intraspinal injection of adeno-associated virus serum type 2 carried agrin (50 kDa) gene (AAV2-Ag50) suppressed neuropathic pain in rat peripheral nerve NP models. Based on our new results and published data, we hypothesize that AAV2-Ag50 injected into sciatic nerve will express Ag50 in the DRG and DH and suppress NP in a quisqualic acid- induced SCI NP rat model. All experiments met NIH guidelines and were approved by the University of Miami IACUC. Male Sprague-Dawley rats (240-250g) underwent quisqualic acid (QA) injection into lumbar dorsal spinal cord, which resulted in -SCI. A week after SCI, withdrawal threshold was decreased, measured by a series of Von Frey filaments. If the threshold is below 8 gram, this value is defined as tactile allodynia; if a withdrawal threshold is 20g or more after AAV2-Ag50 treatment, the threshold is defined as

normalized. Allodynic rats were randomly divided into groups subjected to an intraneural (left sciatic nerve) injection of AAV2-null, AAV2-Ag25, or AAV2-Ag50. AAV2-GFP intraneural injection was used as controls. The paw thresholds were assessed daily before and after AAV2-Ag sciatic nerve injection for three days, then the rats were perfused for immunohistochemistry or were performed for protein extraction and western blot analysis. The results were analyzed together. **I**ntraneural injections of AAV2-GFP resulted in good delivery and expression of GFP in the dorsal root ganglia and dorsal spinal cord. Intraneural injection of AAV2-Ag50 improved SCI-NP at 24 hrs and suppressed SCINP at 48 -72 hrs post-injection, while AAV2-Ag25 injection did not change the threshold. Our preliminary results suggest that 50 kDa agrin by intraneural AAV2 vector delivery can be expressed in the DRG and DH, thus suppresses SCI-NP in the rat SCI model. These results suggest that AAV2-Ag50 sciatic nerve delivery is a very promising approach for NP treatment.

Title: Imaging synaptic zinc release in the dorsal cochlear nucleus with newly developed zinc sensors and chelators

Authors: *C. T. ANDERSON[1], R. J. RADFORD[3], U. PETER-APFEL[3], S. J. LIPPARD[3], T. TZOUNOPOULOS[2];

Abstract: Vesicular zinc exists at many glutamatergic synapses in the brain. This d-block metal is loaded into presynaptic glutamatergic vesicles and is co-released with glutamate during synaptic transmission. The molecular layer of the dorsal cochlear nucleus (DCN) contains high levels of vesicular zinc. Our group has recently reported that synaptically-released zinc initiates endocannabinoid synthesis that subsequently modulates synaptic strength (Perez-Rosello et al.,

2013). However, the amount of synaptic zinc that reaches the postsynaptic membrane during synaptic stimulation remains unknown, mainly due to the lack of appropriate zinc sensors and chelators. Here, we have used new generation of fluorescent zinc sensors and chelators to examine how much, and under what conditions zinc is released in the DCN.

Title: Evaluation of neuromuscular transmission in organophosphorus toxicity

Authors: *K. N. DISSANAYAKE[1], V. PATEL[3], J. MCARDLE[3], M. EDDLESTON[2], R. R. RIBCHESTER[1];
[1]Ctr. for Integrative Physiol., [2]Ctr. for cardiovascular science, Univ. of Edinburgh, Edinburgh, United Kingdom; [3]Univ. of Med. and Dent. New Jersey, Newark, NJ

Abstract: Organophosphorus (OP) toxicity through pesticide ingestion is a global health problem. The medical signs are complex, including an 'intermediate syndrome' from which some patients die due to respiratory paralysis. A hypothesized mechanism is initial excitotoxicity through inhibition of acetylcholinesterase followed by failure of neuromuscular synaptic transmission. We tested this electrophysiologically *in vitro* by measuring properties of spontaneous miniature endplate potentials (MEPPs) and evoked endplate potentials (EPPs) in isolated sciatic nerve/flexor digitorum brevis muscles from mice, bathed in HEPES-buffered mammalian physiological saline (MPS). Muscle action potentials were abolished with μ-conotoxin (2μM). First, we tested the effects of plasma taken from Göttingen minipigs instilled orally (isofluorane anaesthesia) with a formulated pesticide whose active ingredient is dimethoate dissolved in cyclohexanone. This plasma abolished evoked synaptic transmission and increased spontaneous MEPP frequency within 60-180 minutes of bath application. Plasma from minipigs instilled with dimethoate alone produced no failure of transmission but significantly increased the half decay time of EPPs (MPS,3.44 ±0.60 ms; control plasma,3.24±0.49 ms;

pesticide plasma, 4.10±2.38sec; dimethoate plasma,6.91±2.04sec; $p < 0.001$, ANOVA, n=20-30 fibres in each of 3-6 mice). However, pesticide-plasma also contained the metabolites omethoate (100µM) and cyclohexanol (5 mM). We found that bath application of omethoate alone caused a potent dose-dependent increase in EPP decay time. Cyclohexanol also increased EPP decay time but it also decreased both the excitability of axons and MEPP amplitude. In combination, omethoate and cyclohexanol produced greater disruption of neuromuscular transmission than either dimethoate or cyclohexanone, alone or in combination. Voltage-clamp recordings of endplate currents supported the EPP observations. Quantal analysis of EPP's also suggested that the metabolites reduced evoked neurotransmitter release. Together, the data indicate that neuromuscular transmission failure by pesticide-plasma cannot be explained solely by dimethoate-mediated inhibition of acetylcholinesterase. Rather, a combination of metabolic breakdown products exerts harmful presynaptic and postsynaptic effects. Blocking the metabolic breakdown of the constituents of OP pesticides could therefore be an effective strategy for treatment of OP pesticide toxicity.

Title: Direct and heterogeneous control of striatal cholinergic neuron firing by midbrain dopamine neurons

Authors: *N. CHUHMA[1,2], S. MINGOTE[1,2], H. MOORE[1,2], S. RAYPORT[1,2];
[1]Columbia Univ., NEW YORK, NY; [2]NYS Psychiatric Inst., New york, NY

Abstract: Cholinergic interneurons (ChIs) comprise less than 1% of striatal (Str) neurons, yet they play crucial roles in normal reward-related behavior and motor control as well as the pathophysiology of major neuropsychiatric disorders. Str acetylcholine and dopamine (DA) reciprocally modulate each others' release; however, direct action-potential dependent control of ChIs by DA neurons has not been elucidated. We studied DA neuron input to ChIs in mouse

brain slices in three striatal domains, the dorsal striatum (dStr), nucleus accumbens (NAc) core (core) and NAc medial shell (m-shell), to address regional heterogeneity. To activate DA neuron terminals selectively, we injected a conditional channelrhodopsin 2 adeno-associated virus into the ventral midbrain of DAT-IRES-cre mice. Responses of ChIs to photostimulation of DA neuron terminals were recorded with whole cell current clamp. Short illumination (5 msec) with blue light (470 nm) evoked an IPSP in ChIs in the dStr, little response in the core, and a strong EPSP, capable of driving action potential firing in the m-shell. When DA neuron bursting was mimicked by train photostimulation (5 pulses at 20 Hz), ChIs in the dStr were hyperpolarized and paused their firing; this was mediated solely by D2 receptors. In the NAc core, train photostimulation reduced firing but did not reliably pause firing; this was mediated by GABAA and D2 receptors. In the NAc m-shell, train photostimulation caused ChIs to fire in a burst followed by hyperpolarization; the burst was glutamate mediated, while the post-burst hyperpolarization was mediated mainly by Ca2+ dependent K+ channels, and also partly by D2 and muscarinic acetylcholine receptors. Conditional knockout of vesicular glutamate transporter 2 (VGLUT2) from DA neurons eliminated the excitation, so that the response of ChIs became uniformly inhibitory across the Str domains, suggesting the regional heterogeneity was mainly due to DA neuron glutamate cotransmission. To examine plasticity in the regional heterogeneity, we treated mice with low dose (2 mg/kg) or high dose (16 mg/kg) amphetamine (AMPH), and 2.5 hours later recorded the responses of ChIs to DA neuron terminal photostimulation. Low-dose AMPH attenuated bursts in m-shell ChIs, without affecting responses in the core or dStr. High dose AMPH attenuated both the pause in the dStr and bursting in the m-shell. Thus, DA neurons transmit a fast signal to ChIs with regional heterogeneity due to blending of the synaptic actions of DA and glutamate release. The dramatic amphetamine-induced alteration in DA neuron control of ChIs is likely to figure prominently in the initial response to psychostimulants.

Title: Measuring bioenergetic function at the nerve terminal

Authors: *D. PATHAK[1], L. SHIELDS[1], H. KIM[1], R. EDWARDS[2], K. NAKAMURA[1,2]; [1]The J. David Gladstone Inst., San Francisco, CA; [2]Dept. of Neurology, UCSF, San Francisco, CA

Abstract: Synaptic mitochondria are thought to have a critical role in supporting energy requirements at the synapse, and bioenergetic failure at the synapse may impair neural transmission and contribute to neurodegeneration. However, energy levels at the synapse have not been directly measured, due to a lack of tools to study bioenergetic function at the nerve terminal. To address this, we designed a functional assay for mitochondria-derived ATP at the synapse. The assay is based on the extent of synaptic transmission after electrical stimulation in the presence of glucose or pyruvate, and uses vesicular glutamate transporter 1 (VGLUT1)-pHluorin as a probe to monitor synaptic transmission on a bouton-by-bouton basis. We found that basal synaptic transmission can be maintained by either aerobic or anaerobic respiration. However, inhibitors of oxidative phosphorylation blocked endocytosis when glucose was absent, indicating that mitochondria-derived ATP is required for endocytosis. Further, by segregating those synaptic boutons with and without mitochondria, we showed that functionally sufficient levels of ATP diffuse into those boutons without mitochondria. To define the threshold levels of ATP required to sustain endocytosis, we also applied recently described ATP FRET sensors to dynamically monitor ATP levels at the synapse. These assays provide some of the first measurements of mitochondrial-derived energy at the nerve terminal and should be valuable tools in the assessment of energy metabolism at the synapse in health and disease.

Title: Developmental and NMDA receptor-dependent mechanisms contribute to changes in expression of prostaglandin E synthase isozymes in cultures of cortical neurons

Authors: Y. GONG[1], W. WANG[1], *J. A. HEWETT[2];
[1]Dept. of Biology, Program in Neurosci., [2]Dept. of Biol., Syracuse Univ., Syracuse, NY

Abstract: Prostaglandin E_2 (PGE_2) is a potent prostanoid metabolite of the cyclooxygenase (COX) pathway of arachidonic acid. It is generated by neurons in response to excitatory neuronal activity and, as such, is considered to be an important neuromodulator in the brain. PGE_2 is produced from free arachidonic acid by the sequential actions of COX and prostaglandin E

synthase (PGES). Two COX and three PGES isoforms have been identified. In general, expression of COX-2 and PGES-1 is inducible, whereas COX-1 and PGES-3 are constitutively expressed. Moreover, the respective isoforms couple preferentially with each other in the production of PGE_2. In contrast, PGES-2 appears to couple with either COX isoform. The specific isoforms of COX and PGES that contribute to the activity-dependent production of PGE_2 in the brain remain unknown. The purpose of this study was to assess the possible coupling of PGES-1 with COX-2 in cultures of pure cortical neurons derived from embryonic day 15 mice. Functional NMDA receptors develop after 4 days *in vitro* (DIV). COX-2 mRNA expression, as measured by quantitative PCR analysis, increased after 4 DIV as it was completely blocked by addition of the NMDA receptor antagonist, APV (30μM), on DIV 5. These results are consistent with a primary role of COX-2 in the production of PGE_2 associated with excitatory neuronal activity. Since COX-2 is coupled to PGES-1 preferentially, it is hypothesized herein that PGES-1 mRNA expression will be regulated by NMDA receptor in parallel with COX-2. Interestingly, in contrast to COX-2 expression, preliminary results suggest that PGES-1 mRNA expression was highest on DIV 1 and decreased with time in culture. Moreover, the residual expression on DIV 7 did not appear to be affected by APV treatment. Unexpectedly, however, PGES-2 mRNA expression gradually increased over 9 DIV and this was attenuated but not completely blocked by APV. These results suggest that mRNAs for PGES-1 and -2 change inversely as cortical neurons develop in culture and that the latter may be at least partly regulated by NMDA receptor activity. To date, the role of PGES-2 in production of PGE_2 in the brain has not been clearly defined. The coordinated regulation of COX-2 and PGES-2 expression raises the possibility that the production of brain PGE_2 associated with excitatory neuronal activity may be the result of specific coupling of these isoforms in neurons.

Title: Dopamine D_1-family receptors enhance excitatory synaptic currents in layer II of the entorhinal cortex via activation of cAMP-PKA, PP-1, and calcium influx

Authors: *I. GLOVACI, C. A. CHAPMAN;
Concordia Univ., Montreal, QC, Canada

Abstract: The entorhinal cortex receives dopaminergic inputs that can modulate its responsiveness to synaptic inputs from other cortical areas. We have previously shown that dopamine produces reversible concentration-dependent changes in synaptic transmission in neurons in layer II of the rat lateral entorhinal cortex, such that evoked EPSPs are suppressed by high concentrations of dopamine, and facilitated by lower concentrations of dopamine. Here, we have used voltage-clamp recordings in layer II entorhinal neurons to investigate the intracellular mechanisms that mediate the synaptic facilitation effect. Results show that dopamine (1 μM), acting via D_1-family receptors, enhances pharmacologically isolated AMPA, but not NMDA, glutamate receptor-mediated currents. Elevations in PKA resulting from D_1 receptor-mediated increases in cAMP could lead to direct phosphorylation of AMPA-receptors, and might also enhance synaptic responses by increasing activity of inhibitors of protein phosphatase 1 (PP-1). Here, we found that the synaptic facilitation was blocked by intracellular application of the PKA inhibitor H-89, and that the facilitation was also blocked by the PP-1 inhibitor okadaic acid, suggesting that dopamine may facilitate AMPA-mediated responses by an inhibition of PP-1 activity. In addition, we found that intracellular application of the Ca^{2+} chelator BAPTA completely blocked the dopamine-induced facilitation of EPSCs, indicating that the facilitation of EPSCs is dependent on elevated intracellular calcium. The Ca^{2+}/calmodulin-dependent protein kinase CaMKII can enhance synaptic transmission, but we found that intracellular application of the CaMKII inhibitor KN-93 failed to reliably block the facilitation, suggesting that Ca^{2+}-induced changes in CaMKII activity are not required for the synaptic facilitation effect. The present results therefore suggest that the dopamine-induced facilitation of AMPA receptor-mediated synaptic responses in layer II entorhinal neurons is mediated via a D_1 receptor-dependent activation of the cAMP-PKA pathway, inhibition of the activity of PP-1, and elevated intracellular calcium.

Title: Features of synaptic activity in primary culture of rat cortical neurons

Authors: *D. A. SIBAROV[1,2], S. M. ANTONOV[1,2];
[1]Sechenov Inst. of Evolutionary Physiol. and Biochem., Saint-Petersburg, Russian Federation;
[2]Lab. of Mol. Neurodegeneration, Saint-Petersburg State Polytechnical Univ., Saint-Petersburg, Russian Federation

Abstract: Primary cultures of neurons from different brain regions are popular models to study neuronal physiology. Numerous studies were performed in primary cultures of neurons devoted to cellular network activity, differentiation, protein expression, intracellular calcium dynamics etc. The functional characteristics of neuronal activity in primary culture are similar to those in whole brain or in brain slices. However, some features of cultured neuron homeostasis like flat topology, deficit of glial cells and time-dependent development of synaptic functions may alter synaptic transmission. Whereas synaptic currents were widely studied in hippocampal and cerebellar cultures, few publications describing only frequencies or synaptic plasticity in primary culture of cortical neurons are available. Here we study the features of postsynaptic currents in primary culture of cortical neurons at 7 - 20 days in vitro (DIV). The use of selective blockers of ligand-gated postsynaptic ion channels in these neurons after 10 DIV revealed all types of electrical activity found in adult cortex including miniature inhibitory (mIPSCs), excitatory (mEPSCs) and spontaneous giant excitatory currents and spikes. The frequency of mEPSCs increased exponentially from 7 to 20 DIV doubling every 2.2 days in parallel with changes in action potentials generation. The mEPSCs generated by NMDA and AMPA or by only AMPA receptor activation were recorded in magnesium-free solution exhibiting postsynaptic zones of different receptor composition. In brain slices NMDA-receptors does not contribute to mEPSC amplitude in Mg-free solution. In contract to brain slices, the inhibition of presynaptic NMDA receptors by magnesium ions or AP5 influence mEPSCs amplitude by modulating their quantal content. Found discrepancies in the mechanisms of mEPSCs generation are probably due to the lack of glial control of synaptic environment.

Title: Nerve injury increases GluR2-lacking ampa receptor prevalence in spinal cords

Authors: *S.-R. CHEN[1], H.-Y. ZHOU[2], H. BYUN[2], H.-L. PAN[2];
[1]Anesthesiol. & Perioperative Med., Univ. of Texas MD Anderson Cancer Ctr., HOUSTON, TX;
[2]MD Anderson Cancer Ctr., Houston, TX

Abstract: The glutamate AMPA receptors (AMPARs) are critically involved in the excitatory synaptic transmission, and blocking AMPARs at the spinal level reverses neuropathic pain. However, little is known about changes in the composition of synaptic AMPARs in the spinal dorsal horn after peripheral nerve injury. AMPARs lacking GluR2 subunit are permeable to Ca2+ and their currents show unique inward rectification. We found that AMPAR-mediated excitatory postsynaptic currents (AMPAR-EPSCs) of spinal dorsal horn neurons exhibited a linear current-voltage relationship in control rats, whereas AMPAR-EPSCs of dorsal horn neurons displayed inward rectification in rats with spinal nerve injury. In nerve-injured rats, compared with control rats, the GluR2 protein level was significantly less in the plasma membrane but was greater in the cytosolic vesicle fraction in the dorsal spinal cord. However, the GluR1 protein levels in these fractions did not differ significantly between nerve-injured and control rats. Blocking NMDA receptors abolished inward rectification of AMPAR-EPSCs of dorsal horn neurons in nerve-injured rats. Furthermore, inhibition of calpain or calcineurin, but not protein kinase C, completely blocked nerve injury-induced inward rectification of AMPAR-EPSCs of dorsal horn neurons. In addition, blocking GluR2-lacking AMPARs at the spinal cord level reduced nerve injury-induced pain hypersensitivity. Our study suggests that nerve injury increases GluR2 internalization and the prevalence of GluR2-lacking AMPARs in the spinal dorsal horn to maintain chronic neuropathic pain. Increased prevalence of spinal GluR2-lacking AMPARs in neuropathic pain is mediated by NMDA receptor activation and calpain-calcineurin signaling.

Title: ARPP-16, protein kinase A and MAST3 kinase: A newly identified pathway for regulation of protein phosphatase PP2A in striatal neurons

Authors: *V. MUSANTE[1], E. ANDRADE[3], J. CANIO[2], P. GREENGARD[4], A. C. NAIRN[1,4]; [1]Dept. of Psychiatry, [2]W.M. Keck Foundation,Keck MS and Proteomics, Yale Univ. Sch. of Med., New Haven, CT; [3]Lab. of molecular biology, [4]Lab. of molecular and cellular neuroscience, Rockefeller Univ., New york, NY

Abstract: Protein phosphorylation is the most common post-translational modification in neuronal signaling and results from the balanced action of kinases and phosphatases.
We previously identified a family of striatal-enriched phospho-proteins substrates for PKA: DARPP-32, RCS and ARPP-16 (Walaas et al.,1983).
While the role of DARPP-32 and RCS in the dopamine (DA)-mediated regulation of serine/threonine phosphatases in striatal medium spiny neurons (MSNs) has been well characterized (Walaas et al. 2011) little has been known about the role of ARPP-16.
ARPP-16 is related to two other members of ARPP family, ARPP-19 and ENSA. ARPP-19 and ENSA are ubiquitously distributed and have been identified as phosphatase PP2A inhibitors in mitotic cells. In Xenopus oocytes, phosphorylated by Greatwall kinase (GWT), ARPP-19/ENSA inhibit PP2A during the G2/M phase (Lorca&Castro 2013).
Recently, we found ARPP-16 directly interacts with PP2A in striatum and it is phosphorylated at Ser46 by microtubule-associated serine/threonine kinase 3 (MAST3), a mammalian analogous of GWT, enriched in striatum and still poorly characterized.
Phosphorylation of ARPP-16 at Ser46 by MAST3 converts the protein into an inhibitor of PP2A towards selective substrates including DARPP-32. Moreover, Ser46 of ARPP-16 is phosphorylated to a high basal stoichiometry in striatum, while activation of PKA by cAMP leads to marked dephosphorylation of Ser46 in striatal slices.
In the current study we further investigate the role of the phosphorylation mechanisms in ARPP-16 regulation. We demonstrated, both in vitro and in intact cells, that PKA plays a fundamental role in the MAST-mediated phosphorylation of ARPP-16 and regulation of PP2A. PKA phosphorylation of ARPP-16 at Ser88 negatively acts in an intramolecular fashion on Ser46 phosphorylation, leading to an inhibition of its ability to regulate PP2A. The phosphomimetic S88D-ARPP16 strongly suppresses MAST3 phosphorylation at Ser46 while the single PKA phosphorylation of Ser88 does not have any effect on the phosphatase inhibition. We also find that PKA phosphorylates MAST3 in vitro resulting in kinase inhibition, and that activation of cAMP by forskolin in transfected HEK cells significantly decreases MAST3 activity.
Overall these data suggest that P-Ser46-ARPP-16 acts to basally control PP2A in MSNs, but that DA, acting via PKA, regulates this pathway by inactivating ARPP-16 and/or MAST3 leading to selective potentiation of PP2A signaling.

Further experiments are in progress to identify other specific MAST3 substrates in order to characterize and better understand the role of this kinase in the regulation of the synaptic activity in striatum

Title: Lactate modulates neuronal excitability through both NMDA and KATP receptors: role in plasticity genes expression

Authors: *P. J. MAGISTRETTI[1,2], P. JOURDAIN[1,2], J. YANG[1], G. GRENNINGLOH[1], E. RUCHTI[1], J.-M. PETIT[1,2], I. ALLAMAN[1];
[1]Ecole Polytechnique, Lausanne, Switzerland; [2]CHUV-Département de Psychiatrie, Ctr. de Neurosciences Psychiatriques, Prilly/Lausanne, Switzerland

Abstract: Release of glycogen-derived L-lactate from astrocytes has been shown to play an important role in the establishment of long term memory (Suzuki et al, Cell, 2011). In an accompanying poster, we present data demonstrating that in cultured neurons L-lactate, but not L-pyruvate, induces plasticity-related genes expression through a NMDA-dependent mechanism (i.e. Arc, Zif268 and c-Fos). Here, we describe the effect of L-lactate on neuronal excitability as revealed by electrophysiological recordings of cultured cortical neurons. We observed that application of L-lactate (10 mM) triggers an inward current with an amplitude of -0.55 +/- 0.1 nA and slow kinetics, with a peak reached at 189 +/- 55s (called Ilac). The membrane current decreases gradually to reach a plateau, with a mean inward current of -0.13 +/- 0.04 nA persisting up to 780s (13 minutes) after addition of L-lactate (called Ipyr). In order to assess L-lactate specificity in the generation of these currents, L-pyruvate as well as D-lactate, the non-metabolized enantiomer of L-lactate, were tested. In contrast to L-lactate, L-pyruvate (10 mM)

induced only a low-amplitude sustained current (-0.07 +/- 0.03 nA) similar to the late-phase slow current evoked by L-lactate (i.e Ipyr). D-lactate did not elicit any specific current. Pharmacological characterization of Ilac and Ipyr currents demonstrate that Ilac is generated by NMDA receptors (as it is blocked by MK801) and relies on active NMDA receptors (as it is blocked by either glutamate or glycine binding sites antagonists). In contrast, generation of Ipyr by both L-lactate and L-pyruvate is prevented by diazoxide, a KATP opener. In conrast Ilac was unaffected by diazoxide treatment. In order to determine the involvement of KATP for plasticity-related gene expression, the KATP closer glibenclamide (200 uM) was applied to neurons and mRNA gene expression of Arc and Zif268 determined. Results obtained demonstrate that Arc and Zif268 mRNA expression are unaffected by glibenclamide. As a whole this set of data demonstrates that L-lactate generates two types of inward currents in neurons i.e. NMDA-dependent (Ilac) or KATP-dependent (Ipyr). Moreover, they identify the NMDA-dependent Ilac current as the key mediator, in contrast to KATP, for L-lactate-induced plasticity gene expression. This set of results provides novel insights into the mechanisms of action of L-lactate in inducing plasticity gene expression, and reveals its role as a signaling molecule for neuronal plasticity.

Title: Local agmatine injection increases striatum extracellular dopamine in rats

Authors: *L. R. BETANCOURT[1], M. SKIRZEWSKI[2], B. CATLOW[3], D. PAREDES[3], P. RADA[1], L. HERNANDEZ[1];
[1]Univ. Los Andes, Merida, Venezuela, Bolivarian Republic of; [2]Huang Lab: Section on Metabolic Redulation, NICHD, Bethesda, MD; [3]Circuit Activation & Neuronal Death, Lieber Inst. for brain development, Baltimore, MD

Abstract: NMDA receptor channel blockers like phencyclidine and ketamine, two psychotogenic drugs, enhance extracellular dopamine. Due to its highly positive charge, agmatine is attracted towards the cytoplasm through opened NMDA glutamate receptor. In the

process, agmatine plugs these cationic channels and behaves as a NMDA receptor blocker. We now report that agmatine applied by reverse microdialysis in the striatum increases extracellular dopamine in rats. A 10 mm long guide shaft, made of 21 gauge stainless steel tubing was inserted into the brain and aimed to the striatum (coordinates: 2.6 mm lateral to the midsagittal suture, 1.0 mm anterior to Bregma and 2.0 mm ventral to the surface of the brain). After a minimum of six days of recovery the rats were microdialyzed by inserting a microdialysis probe that protruded 4.0 mm from the tip of guide shaft. The inlet of the probe was connected to a syringe pump filled with artificial cerebrospinal fluid (ACSF). A basal sample was obtained 4 hours after the microdialysis probe was inserted. After 50 minutes we collected a microdialysis sample. Then we intercalated a 10 cm long PE-50 piece of tubing containing a 4.38 micromolar solution of agmatine sulphate in ACSF and after that we collected a second (50µl) microdialysis sample. The probe placement was verified by slices obtained on a Leica vibratome. Sections (40 µm) were taken through the brain areas of cannula placement, mounted onto slides and visualized in a microscope without stain by birefringency. The samples were analyzed by HPLC and EC detection as described elsewhere. Agmatine injection significantly increased DA: 237% and this increase was statistically significant ($p<0.02$). The three main matabolites of Dopamine i.e., Dihydroxiyphenilacetic acid (DOPAC), Homovanillic acid (HVA) and 3-Methoxytiramine (3MT) increased too ($p<0.04$, $p<0.04$ and $p<0.004$ respectively).These results show that agmatine injections enhance dopaminergic activity in the striatum. Evidence that rats injected with a high dose of agmatine developed schizophrenia suggest that agmatine enhances dopaminergic activity. The present experiments show a mechanism for the psychotogenic action of agmatine

Title: Platelet activating factor modulates synaptic vesicle release

Authors: *J. W. HAMMOND[1], S.-M. LU[2], H. A. GELBARD[2];
[2]Ctr. for Neural Develop. and Dis., [1]Univ. of Rochester, Rochester, NY

Abstract: Platelet activating factor (PAF) is an inflammatory lipid messenger that has both physiologic and pathological functions in the brain. Normal synaptic activation leads to the formation of PAF in the postsynaptic neuron which acts as a retrograde messenger to enhance presynaptic glutamate release and thus facilitate long-term potentiation (LTP). Under pathological conditions such as HIV-1 associated dementia, seizures, and ischemia, PAF is produced by activated microglia and infiltrating monocytes. In these cases, PAF can promote neuronal excitotoxicity in a calcium, NMDA-receptor, and caspase dependent manner. The mechanism of how PAF enhances presynaptic glutamate release is poorly understood but is believed to be mediated by small G protein signaling downstream of the PAF receptor (PAFR). We show that the PAFR is indeed localized to presynaptic terminals. Using FM 1-43FX and synaptophyluorin we investigated the role of PAF in promoting spontaneous and evoked glutamate release via altering the probability of release and/or the number of the readily releasable pool of synaptic vesicles.

Abstract: Narcolepsy is a disabling condition characterized by sleep attacks, cataplexy and excessive daytime sleepiness. Despite that the pharmacological treatment of this sleep disorder involves the use of modafinil (MOD), the molecular mechanisms that could be involved in the wake-inducing effects caused by this drug are unknown. In the present experiment, we described

the pharmacological properties of MOD if injected into two wake-related brain areas: Anterior hypothalamus (AH) or pedunculopontine tegmental nucleus (PPTg) on expression of mitogen-activated protein kinase (MAP-K). To achieve this, male Wistar rats were housed at constant temperature and under a controlled light-dark cycle. Food and water were provided ad libitum. Animals were anesthetized and a cannula was stereotaxically placed either into the AH or PPTg. One week after the surgery, the rats received an administration of MOD (10μg/1μL) at the beginning of lights-on period into either AH or PPTg and 1h after microinjections, animals were sacrificed by decapitation. Brain was collected and AH and PPTg were extracted for MAP-K analysis using Western Blot means. Preliminary results showed that MOD, injected in these two wake-related areas, promoted expression of MAP-K, compared to the respective control. Together, these results suggest that the wake-inducing properties of MOD could involve the activity of MAP-K. Further experiments are required to describe the intracellular pathway activated by MOD, which engages MAP-K.

Title: Spontaneous neurotransmitter release and synaptic plasticity

Authors: *E. D. NOSYREVA, L. MONTEGGIA, E. KAVALALI;
UTSW Med. Ctr., Dallas, TX

Abstract: Spontaneous neurotransmitter release is a salient feature of all presynaptic nerve terminals. Recent studies have shown that these action potential independent release events are essential regulators of synaptic homeostasis; in particular, they are involved in the maintenance

of synaptic strength in terms of both presynaptic release rate and postsynaptic sensitivity. Moreover, there is growing evidence that postsynaptic receptors and signaling elements that respond to spontaneous release events diverge from those that respond to evoked release, suggesting a spatial segregation of these two forms of neurotransmission. We have previously shown that application of NMDA receptor antagonists - ketamine(20 μM) and MK801 (10 μM) at rest potentiates synaptic responses in the CA1 regions of rat and mouse hippocampus. This potentiation requires protein synthesis, brain-derived neurotrophic factor expression, eukaryotic elongation factor-2 kinase function, and increased surface expression of AMPA receptors. The same synaptic potentiation could be elicited by depleting neurotransmitter selectively from spontaneously recycling vesicles. In recent experiments, we found that this form of synaptic potentiation does not fully occlude subsequent long-term potentiation elicited by theta burst stimulation (100 Hz theta-burst protocol: 100 Hz, four pulses per burst; 15 bursts at 200 ms intervals). In these experiments, we detected an additional ~20% increase in synaptic efficacy following ketamine mediated potentiation of responses (~30% above baseline). In this setting, theta burst stimulation alone could elicit up to ~50% potentiation above baseline. Taken together, these findings demonstrate that selective presynaptic impairment of spontaneous release, without alterations in evoked neurotransmission, is sufficient to elicit synaptic potentiation, which shows overlap with canonical long term potentiation elicited by repetitive activity.

Title: The adenosine A2A receptor modulates synaptic transmission in layer 2/3 pyramidal cells of visual cortex

Authors: *N. M. BANNON, P. ZHANG, V. ILIN, M. CHISTYAKOVA, M. VOLGUSHEV; Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Adenosine is an endogenous neuromodulator which is wide spread in the central nervous system. Out of four types of adenosine receptors found in the brain (A1, A2A, A2B, and A3), the A1Rs and A2ARs are the most abundant and well-studied. A1Rs and A2ARs have different affinities to adenosine, are coupled to different G-proteins and their activation has opposite effects on synaptic transmission. Activation of A1Rs has a generally suppressive effect

on synaptic transmission that has been demonstrated in nearly every brain area, including the cortex, subcortical areas, and cerebellum. In contrast, activation of A2ARs has a facilitatory effect. A2ARs are most densely expressed within the striatum, but have been also found in the cortex. In synaptosomes from cortical tissue, A2ARs mediated facilitation of glutamate release (Marchi et al. 2002), and an antagonistic interaction between A1Rs and A2ARs has been demonstrated (Lopes et al. 1999). Some in vitro work has corroborated these actions of A2ARs in the hippocampus, but a demonstration of A2ARs effects on neocortical synaptic transmission is lacking. Due to the heterogeneity of A2AR distribution and its varied association with other receptors and intracellular cascades (Ciruela et al. 2011; Orrú et al. 2011), an understanding of the actions of A2ARs within the neocortex cannot be generalized from other structures.
Here we sought to characterize adenosine's effects on synaptic transmission in visual cortex. Using in vitro whole-cell recordings from layer 2/3 pyramidal neurons in slices of rat visual cortex, we measured effects of bath application of adenosine, the A1R antagonist DPCPX, and the A2AR antagonist SCH58261 on excitatory synaptic transmission. High concentrations of adenosine (100 - 150 μM) reduced the EPSP amplitude yet revealed an upper limit of this action. This may be due to saturation of A1Rs, but may also indicate an interaction between inhibitory A1Rs and facilitatory A2ARs. This latter scenario is supported by the following results. Application of the selective A2A antagonist SCH58261 on the background of high concentrations of adenosine revealed a small yet significant further decrease in the EPSP amplitude. Significant reduction of the EPSP after A2AR antagonist application was observed in 6 out of 24 inputs (25%). These results suggest that functional A2ARs are present in the neocortex where they oppose the effects of A1R activation, but are distributed sparsely and present not at every synapse. Thus, A1Rs might mediate an overall suppressive effect of adenosine, while A2ARs located at selected synapses and activated under specific conditions may fine-tune the neocortical transmission.

Title: Effect of adenosine A1 and A2A receptors on inhibitory and excitatory transmission in layer 2/3 of rat visual cortex

Authors: *P. ZHANG[1], N. BANNON[2], V. ILIN[2], M. CHISTYAKOVA[2], M. VOLGUSHEV[2]; [1]Dept. of Physiol. and Neurobio., [2]Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Adenosine is an endogenous neuromodulator which is wide spread in the central nervous system. In the brain, there are four recognized adenosine receptors (A1, A2A, A2B, and A3), the A1 and A2A being the most abundant and well-studied. A1Rs and A2ARs have different affinities, are coupled to different G-proteins and their activation has opposite effects on synaptic transmission. Activation of A1Rs generally suppresses, but activation of A2ARs has facilitatory effect on synaptic transmission. As a result, the net effect of adenosine depends on its concentration, the presence A1Rs and/or A2ARs, and their distribution, which is highly heterogeneous in different brain regions. Evidence from several brain structures demonstrates that adenosine can modulate both excitatory and inhibitory synaptic transmission.
Here we asked: How does adenosine modulate excitatory and inhibitory transmission to layer 2/3 pyramidal neurons in rat visual cortex? Does it change the excitatory/inhibitory balance? Which receptors mediate adenosine effects? To address these questions, we made in vitro whole-cell recordings from layer 2/3 pyramidal neurons in slices of rat visual cortex, and measured effects of bath application of adenosine (5 μM to 100 μM) and antagonists of A1Rs (DPCPX, 50 nM) and A2ARs (SCH58261, 30 nM), on excitatory and inhibitory synaptic responses. We show that adenosine reduced both excitatory and inhibitory synaptic responses in a reversible and concentration dependent manner. However, concentration dependence of the reduction of inhibitory transmission was shifted towards higher concentrations relative to that of excitatory transmission. At concentrations up to 50 μM, excitatory transmission was suppressed stronger than inhibitory, resulting in a net shift of the balance towards inhibition. The adenosine-mediated suppression of either excitatory or inhibitory responses was abolished by 50 nM DPCPX, indicating the involvement of A1R. Application of A2AR antagonist SCH58261 (30 nM) on the background of 100 μM adenosine led to further suppression of excitatory responses in 6 out of 24 (25%) cases. However, when A1Rs were blocked with DPCPX (50 nM), neither 100 μM adenosine nor 30 nM SCH58261 had significant effect on synaptic responses. This indicates that facilitatory effects of A2ARs in the neocortex may be mediated via modulation of A1R affinity to adenosine and thus modulation of A1R-suppression, rather than via an independent pathway. These results suggest the role of adenosine in regulation of excitatory and inhibitory balance, and thus fine tuning of the operation of neuronal circuits of the neocortex.

Title: Picomolar concentrations of pregnenolone sulfate stimulate synaptic NMDAR-mediated CREB phosphorylation via an Erk signaling pathway

Authors: *C. C. SMITH, K. SUGUNAN, V. KUMARESAN, S. J. RUSSEK, T. T. GIBBS, D. H. FARB;
Pharmacol. and Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA

Abstract: Preclinical results support the use of n-methyl d-aspartate receptor (NMDAR) modulators for cognition enhancement therapeutics. In this study we present the first report of a novel high affinity Ca++ and synaptic NMDAR-dependent effect of the neuroactive steroid pregnenolone sulfate (PregS), which we find effective at low picomolar concentrations to activate Erk-dependent phosphorylation of cyclic AMP response element binding protein (CREB). CREB is a transcription factor critical to the protein synthesis-dependent component of long term potentiation and important in associated behavioral measures of learning and memory. At micromolar concentrations, PregS is a subtype selective positive allosteric modulator of NMDARs at NR2A and NR2B containing receptors, and at concentrations ranging from pM - nM PregS induces NMDAR-dependent dopamine release in the striatum (Sadri-Vakili et al. (2008) 327: 840) and from striatal synaptosomes (Whitaker et al. (2008) 107:510). We previously demonstrated that PregS increases NMDAR surface expression in oocytes with higher potency than rapid (msec) positive allosteric modulation of NMDAR transmission. Moreover, PregS stimulated upregulation of surface NR1 subunits in cortical neurons is dependent on NMDARs but independent of channel activity. We report here that PregS increases intracellular Ca++ release in cortical neurons in a voltage-gated Na+ channel and NMDAR-NR2B dependent manner with an EC50 of ~2 pM, at least 6 orders of magnitude higher affinity than its rapid potentiating effect upon the NMDAR mediated ionotropic response, and within the range of PregS detected in bulk brain tissue. Increased intracellular Ca++ is known to induce CREB activation and we show that 50 pM PregS induces a 44 ± 13% increase in the ratio of pCREB to total CREB that is dependent upon ERK signaling and canonical excitatory synaptic transmission: this includes voltage gated Na+ channels, NMDARs, and voltage gated Ca++ channel activation. Steroid activity requires a C-3 negative charge and a saturated B-ring. Additionally, we find that 50 pM PregS increases pCREB by 65 ± 26% in hippocampal brain slices consistent with prediction from cell culture experiments. The results indicate that PregS may be a useful platform for development of novel high-affinity positive modulators of NMDAR-signaling as cognitive enhancers or therapeutics in the treatment of neurological

disorders such as Alzheimer's disease, Parkinson's disease and schizophrenia with symptoms associated with cognitive deficits.

Title: NMDA receptor currents in pyramidal neurons of the orbitofrontal cortex are potentiated through activation of a PLC-coupled dopamine receptor pathway in juvenile but not adult rats

Authors: *J. L. THOMPSON[1], S. L. BORGLAND[2];
[1]Anesthesiology, Pharmacol. and Therapeut., Univ. of British Columbia, Vancouver, BC, Canada; [2]Physiol. & Pharmacol., Univ. of Calgary, Calgary, AB, Canada

Abstract: The orbitofrontal cortex (OFC) is important for decision-making about outcome expectancies of rewarding events. Alterations in excitatory synaptic transmission, including activation of NMDA receptors (NMDARs), may underlie neural processing required for decision making. Dopamine neurons project to the OFC where dopamine acts on D1-like or D2-like G protein-coupled receptors to influence decision-making. It is unknown how dopamine receptor activation modulates NMDAR EPSCs in OFC pyramidal neurons in adult and juvenile rats. We determined the effects of D1 or D2 receptor agonists on NMDAR currents in OFC pyramidal neurons from sagittal brain slices extracted from juvenile or adult male wistar rats. SKF38393, a D1-like receptor agonist, selectively potentiated NMDAR excitatory post synaptic currents (EPSCs) via a postsynaptic mechanism requiring protein kinase A in lateral OFC neurons, but not in ventral or medial OFC of adult or young rats. In contrast, quinpirole, a D2R agonist, inhibited NMDAR currents of all three OFC subregions in young or adult rats. Interestingly, co-activation of D1 and D2Rs synergistically potentiated NMDAR EPSCs significantly more than D1R activation alone in juvenile but not adult rats. This effect was attenuated by chelating intracellular calcium with BAPTA or blocking phospholipase C signaling. The synergistic effect of D1 and D2R co-activation suggested a switch in G-protein coupling through actions at D1:D2

heterodimers. Consistent with this, we found that SKF83959, an agonist which selectively activates D1:D2 dimers by the agonist potentiated currents through NMDARs in juvenile but not adult rats. These data indicate a novel mechanism by which NMDAR currents are differentially potentiated in juvenile rats versus adult rats. Furthermore, these findings provide further insight into to how dopamine modulates synaptic transmission onto OFC neurons of both adult and young rats, and may be underlie cognitive processing such as decision-making about rewards.

Title: Pharmacological characterization of TMS-evoked EEG responses by positive modulators at the GABA-A receptor

Authors: I. PREMOLI[1,2], N. CASTELLANOS[3], R. BAJO[3], D. RIVOLTA[4], *F. MULLER-DAHLHAUS[1,2], C. ZIPSER[2], T. HEIDEGGER[2], U. ZIEMANN[1,2];

Neuroscience, Ctr. for Biomed. Technol., Univ. Politécnica de Madrid, Madrid, Spain; [4]Ernst Strüngmann Inst. (ESI) for Neurosci., Frankfurt/Main, Germany

Abstract: Simultaneous registration of electroencephalography (EEG) during transcranial magnetic stimulation (TMS) enables a direct investigation of TMS-evoked cortical responses in humans at high temporal precision. Focal TMS over the primary motor cortex of one hemisphere evokes a sequence of positive and negative EEG deflections across both hemispheres lasting for about 300ms (TMS-evoked potentials, TEPs). As EEG can detect fast inhibitory postsynaptic potentials, which are linked to GABA-A receptor activity, it has been suggested that early TEPs (<50ms) are mediated, at least in part, by GABA-A receptor activity. However, the exact physiological mechanisms underlying TEPs have not been studied yet.
In this study we combined TMS-EEG with pharmacological modulation of GABA-A receptor activity to characterize the neurotransmitter systems involved in the generation of TEPs. In healthy volunteers, we conducted a pseudo-randomized, placebo-controlled, double-blind crossover study using a single oral dose of alprazolam (ALP), a classical benzodiazepine preferentially binding to alpha1, alpha2, alpha3 and alpha5 subunits of the GABA-A receptor,

and zolpidem (ZOL), which mainly binds to the alpha1-subunit. TEPs were recorded before and 90 minutes after drug administration. Drug effects on TEP amplitudes and functional cortico-cortical connectivity patterns at the sensor level using mutual information analysis were investigated. Results showed that both ALP and ZOL increased the amplitude of the negative potential at around 45 ms after stimulation (N45) to the same extent. In contrast, ALP, but not ZOL, decreased the amplitude of the negative potential at around 100 ms (N100). In addition, ALP reduced intrahemispheric connectivity contralateral to the stimulation site during early time windows after stimulation (< 50 ms), as well as long-range interhemispheric connectivity at later time windows (> 100 ms). ZOL, in contrast, decreased the connectivity between contralateral channels in the late time window only. Our results provide evidence that the N45 potential reflects activity of alpha1-subunit containing GABA-A receptors. In contrast, the breakdown of interhemispheric functional connectivity after ALP, but not ZOL, may be due to activity of non-alpha1-subunit containing GABA-A receptors.

Title: Effects of mood stabilizers on synaptic protein levels and dendritic outgrowth in hippocampal neuronal cultures

Authors: M. SEO[1], C. LEE[1], H. CHO[1], J. LEE[1,2], B. LEE[2], W. SEOL[3], Y. KIM[1,2], *S. PARK[1]; [1]Paik Inst. for Clin. Res., [2]Dept. of Psychiatry, Sch. of Medicine, Haeundae Paik Hosp., Inje Univ., Busan, Korea, Republic of; [3]Wonkwang Univ., Gunpo, Korea, Republic of

Abstract: Purpose: Bipolar disorder is a devastating illness that is characterized by cycling periods of mania and depression. Conversing lines of evidences indicate that mood disorders, including bipolar disorder, affect abnormalities in signaling cascade mechanisms that lead to impairments in structural and functional synaptic plasticity as well as alterations in glutamatergic neurotransmission. In this study, we investigated whether mood stabilizers (lithium, valproic acid, carbamazepine, and lamotrigine) altered the expression of synaptic proteins and dendritic outgrowth in rat hippocampal neurons.

Methods: The expression of synaptic proteins, postsynaptic density protein-95 (PSD-95), brain-derived neurotrophic factor (BDNF), neurolignin 1 (NLG1), β-neurexin, and synaptophysin (SYP) in rat hippocampal neuronal cultures under toxic conditions induced by B27 deprivation was evaluated by Western blot. Additionally, dendritic outgrowth was examined to determine whether these drugs affect the dendritic morphology of hippocampal neurons.
Results: Lithium, valproic acid, and carbamazepine, significantly prevented B27 deprivation-induced decrease in levels of PSD-95, BDNF, NLG1, β-neurexin and SYP ($p < 0.05$ or $p < 0.01$), whereas lamotrigine had no effect in this regard. All the drugs significantly increased the total outgrowth of hippocampal dendrites ($p < 0.01$). Moreover, this effect of lithium and valproic acid is blocked by specific inhibitors of calcium/ calmodulin kinase II (CaMKII), KN-93 (1 μM), protein kinase A (PKA), H-89 (1 μM), phosphatidylinositol 3-kinase (PI3K), LY294002 (10 μM), or MAPK/ERK kinase (MEK), PD98059 (1 μM) signaling ($p < 0.05$ or $p < 0.01$), whereas other mood stabilizers do not affect these signaling.
Conclusions: Taken together, these results suggest that certain mood stabilizers may regulate synaptic plasticity by enhancing synaptic protein levels and dendritic outgrowth in hippocampal neurons. In addition, these effects on dendritic outgrowth likely require CaMKII, PKA, PI3K or MEK signaling pathways.
Key words: Mood stabilizers; Hippocampal plasticity; Synaptic proteins; Dendritic outgrowth; Signaling

Title: Fluoxetine impairs GABAergic signaling in hippocampal slices from neonatal rats

Authors: *M. D. CAIATI[1], E. CHERUBINI[2];
[1]Mol. and Cell. Biol., Harvard Univ., Cambridge, MA; [2]SISSA, Trieste, Italy

Abstract: Fluoxetine (Prozac), an antidepressant known to selectively inhibit serotonin reuptake, is widely used to treat depression during pregnancy and postpartum period. Several lines of evidence suggest that this drug exerts its action not only by interfering with serotoninergic but also with GABAergic transmission which, early in postnatal life, plays a crucial role in the

construction of neuronal circuits.
Here we tested the hypothesis that fluoxetine may interfere with GABAergic signaling at early developmental stages, thus producing harmful effects on brain development.
Correlated network activity such as GDPs, a hallmark of developmental circuits, were recorded in whole cell configuration of the patch clamp technique in acute hippocampal slices from P2-P6 old rats. Bath application of fluoxetine (20 μM) reversibly reduced GDPs frequency (from 0.08 ± 0.04 Hz to 0.045 ± 0.031 Hz; n=5; p = 0.021). This effect was concentration dependent (IC_{50} value: 22 μM) and independent of serotonin action since it persisted in the presence of citalopram, a selective serotonin uptake inhibitor and after pharmacological occlusion of monoamine receptors with asenapine.
We next examined whether fluoxetine-induced changes in spontaneous action potential dependent and independent GABA and glutamate release. The drug reduced the frequency (from 4.7 ± 0.9 Hz to 3.3 ± 0.76 Hz; n = 8; p = 0.007) and the amplitude (57 ± 7 pA to 47 ± 8 pA; n = 8; p = 0.004) of spontaneous $GABA_A$-mediated postsynaptic currents without altering spontaneous AMPA-mediated excitatory postsynaptic currents, indicating that the reduction in GDPs frequency probably involves GABAergic but not glutamatergic signaling.
To evaluate whether fluoxetine selectively affects a particular interneuron population we used WIN55,212-2, a CB1/CB2 receptor agonist, to occlude cannabinoid receptors present on axon terminals of cholecystokinin-positive (CCK) regular spiking cells. In the presence of WIN55,212-2 (1μM), fluoxetine was still effective, indicating that CCK-positive GABAergic interneurons were not involved.
In addition, fluoxetine reduced the firing rate of both principal cells (from 1.57 ± 0.74 Hz to 0.56 ± 0.37 Hz; n = 5; $p < 0.05$) and interneurons (from 2.7 ± 1.7Hz to 0.33 ± 0.22 Hz; n = 5;$p < 0.05$) further suggesting that changes in network excitability account for fluoxetine-induced GDPs disruption. This may have critical consequences on the functional organization and stabilization of neuronal circuits early in postnatal development.

Title: Role of kainate receptors in the pathophysiology of temporal lobe epilepsy

Authors: *V. CREPEL[1], A. PERET[1], L. CHRISTIE[1], D. OUEDRAOGO[1], J. EPSZTEIN[1], A. GORLEWICZ[2], C. MULLE[2];
[1]INMED, INSERM, U901, Marseille Cedex09, France; [2]Interdisciplinary Inst. for Neuroscience, CNRS UMR 5297, Bordeaux, France

Abstract: Kainate (KA), an analogue of glutamate, is a potent neurotoxin known to induce seizures reminiscent of those found in patients with temporal lobe epilepsy (TLE) (Ben-Ari & Represa, 1990). Whether KA receptors (KARs)are key elements in the triggering and propagation of seizure discharges is yet unclear. In both human patients and animal models of TLE, neuronal tissue undergoes major reorganization; some neurons die while others sprout and form novel aberrant connections (Represa, et al. 1989; Nadler, 2003; Blaabjerg & Zimmer, 2007; Dudek & Sutula, 2007; Ben-Ari et al., 2008). This phenomenon is best documented in the dentate gyrus where mossy fiber (MF) axons sprout to form aberrant glutamatergic excitatory synapses onto other dentate granule cells (DGCs) leading to the formation of functional recurrent excitatory circuits (Tauck & Nadler, 1985; Wuarin & Dudek, 1996; Molnar & Nadler, 1999; Lynch & Sutula, 2000; Buckmaster et al., 2002; Scharfman et al., 2003). This accounts for, in part, the enhanced ability of the hippocampus to generate epileptiform activity (Patrylo & Dudek, 1998; Hardison et al., 2000; Gabriel et al., 2004). MF sprouting also induces a reorganization of KAR-mediated synaptic transmission, with a shift in the nature of glutamatergic transmission in DGCs. 50% of recurrent MF inputs that impinge on DGCs operate via KARs and drive synaptic events with abnormal long lasting kinetics not present in naïve conditions (Epsztein et al., 2005, Epsztein et al., 2010). As a result, the sparse firing of DGCs is switched to an abnormal sustained and rhythmic mode (Artininan et al. 2011). The present study explores the pathophysiological implications of KARs in animal models during the chronic phase of TLE through the use of KAR-subunit deficient mice and selected pharmacological agents.

Sch. of Med., Stanford, CA; [5]Dept. of Mol. and Cell. Physiology, Stanford Univ., Stanford, CA

Abstract: Stroke is a major cause of severe disability, yet pharmacological therapy to promote post-stroke recovery is deficient. Understanding the stroke induced molecular and cellular alterations in the peri-infarct area, the region adjacent to the damaged stroke site, is critical to developing new therapeutics to enhance stroke recovery. Reducing excessive tonic neuronal inhibition, mediated by extrasynaptic $GABA_A$ receptors, promotes functional recovery after stroke. However, the role of the phasic (synaptic) GABA inhibition in recovery remains unknown. We previously reported a transient structural and functional increase in phasic inhibition of layer 5 pyramidal neurons in the peri-infarct area. We found, using array tomography, an increase in the number of GABAergic synapses containing the α1 receptor subunit in layer 5 of the peri-infarct cortex, but not layer 2/3, and an associated increase in spontaneous inhibitory post-synaptic currents specific to layer 5 pyramidal neurons. This effect was transient, occurring during the onset of functional recovery. To test whether the increased phasic inhibitory GABAergic signaling promotes stroke recovery, we treated animals with zolpidem, an agonist with high affinity for α1 subunit-containing $GABA_A$ receptors. We find that low dose zolpidem increases $GABA_A$ phasic signaling in layer 5 pyramidal cells and notably increases the rate and extent of behavioral recovery without altering the infarct size. These data provide the first evidence that enhanced phasic $GABA_A$-mediated synaptic activity improves recovery after stroke. Our results introduce modulation of phasic $GABA_A$-mediated synaptic inhibition as a novel therapeutic strategy, identify zolpidem as a potential pharmacological agent to improve stroke recovery, and underscore the necessity to distinguish the role of tonic inhibition (extrasynaptic) and phasic inhibition (synaptic) in stroke recovery. We propose that phasic GABA signaling is as critical for adaptive plasticity after stroke as during development.

Title: JZ-V improved learning and memory impairment and accelerated perforant path-dentate gyrus LTP in intact animals

Authors: *X. WANG, X. CHEN, X. LIU, Y. XIE, T. QIAN;
Pharmacol. department, Inst. of Medicinal Plant Development, Chinese Acad. of Med. Sci., Beijing, China

Abstract:
Aim: The purposes of this study were to investigate the effect of JZ-V, a novel peptide neurotoxin isolated from the venom of spider Chilobrachys jingzhao and composed of 29 residues including six cysteines and three exposed tryptophan residues on learning and memory and LTP. **Methods:** Learning and memory impairment was induced by beta-amyloid1-42 and Scopolamine, and the behavior was evaluated by Morris water maze and Step-through experiments to investigate the effect of JZ-V on spatial leaning and memory and passive avoidance learning and memory. In Morris water maze test, the latency, swimming distance, the searching strategy were recorded and the error numbers and the latency were recorded in Step through test. In addition, extracellular technique was used to determine the effect of JZ-V on LTP induction in medial perforant path dentate granule cell synapses, single- pulse stimulation was delivered to perforant path fibers in vivo. In slice recording system, the Schaffer-CA1 pathway LTP was recorded in 400 microm-thick transverse hippocampal slices. **Results:** JZ-V significantly enhanced LTP induction, the population spike was increased from180±11 % to about 332± 28 % of control in perforant path-dentate gyrus pathway 20 minutes after, high frequency stimulation. However, the results from slice recording was quite difference with that of anesthetized rats, the slope of EPSP was increased from about 141± 12 % to 159±14 % of control 10 minues after high frequency stimulation. From behavior results, JZ-V significantly reduced escape latency and swimming distance in place navigation test, and it significantly prolonged passive avoidance latency and decreased the error numbers during 5 minutes in step-through test. **Conclusions:** JZ-V significantly improved impaired learning and memory induced by beta-amyloid and Scopolamine, which showed some potential to be a promising new trial

drug for Alzheimer's disease. The present study gave the strong evidence that learning and memory behavior is associated with LTP, and this is the first report about JZ-V on learning and memory and LTP.

Title: Identification of synergistic drug combinations using modeling and simulation of Long-Term Potentiation

Authors: A. F. KELLER[1], N. AMBERT[1], A. LEGENDRE[1], R. GREGET[1], M. SARMIS[1], M. BEDEZ[1], F. LALOUE[1], J. KOENIG[2], J.-M. C. BOUTEILLER[1,3], *S. BISCHOFF[4], T. W. BERGER[1,3], M. BAUDRY[1,5];

Abstract: Cognitive deficit is a common feature of many neurodegenerative diseases, such as Alzheimer's disease. While several drugs are currently available, their effects on cognition are relatively minimal and there is a need to identify better treatment. Long-term potentiation (LTP) of synaptic transmission has been widely used as a cellular model of learning and memory, and has been typically elicited by either a 1 second-long high frequency stimulation (HFS) at 100 Hz, or a succession of 4-6 stimuli at 100 Hz, called bursts, spaced by 200 ms (theta burst stimulation, TBS). We first used a simulation approach modeling CA1 pyramidal cells and the CA3 afferents with 30 synapses distributed on a branch of a CA1 pyramidal neuron. NMDA, AMPA, and the metabotropic type 1 glutamate receptors were included at each synapse. The LTP model was based on Shouval (2005) and links changes in intracellular calcium to the number of AMPA receptors. In vitro experiments were performed with acute rat hippocampal slices, and field potentials elicited by stimulation of the Schaffer collaterals were recorded in CA1 stratum radiatum. In vivo, a fear-conditioning paradigm was used to assess effects of drug combinations on learning and memory of adult rats. A glutamatergic drug and three cholinergic modulators were tested separately and in combination to evaluate possible synergistic effects on in silico LTP, experimental LTP and behavior. One combination was predicted to be synergistic with the simulation using the TBS paradigm but not HFS, which was due to the saturation of potentiation with HFS at each synapse. The synergic effects of this combination was verified both experimentally in vitro with TBS of hippocampal slices, and in vivo with the fear-conditioning behavior. Thus, these results demonstrated that drugs have different effects depending on the experimental protocol used, identified a specific combination with synergistic effects on LTP and on learning and memory. They also indicate that synergistic drug combinations can be discovered using first computer modeling and simulation. As drug combinations are likely to become the future for treating complex diseases such as neurodegenerative ones, the results open new avenues for improved treatments.

Title: Regular exercise prevented hippocampal L-LTP impairment and aberrant alterations in levels of L-LTP related signaling molecules in Alzheimer's disease-like pathology

Authors: *A. DAO[1], M. ZAGAAR[2], S. SALIM[1], K. ALKADHI[1];
[1]Pharmacol. and Pharmaceut. Sci., Univ. of Houston, Houston, TX; [2]Pharmacol. and Pharmaceut. Sci., Texas Southern Univ., Houston, TX

Abstract: Alzheimer's disease (AD) is an insidious gradual deterioration of intellectual and emotional wellbeing. The disease is hallmarked by extracellular accumulation of high levels of neurotoxic amyloid-beta (Aβ) peptides, followed later by intracellular aggregation of hyperphosphorylated tau protein, leading to neuronal death and progressive loss of mental abilities. Current AD medications delay the disease symptoms for only 6 months and are effective only in half of the patients; thus, there is an urgent need for innovative therapies. Regular exercise has been shown to be beneficial for brain health. We have reported that 4 weeks of treadmill exercise prevented short-term memory impairment and suppression of early phase long-term potentiation (E-LTP) in CA1 area in a rat model of AD (Aβ1-42 peptides, 250 pmol/day, i.c.v. infusion for 2 weeks). In continuation of our previous study, we investigated whether this exercise regimen was able to prevent late phase LTP (L-LTP) inhibition in both CA1 and DG areas and the molecular pathways that could be involved in the beneficial effect of exercise in our AD model. We found that AD pathology blocked L-LTP in both CA1 and DG areas of the hippocampal formation and that this effect was prevented by 4 weeks of treadmill exercise. Additionally, treadmill exercise also prevented AD-induced reduction in the levels of signaling molecules such as phosphorylated cAMP response element-binding protein (CREB), calcium-calmodulin dependent protein kinase IV (CaMKIV) and brain derived neurotropic factor (BDNF). Together, these findings suggest a neuroprotective action of exercise against AD pathologies and possibly other neurodegenerative diseases.

Title: Analysis of atypical PKCs in hippocampal synaptic plasticity and memory

Authors: *L. J. VOLK[1], J. L. BACHMAN[1], R. C. JOHNSON[1], Y. YU[1], X. YUE[1], M. LEITGES[2], R. L. HUGANIR[1];

Abstract: Long-term potentiation (LTP), a well-characterized form of synaptic plasticity, has long been postulated as a cellular correlate of learning and memory. While LTP can persist for very long periods of time, the mechanisms underlying LTP maintenance, in the midst of on-going protein turnover and synaptic activity, remain elusive. Sustained activation of the brain-specific atypical protein kinase C isoform, protein kinase M zeta (PKMζ), has been reported to be necessary for both LTP maintenance and long-term memory. Inhibiting PKMζ activity using a synthetic peptide (ZIP) based on the PKCζ pseudosubstrate sequence reverses established LTP *in vitro* and *in vivo*. More strikingly, infusion of ZIP eliminates memories for an ever-growing list of experience-dependent behaviors. However, the specificity of ZIP remains controversial, and most of the evidence supporting a role for PKMζ in LTP and memory relies heavily on pharmacological inhibition of PKMζ by ZIP. In recently published data we found that both conventional and conditional PKC/Mζ knockout (KO) mice show normal synaptic transmission and LTP at Schaffer collateral-CA1 synapses. Additionally, mice lacking PKMζ showed no deficits in several hippocampal-dependent learning and memory tasks indicating that normal synaptic plasticity, learning, and memory can occur in the absence of PKMζ. Surprisingly, ZIP still reversed LTP in PKC/Mζ KO mice indicating that ZIP's effects, while remarkable, are independent of PKMζ.
We are currently conducting experiments to identify the functional target(s) of ZIP and to determine if PKCλ/ι, the other atypical PKC, can support LTP in the absence of PKMζ. *In vitro* kinase assays suggest that ZIP is a general PKC inhibitor, exhibiting no appreciable specificity across multiple isoforms. Using an alternative method to generate conditional PKC/Mζ knockout in adult mice (AAV-mediated Cre expression in the hippocampus), we have confirmed our previous results that, in the absence of potential developmental compensation, hippocampal neurons lacking PKMζ are capable of exhibiting normal long lasting LTP. Additionally, our preliminary findings suggest that LTP is also unaffected by conditional knockout of PKCλ. Future studies in double PKCζ/PKCλ knockout mice will determine if the presence of at least one atypical PKC is necessary for normal hippocampal LTP and memory.

Title: Dynamic activity-dependent dephosphorylation of CRTC1 regulates synapse to nuclear transport

Authors: *M. DESALVO, T. H. CH'NG, A. VASHISHT, J. WOHLSCHLEGEL, K. C. MARTIN;
UCLA Biol. Chem., UCLA, Los Angeles, CA

Abstract: CREB Regulated Transcriptional Co-activator 1 (CRTC1) undergoes activity-dependent synapse to nucleus translocation and has been shown to play a role in neuronal plasticity and memory. In non-neuronal cells, CRTC1 is sequestered in the cytoplasm by interacting with 14-3-3 proteins. Increased levels of calcium and cAMP lead to CRTC1 dephosphorylation, which releases it from 14-3-3 and allows it to enter the nucleus. In the nucleus, CRTC1 binds CREB (and other bZIP transcription factors) and recruits transcriptional machinery to robustly potentiate CRE-dependent transcription, which is crucial for induction of the late phase of long-term potentiation (L- LTP). Our lab has shown that CRTC1, at rest, interacts with 14-3-3 ε and localizes to the synapses in rodent hippocampal neurons. Glutamatergic stimulation causes dynein-dependent retrograde transport along microtubules and nuclear import of CRTC1.
We have shown that CRCT1 is heavily phosphorylated and that its phosphorylation state changes upon stimulation. Our current efforts are focused on identifying the phosphorylation sites that are important for synapse to nuclear transport of CRTC1. We hypothesize that different types of stimulation lead to distinct phosphorylation states, which in turn regulate the nucleocytoplasmic trafficking of CRTC1 as well as its transcriptional activity in the nucleus. We are in the process of identifying and characterizing phosphorylation sites that could be important for these processes in neurons. Using affinity purification and mass spectrometry, we have also identified several kinases and phosphatases that interact with CRTC1 and that may play a role in its nuclear accumulation. Understanding the role of phosphorylation in the nuclear transport of CRTC1 will give us a deeper understanding of its role in activity-dependent plasticity in neurons.

Abstract: The size of the synapse is dynamically regulated during synaptic plasticity, therefore, it is conceived that the mechanism regulating the size of synapse is tightly linked to the mechanism of plasticity. Here we demonstrate that Ca^{2+}/calmodulin-dependent protein kinase (CaMKII), a pivotal kinase in synaptic plasticity, mediates activity-dependent structural modification of excitatory synapses through a novel activity-regulated F-actin stabilizing function, apart from well-known kinase signaling. When CaMKII is inactive state, it bundles F-

actin but when it is activated by Ca^{2+}/calmodulin, it undergoes autophosphorylation reaction on newly identified sites within the actin-binding domain and unbundles F-actin. This mechanism opens a temporary time window of ~1 min where F-actin is remodeled by actin modulating proteins such as cofilin, Arp2/3, and gelsolin, leading to the structural modification of dendritic spines. These observations make CaMKII a unique F-actin regulatory molecule with a permissive role in gaiting activity-dependent modification of synaptic structure.

Title: Persistent activation of protein kinase A is involved in serotonin-induced long-lasting potentiation of TA-CA1 excitatory synaptic transmission in rodent model of depression

Authors: *X. QI[1,2], Z. YUAN[1], P. R. PATRYLO[1,2,3], G. M. ROSE[2,3], S. M. THOMPSON[4], X. CAI[1];

Sch. of Med., Carbondale, IL; [4]Dept. of Physiol., Sch. of Medicine, Univ. of Maryland at Baltimore, Baltimore, MD

Abstract: Depression is a leading cause of suicide and one of the top ten causes of mortality and morbidity worldwide. The biological basis of cognitive dysfunction in major depression remains unknown. Emerging evidence indicates that malfunction of excitatory synapses is involved in the pathophysiology of depression. Our previous work showed that activation 5-HT_{1B} receptors by endogenous serotonin selectively potentiated excitatory synapses formed by the temporoammonic (TA) pathway with CA1 pyramidal cells via activation of 5-HT_{1B}Rs without affecting nearby Schaffer collateral synapses. Serotonin induced a long-lasting potentiation of TA-CA1 EPSPs in animals subjected to chronic unpredictable stress (CUS), an animal model of

depression. In the current study, we compared the phosphorylation of Ser831 and Ser845 on AMPA receptor GluR1 subunit upon application of 5-HT_{1B}Rs agonist, anpirtoline, between control and CUS animals. We observed that anpirtoline increased Ser831 phosphorylation in both control and CUS animals. However, anpirtoline only enhanced phosphorylation of S845 in CUS animals; this phosphorylation remained elevated even after washout of anpirtoline. Moreover, slices from control animals pretreated with Sp-cAMPs, an activator of protein kinase A, prolonged anpirtoline-induced TA-CA1 EPSPs, which mimicked anpirtoline-induced the long-lasting potentiation in CUS animals . Our results suggest that pathological activation of PKA participates in serotonin-induced long-lasting potentiation of TA-CA1 EPSPs in brain slices from CUS animals.

Title: Abnormal hippocampal synaptic plasticity in c-Jun N-terminal phosphorylation mutants mice

Authors: *S.-Y. CHOI, J. SEO, J. HONG, S. LEE;
Sch. of Dent., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: c-Jun N-terminal kinase (JNK), a member of the MAPK family, is an important regulatory factor of synaptic plasticity as well as neuronal differentiation and cell death. Recently, JNK has been reported to modulate synaptic plasticity by the direct phosphorylation of synaptic proteins. The specific role of c-Jun phosphorylation in JNK mediated synaptic plasticity, however, remains unclear. In this study, we investigated the effects of c-Jun phosphorylation on synaptic structure and function by using c-Jun mutant mice, c-JunAA, in which the active phosphorylation sites at serines 63 and 73 were replaced by alanines. The gross hippocampal anatomy and number of spines on hippocampal pyramidal neurons were normal in c-JunAA mice. Basal synaptic transmission, input-output ratios, and paired-pulse facilitation

(PPF) were also no different in c-JunAA compared with wild-type mice. Notably, however, the induction of long-term potentiation (LTP) at hippocampal CA3-CA1 synapses in c-JunAA mice was impaired, whereas induction of long-term depression (LTD) was normal. These data suggest that phosphorylation of the c-Jun N-terminus is required for LTP formation in the hippocampus, and may help to better characterize JNK-mediated modulation of synaptic plasticity.

Title: CaMKIINα and GluN2B exhibit similar modes of regulation of CaMKII function

Authors: *R. V. OMKUMAR[1], S. JOHN[2], M. MADHAVAN[2];
[1]Mol. Neurobio. Div., Mol. Neurobio. Div., Thiruvananthapuram, India; [2]Mol. Neurobio. Div., Rajiv Gandhi Ctr. for Biotech., Thiruvananthapuram, India

Abstract: Calcium/calmodulin dependent protein kinase II (CaMKII) is a Ser/Thr protein kinase with a unique multimeric structure. It supports many higher order brain functions such as learning and memory. There are multiple mechanisms for the intracellular regulation of CaMKII activity. CaMKIINα has been identified as a natural protein inhibitor of CaMKII and resembles the NMDA receptor 2B subunit (GluN2B) in its mode of interaction with CaMKII (Vest et al, 2007, Mol Biol Cell; Vol.18; p5024). This prompted us to investigate whether CaMKIINα regulates the function of CaMKII in a manner similar to GluN2B. We have used purified preparations of the proteins and *in vitro* assays for phosphorylation and dephosphorylation activities. We find that dephosphorylation of phospho-Thr^{286}-α-CaMKII by protein phosphatase 1 (PP1) is attenuated by CaMKIINα similar to the regulatory effect reported for GluN2B (Cheriyan *et al*, 2011, PLoS One; Vol. 6: e16495). This suggests that the structural changes on CaMKII brought about by the interaction of CaMKIINα and GluN2B are likely to be similar. We are currently investigating

whether there are similarities in the modulation of catalytic activity of CaMKII brought about by CaMKIINα and GluN2B.

Title: Mechanisms of compartmentalization of the activated cAMP dependent protein kinase

Authors: *S. E. TILLO, H. ZHONG;
Vollum Inst., Portland, OR

Abstract: Throughout the brain, the cAMP dependent protein kinase (PKA) plays critical roles in neurotransmission, cell excitability, and synaptic plasticity. All of these processes require high specificity in PKA phosphorylation profiles. Previous studies have shown that PKA specificity is established by a class of proteins called A-kinase anchoring proteins (AKAPs), which target upstream activators and downstream substrates of PKA to specific subcellular locations. However, AKAPs only bind the regulatory subunit of PKA. Once activated by cAMP, the catalytic subunit of PKA is released from the regulatory subunit and is free to diffuse. A cytosolic protein of comparable size to the PKA catalytic subunit will equilibrate synaptic compartments, such as dendrites and their spines, in tens of milliseconds and exit these compartments within hundreds of milliseconds. As these time scales are significantly shorter than the known time scales of PKA signaling, such diffusion would be expected to break down the PKA specificity established by AKAPs. How does PKA signaling maintain its specificity despite the freely diffusing catalytic subunit? Our results suggest that in addition to the subcellular targeting provided by AKAPs, that constrained diffusion of the PKA catalytic subunit is necessary for proper and efficient phosphorylation of downstream targets.

Title: Dual and opposite functions for calpain in long-term potentiation induction and consolidation

Authors: *G. ZHU[1], Y. WANG[1], V. BRIZ[1], Y.-T. HSU[2], X. BI[3], M. BAUDRY[1];
[1]Grad. Col. of Biomed. Sciences, Western Univ. of Hlth. Sci., Pomona, CA; [2]Stanford Inst. of NeuroInnovation and Translational Neurosci., Stanford, CA; [3]Col. of Osteo. Med. of the Pacific, Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Long-term potentiation (LTP) is widely recognized as a cellular model of learning and memory. While much has been learned regarding the role of various cellular mechanisms in LTP, the role of the calcium-dependent protease, calpain, has remained controversial. Here we report that calpain performs two distinct and opposite functions in LTP induction and consolidation elicited by theta burst stimulation (TBS): on the one hand, calpain activation is necessary for LTP induction, as calpain inhibition before TBS prevents LTP; on the other hand, calpain activation limits the magnitude of LTP during the consolidation period, as calpain inhibition up to 1 hour after TBS enhances LTP. Moreover, these dual functions of calpain are directly related to its sequentially opposite effects on ERK activation. Calpain rapidly activates ERK by degrading suprachiasmatic nucleus [SCN] circadian oscillatory protein (SCOP), a negative ERK regulator, during LTP induction, and restricts ERK activation by stimulating the mTOR-dependent synthesis of SCOP during LTP consolidation. Blocking local protein synthesis with rapamycin shortly after TBS also results in LTP enhancement. These results provide a new framework to understand the spatio-temporal events underlying synaptic plasticity and learning and memory, and could provide a molecular mechanism for the beneficial effects of space vs massed trial learning.

Title: The role of calpain-mediated cleavage of GluN2B in dendritic spine signaling and remodeling

Authors: *F. EL GAAMOUCH, K. DORE, S. LABRECQUE, M. LEMIEUX, B. TOURNIER, P. DE KONINCK;
Neurobiologie Cellulaire, CRIUSMQ, Quebec, QC, Canada

Abstract: Synaptic plasticity in the hippocampus is a prominent cellular mechanism of learning and memory. During elevated activity at excitatory synapses, the Ca2+ influx through NMDA-type glutamate receptors (NMDAR) activates a multitude of signaling processes in spines, leading to long-term potentiation (LTP) of synaptic transmission. The cytoplasmic tail of GluN2 subunits of NMDARs acts as a central hub for several critical interactions in synaptic plasticity. Previous work suggests that CaMKII interaction with GluN2B plays a central role in LTP. This interaction was shown to support the specific activation of the ERK/MAPK pathway, which is critical in long-term memory. Meanwhile, LTP induction leads to the transient exit of PSD95 from the spine. Finally, NMDAR activation was shown to activate calpain, leading to the cleavage of several substrates including the cytoplasmic tails of GluN2 subunits.
The molecular dissection of these dynamic interactions in the context of spine remodeling is challenged by the limited resolution of optical microscopy. In this study, we combined Fluorescence Lifetime Imaging (FLIM) and Forster Resonance Energy Transfer (FRET) with biochemical techniques to investigate the implication of calpain in synaptic signaling and remodeling in cultured hippocampal and cortical neurons.
We first examined the interaction between PSD95 and the NMDAR subunits with FRET-FLIM using GFP and mCherry as donor/acceptor tags. Our results indicate that PSD95 interacts with the NMDAR in spines, but that synaptic activation of NMDARs, produced by a cLTP protocol, leads to the dissociation of this interaction. Blocking calpain activation prevented this dissociation, suggesting that NMDAR activity triggers a cleavage process in spines. Biochemical analyses from synaptic fractions of cortical neurons indicated that synaptic NMDAR activation leads to the cleavage GluN2B, but not to PSD95.
To examine the role of calpain-mediated cleavage of GluN2B on synaptic signaling and remodeling, we measured the impact on ERK phosphorylation and spine remodeling. Our results indicate that blocking calpain activity or removing putative calpain cleavage sites on GluN2B both prevented activity-dependent phosphorylation of ERK, spine volume increase. Our experiments thus suggest that synaptic activation of NMDARs leads to the cleavage of GluN2B by calpain which supports synaptic plasticity.

Title: Membrane-to-cytosol translocation of activated AKT kinase disrupts expression of Long-Term Potentiation

Authors: *I. MICHAELEVSKI, Y. PEN, A. SHEININ, N. BOROVOK;
Tel Aviv Univ., Tel Aviv, Israel

Abstract: Background: Serine/threonine kinase AKT/PKB plays a fundamental role in a wide variety of cellular functions, including protein synthesis, regulation of cell survival, metabolism and proliferation. In neuronal cells, AKT has been shown to be involved in neuronal cell development, axonal growth and synaptic plasticity. Recently, a further downstream mechanism of AKT involvement in long-term depression (LTD) prevention and late phase long-term potentiation (LTP) has been revealed. Moreover, AKT is also known to be involved in early phase LTP; however no solid knowledge has been accumulated regarding the downstream effectors mediating AKT's effects on LTP. Here, we present our preliminary findings describing a mechanism of AKT's effect on LTP. Results: Using different regimes for application of the AKT inhibitor A6730 (30 min drug exposure before high frequency stimulation (HFS), drug for 30 min before and 20 min after HFS, drug for 20 min 30 min after HFS), to acute hippocampal slices trained with the HFS paradigm, we observed that AKT regulates LTP induction and expression without affecting its maintenance. Further, we delivered an AKT activator to combine with inhibitors of various signaling pathways to prevent AKT activation-induced effect on LTP and to characterize a potential downstream mechanism of LTP regulation. Unexpectedly, SC79 (activator of AKT), which also prevents AKT translocation to the plasma membrane, induced a significant decrease in basal synaptic activity and in expression of LTP. Conclusions: We consider that translocation of AKT towards the plasma membrane is necessary for regulation of synaptic activity and LTP. Moreover, AKT related LTP expression is not dependent on downstream cytosolic factors, but is mediated via direct effects of AKT on post-synaptic density components and glutamate receptors.

Title: Oxytocin promotes long-term potentiation by enhancing epidermal growth factor receptor-mediated local translation of protein kinase Mζ

Authors: Y.-T. LIN[1], *Y.-C. LIU[2], C.-C. HUANG[1], K.-S. HSU[1];
[1]Natl. Cheng Kung Univ., Tainan, Taiwan; [2]Natl. Cheng Kung Univ. Hosp., Tainan City, Taiwan

Abstract: In addition to triggering the birthing process and milk release, the hypothalamic neuropeptide oxytocin (OXT) plays an important role in the regulation of complex social cognition and behavior. Previous work has shown that OXT can regulate hippocampal synaptic plasticity and improve hippocampus-dependent cognitive functions in the female mice, but the underlying mechanisms remain largely unclear. Here, we demonstrate that OXT promotes the maintenance of long-term potentiation (LTP) induced by one train of tetanic stimulation (TS) in the CA1 region of hippocampal slices from both nulliparous female and male rats through a previously unknown mechanism involving OXT receptor (OXTR)-dependent and epidermal growth factor receptor (EGFR)-mediated local translation of an atypical protein kinase C isoform, protein kinase Mζ (PKMζ), in dendrites. Using pharmacological and biochemical approaches, we show that both the conventional OXTR-associated signaling pathway (Gq/11-coupled phospholipase C) and the transactivated EGFR downstream signaling pathways (phosphatidylinositol 3 kinase and extracellular signal-regulated kinase 1/2) are involved in the regulation of OXT. In addition, OXT stimulates local dendritic PKMζ mRNA translation via activation of a mammalian target of rapamycin-regulated mechanism. Furthermore, blockade of OXTR results in a modest decrease in the ability to maintain late-phase LTP induced by three trains of TS. These results reveal a novel OXTR-to-EGFR communication to regulate the new synthesis of PKMζ, which functions to promote the maintenance of LTP at hippocampal CA1 synapses.

Title: Regulation of striatal CaMKII by extracellular calcium influx

Authors: *J. C. GANDY, R. COLBRAN;
Mol. Physiol. and Biophysics, Vanderbilt Univ., Nashville, TN

Abstract: Normal habit learning, motor control, and decision making requires striatal GABA-ergic medium spiny neurons (MSNs) to integrate excitatory inputs with modulatory inputs from other basal ganglia structures. Extracellular calcium influx into striatal MSNs contributes to these functions by regulating a multitude of processes including ion channel activity and synaptic plasticity. Coupling of calcium influx to synaptic regulation occurs through the calcium-dependent signaling proteins, such as Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII). Calcium promotes CaMKII autophosphorylation at Thr286, which results in sustained calcium-independent CaMKII activity after the calcium signal dissipates. Activated CaMKII can translocate to the postsynaptic density, phosphorylate synaptic proteins, and regulate NMDAR-dependent LTP in the hippocampus. CaMKII is also expressed in both direct (D1R) and indirect (D2R) pathway MSNs, modulates endocannabinoid dependent synaptic depression, and has a higher basal autophosphorylation at Thr286 as compared with other brain regions. However, little is known about the mechanisms regulating striatal CaMKII. Therefore, we acutely isolated striatal slices from adolescent mice, treated them pharmacologically, and then homogenized punches of dorsal striatum for immunoblotting using antibodies that detect Thr286 autophosphorylation as an index of CaMKII activation. We found that blocking spontaneous neuronal excitability with the voltage gated sodium channel blocker TTX failed to change basal CaMKII activity. However, chelation of extracellular calcium with BAPTA robustly decreased CaMKII autophosphorylation at Thr286 in a time dependent manner. This was coupled to significant decreases in the phosphorylation of Ser1303 in the NMDA receptor GluN2B subunit and Ser-831 in the AMPA receptor GluA1 subunit, which are targets of active CaMKII. Calcium depletion also promoted total CaMKII re-localization to non-synaptic subcellular fractions. In order to identify the calcium permeable ion channels that promote basal CaMKII activation, we

selectively modulated L-type voltage gated calcium channels (LTCCs) and T-type voltage gated calcium channels (TTCCs). Our preliminary findings show these channels differentially regulate basal CaMKII autophosphorylation at Thr286. Our ongoing studies are exploring the roles of these channels in CaMKII regulation in specific striatal MSN cell types through immunohistochemical studies. Together these studies will elucidate signaling mechanisms coupling calcium entry to regulation of striatal function.

Title: A FRET-FLIM-STED approach to dissect protein interactions at nanoscale: Localizing CaMKII interactions within dendritic spines

Authors: *C. TARDIF, D. CÔTÉ, P. DE KONINCK;
Univ. Laval, Québec, QC, Canada

Abstract: The specific localization of protein interactions in the synaptic area, such as synaptic receptors and signaling proteins, can impact on the signaling cascade implicated in learning and memory. Knowing at nanoscale the position of those interactions inside and around the post-synaptic density could provide insights on the role of their partnership. This is particularly interesting in the context of synaptic plasticity, more specifically long term potentiation and depression (LTP & LTD). Optical methods using Fluorescence Lifetime Imaging (FLIM) to quantify Foster Resonant Energy Transfer (FRET) are useful to study protein interactions. FRET-FLIM approach provides limited spatial resolution due to the diffraction of light, particularly for studying interactions in synaptic domains, where the spine size is in the order of 0.5 μm. Super resolution methods, for instance STimulated Emission Deplession (STED), have been developed to beat this resolution limit. We combined STED with FRET-FLIM technique to study molecular interactions within dendritic spines at nanoscale resolution. We built a STED

microscope that uses a pulsed supercontinuum laser on which we added a Time Correlated Single Photon Counting (TCSPC) device to perform FRET-FLIM method. This microscope currently achieves an x/y resolution of 60 nm. To measure protein interactions, we used an immuno-FRET approach exploiting ATTO dyes, (e.g ATTO-594 as a donor and ATTO-647N as an acceptor). We first performed an immuno-FRET-FLIM-STED approach on a known, activity-regulated, interacting pair of proteins in cultured hippocampal neurons: The Calcium/Calmodulin-dependent protein kinase β (β CaMKII) and actin filaments (F-actin). We demonstrated the effectiveness of the method to resolve βCaMKII-F-actin interaction within subdomains of spines and dendrites. We are now investigating the interaction of αCaMKII with the N-methyl-D-aspartate receptor (NMDAR) under different levels of synaptic activity and cLTP conditions. Localizing the interaction of NMDAR with αCaMKII at nanoscale should help understanding the mechanisms underlying NMDAR-dependent synaptic plasticity.

Title: Effects of ZIP infusion on the persistence of *in vivo* hippocampal mossy fibers synaptic plasticity

Authors: V. A. CÁCERES-CHÁVEZ, *M. L. ESCOBAR;
Div. de Investigacion Posgrado, Fac Psicol, UNAM, Mexico, D.F., Mexico

Abstract: Persistence is a characteristic attribute of long-term memories. However, little is known about the molecular mechanisms that mediate this process. Recent experimental evidence shows that the persistence of some forms of long-term memory and long-term potentiation (LTP) can be disrupted with the administration of the atypical protein kinases C (aPKCs) inhibitor ZIP (ζ-pseudosubstrate inhibitor protein, also named Myr-aPKC-Pseudosubstrate peptide). In these sense it has been reported that ZIP administration reverses the late-phase of hippocampal LTP on the perforant and Schaffer collaterals pathways, but this effect has not been explored on the atypical hippocampal mossy fibers (MF)-CA3 pathway that exhibit an NMDA-receptor independent form of LTP. In a similar manner, the relationship between ZIP effects and morphological synaptic modifications that have been proposed to underlie memory persistence

has not been clearly observed in the adult brain. Our previous studies show that in vivo delivery of high-frequency stimulation (HFS) sufficient to induce LTP at the MF pathway elicits MF structural reorganization at the striatum oriens of CA3 area seven days after HFS. In the present study we administrated acute microinfusions of ZIP in the hippocampal CA3 area of adult rats during the late-phase of in vivo MF-CA3 LTP, with the purpose to evaluate the participation of aPKCs on the persistence of this atypical form of LTP as well as on its concomitant presynaptic structural reorganization. Our results show that ZIP inhibition of aPKCs activity neither reverses MF potentiation nor modifies its concomitant structural reorganization, even when it is able to reverse the perforant pathway LTP in our own preparations. These findings suggest that synaptic plasticity persistence on these atypical synapses does not requires of aPKCs activity in the same degree as other expressions of synaptic plasticity.

Title: Nonlinear decoding and asymmetric representation of neuronal input information by CaMKIIα and calcineurin

Authors: *H. FUJII[1], M. INOUE[1], H. OKUNO[1], Y. SANO[2], S. TAKEMOTO-KIMURA[1], K. KITAMURA[2], M. KANO[2], H. BITO[1];
[1]Dept of Neurochemistry, Univ. of Tokyo Sch. of Med., Tokyo, Japan; [2]Dept of Neurophysiology, Univ. of Tokyo Sch. of Med., Tokyo, Japan

Abstract: The nervous system adapts to a fluctuating environment through activity-dependent modulation of neuronal properties such as synaptic plasticity. The direction and extent of such sustainable modulation are determined by the stimulus parameters, suggesting that the biochemical machineries in synapses can readily compute the input information. Previous studies have suggested that Ca2+- and calmodulin-dependent kinase II (CaMKII) and calcineurin play

key roles in these decoding of input parameters and changes in spine morphology.
However, several important theoretical postulates underlying the role of CaMKII and calcineurin during synaptic plasticity_e.g. that CaMKII in spines functions as a high-frequency input detector or that calcineurin is uniquely activated by low-frequency stimulation_remain untested in living neurons. In particular, evidence is lacking whether distinct sets of incoming glutamate stimulation parameters can be transformed into a differential spatio-temporal activation patterns of the Ca2+-sensitive biochemical effectors. Furthermore, in spite of some models proposing a critical role of the calcineurin - inhibitor-1 - protein phosphatase-1 pathway in regulating CaMKII activity during plasticity, these ideas were not directly examined in hippocampal neurons.
To address these issues, we developed dFOMA (dual FRET with optical manipulation) imaging that permitted simultaneous measurement of two independent FRET probes along with local uncaging. Using this, we recorded CaMKIIα and calcineurin activities in hippocampal neurons, while varying glutamate uncaging frequencies. 5 Hz spine glutamate uncaging strongly stimulated calcineurin but not CaMKIIα, with little spine morphological change. In contrast, 20 Hz spine glutamate uncaging which induced spine growth activated both CaMKIIα and calcineurin, with distinct spatiotemporal kinetics. Treatment with a calcineurin inhibitor FK-506 did not significantly change the CaMKIIα responses triggered by either 20 Hz or 5 Hz glutamate uncaging, although it modestly increased baseline CaMKIIα activity. Higher temporal resolution recording in the soma revealed that CaMKIIα activity summed supralinearly and sensed both higher frequency and input number, thus acting as an input frequency/number decoder. In contrast, calcineurin activity summated sublinearly with increasing input number and showed little frequency-dependence, thus functioning as an input number counter.
These results provide evidence that CaMKIIα and calcineurin are fine-tuned to unique bandwidths and compute input variables in an asymmetric manner.

Title: *In vitro* reconstitution of an erasable memory switch of CaMKII

Authors: *H. URAKUBO[1,2], S. ISHII[1], S. KURODA[2];
[1]Dept Syst Sci., Kyoto U, Kyoto, Japan; [2]Dept Biophys Biochem, U Tokyo, Tokyo, Japan

Abstract: Information is stored in our brain as changes in efficacy of synaptic connection, known as synaptic plasticity. In synaptic plasticity, a synaptic molecule 'Ca^{2+}/Calmodulin (Ca^{2+}/CaM)-dependent protein kinase II' (CaMKII) has been considered to provide a key mechanism. Autophosphorylation of CaMKII at T286 keeps CaMKII activated even after removal of Ca^{2+} stimulation, and CaMKII functions as a memory switch for maintenance of synaptic plasticity (Lisman 2002, Nat Rev Neurosci 3, pp. 175-190). Theoretical studies has predicted that both dephosphorylated 'OFF' and phosphorylated 'ON' states of CaMKII are stable in the presence of phosphatase, termed by 'bistability' (Zhabotinsky 2000, Biophys J 79, pp. 2211-2221; Okamoto 2000, Biol Cybern 82, pp. 35-47). Further, the interaction of CaMKII and *N*-methyl-*D*-aspartate (NMDA) receptor subunit GluN2B has been suggested to form a memory switch (Bayer 2001, Nature 411, pp. 801-805; Sanhueza 2013, Molecular brain 6:10). CaMKII has been shown to exhibit switch-like response to Ca^{2+} in vitro, but not to exhibit hysteresis, an essential property of memory (Bradshaw 2003, PNAS 100, pp. 10512-10517). Thus, it remains unclear whether CaMKII shows a memory switch with a hysteresis *in vitro*. Here, in an *in vitro* reconstitution system, we demonstrated that phosphorylation of CaMKII at T286 functions as a memory switch through interaction of a GluN2B-derived peptide. T286 phosphorylation clearly exhibited hysteresis, i.e., once Ca^{2+} stimulation reached a sufficient level to switch CaMKII to a phosphorylated 'ON' state, CaMKII remained the phosphorylated 'ON' state even if Ca^{2+} stimulation is lowered back below the threshold, indicating the memory function. This memory switch was achieved by the balance between CaMKII autophosphorylation and its dephosphorylation by protein phosphatase 1 (PP1), and the requirements of Ca^{2+} and PP1 concentration for the hysteresis showed reversibility and modifiability of the memory switch. Interestingly, T286 phosphorylation never propagated to neighboring molecules, and the CaMKII solution could have multiple steady states by mixing dephosphorylated 'OFF' and phosphorylated 'ON' states of CaMKII. Together with roles of a phosphosite of N2Bs, these findings demonstrate how the autophosphorylation of CaMKII at T286 contributes to our learning and memory.

Title: PKA-dependent activation of presynaptically silent cortical synapses using a fluorescent probe

Authors: *T. HIKIMA, G. ARBUTHNOTT;
Brain Mechanisms for Behaviour Unit, Okinawa Inst. of Sci. and Technol. Grad. Univ., Onna-Son, Okinawa, Japan

Abstract: Neurotransmitter synaptic vesicle release has a compelling influence in neuronal network activity. It provides a resource and reserve capacity for neuronal network processing. The presence and awakening of silent synapses is one of the most dynamic resources in a neuronal network. We have previously observed a protein kinase A (PKA)-dependent activation of silent cortical synapses following administration of forskolin (FSK). It has been reported (Kaneko and Takahashi, 2004, J. Neurosci. 24:5202-5208) in the nerve terminal of the calyx of Held that cAMP facilitates release by activating the PKA-independent sensitive guanine nucleotide exchanging factor (GEF) also called (exchange protein directly activated by cAMP) Epac pathway. Therefore our objective here was to determine if a forskolin-induced increase in cAMP in our cultures also activated the Epac pathway. The experiments were performed on primary cultures of cortical neurons (E14-16) from C57BL/6J mice. To obtain direct measurements at presynaptic terminals two intracellular reporters were transfected at 7 DIV: Synaptophysin-pHluorin 2x (SypH2x) and G-Camp-3. G-Camp-3 reports on the internal calcium concentration and SypH2x on exocytosis and endocytosis. FSK (10µM) and Epac selective agonist 8-CPT2'-O-me-cAMP (100µM) were bath applied in the presence of AMPA receptor antagonist DNQX (10µM). Data analysis revealed that whereas FSK treatment did not change the internal calcium or endocytosis rate it increased the size of the readily releasable pool (RRP). The increase of the RRP confirms previous results of the effect of FSK on cortical synapses and suggests that activation of cAMP-dependent PKA is the necessary mechanism to uncover silent synapses.

Title: Thyroid hormone signaling through the phosphatidylinositol 3-kinase acutely potentiates Schaffer collateral synapses on postnatal mouse hippocampal CA1 neurons through a presynaptic mechanism

Authors: F. MIZUNO, B. GLOSS, E. SCAPPINI, C. ERXLEBEN, *D. L. ARMSTRONG; Lab. Neurobio., NIEHS NIH, DURHAM, NC

Abstract: We reported previously that chronic blockade of thyroid hormone, 3,3′,5-triiodo-L-thyronine (T3), signaling through the phosphatidylinositol 3-kinase (PI3K) by a point mutation in the THRB gene, which produces TRbeta1 Y147F, interfered with the maturation and plasticity of Schaffer collateral synapses from CA3 pyramidal neurons onto CA1 neurons in the postnatal mouse hippocampus. Here we report that T3 also has rapid presynaptic effects on the strength of those synapses in slices from wild-type C57BL/6 mice. Thus, an 8 min application of 100 nM T3 rapidly increased the amplitude of evoked EPSCs by 50%, which is comparable to the increase produced by brief high-frequency stimulation, and this effect persisted for more than 1 hr. In contrast, the reverse isomer (3,3’,5’) of the hormone had no effect at the same concentration. T3 –induced potentiation did not depend on either postsynaptic calcium or activity, but it was blocked completely by 50nM wortmannin, a selective antagonist of PI3K. In slices from THRB mutant animals, the acute potentiating effect of T3 on synaptic responses in CA1 was eliminated completely, corroborating the involvement of PI3K signaling in this effect. Like other growth factors, such as BDNF, that potentiate hippocampal synapses through PI3K signaling, the effect of T3 appears to be primarily presynaptic. T3 increased the frequency of spontaneous EPSCs by 32% without affecting their amplitude. Moreover, T3 increased the paired pulse ratio by 15% at an inter-pulse interval of 50 ms. Further evidence for a presynaptic effect of thyroid hormone on synaptic plasticity was obtained by rescuing signaling in slices from the mutant. First we verified that the acute effect of thyroid hormone persisted for up to three weeks in cultured slices from wild type animals. Then we infected either the CA1 or the CA3 region of cultured slices from mutant animals with a neurotropic adeno-associated virus (AAV2/9) encoding the human synapsin promoter driving expression of wild type mouse TRbeta1 receptor linked with an IRES to green fluorescent protein (GFP). Ten days later, we recorded the effect of T3 on synaptic responses in CA1 neurons. Infection of CA3 neurons, which give rise to the Schaffer collaterals, totally restored T3-dependent potentiation of their synapses on CA1 neurons. In contrast, infection of the postsynaptic CA1 neurons restored T3-dependent potentiation of EPSC amplitude by only 10%. Thus, T3 signaling through PI3K stimulates postnatal synaptic plasticity in the mouse hippocampus by potentiating presynaptic glutamate release, and we hypothesize that TRbeta receptors in the mouse and human cortex may have similar effects.

Title: Molecular network models that can account for long-term plasticity and memory

Authors: *S. J. JALIL[1], T. C. SACKTOR[2], H. Z. SHOUVAL[1];
[1]Neurobio. and Anat., The Univ. of Texas Med. Sch. At Houston, Houston, TX; [2]Physiol. and pharmacology, SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: Memory and its cellular substrate, synaptic plasticity, can outlast by several orders of magnitude the dwell-time of the biomolecules in the synapses, which are assumed to be responsible for memories. Although the mechanism for such long lasting memories remains unknown, many types of memories are found to disappear following the injection of zeta inhibitory protein (ZIP) in small, targeted areas of the nervous system. Chronic pain and addictive behavior are affected in multiple studies when experimenters manipulated ZIP's target, PKMζ, an atypical protein kinase C isoform. The idea that ZIP erases memory by inactivating PKMζ has been contested, however, by the findings that animals with gene knockouts for this protein show normal memory, although more recent studies have shown compensation in such animals by the PKMζ paralogous isoform PKC/PKMι/λ (see Yao et al., Soc Neuro Abstr, 2013). Here, we examined, using a mathematical formulation, several possible types of minimal network models that can account for long-lasting memories and for different key experimental observations, such as the dependence of memories on de novo protein synthesis, memories' sensitivity to ZIP, and the effects of various pharmacological agents and mutants on memories. In addition, we examined the types of feedback mechanisms that are most likely to account for these experimental observations. Our analysis indicated that a model with auto-phosphorylation and differential synaptic dwell times (APDD) was the best match for multiple experimental results. Consequently, we were able to accurately model the experimental observations that a small amount of ZIP reduces late phase long-term potentiation (L-LTP), and a larger dose completely abolishes L-LTP.
We further examined several new experimental results, which question the importance of PKMζ,

as well as other observations which suggest that PKCλ (or PKMλ), the compensatory kinase, can also play a role in memory maintenance and can be up-regulated in PKMζ knock-out mice. We developed a model that includes these redundancies in the molecular substrates of memory and explore how this new parallel pathway model can account for the observed results. Finally, we propose an explanation for the apparent contradiction in the experimental data, and the enhanced robustness of the long-term memory resulting from the new parallel pathway model.

Abstract: Protein kinase Mζ (PKMζ) is a brain-specific, constitutively active isoform of the atypical class of PKC that plays a key role in maintaining protein synthesis-dependent late-LTP (L-LTP) and long-term memory (LTM). During the induction of L-LTP or the consolidation of LTM in the hippocampus, PKMζ is synthesized from a PKMζ mRNA encoding a PKCζ catalytic domain without a regulatory domain. Using the selective atypical PKC inhibitor ZIP, the PKC

catalytic domain inhibitor chelerythrine, or a dominant negative mutant of PKMζ, previous studies have indicated that the persistent kinase activity of PKMζ is essential for the maintenance of L-LTP and LTM.
Because of the compensation in the constitutive PKMζ knockout (Yao et al., Abstr. Soc. Neuro., 2013), we used a conditional knockout (KO) approach to specifically delete the source of PKMζ mRNA. We injected Cre recombinase-expressing AAV into the hippocampi of adult mice in which exon 9, encoding the ATP-binding site of the PKC/PKMζ gene, is floxed. This selectively deletes PKMζ, because the hippocampus of wild-type mice expresses PKMζ, but not PKCζ. In conditional PKMζ-KO mice, a ~75% drop in the amount of PKMζ mRNA was found by qRT-PCR at 5 weeks post-injection. This was accompanied by a smaller (~12%) drop in PKMζ protein at 2-3 months post-injection, suggesting a long half-life for the kinase.
Immunocytochemistry of tetanized hippocampal slices from AAV-Cre-injected and contralateral control virus-injected hippocampi showed that conditional knockout prevented activity-depended synthesis of PKMζ protein in CA1 stratum radiatum. In the AAV-Cre-injected slices from conditional PKMζ-KO mice, tetanization induced only a decremental LTP (early-LTP), lasting ~2 hrs. Moreover, conditional PKMζ-KO mice were unable to consolidate spatial LTM of active place avoidance, 24 hr after training, but had intact short-term memory (STM). Control virus-injected mice had normal L-LTP and LTM.
These results were reproduced by acutely blocking de novo PKMζ protein synthesis, without affecting basal amounts of the kinase, using single intrahippocampal injections of PKMζ-antisense oligodeoxynucleotides (AS-ODNs). Acute AS-ODN injections blocked both new, activity-dependent PKMζ synthesis and L-LTP. AS-ODN injected 20 min prior to active place avoidance training blocked de novo PKMζ synthesis and prevented LTM consolidation measured 24 hr after training. STM was unaffected. SCR-ODN had no effect on new PKMζ synthesis, LTP, STM, or LTM.
These results demonstrate that, under physiological conditions or when compensation is avoided, newly synthesized PKMζ is crucial for the consolidation of late-LTP and spatial LTM.

Title: Compensation by PKCι/λ activation and PKMι/λ formation in PKMζ knock-out mice

Authors: *Y. YAO[1], P. TSOKAS[2], D. JOTHIANANDAN[1], A. TCHEREPANOV[1], P. VAN DE NES[1], T. SACKTOR[3];
[1]Physiol. and Pharmacol., [2]Physiol. and Pharmacology, Anesthesiol., [3]Physiol. and Pharmacology, Neurol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: PKCι/λ is a paralogue of PKCζ, the result of duplication of the single ancestral atypical PKC gene. The PKM form of PKCζ has been implicated in the maintenance of late-phase LTP and long-term memory. In rat hippocampal CA1 region, the amount of activated PKCι/λ also increases after induction of LTP (Kelly, J Neurosci, 27:3439, 2007), and it plays a critical role in early-LTP expression (Ren, et al., EMBO, 2013). Recent studies have found that constitutive PKC/PKMζ knock-out mice show unimpaired LTP and memory (Lee, et al., Nature. 493:416, 2013; Volk, et al., Nature, 493:420, 2013). Therefore, we investigated the possibility that PKCι/λ compensates for the loss of PKMζ. Biochemical studies show that in rat, mouse and human hippocampus, PKCι/λ is expressed in both full-length PKC form and a shorter PKM form consisting of the independent catalytic domain of the kinase. Moreover, the amount of both activated PKCι/λ and PKMι/λ in hippocampus are significantly increased in constitutive PKC/PKMζ knock-out mice, compared to their wild-type litter mates. Postsynaptic perfusion of activated PKCι/λ into rat hippocampal CA1 pyramidal cells caused a doubling of AMPA receptor-mediated EPSCs, similar to the potentiation observed by perfusing PKMζ. The PKMζ inhibitors, ZIP and chelerythrine, also inhibit PKCι/λ and PKMι/λ. Thus, PKCι/λ and PKMι/λ may compensate for the loss of function of PKMζ during the maintenance of LTP and long-term memory in constitutive PKC/PKMζ knock-out mice.

Title: Persistent increases of PKMζ correlate with the retention and duration of spatial long-term memory

Authors: *C. HSIEH[1], P. TSOKAS[1,2], B. R. HARTLEY[3], P. A. SERRANO[5], A. A. FENTON[6], T. C. SACKTOR[1,4];

Abstract: PKMζ is a constitutively active and brain-specific atypical PKC isoform that plays an important role during long-term memory (LTM) storage. Overexpressing PKMζ enhances LTM (Shema et al., Science 331:1207 [2011]), and inhibiting PKMζ by overexpressing a dominant negative version of PKMζ or injecting ζ-pseudosubstrate inhibitory peptide (ZIP) disrupts LTM, even very long-term spatial memory 1 month posttraining (Pastalkova et al., Science 313:1141 [2006], Shema et al., Science 317:951 [2007], Shema et al., Science 331:1207 [2011]). Here we examined endogenous PKMζ expression at different time points after short- or long-term memory and correlated the amount of expressed PKMζ with LTM retention.
Adult male Long-Evans rats and C57BL/6J mice were trained by massed and spaced active place avoidance, respectively. Massed training consisted of eight 10-min-shock trials with 10 min inter-trial interval (ITI), and spaced training consisted of three 30-min-shock trials with 120 min ITI. Quantitative immunoblotting showed that dorsal hippocampal PKMζ increased by the end of the massed training phase, and 1 day after both massed and spaced training, compared to animals that had not received shock when placed in the apparatus. The increase in PKMζ remained at least 30 days after the spaced training. Moreover, the PKMζ level significantly correlated with 1 day LTM retention (Spearman's $\rho = -0.81$, $p < 0.01$), but not with the number of shocks during the training phase (Spearman's $\rho = 0.18$, $p = 0.63$). No PKMζ increase was detected after either short-term memory training or 1 day after the administration of the tethered shocks in which animals received the same number and timing of shocks as the avoidance-training group, but without association with spatial information. No long-term contextual fear conditioned behaviors, such as freezing, or locomotor activity change was observed in the tethered shock-training group. Immunohistochemistry demonstrated that the increased PKMζ after the spatial training localized in the strata pyramidale, radiatum, and lacunosum-moleculare in CA1 region at both 1 day and 1 month posttraining. These results support the hypothesis that persistently increased hippocampal PKMζ might be the molecular mechanism of the spatial LTM storage.

Title: Long-term potentiation at hilar mossy cell to dentate granule cell synapses

Authors: *Y. HASHIMOTODANI, A. E. CHÁVEZ, P. E. CASTILLO;
Albert Einstein Col. of Med., Bronx, NY

Abstract: Hilar mossy cells (MCs) of the dentate gyrus receive inputs from dentate granule cells (DGCs) and project their glutamatergic axons back to DGCs, thereby establishing a positive feedback loop. While MCs have been implicated in epileptogenesis and could participate in some forms of memory, little is known about the dynamic properties of MC-DGC synapses. Here, we investigated whether MC-DGC synapses can undergo long-term, activity-dependent forms of plasticity. To this end, we performed whole-cell patch clamp recordings from DGCs in acute hippocampal slices of young-adult rats. Monosynaptic responses (excitatory postsynaptic currents, EPSCs) were monitored in the presence of the $GABA_A$ receptor antagonist picrotoxin (100 μM) while presynaptic MC fibers (MCFs) were activated by local extracellular stimulation (<150 μm from the recorded DGC) in the inner third of the dentate molecular layer (a.k.a. supragranular layer). We found that high frequency stimulation of MCFs in the presence of the NMDA receptor antagonist d-APV (50 μM) induced long-term potentiation (LTP) of MCF-EPSCs. This LTP was observed at both AMPAR- and NMDAR-mediated components of excitatory transmission, and was accompanied with a decrease in paired- pulse ratio and coefficient of variation, all of which suggest a presynaptic locus of expression. MCF-LTP was blocked by the PKA inhibitor H89 but not by the postsynaptic loading of the membrane impermeable PKA inhibitor peptide PKI_{6-22}. In addition, brief bath application of the adenylate-cyclase activator forskolin (50 μM, 10 min) induced a long-lasting enhancement of MCF-EPSCs that occluded synaptically-induced MCF-LTP. These results strongly suggest that presynaptic cAMP-PKA signaling is necessary and sufficient for MCF-LTP. Remarkably, postsynaptic loading of the Ca^{2+} chelator BAPTA (20 mM), or cyclopiazonic acid (CPA, 30 μM) to deplete intracellular Ca^{2+}stores, abolished MCF-LTP, indicating that a postsynaptic increase in Ca^{2+}

mainly arising from intracellular stores is required for induction. Thus, our findings provide evidence for an NMDA receptor-independent, cAMP/PKA-dependent form of LTP at MC-DGC synapses. The postsynaptic Ca^{2+} requirement for LTP induction together with a presynaptic mechanism of expression suggests the involvement of some form of retrograde signaling. While the precise role of MCs remains to be elucidated, the ability of the MC-DGC synapse to undergo a presynaptic, non-Hebbian form of LTP may have important implications for information processing in the dentate gyrus.

Title: Inositol polyphosphate multikinase enhances immediately early gene transcription via regulation of CBP

Authors: *R. XU[1], B. D. PAUL[2], R. TYAGI[2], F. RAO[2], A. B. KHAN[2], D. J. BLECH[2], P. GUHA[2], N. SEN[2], S. H. SNYDER[2];

Abstract: Inositol polyphosphate multkinase (IPMK) is the rate-limiting enzyme in the formation of multiple higher inositol polyphosphate species, including both lipid-soluble PIP3 as well as water-soluble inositol tetrakisphosphates and inositol pentakisphosphate. Originally discovered in yeast as a transcriptional regulator of arginine metabolism, IPMK was subsequently shown to regulate chromatin remodeling complexes (Swi/Snf, ISWI, INO80, etc) in yeast via its metabolites. To date, however, the role of mammalian IPMK is less well understood. Conventional deletion of IPMK in mice is embryonic lethal at E9.5 with abnormal folding of the neural tube, precluding its study in neurons directly. Here, we generated brain-specific IPMK knockout mice using a nestin-Cre loxP system. Immediately early gene (c-fos, egr2, egr3, VGF, c-jun) induction in these mice are severely impaired after electroconvulsive shock, both at the mRNA and protein levels. Overexpressed and endogenous IPMK binds to, and recruits CBP to the c-fos promoter in both primary neurons and in mouse brain. Interestingly, rescue of IPMK knockout neurons with wild-type versus kinase-dead IPMK revealed that IPMK is able to enhance CBP recruitment to the c-fos promoter independent of its catalytic ability. Indeed,

overexpression of a dominant negative fragment of IPMK which blocks IPMK-CBP association decreased transcription of c-fos mRNA. Taken together, these results show that IPMK enhances immediate early gene transcription via recruitment of CBP.

Title: Effect of impaired neurotransmitter release on Long Term Potentiation

Authors: *S. NADKARNI[1], A. MADUSKAR[2], H. LEVINE[3];
[1]Computat. Neurobio. Lab., Indian Inst. of Sci. Educ. and Res. Pune, Pune, India; [2]Biol., Indian Inst. of Sci. Educ. and Research, Pune, Pune, India; [3]Dept. of Bioengineering, Rice Univ., Houston, TX

Abstract: Changes in Short-Term Plasticity (STP) leading up to modified Long-Term Plasticity (LTP) and synaptic dysfunction has been reported as a basis of initial pathological changes seen in Alzheimer's Disease (AD). Specifically, Rynanodine Receptors (RyRs) in the presynaptic terminal at the CA3-CA1 synapse have been implicated. However the exact chronology of signaling pathways that lead to aberrational LTP are difficult to identify experimentally. We have developed a biophysically detailed computational model of the CA3 presynaptic terminal in the hippocampus that includes the action of Ryanodine Receptors (RyRs) and Inositol Triphisphate Receptors (IP3). We simulate, within a range of physiologically relevant input frequencies, the effect of impending calcium release from the Endoplasmic Reticulum (ER) via the IP3 and RyR receptors on STP. Further we investigate how pathological excess calcium release from the ER affects neurotransmitter release profile. Our model suggests that the competing dynamics of neurotransmitter recycling compared to modified neurotransmitter release as a result of excess calcium release from the ER may lead to the depletion of the small readily releasable pool (~ 7 vesicles) in the CA3 terminal. The reduced Paired Pulse Facilitation

seen in experimental models of AD may thus be a consequence of altered calcium signaling from the RyRs. Further, we show how altered presynaptic calcium dynamics as seen in experimental models of AD lowers LTP.

Title: Humor associated mirthful laughter enhances brain EEG power spectral density gamma wave band activity (31-40Hz)

Authors: *L. S. BERK, P. PAWAR, C. ALPHONSO, N. REKAPALLI, R. ARORA, P. CAVALCANTI;
Allied Hlth. Studies, Schl Allied Hlth. Prof, Loma Linda Univ., Loma Linda, CA

Abstract: Humor associated mirthful laughter experiences (HAML) relate to various fundamental aspects of human behavior. Some of these experiences are characterized by modulating emotions, enhancing "higher mental activity", memory, sensory perception, consciousness and happiness. To date, no known electroencephalographic (EEG) study has been conducted to identify and differentiate Power Spectral Density (PSD) correlates across frequency bins1-40Hz, with particular interest of the 31-40Hz gamma band, for the comparative experience between the eustress HAML with a classic distress experience. It is known that gamma brain activity (GBA) is the fastest brainwave frequency with the smallest amplitude, however, GBA is associated with peak mental concentration ("in the zone"), memory enhancement and high levels of cognitive function. Purpose: This study measured EEG spectral power in 20 healthy university students, mean age 28±6.2, during HAML and stress experiences to differentiate PSD correlates across frequency bins1-40Hz. Methods: EEG activity was recorded from 9 scalp locations/channels F3, Fz, F4, C3, Cz, C4, P3, POz, and P4 using the EEG B-Alert 10X System™. In a cross-over design each subject was randomly administered (with an appropriate washout period) two separate 10 minute videos: Humor (America's Funniest Home Videos) and Stress (Movie - Saving Private Ryan). Results: Comparing HAML vs. stress, all nine channels showed greater Beta Band Activity (13-30Hz) (BBA) (p=0.01) and GBA (31-40HZ) (p=0.001) for HAML. Most significant was that Humor GBA was greater than Humor BBA (p=0.01) for all nine channels. Comparing HAML vs. Stress, Theta (3-7Hz) and Alpha (8-12Hz) for Parietal Left

(P3) vs. Parietal Right (P4) showed Humor greater in the P3 region than P4, for both bandwidths. Conclusions: These results indicate that HAML have correlates of marked changes in EEG PSD for specific bandwidths but most significantly for (GBA) across the whole hemispheric brain as measured by the B-Alert 10X System™. Other research suggests 1) GBA offers an adequate tool for studying cortical activation patterns during emotional processing and 2) GBA is suitable for EEG-based emotion classification of happiness and sadness. Our EEG findings support these findings and further suggest that HAML can increase PSD of GBA to potentially modulate states of "higher mental activity", sensory perception, enhancement of memory/recall and happiness. We suggest that PSD of GBA may be a functional neurofeedback marker of these states. Further research is being conducted to expand and elaborate these findings.

Title: Method for event-based cross-frequency coupling analysis of neural oscillations

Authors: *D. DVORAK[1], B. RADWAN[2], A. A. FENTON[2,1];
[1]Physiol. & Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Phase amplitude coupling (PAC) of neural oscillations was proposed as a possible mechanism for cross-scale organization of neural network activities. As an example, the phase of a slow rhythm like hippocampal theta oscillations modulates the amplitude of a faster rhythm like hippocampal gamma oscillations. To quantify this cross-frequency interaction, one has to use relatively long time windows (> 10 seconds). However, such long time windows are well beyond the relevant behavioral and physiological timescales for most cognitive events, and therefore provide only a global estimate of PAC, that is difficult to directly associate with cognitive events. In order to study PAC at sub-second time resolution, we developed a parameter-free data-driven algorithm, which considers fast frequency oscillations as time-

specific events rather than averaged power estimates obtained from long time windows. To test the performance of our algorithm we first compared it with a standard PAC algorithm (Tort 2010) for detecting individual oscillatory bands of phase-modulated oscillations. Second, we extracted features of the detected oscillations such as bandwidth, duration, power or number of oscillatory cycles and demonstrated frequency- and phase-specific modulation of these features and therefore their ability to capture ongoing cross-frequency interactions at the scale of single oscillations. Third, we compared the relationship between the modulation index obtained from the standard PAC algorithm with the single phase-modulated oscillations detected by our algorithm and show that increased modulation indexes correspond to higher numbers of phase-modulated oscillatory events, their increased power as well as their reduced phase variance.

Title: Event-based cross-frequency coupling of neural oscillations in the rodent hippocampus during cognitive events

Authors: *A. A. FENTON[1,2], D. DVORAK[3], B. RADWAN[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Physiol. & Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY; [3]SUNY Downstate Med. Ctr. / NYU-Poly, Brooklyn, NY

Abstract: It has been hypothesized that phase amplitude coupling (PAC) of neural oscillations might play a role in multiple brain functions such as cross-scale organization, selection of attention, routing the flow of information, memory processing, information coding and integration. To date, attempts to quantify PAC relied mainly on global estimates of cross-frequency relationships obtained from long time windows (> 10 seconds). In this framework, PAC is characterized as a statistical bias of the amplitude of the fast rhythm (such as hippocampal gamma oscillations) by phase of the slow rhythm (such as hippocampal theta oscillations). These estimates, however, provide only global information about the cross-frequency interaction but do not allow insight into the instantaneous changes in oscillatory

dynamics i.e. appearance of fast oscillations during single cycles of slow oscillation, that relate to neural function. In this study we present dynamic properties of individual phase-modulated oscillations obtained from rodent hippocampus (mouse and rat) during a variety of discrete behaviors, including i) pausing with and without vicarious trial-and-error, ii) switching between spatial reference frames, and iii) successful and failed place avoidance. The frequency-specific (i.e. slow gamma, fast-gamma and high frequency oscillation) characteristics of the individual phase-modulated oscillations associated with these cognitive-behavioral events are characterized for each set of events. Furthermore, the use of multiple, linearly spaced electrodes allowed linking of these ongoing oscillatory activity to specific layers around hippocampal CA1-CA3/DG axis.

Title: Gamma events and functional connectivity between brain areas

Authors: *A. BRAGIN, F. KHEIRI, J. ENGEL, Jr;
Dept Neurol, David Geffen Sch. Med. UCLA, LOS ANGELES, CA

Abstract: In this study we investigated functional connectivity between brain areas by analysis of gamma activity. We have considered gamma activity as a sequence of events generated by local modules. We found that the size of these modules is within the range of 2-3mm. The temporal relationship between gamma events generated in different brain areas was estimated by calculation of perievent histograms. The strength of the peak in the histogram was measured using Shannon entropy followed by calculation of the connectivity index, which reflects the strength of functional connectivity between recorded brain areas. The spatial pattern of functional connectivity is represented by color coded matrices and connectivity graphs. Our data show that the spatial pattern of functional connectivity, to a certain degree, reflects morphologically defined connections between brain areas, but is unique for each individual animal. This spatial pattern is stable in a given behavioral state, but changes when animals move

from one behavioral state to another. Pharmacological manipulation of different types of synaptic transmission changes the spatial pattern of functional connections. This approach opens a new horizon for investigation of brain functional connectomics and may be applied for merging fMRI and electrographic data in investigation of functional properties of neuronal networks.

Title: Different mechanisms underlying feedforward and feedback influences on low and high frequency oscillations in visual attention

Authors: *M. BAUER, K. J. FRISTON, R. J. DOLAN;
UCL, London, United Kingdom

Abstract: Human and animal studies show that feedforward sensory signals and feedback influences from higher cortical areas modulate low frequency alpha-/beta- and high frequency gamma-oscillations in sensory cortex in a specific fashion: Alpha-/beta-frequencies are suppressed while gamma-frequencies are enhanced by stimulation and the attentional bias in the sensory cortex contralateral to the relevant stimulus location. We used two visual spatial attention paradigms, in one the task relevant stimulus feature was shown immediately with stimulus onset, in the other with an unpredictable delay and recorded MEG in humans. We show that 1) the timing of attentional alpha-/beta modulation generally differs from that of gamma

modulations in that the former commences before the relevant display onset whereas the latter always follows stimulation onset, 2) the frequency of the attentional modulation differs from both the resting state frequency of alpha oscillations as well as its suppression driven by feedforward stimulation in that the attentional modulation was concentrated between 10 and 20 Hz whereas the feedforward suppression revealed two clearly distinct peaks at around 10 and 20 Hz. Importantly, 3) the timing of the spatial attentional alpha-/beta-modulation strongly depended on the expected onset of the task-relevant stimulus feature and directly preceded this, independent from the onset of stimulation, whereas modulation of gamma more or less invariantly followed the onset of stimulation, independent from the onset of the task-relevant feature (i.e. either before or after presentation of the task relevant stimulus feature). These results reveal that different mechanisms contribute to feedforward vs feedback control of alpha-/beta-oscillations and in the attentional control or feedback regulation of alpha-/beta vs gamma-oscillations.

Title: Activation of thalamic δ-subunit containing $GABA_A$ receptors by hypnotics supports cortical deactivation *In vivo*

Authors: *L. MESBAH-OSKUI[1], B. A. ORSER[3,2,1], R. L. HORNER[2,1];
[1]Med., [2]Physiol., Univ. of Toronto, Toronto, ON, Canada; [3]Anesthesia, Sunnybrook Hlth. Sci. Ctr., Toronto, ON, Canada

Abstract: Enhanced γ-aminobutyric acid (GABA)-ergic neural activity promotes natural sleep. Many hypnotics increase neural inhibition via interactions with binding sites on extrasynaptic δ-subunit-containing $GABA_A$ receptors (δ$GABA_A$R). The thalamus is a key structure in mediating cortical activity and controlling brain arousal. Activation of δ$GABA_A$R in the ventrobasalis complex (VB) of the thalamus elicits a tonic hyperpolarization *in vitro* that promotes a change in neural population activity consistent with brain deactivation. We examined the influence of δ$GABA_A$R activity in response to hypnotics in the VB on cortical activity. Experiments were conducted in 42 freely behaving δ$GABA_A$R knockout (*Gabrd*$^{-/-}$) and wild type (WT) mice.

Electrocortical activity was recorded during bilateral microperfusion of artificial cerebrospinal fluid (aCSF), 10μM and 50μM THIP (a δGABA$_A$R-preferring agonist), and 10μM and 30μM etomidate into the VB. Mice of each genotype also served as time-controls, receiving only aCSF. In WT mice, 50μM THIP at the VB increased 1-4Hz electrocortical activity in non-rapid eye movement (NREM) sleep and waking. Delivery of 50μM THIP to the VB also influenced state dynamics, with transitions into NREM and REM sleep occurring more rapidly. Sigma power (10-15Hz) and spindle density (7-14Hz) during NREM sleep were also reduced. Importantly, no such changes occurred with THIP in *Gabrd*$^{-/-}$ or time-control mice. Surprisingly, 10μM etomidate in the VB of WT and *Gabrd*$^{-/-}$ mice decreased 1-4Hz electrococritcal activity and increased sigma oscillatory power. Consistent with the increased sigma power, spindle incidence was markedly increased, as was average spindle duration. Transitions into NREM and REM sleep were unaffected; however, there was an increase in the incidence REM sleep in both strains of mice. Interestingly, 30μM etomidate at the VB promoted slow, 1-4Hz, oscillations in WT and *Gabrd*$^{-/-}$ mice. Sigma power, spindle incidence and duration were dampened and transitions into NREM and REM sleep occurred more rapidly. Importantly, all of the differences seen with 30μM etomidate at the VB were less pronounced in *Gabrd*$^{-/-}$ relative to WT mice. Since prominent delta (1-4Hz) oscillations are a hallmark of sleep and anesthetic states, these data suggest that δGABA$_A$R at the VB promote cortical deactivation, and as such are positioned to contribute to the induction of sleep and sedation. Our findings also indicate that intermediate levels of etomidate (consistent with amnestic brain concentrations) in the thalamus elicit changes in cortical activity that are not primarily mediated through δGABA$_A$R.

Title: Electrophysiologic correlates of resting-state fMRI networks

Authors: *C. D. HACKER[1], A. SNYDER[2], M. PAHWA[2], M. SHARMA[2], D. BUNDY[2], A. DAITCH[2], N. SZRAMA[2], K. BANDT[2], T. MITCHELL[2], M. CORBETTA[2], E. LEUTHARDT[2];

Abstract: Investigations of ongoing brain activity in the resting state (in the absence of salient sensory and motor events) have revealed spontaneous correlations within widely distributed brain regions known as resting-networks (RSNs). Each RSN is putatively associated with a specific function such as vision, motor control and language. However, the physiological underpinnings of RSNs are incompletely understood. RSNs have thus far been studied primarily with non-invasive neuroimaging techniques (specifically functional MRI). We combined functional MRI and invasive electrophysiology to investigate the electrophysiological correlates of resting state networks.
We investigated the correspondence between electrocorticographic (ECoG, brain surface potential) recordings and RSNs defined using fMRI in patients undergoing invasive monitoring prior to surgical treatment of epilepsy (N=15). Electrodes were segmented from a CT image. Physical brain distortion due to grid implantation was corrected by projection to a pial surface segmentation generated with FreeSurfer. EPI distortion in BOLD data was corrected with retrospective application of a mean field map. Voxel-wise estimates of RSN identity were computed with a multi-layer perceptron (MLP). The MLP had previously been trained to associate fMRI correlation maps of canonical seed regions (generated from a meta-analysis of task responses) with 7 RSNs. We sampled RSN values onto electrodes, weighting each voxel as a dipole and thus accounting for distance and cortical surface angle relative to the electrode.
We determined ECoG-fMRI RSN correspondence by contrasting correlations of ECoG signals between groups of electrode pairs within vs. across fMRI-defined RSNs. We found a significant correspondence at the group level for the dorsal attention, motor, visual, language, and default mode networks. This effect was present from infra-slow to high alpha-range frequencies (0.5 to12 Hz) for raw timeseries. These results extend previous work demonstrating ECoG correlates of the sensorimotor RSN below 4 Hz (He, 2008). We applied the same analysis to infra-slow (< 0.5 Hz) fluctuations of band-limited power (BLP) at carrier frequencies ranging from theta (3-5 Hz) to high gamma (up to 150 Hz). Greater within vs across RSN correlations were sharply tuned in carrier frequency for some RSNs and much more broadly tuned for others. In general, the patterns of BLP correspondence as a function of carrier frequency for different RSNs were highly variable across subjects compared to those of raw ECoG timeseries.

Title: Enhanced cortical gamma oscillations and cognitive impairment by selective disruption of inhibition within parvalbumin-networks

Authors: *T. K. HENSCH[1,2], H. H. LEE[2];
[1]Harvard Univ., CAMBRIDGE, MA; [2]Boston Children's Hosp., Boston, MA

Abstract: Gamma oscillations emerge from an intricate interplay between fast-spiking inhibitory interneurons and their pyramidal cell targets. Vulnerability of these parvalbumin (PV)-positive cells in turn underlies various hypotheses of schizophrenia (glutamatergic, dopaminergic, neurodevelopmental, NRG/ErbB4, oxidative stress). Causal relationships between gamma oscillations and cognitive deficits remain elusive. While sensory-evoked oscillations are often reduced in schizophrenia, spontaneous gamma power (30-80 Hz) is paradoxically increased. Gamma band abnormalities may represent a neurobiological endophenotype or simply be a very sensitive readout or epiphenomenon of any perturbed cortical network function. Here, we specifically examined a role for PV-network connectivity in gamma oscillations. We disrupted the major $GABA_A$ receptor subunit, alpha1, within PV-cells in adolescence (alpha1$^{f/f}$ x PV-Cre^{+} mice) and observed elevated levels of spontaneous EEG gamma power across different regions of neocortex (prefrontal: 343±34%, N=6; somatosensory: 190±16%, N=7; visual: 679±87%, N=3, as compared to WT littermates). The prefrontal EEG abnormality was notably associated with behavioral deficits including social memory, novel object recognition, attention-based exploratory activities and an elevated level of pre-pulse inhibition. NMDA receptors on fast-spiking cells may contribute to gamma band synchrony. We confirmed that EEG gamma oscillations are induced in mice by ketamine (171±19% above baseline, N=5), a non-competitive antagonist often linked to cognition and information processing deficits in drug abusers. This ketamine effect on gamma oscillations was largely occluded in alpha1$^{f/f}$ x PV-Cre^{+} mice (118±10%, N=4). Instead, the non-selective allosteric $GABA_A$ receptor modulator, diazepam, suppressed high-range gamma oscillations (60-80Hz) (51±2%, N=6) but not in WT mice (99±3%, N=3), while slightly elevating low-range gamma (30-60Hz) both in mutant (126±14%, N=6) and WT mice (154±15%, N=3). This diazepam treatment further rescued social memory deficits in the alpha1$^{f/f}$ x PV-Cre^{+} mice. Taken together, GABAergic signaling within the PV-network (through alpha1 subunits) normally dampens gamma oscillations and mimics some aspects of cognitive impairment when disrupted. Gamma oscillations may provide a temporal structure for activity-dependent synaptic refinement to take place. Periadolescent disturbance of

PV-circuit connectivity, which normally drives critical periods of brain plasticity, may trigger aberrant synaptic pruning and associated cognitive deficits.

Title: Frontal field stimulation promotes cortico-hippocampal interactions during slow-wave activity

Authors: *A. GREENBERG[1], T. WOLANSKY[2], C. T. DICKSON[3];
[2]Dept. of Psychology, [3]Dept. of Psychology, Ctr. for Neuroscience, Dept. of Physiol., [1]Univ. of Alberta, Edmonton, AB, Canada

Abstract: The signature event of slow-wave sleep (SWS) is the neocortical large amplitude slow oscillation (SO; ~1Hz) that is composed of alternating periods of highly active (UP) and silent (DOWN) states at the neuronal level. On each wave, the SO is generated at a local focus in the neocortex, and is propagated across the cortical network, and even to the hippocampus, in various directional patterns. This potential interaction between the neocortex and hippocampus make the SO a favourable candidate for mediating sleep-dependent declarative memory consolidation. In fact, it has been previously shown that the application of transcranial electrical stimulation at the SO frequency to human subjects during SWS improved declarative memory recall the following day. However, influence of electrical stimulation on cortico-hippocampal spatiotemporal interactions during SO remain unknown. Here, we show in urethane anesthetized rats that rhythmic electrical field stimulation applied to the anterior pole of the cortex entrains cortical and hippocampal local field and cellular activity and biases the spontaneous propagation of the SO in an anterior-to-posterior direction across the cortex and that subsequently appears in the hippocampus. Field stimulation also enhanced long-range gamma synchrony across both cortico-cortical and cortico-hippocampal regions, an effect that transiently persisted following cessation of stimulation. Furthermore, field stimulation also increased the incidence of hippocampal ripples which were modulated by the phase of stimulation and appeared in a non-overlapping fashion with gamma activity. These results shed new insights into the potential

neurophysiological mechanisms supporting plastic processes such as memory consolidation during SWS.

Title: Dynamical features of interictal spikes in the human brain undergoing anesthesia

Authors: *G. A. CECCHI[1], L. ALONSO[2], M. MAGNASCO[2], A. PROEKT[2];
[1]Biometaphorical Computing, IBM Res., YORKTWN HGHTS, NY; [2]The Rockefeller Univ., New York, NY

Abstract: We collected data from ECoG measurements (invasive electrocorticography) in epileptic human patients. These measurements are used by clinicians as part of a procedure prior the approval of surgery. Each electrode is placed on a grid over the exposed cortex and registers the synchronized activity of thousands of postsynaptic potentials. Since the procedure is invasive, the spatial resolution of this measurements is considerably higher than noninvasive EEG.

It is widely believed that there are pathological waveforms in these recordings which can be associated with epileptic seizures. Moreover, interictal spikes are used as a diagnostic tool for determining the spatial location of the seizure focus. The dynamical connection between interictal spikes and the onset of seizures remains elusive [1]. In this work we apply a nonlinear lter to detect interictal spikes in ECoG recordings. We nd highly stereotyped waveforms with at least two timescales which occur when the subject is undergoing anesthesia. The occurrence of these events is highly correlated amongst sites on the grid.

As the subjects undergo anesthesia, several dynamical features of the recorded timeseries are a ected. Previous work by our group and others suggest that the brain operates in a dynamically critical regime [2, 3]. Here, we perform a moving VAR analysis on our dataset and show that the spectral properties of the linear stability matrix change signicantly. When the subject is awake, many modes are poised close to the instability. Finally, when the subject is unconscious, the system becomes more stable.

This empirical evidence is consistent with the idea that dynamical systems capable of optimally performing computations should be poised at the critical regime [4].

Title: Slow (DC) Potentials of the living human brain

Authors: *E.-J. SPECKMANN[1], A. GORJI[2];
[1]Univ. Munster, Munster 48149, Germany; [2]Epilepsy Res. Ctr., University Munster, Germany

Abstract: DC potentials of the brain comprise sustained displacements of the baseline as well as fluctuations between 0 Hz and 100 Hz including the frequency range of the conventional EEG. Neurons, glial cells and blood-brain barriers forming functional units may act as a compound generator of DC potentials. Several investigations both on animal and man have already shown that recordings of DC potentials of the brain provide an objective access to the understanding of higher brain functions as well as pathophysiology of different neurological disorders. The slow components of neocortical DC potential shifts reflect changes in the level of excitation and excitability of the cortex. Epileptiform field potentials, either focal or generalized discharges, are always associated with characteristic deviations of the DC potential in different animal model of epilepsy. Negative DC fluctuation was also observed accompanied by ictal discharges in human brain. In animal experiments, a reduction of the oxygen content of the brain evokes negative DC displacements in both in vivo and in vitro models. The same negative DC deflections were reported in patients suffering from hypoxic brain injuries. Spreading depression, a negative DC deflection, has been shown to play crucial role in aura phase of migraine and cerebrovascular diseases. Psychophysiological studies revealed that DC potentials are highly sensitive to different information processing and to personal characteristics. It seems promising to extend DC potentials studies to provide further insights into mechanisms of brain function and dysfunction.

Title: The effect of ventral tegmental area (VTA) stimulation on slow wave sleep Up-Down states in the prefrontal cortex of anaesthetized rats

Authors: *S. GRETENKORD[1], S. E. GARTSIDE[1], A. REES[1], M. A. WHITTINGTON[2], F. E. N. LEBEAU[1];
[1]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom; [2]Hull York Med. Sch., Univ. of York, York, United Kingdom

Abstract: Cognitive impairment is a key feature of schizophrenia that is associated with abnormal beta (15-30 Hz) and gamma (30-90 Hz) frequency oscillations during wakefulness (Uhlhaas et al., 2008). Sleep abnormalities, however, are also common in schizophrenia where changes in slow wave sleep (SWS) have been linked to cognitive deficits (Manoach et al., 2010, Ramakrishnan et al., 2012). SWS is a brain state that manifests in the local field potential (LFP) as a slow oscillation (<1 Hz) of alternating "Up" states (periods with high frequency gamma activity) and "Down" states (periods with lower frequency activity). The VTA dopamine system is implicated in schizophrenia as well as in sleep regulation.

We have assessed the effect of VTA stimulation on Up-Down states in the prelimbic cortex in male hooded-Lister rats anaesthetized with urethane (1.5-1.8 g/kg i.p.). VTA stimulation changed the LFP from the low frequency-high amplitude SWS pattern to a high frequency-low amplitude rhythm within a few seconds of the onset of the stimulation. This effect was reproducible and lasted for up to 30 seconds beyond the end of the stimulation. Systemic administration of the dopamine $D_{1,5}$ receptor antagonist SCH23390 (0.6 mg/kg i.p.) either delayed the transition or completely blocked the LFP response to the VTA stimulation. This blockade could be reversed by subsequent systemic administration of the $D_{2,3}$ antagonist sulpiride (10 mg/kg i.p.).
There was also a trend for the VTA stimulation to increase Up-state duration (comparing a post-stimulation to a pre-stimulation period): an effect which also appeared to be D_1 receptor mediated.

Our LFP recordings indicate a strong modulation of the prefrontal slow wave activity by dopamine which is $D_{1,5}$ mediated. The effect of sulpiride suggests that electrically-evoked dopamine release in the prefrontal cortex is sensitive to D_2 autoreceptor modulation such that blockade of D_2 (auto)receptors can overcome the effects of postsynaptic $D_{1,5}$ blockade. Our results are consistent with the results of Lewis and O'Donnell (2000) who reported that dopamine release induced by VTA stimulation induces a transition to a long-lasting Up-state in prefrontal pyramidal cells which was $D_{1,5}$ receptor mediated.
A disruption of dopaminergic activity, as apparent in schizophrenia, might also disrupt slow wave sleep in humans. We hypothesize that such a disruption could explain some of the cognitive deficits seen in schizophrenia patients.

Title: Orchestrating the resting brain: Coupling of fast and slow rhythms bypassing alpha

Authors: *A. V. MEDVEDEV;
Ctr. for Functional and Mol. Imaging, Georgetown Univ. Med. Ctr., WASHINGTON, DC

Abstract: Brain oscillations play an important role in the formation of dynamic functional networks involved in information processing. Specific interaction of brain rhythms, or cross-frequency coupling, is observed in sensory processing and memory functions. FMRI-based functional connectivity analysis in the resting state has become a standard tool to study functional networks and their interaction. However, neuronal signatures of the resting state remain largely unknown. We used multimodal brain imaging based on high density EEG in combination with near-infrared spectroscopy (NIRS) to study cross-frequency coupling on a global scale from infra-slow (~0.1 Hz) to fast (~100 Hz) brain rhythms. EEG (Electrical Geodesics, Eugene, OR) and NIRS signals (two bilateral probes covering inferior and middle frontal gyri; CW5, TechEn, Milford, MA) were recorded at rest (4-8 min) in 15 healthy

volunteers. Broadband EEG (0.1-100 Hz) and optical signals (filtered within 0.01-0.1 Hz to target slow spontaneous oscillations of the resting state networks) were acquired. FFT-based time-frequency analysis was performed at frequencies 0.1-100 Hz for EEG and 0.1 Hz for NIRS. Spectrograms were averaged within 9 frequency bands (slow3, slow2, slow1, delta, theta, alpha, beta, low gamma and high gamma) and their time courses were correlated pairwise. Significant temporal correlation between gamma-band (30-100 Hz) and low frequency modulations (preferentially slow1 and delta bands 0.6-4 Hz) was observed in EEG of all subjects. This correlation was highest in the frontal midline electrodes with weaker secondary maxima in the central parietal and inferior frontal-temporal electrodes. The lowest correlation was observed between gamma and alpha activity. Of all EEG frequencies, gamma power modulations showed the highest correlation with infra-slow hemodynamic modulations at 0.1 Hz while alpha activity showed the lowest correlation with NIRS. These results extend previous observations on the correlation of gamma activity with slower rhythms (mostly theta) during specific cognitive tasks. In the resting state, which is distinct from both cognitive processing and slow-wave sleep, gamma-band activity is coupled with slow rhythms 0.6-4 Hz. Interestingly, gamma power modulations also showed the best correlation with hemodynamic activity. Overall, these results demonstrate global coupling between high and low frequency rhythms of the brain including slow hemodynamic processes. This suggests that such coupling is indicative of the cooperation within the global hierarchy of brain rhythms spanning several levels of organization from cellular to neural network to regional vascular.

Title: Dose-dependent effects of isoflurane on large-scale intra-cortical communication in the ferret

Authors: F. FISCHER, *F. PIEPER, E. GALINDO-LEON, G. ENGLER, A. K. ENGEL; Dept. of Neurophysiol. and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Functional connectivity of brain regions is altered by the administration of anesthetics, leading to the intended reversible loss of perception of external stimuli during surgery. However, the emergence of altered connectivity patterns during gradual change of the anesthesia is not yet well understood. Here, we have investigated connectivity changes in anesthetized ferrets during step-wise increase and decrease of isoflurane concentration. We recorded the spontaneous cortical activity using a custom-made 64-channel subdural electrode array (ECoG) adapted to the ferret's left parieto-temporo-occipital cortex (N=5). The recording sites had a diameter of 250µm and were equally spaced at 1.5mm distance. LFP-like data were filtered between 0.1 Hz and 357 Hz, digitized and down-sampled to 1.4 kHz. We systematically varied the concentration of ventilated isoflurane between 0.4% and 1.6% in steps of 0.2%, and the MAC values were recorded. At each step the concentration was kept constant for 20 minutes to allow equilibration of a stable network state. The last three minutes of this epoch were chosen for analysis. All recordings were performed in a sound- and light-attenuated chamber. Data analysis was performed with Matlab, partly using the 'fieldtrip'-toolbox. We show that the spectral composition of the region-specific (primary visual, parietal and primary auditory) cortical activity changes as a function of the isoflurane concentration. Especially at low frequencies around 0.1Hz we find small correlated and phase-locked cortical patches that show a strong, systematic increase in size with increasing isoflurane concentration up to 1.2%. Further increase of the isoflurane concentration, however, yields a breakdown of the large phase-stable patches and distinct groups of spatially separated but synchronized recording sites emerge. For frequencies between ~1Hz up to 128Hz, overall power-correlations gradually increase across the spectrum as a function of the isoflurane concentration with some specific peaks at ~1Hz and ~3.5Hz. However, within primary visual and auditory areas we observe lower synchronization in the delta-, theta-, and alpha-band compared to higher brain regions. Our data suggest that network states vary with the dose of isoflurane, causing intrinsic changes in cortico-cortical information routing. These findings may be important for better understanding the neural mechanisms leading to loss of consciousness under anesthesia.

Title: Electrophysiological correlates of cortical programs during planned and unplanned terminations of movements in humans with different levels of impulsivity and hyperactivity

Authors: *A. B. TREMBACH, D. SAMARSKIY, V. TOLOKONIKOVA, T. PONOMAREVA, O. KLEIMENOVA;
Rehabilitology, Univ. of Physical Educ., Krasnodar, Russian Federation

Abstract: Our studies showed that hyperactivity and impulsivity are the predominant symptoms in adults with Attention-Deficit/Hyperactivity Disorder (ADHD). It may be caused by disturbances in inhibition system during realization of termination of motions. However, its electrophysiological correlates are not clear. Purpose of the study was to analyze dynamics of EEG during planned and unplanned terminations of movements in healthy and ADHD patients. EEG was recorded in the two groups: healthy (23) and ADHD (25) subjects during resting state, initiation, realization and termination of voluntary movement (M.Adduction policis). Termination of movement was analyzed in two experimental conditions: planned voluntary movement on their own accord and unplanned - the prohibition on the movement in the paradigm of GO/NOGO. The Grand-average topographic maps of EEG spectrum power (EEGSP) and inter- and intra- hemispheric EEG spectrum power coherence (EEGCoh) in frequency band 4-47 Hz were compared in each group between experimental situations. TMS was applied for recording motor evoked potentials (MEP) of M. Adduction pollicis for detecting excitability of primary motor cortex during rest state and termination of movement. Healthy subjects. Planned termination of movement is accompanied by improved EEGSP across the cortical surface in the band of 8-10 Hz and in frontal areas in the bands of 25-35, 36-47 Hz. EEGCoh predominantly increased within these ranges between front and parietal areas of the cortex. Unplanned termination of movement was accompanied by improved EEGSP, EEGCoh in frontal areas in band 11-13 Hz and right hemisphere in the band of 14-24 Hz. Amplitude of MEP of M. Adduction pollicis decreased from 2,1 to 1,1mV. ADHD patients. During planned termination of movement increased EEGSP, EEGCoh was detected all surface of the cortex in the band of 4-7, 8-10 Hz, in the central areas of the cortex - in band 11-13, 14-24, 25-35 Hz. However EEGCoh these frequency bands decreased. During realization of unplanned termination of movements EEGSP increased in the left hemisphere in the band of 8-10, 14-24 Hz and in the parietal and occipital regions of the cortex in the band of 11-13 Hz. . Amplitude of MEP had not changed. Increase of cortical activity in most the frequency bands for the planned termination of motion and its reducing in the frontal areas, constancy excitability of the motor cortex in patients with ADHD compared with healthy subjects may be due to disruption of mechanism the inhibition of motor acts.

Title: Effective connectivity mapping in humans using hybrid electrocorticographic recordings

Authors: Y. WANG[1], *A. KORZENIEWSKA[2], F. HIGGEN[4], N. E. CRONE[3];
[1]Biomed. Engin., [3]Neurol., [2]Johns Hopkins Univ., Baltimore, MD; [4]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Electrocorticographic signals reflect cognitive processes of underlying neural networks with unique temporal resolution. Newly introduced hybrid electrodes combining macro with microelectrodes provide high spatial resolution. Therefore, task-related functional cortical interactions can be mapped with finer details. We used hybrid electrodes to investigate the dynamics of high-gamma (70-120 Hz) effective connectivity during word reading, visual naming, and word repetition tasks of different perceptual modalities and speech production pathways using event-related causality (ERC). Patterns of causal flows among large-scale networks revealed stimulus- and response-dependent dynamics in the functional topography of eloquent cortex (Fig 1a). During perceptual processing, word reading and visual naming showed bi-directional flows between basal temporal (visual) cortex and Broca's area, while word repetition showed flows from superior temporal gyrus (STG, auditory) to Broca's. In processing related to spoken responses, visual naming, which required word retrieval, showed flows from Broca's to tongue motor area and interactions between motor and basal temporal cortices, while word reading and repetition showed mostly flows among tongue motor areas with weak flows from motor areas to STG. Patterns of flows among local networks within a microelectrode array over ventral postcentral gyrus (Fig. 1b) showed similar differences in relation to spoken responses. The biggest macroelectrode flow (Fig. 1a) was across the micro array, consistent with the array's location in tongue motor area. Among the tasks the most prominent flows occurred during visual naming. The largest flow occurred consistently between the same pair of electrodes in relation to spoken responses during all tasks. To sum up, microelectrode recordings let us observe patterns of effective connectivity among local networks and demonstrate variability in

cortical interactions that are consistent with macro-scale recordings.

Title: Quantifying the effects of transcranial magnetic stimulation via computational modeling & electrophysiology

Authors: *B. D. GOODWIN[1], C. R. BUTSON[2];
[1]Biomed. Engin., Marquette, Milwaukee, WI; [2]Neurol. and Neurosurg., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Transcranial magnetic stimulation (TMS) is a method to non-invasively modulate neural activity in the brain. During TMS, a coil is held to the head and energized by the discharge of a capacitor bank; the resulting magnetic field induces current flow in cortical tissue. TMS has been used for investigating the pathophysiology of movement disorders, as well as treating conditions such as depression, blepharospasm, and tinnitus. However, we currently lack a way to quickly and accurately predict the effects of TMS. Such information is critical for

quantifying its effects and gaining a more detailed understanding of the interactions between brain tissue and imposed magnetic field. Computational models have been shown to be a useful and accurate way to predict electromagnetic field interactions within the brain incurred by TMS. Two ongoing challenges in these models are their adaptability to individual subjects, and their ability to predict neural activation. Our objectives were to develop a subject-specific finite element model for TMS that provides the following capabilities: 1) predicts electromagnetic fields for a wide range of coil orientations and tissue properties using a single finite element mesh; 2) predicts neural activation that results from the applied electromagnetic fields. We use electroencephalography (EEG) and electromyography (EMG) to corroborate model predictions on a subject-specific basis. We used computational models combined with electrophysiology to predict neural activation in the hand area of motor cortex during TMS. We designed a coil model based on x-ray measurements (Salinas F, et al., 2007) and a subject-specific finite element mesh to predict electromagnetic fields for arbitrary TMS coil positions and orientations. We then used individual biophysically based pyramidal cell models placed in cortex to quantify the neural activation that occurs during stimulation of the hand knob of motor cortex (M1). A navigation system was used to record coil position/orientation; EMG and 128-channel EEG were recorded while simultaneously administering TMS to the hand-knob in M1. EMG was used to measure motor response magnitude while EEG was used for source localization. An independent component analysis algorithm was used to remove TMS signal artifacts from the EEG. Preliminary results indicate that motor response is acutely sensitive to coil position and orientation, and that physiological recordings can be integrated with computational models of TMS to predict and characterize the sensitivity of the neural response.

Title: Synchronized brain activity rebound during REM sleep after selective REM sleep deprivation in man

Authors: R. SIFUENTES-ORTEGA[1], Y. DEL RÍO-PORTILLA[1], A. ROSALES-LAGARDE[2], O. A. ROJAS-RAMOS[1], *M. CORSI-CABRERA[1];
[1]Univ. Nacional Autonoma Mexico, Mexico DF, Mexico; [2]UAEM, Morelos, Mexico

Abstract: Synchrony of fast activity has been postulated to be a common language of the brain involved in processing and integrating information. Converging evidence from neuroimaging and EEG has demonstrated that synchrony/temporal coupling of brain activity changes during rapid eye movement (REM) sleep in comparison to waking and non-REM sleep, increasing between the two hemispheres and decreasing between frontal and posterior association areas. Total sleep deprivation causes homeostatic responses during subsequent recovery sleep; however, total sleep deprivation suppresses both REM and non-REM sleep and homeostatic response of REM cortical synchrony after selective REM sleep deprivation has not yet been studied.

The aim of the present study was to explore the effects of selective REM sleep deprivation (REM-D) on cortical temporal coupling of gamma activity during recovery REM sleep using EEG recordings (19 derivations, 1024 sampling rate). Interhemispheric and intrahemispheric EEG correlations (30-50 Hz) were obtained for the first 3 REM episodes (including phasic events) and for segments without eye movements (tonic REM sleep) during baseline and during recovery nights after one night of selective REM sleep deprivation.

Nineteen healthy subjects were randomly assigned to either selective REM-D, by awakening them at each REM onset, or non-REM interruptions as control for non-specific effects. Subjects slept 4 consecutive nights in the laboratory, the first for habituation, second as baseline, third for sleep manipulation and fourth for recovery.

Interhemispheric temporal coupling and fronto-posterior association areas of the left hemisphere showed a significant homeostatic rebound: interhemispheric temporal coupling increased, while fronto-posterior association areas decreased after REM sleep deprivation.

Present results indicate that after REM sleep deprivation there is a rebound in the increased coupling between the two hemispheres and uncoupling between frontal and posterior association areas normally occurring during REM sleep and suggest that cortical coupling/uncoupling of cortical activity during REM sleep has functional consequences.

In conclusion, these results support the hypothesis that synchronized activity during REM sleep may play an important role in integrating and reprocessing information.

Title: Acute role of corpus callosum on cortical synchrony in humans: Intraoperative electrocorticographic recording before and after callosotomy

Authors: *O. A. ROJAS RAMOS[1], R. ONDARZA[2], J. RAMOS-LOYO[3], I. Y. DEL RÍO-PORTILLA[1], D. TREJO-MARTÍNEZ[4], M. A. GUEVARA[3], M. CORSI-CABRERA[1]; [1]UNAM, Mexico City, Mexico; [2]Inst. Nacional de Neurología y Neurocirugía MVS, Mexico City, Mexico; [3]Inst. de Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico; [4]Hosp. Gen. de México Dr. Eduardo Liceaga, Mexico City, Mexico

Abstract: Synchronization of neural activity between cortical regions is a basic mechanism for integrating information. The use of intraoperative electrocorticography (ECoG) during surgery in patients undergoing callosotomy due to intractable epilepsy offers a unique opportunity to investigate -with greater spatial resolution but no additional surgical intervention- the role of the corpus callosum in cortical synchrony/temporal coupling while avoiding long-term functional reorganization effects.
To investigate the acute role of the corpus callosum on inter and intrahemispheric coherent activity ECoG was recorded during surgery in three patients, in accordance with the Helsinki Declaration, immediately before and after anterior two-thirds callosal transection.
Bilateral electrode grids were placed over frontal cortex and ECoG was recorded and digitized at a sampling rate of 512 Hz, inspected for artifacts and analyzed offline. Spectral power and cross-correlation between inter- and intrahemispheric electrode pairs were obtained for 1 Hz bins and broad bands for each patient immediately before and after callosotomy.
Intrahemispheric temporal coupling decreased significantly in almost all electrode pairs after callosal transaction in the three patients, whereas interhemispheric correlations values were generally very low and did not show significant differences.
In conclusion, interrupting the influence of the corpus callosum acutely affects activity of the contralateral hemisphere by decreasing intrahemispheric temporal coupling. The present results indicate that intrahemispheric temporal coupling does not depend exclusively on ipsilateral cortico-cortical pathways or on subcortical influences, but also on callosal pathways, and suggest that callosal connections play a role in local activity within each hemisphere.
This work constitutes part of an academic thesis of the Psychology PhD program at UNAM.

Title: Considerations regarding the interpretation of standardized low resolution brain electromagnetic tomography source analysis

Authors: *J. A. CORTES, J. D. CAHILL, M. RANGANATHAN, R. A. SEWELL, D. C. D'SOUZA, P. D. SKOSNIK;
Yale Univ., New Haven, CT

Abstract: Standardized low resolution electromagnetic tomography (sLORETA) is one of the most popular linear source analysis techniques for the electro and magnetoencephalogram. In this technique, the solution space (e.g. the cortex) is divided in a number of voxels, each of which is assigned a three dimensional vector representing the magnitude and direction of the local current density flow. It's a common practice to convert each current density vector (CDV) into a single positive number consisting in the vector's absolute value. This step facilitates the graphical representation of the activity (one value per voxel) and the statistical analyses. However, it introduces a number of problems that need to be explored and characterized. First, the neural distribution of current density absolute values (CDAV) is no longer a reconstruction of the neural generators underlying the activity recorded at the scalp sensors. Instead, it is a representation of the strength or magnitude at each voxel of the neural activity that co-occurs with the signals recorded at the scalp. CDAVs lack the information about the direction or the polarity (depending on whether the vector's direction is fixed for each voxel) of the CDVs that allow linking the source reconstruction with the observed distribution of activity at the scalp sensors. Thus, CDAVs may increase the risk of considering as a neural generator of some specific scalp response (e.g. the P300
ERP) the activity of voxels not directly involved in it.
Second, it makes the statistical comparisons between groups at the voxel level a comparison between positive scalars. Therefore, the magnitude of the difference between voxels whose vectors change their directions or polarities in the different groups may be greatly reduced. Thus, significant differences between the neural generators underlying the scalp responses associated with different groups may pass
unnoticed.
Third, the inter-subject variability associated to the changes in the directions or polarities of the CDVs of each single voxel may become artificially decreased. Therefore, the comparison of the absolute values of the neural generators underlying the scalp responses of different groups may incorrectly and unpredictably increase or decrease the statistical significance of the differences between them.
To explore these concerns we conducted source analyses on realistic simulations of scalp EEG

recordings. The CDVs and CDVAs were computed and compared. The results of the simulations supported our concerns, suggesting that some of the conclusions that have been previously drawn on the basis of the CDVs may need to be revised.

Title: Knowledge-based query and classification of event-related potentials: The neural electromagnetic ontology (nemo) portal

Authors: *N. A. DUNN[1], G. FRISHKOFF[3,2], R. M. FRANK[2];
[1]Computer and Information Sci., [2]NeuroInformatics Ctr., Univ. of Oregon, Eugene, OR;
[3]Psychology, Georgia State Univ., Atlanta, GA

Abstract: We introduce the Neural ElectroMagnetic Ontology (NEMO) Portal, a web application for classification and storage of event-related potential (ERP) data. The data are represented in Resource Data Format (RDF) files and are automatically generated by the NEMO analysis workflow. These files encode metrics (e.g., peak latency) for each ERP pattern in a dataset. Each pattern is represented as an instance of the superclass ERP_scalp_recorded_component (NEMO-0000093), and is linked to the metrics through assertions such as "Pattern 001 has_peak_latency 120 ms." Specific patterns have defining rules within the ontology, which are used for pattern classification. For example, the N100 is defined as a subclass of NEMO-0000093 that "is maximal over occipital sensors 140-220 ms after onset of a visual stimulus." Thus, if a pattern instance has these properties, a reasoner can infer that it belongs to the N100 pattern class. Previously, we performed inferences in Protégé and would then upload results to the Portal. The Portal now runs inside a Java Virtual Machine, which allows direct integration with the OWLAPI. Thus, data are now classified and labeled automatically when users upload their RDF files. Additions to the graphical interface make it easy to query and retrieve labeled patterns from different datasets and to display their corresponding waveforms and topographic maps (Fig. 1). This means that we can now process and view multiple datasets using an integrated, online application. This represents a major step

towards our goal of providing support for high-quality meta-analysis of ERP data.

Title: Atypical patterns of EEG activity and functional connectivity in children with autism

Authors: *N. N. LUCAS, M. PINEDA, N. AARON JONES;
Psychology, Florida Atlantic Univ., Boca Raton, FL

Abstract: Autism is a neurodevelopmental disorder characterized by deficits involving social interaction, communication, and perception. Prevalence estimates have dramatically increased with the current prevalence estimated at one in 88 births. Studies using electroencephalogram (EEG) have shown reduced functional connectivity throughout the brains of autistic individuals, particularly in the beta, delta, and theta frequency bands. In addition, increases in theta power and decreases in alpha and beta power have been reported. Anomalies in EEG coherence and power have been associated with deficits in executive function and mental activity. Although there is much research that has examined EEG activity in individuals with autism, none have examined very young children while awake using EEG power and coherence measures. The present study examined neural activation in children ages 3 -5, during an eyes-closed baseline period. During data collection, children were seated in a chair and fitted with a 14-lead EEG cap with electrodes positioned according to the international 10-20 system. A baseline recording of 3 minutes was collected during quiet wakefulness. Discrete Fourier Transform was performed on artifact-free segments of EEG data to produce power density values. Relative power was examined in the frontal (F3, F4, F7, & F8), temporal (T3, T4, T5, & T6), central (C3 & C4), and occipital (O1 & O2) brain regions. Coherence measurements were examined between the frontal,

temporal, and central region electrodes, as well as between the fronto-temporal regions and between occipital and frontal regions to assess functional connectivity in the alpha bandwidth during the baseline recording. The EEG coherence measurements between channels were obtained by using the complex conjugates of the Fourier coefficients and calculating the average cross spectrum. The value was then squared and normalized by the average residual power spectrum to yield the coherence statistic. Children with autism demonstrated reduced alpha coherence in fronto-temporal regions and between right temporal sites when compared to typically developing (TD) children. In addition, the reduction in coherence was based on autism severity, such that high-functioning children with autism showed greater coherence than low-functioning children with autism. Children with autism also displayed reduced power in the alpha, beta, and delta frequency bandwidths in frontal, temporal, central, and occipital regions compared to TD children. Thus, children with autism exhibited abnormal patterns of brain activity and functional connectivity compared to their typically developing counterparts.

Title: Efficacy of tACS depends on endogenous oscillatory power

Authors: T. NEULING[1], S. RACH[1], *C. S. HERRMANN[2];
[1]Exptl. Psychology Lab., [2]Psychology, Oldenburg Univ., Oldenburg, Germany

Abstract: Transcranial alternating current stimulation (tACS) is able to modulate brain oscillations in a frequency specific manner. This offers the possibility to demonstrate a causal relationship between brain oscillations and behavior. Furthermore, tACS is a strong candidate as a tool for clinical applications, however, to fulfill this potential, certain parameters have yet to be evaluated. First, little is known about long-lasting after-effects of tACS with respect to the modulations of rhythmic brain activity. Second, the power of endogenous brain oscillations might play a crucial role in the efficacy of tACS. We hypothesize that the after-effects of tACS depend on the endogenous power of oscillations. To this end, we modulated the power of

endogenous occipital alpha oscillations via tACS. In two experiments, participants either had their eyes open or closed to keep endogenous alpha power either low or high while they were stimulated for 20 min with their individual alpha frequency (IAF) and simultaneously performing a vigilance task. After-effects on IAF power were evaluated over a course of 30 min with a pre stimulation period serving as baseline. After-effects were strongly dependent on IAF power. Enhanced IAF power was observed for at least 30 min after tACS under conditions of low endogenous IAF power, whereas, IAF power could not be further enhanced by tACS under conditions of high IAF power. The current study demonstrates, for the first time, a long lasting effect after tACS on endogenous EEG power in the range of the stimulation frequency. Additionally, we present conclusive evidence that the power of the endogenous oscillations has a critical impact on tACS efficacy. Long lasting after-effects foster the role of tACS as a tool for non-invasive brain stimulation and demonstrate the potential for therapeutic application to reestablish the balance of altered brain oscillations.

Title: The decoding of emotional information: Insights from intracranial recordings in humans

Authors: *A. CHRISTEN[1,2], L. TAMARIT[2], L. SPINELLI[3], M. SEECK[3], D. GRANDJEAN[1,2]; [1]Univ. of Geneva, Geneva, Switzerland; [2]Swiss Ctr. for Affective Sci., Geneva, Switzerland; [3]Dept. of Neurol., Hôpitaux Universitaires Genevois, Geneva, Switzerland

Abstract: The decoding and the orientation of attention towards emotional information is a central ability that ensure efficient social functioning and behavioral adjustments in our daily life. Although functional neuroimaging data reveal that the amygdala and the orbitofrontal cortex (OFC) are strongly involved in emotion perception, their underlying neuronal dynamics and functional connectivity have not yet been directly investigated in humans. We addressed this issue by recording local field potentials (LFPs) from two epileptic patients who had intracranial macro-electrodes implanted along a mediolateral axis in their temporal and orbitofrontal regions, targeting both amygdalae and the right OFC. In order to manipulate voluntary attention orthogonally to emotional prosody, we used a dichotic listening paradigm, in which the patients were asked to pay attention to one ear in order to perform a gender decision task, while two

sounds were delivered simultaneously (one in each ear for each trial) and appeared in a pseudorandom order. The pseudo-words were presented in both ears, being either neutral on both sides (neutral/neutral), or angry on one side and neutral on the other (anger/neutral or neutral/anger). Our results show that the processing of auditory angry stimuli enhances the power of low-frequency bands and entrains selective, early, and sustained amygdalo-medial OFC synchronization in theta and alpha rhythms. Furthermore, attentional modulations on emotion processing increase high-oscillatory activity (beta and gamma bands) within both regions, although the amygdalae and the medial OFC are more sensitive to the processing of unattended and attended anger stimuli, respectively. Moreover, early and later long-range theta phase coupling in amygdalo-medial OFC regions is augmented during reflexive shifts of attention towards anger stimuli. We propose that the detection and perception of incoming emotional information is achieved through rapid, sustained, and long-range functional amygdalo- medial OFC coupling in low-frequency bands.

Title: Excess gamma-band activity in schizophrenia interferes with auditory cortical processing

Authors: *L. HAYRYNEN[1], J. P. HAMM[1], S. R. SPONHEIM[2,3], B. A. CLEMENTZ[1]; [1]Univ. of Georgia, Athens, GA; [2]Minneapolis VA Hlth. Care Syst., Minneapolis, MN; [3]Univ. of Minnesota, Minneapolis, MN

Abstract: Low-gamma band cortical activity and prolonged entrainment to 40 Hz auditory steady state stimuli is augmented in a subset of schizophrenia patients (SZ) and in animals administered NMDA antagonists (e.g. ketamine), possibly indicating in both cases disruptions of signal-to-noise ratio in cortical circuits due to imbalances in GABA/glutamate controlled neuronal activity. The current study sought to further understand how these gamma-band augmentations relate to SZ related abnormalities in basic and complex sensory processing in auditory cortices. 248-sensor magneto-encephalography data were collected for 15 SZ and 15 H during an auditory oddball paradigm (25% targets; 1 sec ISI). Auditory stimuli (pure tones: 1

kHz standards; 2 kHz targets) were administered during 4 continuous background (auditory steady state) stimulation conditions: (1) no stimulation; (2) 24 Hz; (3) 40 Hz; (4) 88 Hz. We quantified the disruption of the auditory steady state response (aSSR). This manipulation allowed a measurement of whether enhanced ongoing gamma entrainment in SZ, and related gamma-band augmentations, came at the cost of salient stimulus processing. A Fast Fourier Transform (FFT) was performed in 300ms steps (starting 300ms prestimulus) on continuous single trial data to index the oscillatory power at the driving frequencies of interest (24, 40, 88Hz). Ten peak sensors (five per hemisphere) were chosen based on signal strength and topography. A repeated measures ANOVA was then performed with one between-subjects factor (Diagnosis: SZ, H) and two within-subjects factors (Time: prestimulus, first, second, third 300ms bins; Stimulus: targets, standards) for each steady state stimulation condition. Results indicate a that SZ have accentuated aSSR entrainment at 40 Hz, but not 88 Hz, stimulation conditions compared to H, consistent with reports of sustained gamma-band augmentation seen in NMDA-hypofunction models of psychosis. Additionally, SZ have a significant decrease in power of the ongoing 40Hz steady-state entrainment at the onset of the oddball stimuli (targets and standards). This finding indicates that augmented aSSRs reflect SZ but not H dependence on local (low gamma range) processing to identify stimuli, thus being more dependent on the physical properties of the stimulus.

Title: Population coding with higher order correlations

Authors: *N. CAYCO GAJIC[1], J. ZYLBERBERG[2], E. SHEA-BROWN[2];
[1]Dept. of Applied Mathematics, [2]Univ. of Washington, Seattle, WA

Abstract: Higher-order correlations (beyond pairwise spiking statistics) have been observed in the brain and have been shown to affect coding facility. In the case of pairwise correlations, having signal and noise correlations of the opposite sign will cancel redundancies and allow for better coding; however, no such general rules have yet been investigated for higher-order

statistics.
To understand the effects that higher-order correlations may have on coding capacity in neural populations, we take the approach of assuming that the stimulus-conditioned lower-order statistics - that is, mean firing rates and pairwise noise correlations - are fixed. What is the range of effects that triplet correlations may have on two-stimulus discrimination between given noisy population responses whose lower moments are constrained, e.g. by experiment? For fixed first and second moments, we sweep over possible third-order cumulants by fitting the third-order maximum entropy distribution using the Improved Iterative Scaling algorithm for small networks (up to N = 10 due to computational time). Then, for all possible third-order cumulants under each stimulus, we calculate the mutual information between the two stimuli and the response distributions. We find that, as long as pairwise noise correlations have realistic (small) values, the optimal solution is to increase triplet spiking for the stimulus that induces lower rates, and to decrease triplet spiking for the stimulus that induces higher rates.
How can such higher-order correlations be realized? Recent work suggests that intrinsic nonlinearities in single neurons contribute to such higher-order correlations at the population level: we explore the role of dendritic nonlinearities. First, we interpret our optimized statistical model in light of the of data of Polsky et al., assigning a functional role for their finding that two small inputs to the same dendritic branch are summed superlinearly whereas larger inputs to the same branch should be summed sublinearly. We investigate the viability of this mechanism to produce beneficial higher-order correlations in a balanced network of integrate-and-fire neurons, computing the information that network responses have about its inputs both with and without dendritic nonlinearities.

Title: Refractory periods following spontaneous ripples create opportunities for cortical feedback

Authors: *D. J. KANAK[1,2], G. M. ROSE[1,2], P. R. PATRYLO[1,2];
[1]Dept. of Physiol., Southern Illinois Sch. of Med., Carbondale, IL; [2]Ctr. for Integrated Res. in Cognitive & Neural Sci., Carbondale, IL

Abstract: The sharp wave ripple complex (SWR) is a network pattern generated in the CA3 subregion of the hippocampus (HC) that is believed to facilitate memory consolidation by coordinating the reactivation and transfer of information to the neocortex (NC). While SWRs can arise independently in CA3, their initiation may be biased by neocortical activity. Our in vitro slice study examined the capacity of perforant path (PP) synaptic excitation to elicit SWRs from a spontaneously active pattern generator. Low-intensity electrical stimulation (25-50 μA, 0.5 Hz, 100 pulses) evoked monosynaptic field EPSPs in CA3 that were closely followed by precisely-timed evoked SWRs (eSWR). Although field EPSP amplitudes were stable throughout the stimulus train, a subset of stimuli failed to elicit eSWRs, particularly when closely preceded by spontaneous SWRs (sSWR). We designed a near real-time MATLAB/Simulink application to control stimulus timing during the ~250 ms refractory periods that followed sSWRs. Stimulus delay (25, 50, 100, and 200 ms) had a highly significant effect on eSWR incidence ($F_{1.85, 14.84} = 48.74$, $p < 0.001$, RM-ANOVA), with a maximum value of 0.72 (95% CI = [0.61, 0.81]) 200 ms after sSWR onset. In contrast, the estimated incidence of sSWRs was much lower throughout the refractory period, reaching a maximum value of only 0.03 (95% CI = [0.015, 0.049]) at 200 ms. Fixing the stimulus delay at 200 ms, we then compared the network and single cell properties of sSWRs and eSWRs. Both exhibited ripple oscillations of comparable power and frequency, and both were associated with similar temporal patterning of single unit activity. Stimulating the medial entorhinal cortex (MEC) could also elicit eSWRs, and lesions targeting the direct PP input to CA3 while sparing the DG substantially reduced eSWR incidence. In summary, direct MEC input to CA3 can initiate SWRs at times when self-organizing mechanisms generally cannot. Assuming sSWRs convey information to the NC, the ensuing refractory periods might allow opportunities for cortical feedback to reinforce the recently engaged cell assembly. In the absence of such feedback, CA3 could then resume the quasi-random process of self-organizing the reactivation of its memory content.

Title: Functionally stable hippocampal network: Role of inhibition vs. short-term plasticity

Authors: *A. M. HUMMOS, S. NAIR;
Dept. of Electrical and Computer Engin., Univ. of Missouri, COLUMBIA, MO

Abstract: The associational recurrent connections in the hippocamapal CA3 area support specialized hippocampal functions from retrieval of memories given partial cues to replaying temporal sequences of memories. Nevertheless, the same property renders the network inherently unstable and susceptible to runway excitation and synchronized aberrant discharges. Such instability poses serious problems in building a functioning hippocampal model while avoiding such catastrophic dynamics.
We developed a biophysical model of entorhinal cortex (EC), dentate gyrus (DG), and region CA3 using biological data and known recordings at multiple levels. We match cell behaviors, kinetics of synaptic currents, short-term and long-term synaptic plasticity, and network connectivity and 3D organization. The model's functionality and validity were assessed by its ability to perform pattern separation and pattern completion matching experimental recordings from DG and CA3. Finally, candidate stability mechanisms used in constructing the model were further evaluated.
Adding the inhibitory basket cells (BC) to the model improved stability, but at the expense of the model's ability to form stable representations. In contrast, implementing short-term synaptic depression at the CA3 associational/commissural recurrent connections proved successful at enhancing stability while maintaining the functional representations needed for the model to perform its tasks. Importantly, and contrary to our initial hypothesis, adding OLM inhibition did not provide significant advantages in network stability.
Our results indicate a prominent role for short-term synaptic depression at AC fibers in the stability of the network. Additionally, the results also suggest a limited homeostatic role for both BC and OLM interneurons at the studied timescale. Such results challenge the current conceptualization of OLM cells as 'feedback' inhibitory cells and point towards other roles, mainly, generation of theta oscillatory behavior which we investigate in detail.

Title: Ventral postrhinal cortex: A strong inhibitory network in the absence of parvalbumin-expressing interneurons

Authors: *A. U. SUGDEN, S. L. PATRICK, A. ANAND, R. D. BURWELL, B. W. CONNORS;
Brown Univ., Providence, RI

Abstract: Synaptic inhibition in the cerebral cortex is vital for gain control, regulating temporal and spatial features of coding, generating gamma oscillations, and preventing seizures. Inhibitory interneurons in neocortex are diverse. The broadest categories include parvalbumin (PV)-, somatostatin (Som)-, and 5HT3aR-expressing cells; PV cells are the most common class, comprising about 40% of the interneurons in most cortical areas. However, in the ventral postrhinal cortex (vPOR; a parahippocampal region), PV cells are essentially absent. We asked how inhibitory functions are achieved in a cortical circuit that lacks PV interneurons. Interneuron distributions were analyzed using immunohistochemistry and transgenic mice that express fluorescent proteins selectively in interneuron subtypes. The density of PV interneurons was dramatically lower in vPOR than in adjacent regions such as dorsal POR (dPOR). The densities of Som and 5HT3aR interneurons, by contrast, were similar in vPOR and dPOR. Thus, there are fewer interneurons overall in the vPOR. Whole-cell recordings from vPOR pyramidal cells showed that spontaneous IPSCs were similar in amplitude but lower in frequency compared to those of dPOR cells. Surprisingly, when all types of interneurons were activated optically or electrically, inhibitory currents in pyramidal cells of vPOR and adjacent dPOR were indistinguishable. Paired-pulse ratios for electrically evoked IPSCs were similar in both regions of POR. Selective optogenetic activation of PV interneurons triggered IPSCs that were ten-fold larger in cells of the dPOR than in cells of vPOR. This suggests that the absence of PV cell-mediated inhibition in vPOR is compensated for by stronger inhibitory circuits from Som or 5HT3aR cells to maintain normal global levels of inhibition.

Title: Transcranial alternating current stimulation (tACS) induces state switching in interconnected cortical networks

Authors: *F. FROHLICH, K. M. KUTCHKO;
Psychiatry, Univ. of North Carolina, Chapel Hill, NC

Abstract: Non-invasive brain stimulation with transcranial current stimulation (TCS) generates a weak electric field that modulates the membrane voltage of cortical neurons. Using sine-wave stimulation waveforms (transcranial alternating current stimulation, tACS) causes enhancement of cortical oscillations that outlasts the application of stimulation. The underlying mechanism of these outlasting effects remains unknown. Understanding the cellular and network level mechanisms by which tACS causes outlasting changes in cortical activity is critical for rational design of stimulation paradigms that optimize the type and duration of outlasting response based on individual therapeutic needs.

We used large-scale computer simulations of two interconnected networks to probe the effects of weak global perturbations generated by weak electric fields on global "internetwork" dynamics. Both networks consisted of a 2D layer of pyramidal cells (PYs, 160,000 Izhikevich model neurons) and a 2D layer of inhibitory interneurons (INs, 40,000 Izhikevich model neurons). PYs were connected by excitatory synapses. PYs also excited INs that inhibited PYs. The local synaptic connectivity was chosen so the networks intrinsically oscillated at 3Hz. Excitatory long-range projections were sparse and exhibited varying delays (up to 50 msec). Introducing these long-range projections with delays caused the emergence of multiple, metastable activity states with qualitatively different spatio-temporal signatures: (1) rapid fire (globally synchronized), (2) slow, propagating planar waves, and (3) spiral waves. The internetwork spontaneously switched between these states with a time-scale of several seconds. Importantly, the application of tACS not only introduced a switch to the rapid fire, synchronized state in the majority of simulations but also had an outlasting effect after offset of tACS. These results suggest that the outlasting effects of tACS may be mediated by the underlying multistability of cortical internetworks. In this framework, tACS acts as a perturbation that induces state transitions. This contrasts with the prevalent view that effects of TCS are mediated by synaptic or intrinsic plasticity.

In summary, computer simulations of the modulation of large-scale brain dynamics by tACS offer (1) new mechanistic understanding of how non-invasive brain stimulation works and (2)

insights for the generation of novel hypotheses about emergent multistable internetwork dynamics that can subsequently be tested in experiments.

Title: Optogenetic dissection of cortical neuromodulation with transcranial current stimulation

Authors: *S. L. SCHMIDT, F. FROHLICH;
Univ. of North Carolina, Chapel Hill, NC

Abstract: Transcranial Current Stimulation (TCS) has shown promise as a treatment for neuropsychiatric disorders and for augmenting cognition. Specifically, TCS with sine-wave stimulation waveforms (transcranial Alternating Current Stimulation, tACS) may augment cortical oscillations in a targeted manner. However, it remains unclear how to choose stimulation frequencies and amplitudes for optimal treatment responses. Such rational design of non-invasive brain stimulation with individualized stimulation frequency requires an understanding of the interaction between intrinsic oscillations and applied stimulation waveform. Our previous modeling results have suggested that network resonance mediates the effects of tACS on cortical oscillations.

Here, we experimentally tested this hypothesis in vitro through the use of optogenetics. We performed multielectrode array (MEA) recordings of multiunit spiking activity in acute cortical slices while applying electric fields that mimicked the effects of TCS. Multiunit activity recorded on 59 channels spaced 200μm apart allowed us to assess responses in all cortical layers. Using Thy1-ChR2 juvenile mice (p15-p30), which express channelrhodopsin in Layer V pyramidal cells, we successfully entrained the network at 1Hz by applying 500ms pulses of light. We then sought to enhance this rhythm by applying an electric field at the entrained frequency. Furthermore, we examined the effect of applying sine-wave electric fields with frequencies differing from the dominant ongoing network oscillation. We hypothesized that the effect strength of tACS is increased when the frequencies of the ongoing network oscillations and the

stimulation are the same. We quantified entrainment both with frequency analysis and with measures of spike timing relative to the phase of stimulation. Using these measures, we found not only that Layer V pyramidal cells oscillate at 1Hz in response to optogenetic stimulation but also that this change propagated through the network, entraining cells in all cortical layers. Such mechanistic study of the interaction of cortical oscillations and sine-wave electric field stimulation provides an important stepping stone towards rational design of non-invasive brain stimulation with optimized, individualized stimulation frequencies. Such improved tACS paradigms may enable the targeted treatment of psychiatric symptoms such as impaired cognition that are associated with deficits in cortical oscillations.

Title: Targeting cortical oscillations and cognition with transcranial alternating current stimulation (tACS) in humans

Authors: *M. R. BOYLE, A. L. CORDLE, W. L. GORIS, K. K. SELLERS, B. V. VAUGHN, J. H. GILMORE, F. FROHLICH;
Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Transcranial current stimulation (TCS) has been shown to (1) modulate macroscopic brain activity measured by electroencephalogram (EEG), (2) alter behavioral performance in a range of cognitive tasks, and (3) alleviate symptoms in patients with neuropsychiatric illnesses [1]. Recent studies have indicated that TCS with sine-wave stimulation waveforms (transcranial alternating current stimulation, tACS) may modulate cortical oscillations in a frequency-dependent manner. Given the fundamental role of cortical oscillation in cognition, tACS has become increasingly promising as a potential non-invasive treatment for neuropsychiatric

illnesses with cognitive impairment such as schizophrenia and autism.
However, the evidence for a causal link between patterns of EEG activity and specific behavioral function remains incomplete. We here combined EEG, tACS, and behavioral measures to probe the causal effect of non-invasive brain stimulation on both endogenous cortical oscillations and behavioral performance in a battery of psychophysical tests.
We performed whole-head EEG (10-20 system) on healthy human subjects. In the first study, we compared the effect of active sham, 0.75 Hz, and 40 Hz tACS on cortical oscillations during resting (0.75 mA peak-to-peak). In the second study, subjects performed visual working memory, visual detection, and visual closure tasks in random order without stimulation. Subsequently, subjects received 1 hour sessions of sham stimulation, individualized alpha frequency (IAF) tACS, and 40 Hz tACS in randomized order during which they completed the same tasks. In this study, 2mA peak-to-peak stimulation was applied to target occipitoparietal areas. EEG signals were analyzed with independent component analysis (ICA), extreme value rejection (EVR), and Morlet wavelets to extract temporally resolved frequency content of cortical activity.
We found that tACS significantly modulated cortical oscillations. In particular, 40 Hz tACS enhanced gamma oscillations and concurrently suppressed alpha oscillations. These results suggest that tACS can dynamically interact with the endogenous balance of slow "offline" (resting) and fast "online" cortical rhythms. Our combined psychophysical and brain stimulation study will further elucidate the role of such targeted stimulation in modulating cognitive performance.

Title: Modulations and plasticity of oscillation amplitudes and synchronization in human amblyopia

Authors: H. JULKU[1], S. ROUHINEN[1], J. MÄKELÄ[2], H. HUTTUNEN[1], E. CASTRÉN[1], J. M. PALVA[1], *S. PALVA[1];
[1]Univ. of Helsinki, Neurosci. Ctr., University of Helsinki, Finland; [2]HUS Med. Imaging Ctr., BioMag Lab., Helsinki University Central Hospital, Finland

Abstract: Amblyopia is characterized by poor or indistinct vision in an eye that is physically normal and caused by cortical structural and functional abnormalities. Amblyopic eye has lowered visual acuity, temporal integration, motion detection, and perception of multiple visual objects (1,2,3). Functional magnetic resonance imaging has revealed that these deficits are associated with decreased neuronal activity (4,5) and connectivity (6) in the primary visual cortex but also at higher levels of visual cortical hierarchy. Less is known of the electrophysiological correlates of human amblyopia.
In recent years, several studies have shown that oscillations and synchronization are key features in the coordination of visual processing and in the formation of visual object representations (7). To address whether amblyopia is associated with abnormal oscillation amplitudes and synchronization, we recorded ongoing neuronal activity with magnetoencephalography (MEG) and used minimum-norm-estimate based source reconstruction to map neuronal dynamics in the individual cortical anatomy of each patient. Patients were recruited from a clinical study (sponsored by HermoPharma Ltd) that investigated effects of fluoxetine and / or visual training on treatment of adult anisometric and strabismic amblyopia (0.30-1.10 LogMAR). We recorded MEG during several types of visual attention, perception, and memory tasks before and after the treatment. We estimated strength of oscillation amplitudes, synchronization, and evoked responses separately to the amblyopic and the fellow eye. We found that both oscillation amplitudes and their phase-locking to stimulus onset were stronger for stimuli presented to the fellow than to the amblyopic eye in several levels of visual cortical hierarchy. The extent of these changes was also larger for complex visual stimuli. Importantly, oscillation amplitudes were stronger to stimuli presented to the fellow eye not only during processing of visual information, but also during memory retention period suggesting that the deficits in amblyopia extend to higher-level cognitive processing. In the follow-up analyses we will investigate whether fluoxetine and / or visual training treatment modulate the strength of visual evoked responses, oscillations amplitudes and synchronization.

Title: Patterns of oscillatory phase relations in human electrocorticography can be explained by temporal delays

Authors: *R. VAN DER MEIJ[1], J. JACOBS[2], E. MARIS[1];
[1]Donders Inst. For Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [2]Sch. of Biomed. Engineering, Sci. and Hlth. Systems, Drexel Univ., Philadelphia, PA

Abstract: In a rapidly changing environment the brain needs to transfer information over many neuronal networks quickly and flexibly. One way this could be achieved is through consistent phase relations, where an ideal phase relation corresponds to the time delay at which two neuronal populations are at peak excitability. These populations could be close together and at a distance, involving respectively small and large synaptic delays. These shared windows of communication occur rhythmically, are measurable at various spatial scales, and occur across many frequencies.
If consistent phase relations are used for the routing of information, then such consistency should be spread out over the cortex. Characterizing spatially distributed phase relations presents us with two challenges. Firstly, phase relations between many electrodes at many frequencies cannot be analyzed by simple pair wise analyses, as the full spatial and spectral structure would not be captured. And secondly, under the assumption that synaptic delays between two

communicating neuronal populations are constant, a time delay between two locations would be reflected in phase relations that are a linear function of the involved frequencies.
To meet these challenges, we developed a new decomposition technique, with which we model the linear relation between phase and frequency as a time delay. We analyzed 61 human electrocorticographic recordings of 28 patients scheduled for resective epilepsy surgery, while patients were performing a working memory task. We were able to decompose Fourier coefficients over electrodes, frequencies and trials into sets of components. Each component is described by four loading vectors: (1) a frequency profile, (2) a trial profile, and a spatial map describing (3) the degree of involvement of each electrode and (4) the time delays between the electrodes. Thus, each component describes a spatio-spectral pattern of phase relations and, importantly, the temporal structure of possible information flow in the underlying network. Using the above model we were able to extract patterns at different spatial scales and in different frequency ranges.

Abstract: Spontaneous synchronous population activity (SPA) emerges from the cortical slices of epileptic and non-epileptic patients maintained in physiological medium in vitro. SPA was recorded until now using sharp intracellular and laminar extracellular methods to analyze the neural mechanisms giving rise to population synaptic/trans-membrane and spiking activity.
In order to gain additional spatial information about the network mechanisms involved in the SPA generation, we introduced the two-photon Ca-imaging technique on human in vitro slice preparations. The excellent spatial coverage and resolution of this technique supplements the lower spatial resolution but higher temporal resolution of laminar extracellular, sharp intracellular and whole cell patch recording techniques.
Human slices were maintained in a dual superfusion chamber of high flow rate physiological incubation medium and otherwise conventional submerged technique to elicit SPA in a two-photon microscope. The population activity was recorded by laminar extracellular electrodes and with extracellular patch electrode. After identifying the active regions of the slice using electrophysiology techniques, bolus loading of OGB-1 and SR101 was applied on the tissue. The neuronal and glial cells took up these dies, thus we were able to image the SPA related Ca-transients in pyramidal cells with two-photon technique, simultaneously with extracellular and whole cell patch measurements.
Combining high spatial resolution two-photon Ca-imaging technique and high temporal resolution extra- and intracellular electrophysiology techniques may permit a deeper understanding about the network properties of SPA in the human cortex.

Title: Theta oscillations link local and interlaminar communication within the Human neocortex

Authors: R. J. MCGINN[1], C. L. FLOREZ[3], V. LUKANKIN[3], J. A. DIAN[1], S. R. SUGUMAR[2], P. L. CARLEN[3], *L. ZHANG[3], T. A. VALIANTE[3];
[1]Electrical and Computer Engin., [2]Physiol., Univ. of Toronto, Toronto, ON, Canada; [3]Toronto Western Res. Institute, Univ. Hlth. Network, U of Toronto, Toronto, ON, Canada

Abstract: Objective: We were interested in exploring interlaminar oscillations and their putative role in neocortical communication and computation. Cross frequency coupling (CFC) is suggested to represent a neural code implicated in memory and attention and to reflect local neural computation. On a large scale, inter-regional oscillatory coherence is thought to underlie long-range communication and network formation, the so-called communication through coherence (CTC) hypothesis. We used human neocortical slices to better understand these two paradigmatic theories. In particular, we hypothesized that the microcircuits that underlie these modes of communication likely overlap, and thus local and long range communication should be coordinated. Here we show that indeed strength of CFC and CTC are correlated, suggesting a dynamical link between local and interlaminar communication.
Methods: Temporal neocortical tissue was resected during epilepsy surgery. 500 um slices were placed in artificial cerebral spinal fluid and local field recordings were obtained from superfical and deep cortical layers. Kainate (50 nM) and carbachol (50uM) were used in order to model exogenous inputs. The metrics used were: 1) modulation index, which quantifies how one frequency modulates another, 2) phase coherence (PC) which assesses the temporal synchrony between the two layers, and 3) PDPC, a mixed metric of amplitude relationships between the two layers as a function of temporal relations. These metrics were computed over a 30s time period and correlated using Spearman rank correlation.
Results: Twenty-five slices from ten patients displayed rhythmic activity above baseline conditions. PC between layers indicated that activity in deep layers led that in superficial layers. CFC between theta (4-15 Hz) and gamma (>30 Hz) frequencies and a novel low-frequency PDPC were observed. At theta frequencies, a linear relationship between the frequencies of maximal CFC and maximal PDPC was observed. Furthermore, the values of these metrics were found to be significantly and positively correlated ($p<0.05$). Fitting the PDPC values to an analytic model suggested that this interlaminar communication at theta frequencies was bidirectional.
Conclusions: Here we show a number of novel findings: 1) theta frequency oscillations appear to be generated from deep cortical layers, 2) PDPC between cortical layers is strongest at theta frequencies, and 3) that such theta PDPC is correlated to CFC between theta and gamma activity. We highlight the privileged role that theta oscillations have been suggested to play in long range communication (PDPC), and link this to a metric of local computation (CFC).

Title: Specific reorganization of theta-phase related gamma activity in experimental models of temporal lobe epilepsy

Authors: *M. VALDERRAMA[1], J. BROTONS-MAS[2], F. LAURENT[2], L. MENENDEZ DE LA PRIDA[2];
[1]Dept. of Biomed. Engin., Univ. of Los Andes, Bogotá, Colombia; [2]Inst. Cajal, CSIC, Madrid, Spain

Abstract: Gamma activities (~ 30-100 Hz) in the hippocampus have been associated with different cognitive processes including the integration of environmental spatio-temporal information, and memory formation and recall. They result from precise circuit interactions that are modulated by the phases of the hippocampal theta waves, especially during active exploration and REM sleep. Here, we study the profile of gamma activities in the hippocampus of epileptic (n=4) and control (n=4) rats performing an object exploration task. In particular, we look for differences of theta-gamma interaction at the hippocampal CA1 region. To this purpose, we recorded local field potentials longwise different strata using multi-site silicon probes in freely moving animals. First, we selected individual theta waves (4-12 Hz) from the stratum lacunosum moleculare that were fulfilling defined amplitude criteria. From these, we selected the corresponding theta waves at the pyramidal layer and considered individual waves centered on the positive peak inside a 1.25 sec window. For each window, we estimated the activity in the entire gamma band through a wavelet transformation. We report here that although gamma activity is properly modulated by theta waves in both, control and epileptic animals, the organization along the 30-100 Hz band is not the same for both groups. In particular, while activities in the epileptic group appeared to be concentrated in the higher gamma band (~ 80 Hz) and absent in intermediate bands (~ 45-70 Hz), oscillations covering the entire gamma range are

present in the control group. The power of oscillations in the high-gamma band is significant higher in epileptics compared to control animals ($p < 0.001$, permutation test). Importantly, similar theta-gamma phase relationship was present between groups, suggesting that similar cellular processes were involved. Taken together, our results suggest a different reorganization of processes involving gamma oscillations in the hippocampus of epileptic animals that could be potentially linked to deficiencies in cognitive or memory functions.

Title: Entropy fluctuations in MEG signals above 150 Hz are similar to low frequency oscillations

Authors: *S. E. ROBINSON[1], A. J. MANDELL[2], R. COPPOLA[1];
[1]MEG Core Group, NIH/NIMH, Bethesda, MD; [2]Multimedia Imaging Lab., Univ. of California San Diego, San Diego, CA

Abstract: Complexity analysis of MEG signals above 150 Hz reveals fluctuations at beta and gamma band frequencies. This may indicate the presence of multi-unit activity (MUA) in the signal. The rank vector entropy (RVE) transform is a broad-band measure of signal complexity and is distinct from measures of power [1]. It is most effective when applied to broadband signals (narrow-band signals have low complexity). MEG signals above 150 Hz generally have poor signal-to-noise ratio and lack distinct spectral peaks, signals. Exceptions are the 600 Hz oscillations coincident with the somatosensory N20 response to median nerve electrical stimulation [2] and the high frequency oscillations (HFOs) and fast ripples in some epilepsy recordings [3]. Functional images of activity in a 150-300 Hz bandpass were imaged using RVE (HF-RVE) from working memory studies of six normal subjects, using a 275-channel MEG instrument (CTF Systems, Inc.). Dorsolateral prefrontal, anterior cingulate, and posterior parietal areas showed significant ($p < 10\text{-}5$) changes between the 2-back and 0-back conditions. In addition to these event-related changes, we observed gamma band oscillations in the time-series from parietal voxels. Oscillations could not be replicated from surrogate data where the sample

order was randomized prior to RVE, indicating that they are hidden property of the high-frequency signals. How do these oscillations in HF-RVE relate to those appearing in a 4 to 150 Hz bandpass (LF)? To test this we analyzed the coherence between the low and RVE-transformed high frequencies. Coherence was small, primarily due to the non-stationary behavior of the oscillations. Tests of mutual information were also performed, yielding larger values. We speculate that the high-frequency signal relates to the regional MUA. If this hypothesis is correct, then it may be possible to discriminate between regional outputs (the HF-RVE) and the inputs to the dendritic tree (LF). Seed based analyses reveal regions with high mutual information relative to the seed. Mutual information was not reciprocal, suggesting directional connectivity.

Title: Role of 5HT2 and 5HT3 receptors in the generation of epileptiform activity: *In vitro*, in silico and *In vivo* studies

Authors: *P. A. PUZEREY, R. FERNÁNDEZ GALÁN;
Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: The broad expression of serotonin (5-HT) receptors in the neocortex is juxtaposed with dense innervation by serotonergic afferents, underscoring the influence of 5-HT on cortical activity. While the effects of 5-HT are well understood at the level of the neuron, its role in network activity remains unclear. We have shown that elevating 5-HT in disinhibited cortical slices with the selective serotonin reuptake inhibitor, fluoxetine (FLX), transforms cortical network dynamics from single bursts, known as paroxysmal depolarizing shifts (PDS), to periodic (15 Hz) burst clusters known as paroxysmal fast runs (PFRs), a form of activity often seen in animal and human epileptic seizures. The emergence of PFRs depends on 5-HT2

receptors (5-HT2Rs) as they are blocked by ketanserin (KSN). We set out to investigate the mechanistic underpinnings of the 5HT2R-dependent switch from temporally random and sparse to periodic and clustered network bursts. To this end, we measured postsynaptic currents during network events in control and FLX-treated cortical slices and observed an increase in excitatory and a decrease in the inhibitory postsynaptic currents (EPSCs & IPSCs). KSN reduced the enhanced EPSCs to control levels, while further decreasing IPSCs. We confirmed the sufficiency of these changes to the emergence of PFRs using a computer simulation of a model cortical network. Furthermore, since the emergence of PFRs depends on 5-HT2Rs, we tested in vivo whether 5-HT2Rs modulate epileptic seizures, the behavioral correlate of the PFRs observed in vitro. Indeed, injection of KSN before seizure induction with pentylenetetrazole (PTZ) significantly delayed the onset of epileptic seizures. In parallel with 5-HT2R-dependent modulation of network activity, we also explored the role of 5-HT3 receptors (5-HT3R) in cortical dynamics. We previously showed that FLX enhances spontaneous synaptic activity through 5-HT3Rs in cortical neurons. Blocking 5-HT3Rs with granisetron in FLX-treated disinhibited slices results in a significant reduction of network bursts, though the emergence of PFRs remains unaffected. Combined, our results present a mechanism by which augmented 5-HT signaling in the cortex alters cortical dynamics: 5-HT2Rs act in concert with 5-HT3Rs on cortical neurons to elevate global levels of excitation, while 5-HT2R activity transforms cortical activity patterns from random bursts to highly periodic fast runs of paroxysmal discharges. These findings emphasize the importance of neuromodulatory control in shaping cortical dynamics and provide a potential therapeutic avenue for treating epileptic seizures that are resistant to typical antiepileptic drugs.

Title: Effect of coupling frequency on information sharing

Authors: *C. A. STETSON;
Caltech, Pasadena, CA

Abstract: It is widely believed that in-phase oscillatory co-modulation can generate functional enhancement between cortical regions. However, oscillatory modulation can also suppress

communication, by narrowing the available times over which neurons can fire. The extent of the suppression will depend on the modulation frequency, and its relationship to fundamental cellular timescales. For example, in the integrate-and-fire cell in the accompanying figure, 20Hz oscillatory modulation reduces the rate of transmitted spikes by 20%. During wave-troughs, post-synaptic potentials are destroyed before they can generate a downstream spikes. Yet the capacity for information transmission returns at higher frequencies (to 93% at 100Hz, and 99% at 200Hz), as more frequent wave peaks resurrect post-synaptic potentials before they dissipate. We explore this phenomenon over a series of physiological parameters, including noise level, number of neurons, average spike rate and refractory period. This kind of bandwidth reduction via low-frequency modulation may help explain the differing roles of local field potentials at different frequencies in the cortex. Whereas gamma-band (30-100Hz) oscillations have been reported to enhance functional interaction between visual areas, beta-band (15-30Hz) oscillations characteristic of parieto-frontal planning activity may suppress information transmission.

Abstract:
In our previous studies, we reported the anti-stress and anti-depressant effect of Nelumbinis Semen (NS) in the rats. In the present study, we investigated the sleep facilitating effect of NS by regulating neurotransmitter systems in rats. In this study, we assessed the hypnotic effects of NS in the locomotor activity and electroencephalogram (EEG). We also assessed the receptor binding assay to the well-known molecular targets for sedative response, $GABA_A$-BZD, 5-HT_{2C}, and adenosine receptor biding test. Extract of NS produced inhibitory effect on caffeine-induced locomotor activity and theta activity. NS also significantly decreased sleep latency and sleep duration time in rats. In the binding assay, NS had high affinity to $GABA_A$-BZD and the 5-HT_{2C} receptor, but not adenosine receptor. NS has the sedative-hypnotic activity possibly by modulating $GABA_A$ and 5-HT_{2C} receptors. NS can be useful as a hypnotic, having not only sleep inducing effects, but also sleep quality-increasing effects.

Title: Severe malnourishment modifies the circadian cycle of DRD1 and DRD2 genes in the dorsal striatum and ventral tegmental area of the rat

Authors: C. LÓPEZ-OVIEDO[1], A. BOYZO-MONTES DE OCA[2], H. N. MORENO-SANDOVAL[1], J. AYALA-DÁVILA[2], L. C. SÁNCHEZ-PEÑA[3], B. A. LEÓN-CHÁVEZ[4], D. MARTÍNEZ-FONG[2], *J. A. GONZALEZ-BARRIOS[1];

Abstract: Anorexia nervosa (AN) is a serious psychiatric disorder of unknown etiology. Recently, alterations in dopamine (DA) transmission have been implicated in its etiology and

development. Some studies have shown that diet restriction reduces DA levels in the hypothalamus, hippocampus and the dorsal striatum, and have linked the motor hyperactivity following diet restriction with increased DA levels in the hypothalamus. Neuroendocrine studies suggest that DA neurotransmission is increased in AN. Supporting this suggestion, recent neuroimaging studies have shown an increased density of dopaminergic receptors in the striatum. To determine whether food intake restriction in a model of AN with severe malnourishment modifies the circadian expression of DA receptors, we evaluated the changes in mRNA transcription of D1-like receptors (D1 and D5) and D2-like receptors (DRD2, DRD3 and DRD4) in the dorsal striatum and ventral tegmental area (VTA) along the day. A transcriptional study was conducted in cDNA samples obtained from male Wistar rats, maintained in constant light-dark cycles of 12-12 h and food intake restriction (10 g/day). The control group were rats feeding ad libitum. Dorsal striatum and VTA were dissected each 2 h starting at 8:00 AM and ending at 6:00 AM of the following day to cover a period of 24 h. The change in gene transcription were assessed by RT-PCR and real-time PCR using TaqMan probes. The severe malnourishment significantly increased DRD1 gene transcription in the VTA ($P < 0.001$) only. DRD2 transcription was up-regulated in the VTA from 22:00 to 04:00 h, whereas in the dorsal striatum was down-regulated ($P < 0.001$) in all times evaluated. DRD3 and DRD5 showed similar transcriptional profile to those of the controls rats. No transcriptional activity of DRD4 gene was detected . Our results support the hypothesis that the increase in DRD2 gene transcription in the dorsal striatum and VTA is responsible for the hyperactivity during food intake restriction period, and suggest that the DRD1 up-regulation in the VTA might account for some of the neuropsychological disorders observed in patients with AN.

Title: Effect of lisdexamfetamine in a rat model of binge-eating disorder

Authors: *S. P. VICKERS[1], D. J. HEAL[1], D. HACKETT[2], P. H. HUTSON[3];
[1]Renasci Ltd, Nottingham, United Kingdom; [2]Shire Pharmaceuticals Limited, Basingstoke, United Kingdom; [3]Shire Develop. Inc, Wayne, PA

Abstract: Binge-eating disorder (BED) is a common psychiatric condition, affecting ~2% of the adult population. It occurs approximately equally in women and men and most often in older adults. It manifests as compulsive, excessive consumption of highly palatable foods and may or may not be associated with obesity. Binge eaters frequently experience intense feelings of guilt and anxiety after a binge session, but do not indulge in purging. lisdexamfetamine dimesylate (LDX; Vyvanse®), a novel prodrug that is metabolized to d amfetamine (d-AMF) primarily by red blood cells (Pennick, 2010, Neuropsychiat Dis Treat 6:317) is approved in the USA, Mexico and Europe for ADHD (ages 6-17). It is being clinically evaluated for managing BED in USA. This study compared the acute effects of LDX in rats trained to binge eat chocolate with its active metabolite, d AMF, and with sibutramine (SIB), which is reported to be moderately effective in clinical trials of BED (Wilfley et al, 2008, Am J Psychiat 165:51-58).
Forty-four adult, lean, female Wistar rats were housed individually on reversed-phase lighting with free access to standard diet and water. Ground milk chocolate was offered to each rat for 2 hour periods at irregular intervals to establish binge eating. LDX, d AMF and SIB were administered orally.
Irregular, limited access to chocolate for ~4 weeks produced reproducible binge eating, but bodyweights were not different from control rats maintained on a standard diet. LDX (0.1-1.5 mg/kg d AMF base) reduced chocolate bingeing by up to 86.1% at the highest dose ($p<0.001$). The intermediate dose of 0.3 mg/kg, LDX reduced chocolate consumption 40.2% ($p<0.001$) whilst having no effect on standard diet intake. LDX treatment did not decrease bodyweight compared with the control group given vehicle. d AMF (0.1 1.0 mg/kg d AMF base) decreased chocolate bingeing at 0.5 mg/kg ($p<0.01$) and 1.0 mg/kg ($p<0.001$). d AMF did not reduce standard diet consumption, but did reduce bodyweight ($p<0.01$) at the highest dose. SIB (0.3 5.0 mg/kg) reduced chocolate bingeing ($p<0.001$ at 1-5 mg/kg); however there were similar reductions of standard diet consumption for all doses ($p<0.05$-0.01). SIB also produced small bodyweight decreases ($p<0.05$-0.001 at 1-5 mg/kg).
Animals allowed irregular, limited access to chocolate developed robust, intermittent hyperphagia that mirrored BED without the associated obesity. Binge eating was markedly reduced by a single treatment with LDX or its metabolite, d AMF. Unlike SIB, both LDX and d AMF reduced chocolate binge-eating without simultaneously decreasing the consumption of normal diet. These results provide support for use of LDX in the clinical treatment of BED.

Title: Iron content of choroid plexus may increase with age

Authors: *T. A. TISHLER[1], A. B. ARONSON[4], P. H. LU[2], P. VILLABLANCA[3], J. P. FINN[3], G. BARTZOKIS[1];
[1]Psychiatry and Behavioral Sci., [2]Neurol., [3]Radiology, UCLA, Los Angeles, CA; [4]Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Objective
Iron is the most abundant transition metal in brain and is essential for various cell functions, including ATP production and myelination. However, iron can promote damaging oxidative reactions. Brain iron increases with age and is a risk factor for age-related degenerative brain diseases such as Alzheimer's disease (AD). Choroid plexus (CP) is the main source of brain transferrin, the major iron delivery protein for neurons. CP undergoes progressive age-related senescence which may contribute to iron dysregulation, iron-mediated toxicity, and the increase in oxidative stress and inflammation that occurs with brain aging. CP dysfunction has been implicated in AD; however, CP calcifications do not seem to be involved. The role of CP in brain aging and disease is relatively unexplored so we assessed whether CP Susceptibility Weighted Imaging (SWI) signals, and therefore possibly iron levels, change in healthy individuals throughout their lifespan.
Methods
We estimated CP iron levels in a large sample of healthy men (N=96) and women (N=84) aged 18 to 89 years old (mean 51.8, sd=22.0). CP iron was assessed using SWI, a magnetic resonance imaging technique that is sensitive to paramagnetic substances including iron. Qualitative ratings of SWI hypointensity severity and counts of the number of slices in which CP hypointensities were observed were obtained by a single rater (ABA), blind to subject demographics. Brain iron

was assessed in putamen (P) using field dependent relaxation rate increase (FDRI).

Results

The prevalence of SWI hypointensities was 89%. Ratings of hypointensity significantly increased with age in the whole sample ($r=.41$, $p<.0001$) and in men ($p=.0043$) and women ($p<.0001$) separately. Ratings of zero (no evidence of susceptibility effects) were observed only in subjects under 65 years of age (chi squared for a rating of zero for individuals under vs. over 65 years was 13.03, $p=.0003$). Ratings of extent of hypointensity (number of slices with hypointensity) were also significantly correlated with age in the whole sample ($r=.48$, $p<.0001$) and in men ($p<.0001$) and women ($p<.0001$) separately. Correlation between CP slice ratings and P FDRI was $r=.27$, $p=.01$.

Conclusions

Qualitative estimates of CP SWI hypointensity are correlated with age. CP hypointensity may serve as a surrogate for increased deposition of iron, as the prevalence of hypointensities is much higher than reports of CP calcification prevalence. This interpretation is also supported by the correlation with P FDRI. The data supports the hypothesis that CP undergoes age-related changes that may contribute to the risk of developing age-related degenerative brain diseases such as AD.

Title: Obesity gene NEGR1 is associated with white matter integrity differently in young and old adults

Authors: *E. L. DENNIS[1], M. BRASKIE[1], N. WARSTADT[1], N. JAHANSHAD[1], O. KOHANNIM[1], T. NIR[1], K. MCMAHON[2], G. DE ZUBICARAY[3], G. MONTGOMERY[4], N. MARTIN[4], A. TOGA[1], M. WRIGHT[3,4], P. THOMPSON[1];

Abstract: Obesity is a major public health issue in the developed world. Obesity is associated with many health issues, and high body mass index (BMI) in midlife has been linked to decreased cognitive functioning in old age. Several studies report abnormalities in white matter volume or diffusivity associated with obesity. This is likely due in part to genes that affect both the brain and obesity risk. We investigated whether common variants in obesity-associated genes might also be associated with brain measures.
We scanned 409 subjects (264 females/145 males, mean age=23.8, range=20-29 years) at 4T with 105-gradient HARDI (high angular resolution diffusion imaging) and T1-weighted MRI. We began with a multi-locus approach that models the combined effect of a number of SNPs (single nucleotide polymorphisms) associated with obesity. This is a novel approach to examine the aggregate influence of genetic variants. We then performed a voxel-wise fractional anisotropy (FA) analysis on the SNP that appeared to be driving the association. We controlled for age, sex, BMI, and kinship (in our twin sample). The sample was split in half to test reproducibility of these results. Additionally, we attempted to replicate our results in an older group from the ADNI2 cohort (78 subjects, 29 females/49 males, mean age 74.3, range=55-90). In our initial multi-locus analysis, our BMI SNP panel was significantly associated with FA in the bilateral posterior corona radiata. The SNP appeared to be driving the association was in NEGR1 (rs2815752). A follow-up analysis yielded lower FA with risk allele dosage across extensive areas of white matter (see Figure 1). This association was robust in our split-sample replication. In the ADNI2 cohort, the same areas were associated with NEGR1 risk allele dosage, but in the opposite direction. Previous research has found that midlife obesity can be cognitively detrimental, while late-life obesity can be cognitively protective. Our results mirror this trajectory, and may be part of the mechanism underlying it.

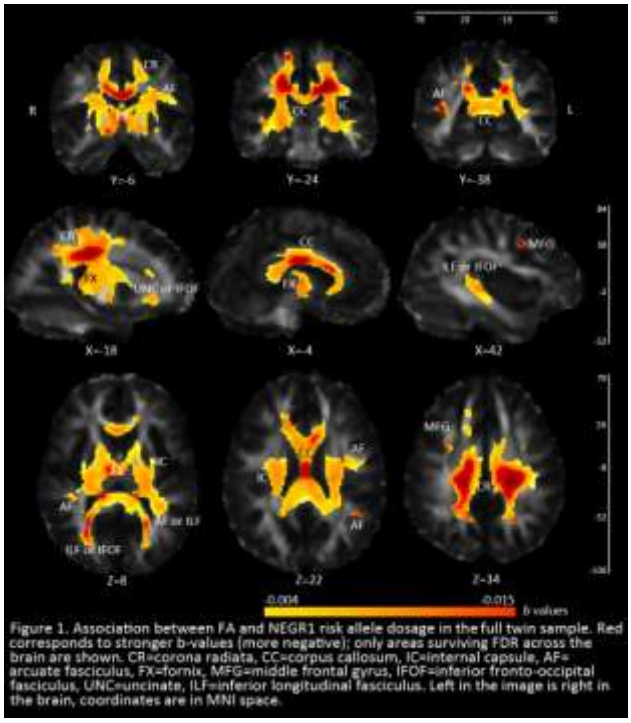

Figure 1. Association between FA and NEGR1 risk allele dosage in the full twin sample. Red corresponds to stronger b-values (more negative); only areas surviving FDR across the brain are shown. CR=corona radiata, CC=corpus callosum, IC=internal capsule, AF= arcuate fasciculus, FX=fornix, MFG=middle frontal gyrus, IFOF=inferior fronto-occipital fasciculus, UNC=uncinate, ILF=inferior longitudinal fasciculus. Left in the image is right in the brain, coordinates are in MNI space.

Title: Theta-phase gamma-amplitude coupling detects EEG abnormalities in persons with internet addiction

Authors: *J. LEE[1], S.-W. CHOI[1], S. KIM[2];
[1]Gangnam, Gangnam Eulji Hosp., Seoul, Korea, Republic of; [2]Gongju Natl. Hosp., Gongju, Korea, Republic of

Abstract: Objective: Internet addiction disorder (IAD) is increasingly recognized as a legitimate clinical disorder and social problem that critically require treatment, yet its pathophysiological mechanism is not well understood. The aim of this study was to determine if cross-frequency phase-amplitude coupling of the electroencephalography (EEG) detects possible abnormalities in functional connectivity in IAD patients.
Methods: 19-electrode EEGs were recorded from 16 IAD patients and 35 healthy subjects. Their cross-frequency phase-amplitude coupling was estimated to compare with clinical measures including daily internet usage (DIU), internet addiction test scores (IAT), Barrett Impulsiveness scores (BIS), Beck depression inventory scores (BDI) and Beck anxiety inventory scores (BAI).
Results: The IAD group showed decreased theta-phase gamma-amplitude coupling (TGC) as well as increased delta and theta powers, compared with the healthy control group. Further, TGC negatively correlated with IU,
IAT, BIS, BDI and BAI in frontal, central, parietal and occipital regions.
Conclusions: The TGC is a valuable marker for abnormal interactions of functional brain networks in IAD patients. We suggest that such abnormal interactions among large-scale brain networks are responsible for the impulsive or maladaptive behavior that is associated with internet addiction.
Significance: The TGC could be a promising neurophysiological indicator for diagnosing the internet addiction.

Abstract: Wooden houses are known to exert some psychological effects due to their odor, humidity conditioning, and the visual elements of interior designs (Nyrud & Bringslimark, 2010, Rice *et al*., 2006, Tsunetsugu *et al*., 2007). In particular, naturally processed woods (NPW, free from chemical processing during lumber sawing) are more restorative than chemically processed woods (CPW, bonded or coated woods) (Jonsson *et al*., 2008). However, the physiological effects of wooden materials at the level of processing are still unclear. In order to clarify the difference in physiological effects between NPW and CPW, we built two experimental huts. One was made of Japanese cedar, *Tsuesugi* (NPW), and the other was made of CPW. The electrophysiological responses of subjects were examined by comparing electroencephalograms (EEG) measured in each hut, both while the subjects were at rest and during a three-stimulus visual oddball task. Ten male students (20–22 years old) participated in this experiment, and each subject came to the two huts on separate days. The measurement was conducted as follows: The resting EEG was recorded continuously for 10 minutes both before and after the task, when subjects lay sprawled out on the floor with their eyes closed. All subjects also completed three 10-minute blocks of the task while seated comfortably in a chair in front of a cathode ray tube display. Significant effects of chemical processing were observed on delta (0.5–3.5 Hz), theta (4–7 Hz), and gamma (30–55 Hz) frequencies as reflected by changes in the resting EEG. The mean amplitudes of the delta-band and theta-band activities did not change between the pre and post periods in the NPW hut, whereas they did increase from pre to post in the CPW hut. The amplitudes of gamma-band activity also did not change in the NPW hut, whereas they decreased in the CPW hut. These results can be interpreted as follows: In the NPW hut, the subjects recovered from the fatigue after the sustained visual oddball task. By contrast, in the CPW hut, the subjects experienced continuous fatigue after the task. From these results, we suggest that NPW may have a restorative effect on brain fatigue.
First three authors equally contributed to this work. We thank Prof. H. Shiratsuchi (Pref. Univ. Kumamoto) for volatile analysis.

Title: Incidence and impact of depression in blast versus non-blast traumatic brain injury in a veteran population

Authors: *G. V. WINDMILLER[1], K. PANIZZON[1], S. JOO[2], R. WALLIS[1];
[1]VA Greater Los Angeles Healthcare Syst., Los Angeles, CA; [2]VA Greater Los Angeles Healthcare Sysytem, Los Angeles, CA

Abstract: OBJECTIVE: To evaluate the incidence and impact of depression in subjects with traumatic brain injury (TBI) from blast versus non-blast mechanisms in a veteran population. BACKGROUND: Many veterans from the Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF) conflicts with TBI have had blast exposure. TBI is associated with a wide array of residual effects, including post-concussive headaches, cognitive dysfunction, and depression. The effects of depression in TBI are particularly disabling. We evaluated the incidence of depression and suicidal ideation in subjects with blast versus non-blast TBI. METHODS: We performed a pilot retrospective chart review of subjects with TBI of greater than one year duration. We confirmed the history of blast or non-blast exposure TBI for each subject. We also examined the incidence of depression and suicidal ideation in these subjects. RESULTS: We reviewed the charts of 186 subjects with TBI. We found that blast exposure occurred in 108 (58%) subjects with TBI, and non-blast TBI in 78 (42%) subjects. Depression was diagnosed in a mean of 81% ± 1 of subjects with blast exposure, while depression was seen a mean of 72% ± 1 of subjects with non-blast TBI. The incidence of suicidal ideation occurred with 24% ± 1 in subjects with non-blast TBI and 22% ± 1 subjects with blast TBI. CONCLUSION: In this study, blast exposure was found to have occurred frequently in this veteran population. Also, depression occurred with a greater incidence in subjects with blast

exposure during TBI. These initial data suggest that blast injury may have a major impact on the psychological well-being of subjects exposed to this mechanism of TBI.

Title: Exercise has positive effects on the capillaries in the white matter of aged brain

Authors: *Y. TANG, C. HUANG, X. QIU, L. CHEN, L. ZHANG, F. CHAO;
Dept. of Histology and Embryology, Chongqing Med. Univ., Chongqing, China

Abstract: Our previous studies found that during aging process, the white matter was significantly shrunk and the myelinated fibers in the white matter were markedly lost. Our previous studies also found that running exercise had positive effects on the white matter and the myelinated fibers in the white matter of aged brain. What are the reasons for the effects of running exercise on the white matter of aged brain? The present study is the first study to investigate the age-related changes of the capillaries in the white matter and the effects of running exercise on the age-related changes of the capillaries in the white matter of Sprague Dawley rats using the immunohistochemistry technique and the unbiased stereological techniques. For the investigation of the age-related changes of the capillaries in the white matter, young rats and aged rats were used. For the investigation of the effects of running exercise on the capillaries in the white matter of aged brain, 14-month-old male and female rats were randomly divided into running group and control group. Control group rats were reared in standard condition without running. Running group rats run 4 months and 14 months. The spatial learning capacity of running rats and control rats were assessed with Morris Water Maze. The white matter volume, the total volume, total length and total surface area of the capillaries in white matter were quantitatively investigated with the immunohistochemistry and the unbiased

stereological methods. The total length, total volume and total surface area of the capillaries in the white matter of aged rats were significantly lower than those of young rats. Running exercise improved the spatial learning and memory ability of aged rats. After 4 month running exercise, the total length of the capillaries in the white matter of male and female exercised rats was significantly higher than that of male and female non-exercised rats. After 14 month running exercise, the total length, total volume and total surface area of the capillaries in the white matter of male and female exercised rats were significantly higher than those of male and female non-exercised rats. The age-related changes of the capillaries in the white mater may have important implications for age-related white matter atrophy and age-related cognitive impairments. The present results indicated that running exercise had positive effects on the capillaries in the white matter of aged brain, which might be one of the structural bases for the running exercise-induced improvement of the spatial learning ability. These results together demonstrated that running exercise could benefit aged brain.

Title: The daily fix: Habitual caffeine doses improve performance in attention and executive functions irrespective of food intake

Authors: *J. L. MARIANO, J. C. F. GALDURÓZ, S. POMPÉIA;
Psicobiologia, Univ. Federal De Sao Paulo, Sao Paulo, Brazil

Abstract: Despite there being some consensus that attention/executive functions and mood/somatic symptoms are positively affected by caffeine in habitual consumers, the nutritional status under which this occurs and the doses that exert these affects are unclear. One possible reason is that studies that have investigated these effects usually include both fasting and caffeine deprivation, factors known to alter cognitive functioning and mood/somatic symptoms. As consumers vary in their habitual caffeine intake and caffeine can modulate blood glucose, it is plausible that differences between caffeine and control conditions may be due to variable reversal of adverse withdrawal effects and fasting. To address this issue, we evaluated the effects of the habitual breakfast dose of caffeine reported by each subject (baseline dose, as the experimental procedures began at 8 am) and a standardized meal (cereal bars), alone or in combination, on: a) mood/somatic symptoms through validated questionnaire (Positive and Negative Mood States, Visual Analogue Mood Scales and Bodily Symptoms Visual Analogue Scales); and b) cognitive performance [sustained and simple attention (Psychomotor Vigilance Test), and 6 executive domains - inhibition and updating (Random Number Generation task), shifting cost (Plus-Minus task), planning (Zoo Map Task), access to long term memory (phonemic and semantic fluency) and dual-task coordination-]. This was a double-blind, placebo-controlled, independent-groups design study including 60 young, healthy male participants who were randomly assigned to one of four treatments: placebo/fasting, caffeine/fasting, placebo/meal, caffeine/meal. Testing was carried out at theoretical peak-plasma concentration of caffeine and blood glucose. Regardless of fasting or meal intake, caffeine significantly improved sustained attention, simple reaction time and decreased number of lapses in an attentional task (PVT). It also improved executive updating, phonemic fluency (in the first 15 s) and subjective somatic symptoms (fatigue, weakness, dry mouth, sweating, and subjective somnolence after the 10-minutes PVT task). The meal intake did not affect performance or mood/somatic symptoms. These findings show that caffeine-induced improvement in various aspects of attention and some executive domains in habitual users is not dependent on food intake and suggest that it may be due to reversal of abstinence or to the fact that users can determine the optimum caffeine dose that leads to enhanced performance.

Title: The role of a nuclear localized 82 kDa choline acetyltransferase in cell stress and the epigenome

Authors: *W. WINICK-NG, R. J. RYLETT;
Phys/Pharm, Western Univ., London, ON, Canada

Abstract: The current studies were designed to explore the functional role of an 82 kDa isoform of choline acetyltransferase (M-ChAT) that is localized in the nucleus of human cholinergic neurons. Retinoic acid differentiated SH-SY5Y neuroblastoma cells were either stably-transfected with M-ChAT or transiently-transfected with a GFP-MChAT fusion protein, then treated with oligomers of amyloid β (Aβ) 1-42 for 4h. Live GFP-MChAT transfected cells were stained with Hoechst stain then imaged by confocal microscopy, or stably-transfected cells were treated with Hoechst stain either prior to or following formalin fixation. MChAT is localized predominantly to the nucleus and has a punctate-like appearance. Following 4h exposure of SH-SY5Y cells expressing M-ChAT to oligomeric Aβ[1-42], aggregations of ChAT protein appear in the nucleus. The distribution of these aggregates was altered depending on how the cells were stained with Hoechst. Applying Hoechst following fixation produces aggregations of M-ChAT that are surrounded by the dye, while applying Hoechst to live cells produces aggregations of dye that are surrounded by accumulations of M-ChAT. Z-stack 3D-renderings of Aβ treated cells show the same pattern of expression. Treatment with the histone deacetylase inhibitor trichostatin A with or without 4h Aβ[1-42] also showed the same Hoechst-dependent M-ChAT distribution change. Treatment for 24h with the histone acetyltransferase inhibitor curcumin in the presence of Aβ following 4h with Aβ alone attenuated the aggregations of M-ChAT. Primary cortical neurons cultured from embryonic mice that are doubly transgenic for mutant human APP and Presenilin were transduced with adenovirus encoding the M-ChAT protein. These neurons showed similar nuclear aggregations of M-ChAT following 10 days in culture. Taken together, these data suggest that M-ChAT protein aggregates in the nucleus following Aβ-induced cell stress, and these aggregates are displaced by Hoechst stain. Further, ChAT accumulation may be a result of increases in histone acetylation, but additional studies are required to confirm this and to determine whether these accumulations are a result of DNA binding or other mechanisms. These studies were funded by a CIHR grant to RJR and a Dean's PhD Scholarship for Graduate Research to WW.

Title: Arctic mutant Aβ modifies CHRNA7's functions through specific binding

Authors: *Y. JU[1], T. ASAHI[2,3], N. SAWAMURA[2,3];
[1]Sch. of Advanced Sci. & Engineering, Waseda Univ., Tokyo, Japan; [2]Advanced Sci. & Engin., Tokyo, Japan; [3]ASMeW, Tokyo, Japan

Abstract: Point mutations within the Amyloid β-protein (Aβ) sequence that are associated with hereditary disease similar or identical to AD are clustered around the central hydrophobic core of Aβ. The nicotinic acetylcholine receptors, key players in neuronal communication, convert neurotransmitter binding into membrane electrical depolarization. CHRNA7 is a type of the neuronal nicotinic receptors and thought to have association with Alzheimer's disease, because Aβ 42 is reported binding to CHRNA7 protein with high affinity. Therefore, we came up with the hypothesis about mutant Aβ modifies CHRNA7's function which could relate to the familial Alzheimer's disease.

We utilized immunoprecipitation to detect the in vitro binding ability of several mutant Aβ with CHNRA7 and found out that Arctic mutant Aβ specifically bound to CHRNA7. We were also able to observe the aggregation form of Arctic mutant Aβ with addition of CHRNA7 through transmission electron microscopy (TEM). CHRNA7 is the cholinergic receptor controlling cellular calcium ion homeostasis and ERK1/2 protein is involved in CHRNA7 function. Thus, we detected whether Arctic Aβ could affect permeability to calcium ions. As a result, we found out that Arctic Aβ could inhibit the CHRNA7 function via decrease in calcium flux and inhibition of ERK1/2 activation.

Based on these results, we are confirming the hypothesis that Arctic mutant Aβ inhibit activation of CHRNA7 and related to familial Alzheimer's disease through binding and aggregation.

Title: The role of caspases in axonal degeneration and synapse loss

Authors: *E. JACOTOT[1], B. DELEGLISE[2], B. LASSUS[2], V. SOUBEYRE[2], E. DUPLUS[2], J.-M. PEYRIN[2], B. BRUGG[2];
[1]CNRS UMR 7102, Inserm, Paris, France; [2]UMR 7102 UPMC, CNRS, Paris, France

Abstract: Axonal and synaptic degeneration are key events in peripheral neuropathies and CNS neurodegenerative diseases. In numerous physiological and pathological conditions, caspases, the effector proteases of apoptosis, are key executionner of neuronal cell body (soma) death. Distinct degenerative processes have been identified for axons, and apoptotic biochemical cascades can be activated locally in synapses, axons, and dendrites, suggesting a role for such local apoptotic signals in neurodegenerative disorders. Although a role for caspases in axon degeneration was initially widely discounted, their potential involvement was however revisited recently due to the genetic and biochemical demonstration that caspase-6 and caspase-3 are implicated in trophic deprivation and developmental axon pruning. To further investigate the role of caspases in key neuronal compartments (soma, axon, synapse), we have developed microfluidic (μFD) devices adapted to neuronal structures, and allowing a fine manipulation of local microenvironment. We grew primary cortical mouse neurons in μFD devices to separate soma from axonal projections in fluidically isolated microenvironments, and applied apoptotic stresses (e.g. β-amyloid peptide, staurosporine, dKCl) locally to the different cellular compartments. We observed that such stresses applied to the somato-dendritic compartment trigger axonal degeneration, and that axonal (distal) co-treatment with the broad-spectrum caspase inhibitor z-VAD-fmk prevents axonal degeneration. Our results suggest that local (axonal) caspases are activated through an anterograde initiator signal. The role of some individual caspases will be presented. We have also designed μFD devices with funnel-shaped microchannels ("axonal diodes") allowing the *in vitro* reconstruction of an orientated functional cortico-hippocampal neuronal network. Using such neuronal networks we show that somato-dendritic deposits of Aβ-peptide on cortical neurons trigger a rapid presynaptic disconnection

followed by axonal dying back pattern. The effects of caspase inhibition in the axonal/synaptic compartment are under investigation.

Title: Synaptic activation or amyloid beta oligomers promote tau trafficking to spines and an interaction with actin

Authors: M. FRANDEMICHE[1], S. DE SERRANO[1], T. RUSH[1], M. DOLLMEYER[1], A. ELIE[1], I. ARNAL[1], F. LANTÉ[1], *A. BUISSON[2];

Abstract: Alzheimer’s disease (AD) is a progressive neurological disorder that is characterized by memory loss and confusion. There is good evidence indicating that the accumulation of the β-amyloid protein (Aβ), a 4-kDa polypeptide derived from the proteolytic cleavage of the Aβ precursor protein (APP), is a primary event in the pathogenesis of AD. Another cardinal feature of AD is the presence of intraneuronal neurofibrillary tangles, composed of insoluble aggregates of the stabilizing Microtubule-Associated Protein (MAP), tau. Once believed to mediate neuronal death and cognitive deficits, observations in mouse models have since shown that tangles exert negligible neurotoxicity compared to non-aggregated (Oddo et al., 2003). The inter-relationships between the two Aβ oligomers or/and soluble tau cytopathologies still need to be characterized. Here, we studied the sub-cellular repartition of tau in cultured primary cortical neurons and hippocampal slices from adult mice following exposure to specific synaptic activation, LTP and soluble Aβo.

First, we investigated the localization of tau in primary cortical neurons (DIV 14) exposed to a synaptic activation using a GABA-A receptor antagonist (bicuculline, 50 µM) in the presence of a voltage-gated K+-channel blocker (4-aminopyridine, 2.5 mM). We then performed synaptosomal fractionation to isolate "PSD-enriched" and "non-PSD-enriched" fractions. We then adapted this protocol to the mouse hippocampal slices after inducing LTP. We showed that synaptic activation and LTP promote tau translocation into the post-synaptic density compartment (2-fold increase vs. controls). This synaptic localization of tau exploits a selective interaction with filamentous actin located into the dentritic spines as revealed by confocal live imaging and immuno-precipitation with phalloidin. Similarly, using a cell free system, we demonstrated that recombinant human tau binds to actin filaments and promotes their organization into bundles. Together, these data suggest that tau participates in a re-organization of the actin cytoskeleton involved in synaptic plasticity. Strikingly, exposure to 100 nM of Aβo (for 15 min) induced a mislocalization of tau into the spines, both during resting conditions and under synaptic activation, as observed with confocal imaging and western blot analysis of fractionated samples. These observations suggest that tau mislocation may represent an early step leading to the synaptotoxicity observed in AD.

Title: Examining the relationship between the Warburg effect and amyloid-beta resistance in a transgenic Alzheimer's disease mouse model

Authors: *R. C. CUMMING[1], R. A. HARRIS[1], J. T. NEWINGTON[1], R. BARTHA[2]; [1]Dept. of Biol., Univ. of Western Ontario, London, ON, Canada; [2]Ctr. for Functional and

Metabolic Mapping, Robarts Res. Inst., Schulich Sch. of Med. & Dentistry, Univ. of Western Ontario, London, ON, Canada

Abstract: Numerous studies of post-mortem brain tissue have revealed amyloid plaque deposition in elderly individuals with no symptoms of Alzheimer's disease (AD). It is believed that asymptomatic individuals with high plaque load likely had undiagnosed mild cognitive impairment or high cognitive reserve. However, we propose that some of these individuals may have developed resistance to the toxic effects of amyloid-beta (Aβ) peptide, a principle component of plaques found within the brains of AD patients. We previously demonstrated that Aβ resistant nerve cells exhibit elevated expression of pyruvate dehydrogenase kinase 1 (PDK1), an enzyme that phosphorylates and inhibits pyruvate dehydrogenase (PDH); a rate limiting enzyme of the citric acid cycle and a central regulator of mitochondrial activity. Elevated PDK1 activity can elicit the Warburg effect (also known as aerobic glycolysis); a form of metabolism frequently employed by cancer cells as an anti-apoptotic strategy. APPswe/PSEN1dE9 double transgenic AD (tg-AD) mice accumulate amyloid plaques in the hippocampus and cortex by 4-6 months of age but exhibit minimal neuronal loss and only display cognitive decline after 9 months of age. Immunoblot analysis of cortical tissue extracts from 3 month old mice, in addition to embryonic primary cortical neuronal cultures, revealed elevated PDK1 expression in tg-AD mice relative to wildtype littermate controls. However, PDK1 expression declined in cortical tissues from 12 month old tg-AD mice compared to control mice; an event that correlated with the age-dependent cognitive decline observed in tg-AD mice. To determine if elevated PDK1 expression in young tg-AD mice contributes to Aβ resistance, we treated mice with dichloroacetate (DCA), a chemical inhibitor of PDK1. Immunoblot analysis of cortical tissue from DCA treated mice revealed decreased phosphorylation of PDH, the substrate of PDK1, compared to untreated mice, indicating that DCA can cross the blood brain barrier. In order to measure aerobic glycolysis in vivo we performed 1H magnetic resonance spectroscopy (MRS) imaging of wildtype and tg-AD mice brains with a focus on measuring lactate, a major product of the Warburg effect. Initial MRS analysis revealed that CNS lactate levels decrease following administration of DCA. We are currently attempting to determine if DCA-mediated inhibition of the Warburg effect potentiates cognitive decline and neuronal loss in young tg-AD mice. Establishing a link between the Warburg effect and Aβ-resistance in vivo may provide valuable clues as to why some individuals exhibit little or no dementia when faced with high Aβ deposition in their brains.

Title: Mechanism of internalization of Abeta oligomer-receptor complexes

Authors: *K. MOZZONI, C. REHAK, C. SILKY, N. J. IZZO, R. YURKO, H. SAFFERSTEIN, G. RISHTON, S. M. CATALANO;
Cognition Therapeut., Pittsburgh, PA

Abstract: Abeta Oligomers accelerate vesicular exocytosis in neurons without affecting endocytosis rate (Lui and Schubert '97). We studied the mechanism of vesicular trafficking deficits caused by Abeta oligomers in DIV21 rat hippocampal cultures using Pitstop2 (Abcam cat# ab120687), a small molecule inhibitor of clathrin-mediated endocytosis and dynasore (Tocris cat# 2897), a peptide inhibitor of the dynamin-dependent endocytotic scission process using measurement of a vesicular cargo dye. Pitstop2 did not affect trafficking rate when dosed from 0.25uM-20uM, nor did it change Abeta-mediated trafficking abnormalities. Dynasore treatment induced the formation of enlarged vesicles in swollen neurites and cell bodies and slowed the rate of exocytosis (EC50=3.5uM, decrease of 40%). Dynasore counteracted the acceleration of Abeta-induced exocytosis, restoring trafficking rates and neurite appearance (100% of normal at 80uM**,** EC50=2.6uM). We conclude that Abeta acts on a dynamin-independent exocytosis process. Abeta oligomers exhibit saturable oligomer binding (Kd =1.4uM) to cell surface receptors causing internalization of oligomer-receptor complexes over time (Lacor et. al '04). Immunofluorescent labeling with and without detergent was used to measure total vs. surface oligomer binding (statistical comparisons pairwise Student's t-test). Abeta oligomers bound to surface receptors are gradually internalized by endocytosis, resulting in decreased binding intensity at the cell surface (1 uM total abeta concentration; 1 hour = 3.5% ±8, $p>0.05$, 2 hours = 27% ±3.3, $p<0.05$). Pitstop2 did not significantly affect internalization of receptor-bound oligomers (1 hour = 7% ± 3, $p>0.05$, 2 hours = 12% ±1.8, $p>0.05$). Dynasore significantly increased the amount of internalized oligomers (1 hour = 27% ±1.3, $p<0.05$) but this effect was transient (2 hours = 27% ± 1.5, $p>0.05$). We conclude receptor-bound Abeta oligomer is internalized by a dynamin-dependent process. Pitstop did not significantly affect the total amount of receptor bound oligomers (1 hour= 3%±5.5, $p>0.05$, 2 hours=8% ± 3.5, $p>0.05$). Dynasore significantly decreased the total amount of receptor bound oligomers at 2 hours (17% ± 1, $p<0.05$) but did not significantly decrease the total amount in 1 hour (2% ± 1.3, $p>0.05$). We

conclude that receptor-bound Abeta oligomer binding is decreased by dynasore due to depletion of receptors that have not been recycled back to the surface of the cell.

Title: A pharmacological model for treating Abeta synaptotoxicity at a receptor target

Authors: *N. J. IZZO, JR[1], K. MOZONNI[1], C. SILKY[1], C. REHAK[1], R. YURKO[1], R. MACH[2], J. XU[2], C. ZENG[2], G. RISHTON[1], H. SAFFERSTEIN[1], S. M. CATALANO[1]; [1]Cognition Therapeut., Pittsburgh, PA; [2]Washington Univ., St Louis, MO

Abstract: Soluble Abeta oligomers are implicated in synaptic loss and memory deficits seen in Alzheimer’s disease, but the molecular target mediating the synaptotoxic effects of these oligomers has not been identified. Alterations in intracellular trafficking are key mechanism by which Abeta oligomers affect synapse plasticity (Ehler 2006). We synthesized novel, blood brain barrier penetrable small molecules that are selective, high affinity ligands for a receptor in the brain which has not been previously implicated in Alzheimer’s pathology. CT109 and CT093 compete with Abeta oligomers for binding to neurons (72% and 68% reduction in binding,

respectively), reverse the effects of Abeta oligomers on vesicular trafficking in neurons (EC50 = 2.5 uM and 4.9 uM, respectively) and reverse deficits in memory and learning in huAPP-Swe/Ldn mice. Immunofluorescent labeling of DIV21 rat hippocampal neurons demonstrates punctate localization of the receptor in DIV21 rat neuronal synapses in close juxtaposition with presynaptic synaptophysin-1 labeling. Previously characterized ligands for the receptor were used in a vesicular trafficking assay and were found to express distinct functional phenotypes. CT1357 reversed Abeta-induced effects on trafficking (EC50 = 6.4 uM) with a toxic effect above 10 uM as indicated by an inhibition of cellular metabolism (MTT, Alamar Blue) and decreases in nuclear size. CT1357 also caused cleavage of Caspase-3 and activation of Caspase-3 enzymatic activity with a maximum effect at 40 uM (fold increase = 1.95 +/- 0.27, $p< 0.001$). CT1359 reversed Abeta effects on trafficking (EC50 = 2.5 uM) but without a cytotoxic effect on the neurons and without activation of Caspase-3. CT109 and CT0093 did not induce neuronal toxicity or activation of Caspase-3 and block the activation of Caspase-3 by 84% +/- 14% and 100% +/-12%, respectively ($p<0.001$). We conclude that CT109 and CT0093 bind to a specific receptor at post-synaptic sites where they compete for binding with Abeta oligomers, blocking the synaptotoxic effects of the Abeta oligomers. These compounds are antagonists of the receptor and do not induce activation of Caspase-3 and apoptosis in neurons as do agonists of the receptor. The ability to functionally block the synaptotoxic effects of Abeta oligomers without inducing apoptosis gives CT109 and CT0093 a desired therapeutic profile of a disease modifying treatment for Alzheimer’s disease.

Title: Spreading of amyloidosis to unaffected areas of the hippocampus studied *In vivo* by nervous tissue transplantation

Authors: M. SADALLAH[1], *F. TEMPIA[1,2];
[1]N.I.C.O. - Neurosci. Inst. Cavalieri Ottolenghi, Orbassano, Italy; [2]Dept. of Neurosci., Univ. of Torino, Torino, Italy

Abstract: Alzheimer's disease is the most common form of dementia, presenting with a progressive cognitive impairment. It is characterized by the presence of two principal hallmarks: amyloid plaques and neurofibrillary tangles. There is growing evidence that aggregated amyloid peptides and phosphorylated Tau proteins can spread from affected to unaffected neighboring areas of the brain. In this study we tried to assess this hypothesis by using a new in vivo methodological approach. To determine whether the spread of amyloid-beta peptide (Aβ) to healthy tissue causes different cell damage compared with endogenous production, we studied the survival of solid embryonic hippocampal grafts, derived from E15 GFP+ wild-type embryos, within a period of two months after transplantation in the hippocampi of adult wild type or APP/PS1 transgenic mice, model of Alzheimer's disease. Tissues grafted in APP/PS1 hippocampi displayed a 40% decrease in the number of neurites extending into the host ($P<0.05$) and a 27% lower dendritic spine density ($P<0.05$) compared to those grafted in wild-type recipients. The reduction was more severe for stubby-shaped spines. Moreover, some amyloid plaques were detected within the tissue transplanted in APP/PS1 mice along with dystrophic neurites and activated glial cells that surrounded the amyloid deposits. Our results show that amyloid plaque deposition can propagate very quickly to previously healthy tissue, thereby inducing neurite abnormalities and gliosis, in line with the current hypothesis of a prion-like propagation of brain amyloidosis.

Title: Exosomes can bind to and neutralize the activity of plasticity-disrupting Aβ assemblies *In vivo*

Authors: Y. SON, J. JUNG, T.-Y. JEONG, J. LEE, S.-J. KIM, S. LEE, S. LEE, H.-J. JO, *J.-H. KIM;
Life Sci., Pohang Univ. of Sci. & Technol. (POSTECH), Pohang, Korea, Republic of

Abstract: Accumulated studies have indicated that oligomeric forms of amyloid beta (Aβ) interfere with long-term potentiation (LTP), a cellular correlate of learning and memory, when they are administrated to cultured neurons, acute brain slices or hippocampus regions of live animal. However, the levels of LTP inhibition markedly vary depending upon the concentration of soluble Aβs used or their status. It was previously suggested that there are several factors that can regulate Aβs in the interstitial fluid (ISF), for example, transporting proteins through blood-brain barrier, Aβ-degrading enzymes, etc. In this study, we found that the exosomes, a small secreted lipid vesicles that contain lots of membrane proteins including insulin-degrading enzyme, cellular prion proteins can ameliorate the synaptic impairment caused by oligomeric form of Aβ (ADDLs) through in vivo LTP. We also provide in vivo evidence that N2a cell-derived or human CSF-derived exosomes can neutralize the synaptic-plasticity-disrupting activity of AD brain-derived Aβ and that this effect involves sequestration of synaptotoxic Aβ assemblies by exosomal surface proteins such as PrPC.

Title: P2XR activation contribute to acute Aβ excitotoxicity through an ATP-dependent mechanism

Authors: *F. SÁEZ-ORELLANA, A. DIBARRART, P. A. GODOY, C. A. RIVERA-VERA, J. GUZMAN, L. G. AGUAYO, J. FUENTEALBA;
Fisiología, Univ. De Concepción, Concepción, Chile

Abstract: Alzheimer´s Disease (AD) is the most common form of dementia in the elderly. To date, the main recognized toxic agents of the disease are the oligomeric forms of the amyloid beta (Aβ) peptide. One the proposed toxic actions of Aβ is the ability to bind to cell membranes and form non-selective pores or channel-like structures. Recent studies suggest that these pores have an inner diameter about 1.0 - 2.0 nm; large enough to allow the passage of molecules such as dyes and, more interestingly, cellular metabolites like ATP. The presence of pre-synaptic purinergic receptors that can modulate the release of neurotransmitters provide a unique feedback mechanism to promote the synaptotoxicity of Aβ. The aim of this work was to study the modulation induced by ATP on Aβ toxicity through P2X receptor activity.
Aβ induced a 2-fold increase in $[ATP]_e$ with respect to basal levels. This increase could promote the activation of P2X receptors and induce changes in $[Ca^{2+}]_I$ that can be partially blocked by PPADS (10 µM) and Apyrase (3 U/ml). We recorded miniature excitatory (mEPSC) and inhibitory (mIPSC) spontaneous post-synaptic currents pharmacologically isolated (mIPSC: TTX 25 nm + CNQX 5 µM + DAP5 50 µM;
mEPSC: TTX 25 nm + Bicuculline 5 µM) and quantified the frequency of events. The effect of Aβ on the mIPSC frequency did not show a significant decrease (Control: 100 ±18%; Aβ: 70 ±11%); whereas the mEPSC were increased 2.5-fold (Control: 100 ±15%; Aβ: 248 ±32%). These data correlate with previous results from our group that demonstrate a more elevated affinity of Aβ for excitatory versus inhibitory neurons. The effect of Aβ on the frequency of mEPSC can be prevented by the non-specific P2X blocker PPADS (10 µM) (Aβ: 248 ±32%; Aβ + PPADS: 111 ±18%) and also by Apyrase (3 U/ml) (Aβ: 248 ±32%; Aβ + Apy + DPCPX: 131 ±13%). Our results demonstrate that Aβ differentially affects glutamatergic neurons and this effect could be related to the activation of P2X receptors by a leak of ATP. The direct effects of Apyrase on Aβ oligomers and direct interaction between Aβ and P2X receptors was discarded using Thioflavin T assay and immunocytochemistry. These results can be useful to develop a new pharmacological target and drug discovery model to search for new therapies in the treatment of AD, and also for other pathologies related to ATP dyshomeostasis.

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder associated with an increased brain production, accumulation and aggregation of amyloid beta (Aβ) peptides. These processes are influenced by different modulators. Iron is one of these modulators, which is particularly relevant given its ability to regulate the expression of amyloid precursor protein and to drive Aβ aggregation into toxic oligomers. Herein we describe that lipocalin 2 (LCN2), a mammalian acute-phase protein involved in iron homeostasis, is highly produced in vitro by choroid plexus (CP) epithelial cells and cortical astrocytes, in response to Aβ1-42. These findings point to a role of LCN2 on Aβ-mediated toxicity.

Title: APP and Prion interaction with Aβ

Authors: *C. M. PETERS[1], M. ESPINOZA[1], C. OPAZO[2], L. G. AGUAYO[1];
[1]Dept. de Fisiologia, Univ. De Concepcion, Concepcion, Chile; [2]Oxidation Biol. Lab., Univ. of Melbourne, Melbourne, Australia

Abstract: Alzheimer´s disease (AD) is a progressive neurodegenerative disease that affects the human brain and causes cognitive and behavioral disorders. A major characteristic of AD is the presence of β-amyloid peptide (Aβ) oligomers in the brain. We have previously shown that Aβ oligomers (Aβo) associate with the neuronal membrane and induce the formation of perforations, causing an influx of calcium ions and increasing the release of synaptic vesicles that leads to a delayed synaptic failure produced by vesicle depletion.
Recent studies suggested that Aβ interacted with several proteins of the plasma membrane, such as the amyloid precursor protein (APP) and cellular Prion (PrPc). Therefore, these proteins could be participating in some of the toxic effects of Aβ in the brain. With the aim of determining if the levels of these two proteins affect the association and the toxic effects of Aβ on hippocampal neurons, we performed a series of experiments enhancing and reducing the membrane levels of APP and PrPc. Our results show that Aβ readily associated to the plasma membrane of HEK cells and hippocampal neurons after 1 h of incubation. The use of phospholipase C (PLC) decreased the levels of membrane PrPc in hippocampal neurons and also reduced Aβo association to these neurons (Aβo 544.5 ± 6.5, Aβo plus PLC 466.5 ± 13.5 RU). On the other hand, overexpression of APP in HEK cells increased association of Aβ fibrils (Aβf) (Aβf 3.388 ± 1.249, APP overexpressed plus Aβf 16.74 ± 5.184 RU), but not the association of Aβo to the membrane (Aβo 3.180 ± 1.349, APP overexpressed plus Aβo 1.427 ± 0.608). The latter suggests that the state of Aβ aggregation is important for its interaction with other membrane proteins. Finally, we performed functional experiments using patch clamp recordings to directly evaluate the capacity of Aβ to disrupt the membrane by reducing the levels of these proteins. The results support the idea that the interaction of Aβ with APP and PrPc is critical for peptide association and membrane disruption.

Title: Staged spatial correspondence between patterns of amyloid-β plaque deposition and intrinsic functional connectivity in prodromal Alzheimer's disease

Authors: *C. SORG[1], J. GÖTTLER[1], T. GRIMMER[1], M. MÜHLAU[1], A. KURZ[1], H. FÖRSTL[1], C. ZIMMER[1], A. WOHLSCHLÄGER[1], V. RIEDL[1], N. MYERS[2];
[1]Neuroradiology, Technische Univ. München, Munich, Germany; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Accounting for widespread amyloid-ß-pathology (Aß) beyond the default mode network (DMN), we extend DMN-centered models of Aß-propagation in Alzheimer's disease (AD) by proposing Aß-pathology to disrupt functional connectivity of intrinsic brain activity (iFC) in associative hubs and then to spread out along an iFC gradient across and within intrinsic networks. This model implies that the spatial correspondence between patterns of Aβ-pathology and iFC is distinctive across and within networks in an essentially staged pattern.
Pittsburgh-Compound-B (PiB)-PET and resting-state functional MRI was used to determine regional Aβ-plaque deposition and iFC in 40 asymptomatic and symptomatic (mild cognitive impairment MCI) elderly with and without PiB-uptake. Spatial iFC-pattern of intrinsic networks were derived from fMRI data via independent component analysis. We defined global and local spatial correlation (SpC) between Aβ-plaque pattern and iFC pattern and analyzed whether (i) global-SpC is the more positive the more Aβ-plaques in the network, and (ii) local-SpC is negative in hubs affected by Aβ-plaques.
In patients, we found a positive spatial correlation between global Aβ-plaque- and iFC-patterns in several fronto-parietal networks, with strongest correlations in the DMN, followed by lateral attention-networks (ATN). Conversely, in hubs of ATNs and the DMN, local correlations between Aβ and iFC were negative and progressively reduced. Correspondingly, Aβ-plaque-deposition was higher in the DMN than ATNs or other networks.
These results provide evidence for a staged pattern of spreading Aβ-pathology along intrinsic connectivity across and within intrinsic networks in AD. Data suggest a graded network degeneration model beyond the DMN in Alzheimer's disease.

Title: Beta amyloid, transmitter release and free radicals in cultured avian retinal cells

Authors: S. J. WALAS[1], B. STIEFEL[1], C. COUGHLIN[1], M. PAZ[1], S. SAJJAD[1], *D. GRAY[2]; [1]Biol., Simmons Col., Boston, MA; [2]Simmons Col., BOSTON, MA

Abstract: Beta-amyloid (Aβ) peptides have long been associated with senile neuritic plaques in the brains of Alzheimer's Disease (AD) patients. Previously published data using 14 day embryonic neuronal terminals in avian choroids and retinas demonstrate that Aβ peptide oligomers can significantly inhibit potassium-evoked acetylcholine (ACh) release. This modulation pathway requires nitric oxide (NO), cGMP, and activation of PKG as well as the generation of free radicals as evidenced by sensitivity to superoxide dismutase (SOD). Aβ is associated with retinas in animal models of glaucoma. To study the connection between neuromodulation and cell death, an in vitro model was developed using cultured retinal cells from the avian embryo. Retinas from 14 day chick embryos were dissociated and plated on 24 well plates coated with poly-ornithine and incubated with DMEM (Dulbecco's Modified Eagle Medium) and chick embryo extract. Survival, basal and evoked ACh release were measured and compared to values after exposure to aged soluble oligomers of Aβ with and without various pharmacological treatments. Cell survival was optimal over 4 days in culture. Potassium-evoked, calcium-dependent ACh release was significantly inhibited with overnight exposure to Aβ oligomers without obvious decreases in cell survival. Studies quantitating neuronal death of cultured avian retinal cells in conditions described above are underway. The presynaptic inhibition by Aβ was sensitive to inhibitors of nitric oxide synthase and was mimicked by nitric oxide donors. These results are similar to those in all other cholinergic neuron preparations studied by this lab, suggesting that Aβ may serve as a universal cholinergic modulator. Addition of superoxide dismutase also decreased the Aβ effect implying that free radical formation may be required for this type of synaptic modulation. One of the most common and toxic free radicals formed by combination of nitric oxide and mitochondrial superoxides is peroxynitrite. However, a specific inhibitor of peroxynitrite, 5-aminosalicylate, had no effect on transmitter release or its inhibition by Aβ. These results suggest that it may be possible to separate the neuromodulatory actions of Aβ from its associated pathology.

Title: The Aβ oligomer count in CSF is a biomarker for Alzheimer's disease

Authors: *D. WILLBOLD[1,2], L. WANG-DIETRICH[3], O. BANNACH[2], E. BIRKMANN[3], S. A. FUNKE[3];
[1]Forschungszentrum Jülich Gmbh, Jülich, Germany; [2]Inst. of Physical Biol., Heinrich-Heine-Universität Düsseldorf, Düsseldorf, Germany; [3]Forschungszentrum Jülich GmbH, Jülich, Germany

Abstract: Alzheimer's disease (AD) is a fatal neurodegenerative and progressive disorder. Currently, no reliable biomarkers for pre-symptomatic diagnosis or therapy monitoring are available. Recent studies indicate that especially soluble amyloid beta peptide (Aβ) oligomers are the major toxic species during development and progression of AD. Therefore, we suggest that the number of Aβ oligomers in body fluids can be used as the most relevant and direct biomarker for AD.
Our new surface-based fluorescence intensity distribution analysis (sFIDA) assay for quantification of Aβ oligomers with single particle sensitivity, is able to count Aβ oligomers in human cerebrospinal fluid (CSF). We challenged the assay with CSF samples from 14 AD patients and 12 age-matched control subjects. The Aβ oligomer count revealed a surprisingly clear distinction between both groups. All samples of the control group showed homogenously low numbers of Aβ oligomers, while the samples of the AD group exhibited significantly higher levels of Aβ oligomers. The Aβ oligomer levels clearly correlated with the patients' mini-mental state examination (MMSE) scores.
Our results support the idea that Aβ oligomers play a crucial role in AD pathology and in turn can be used as a diagnostic biomarker. The sFIDA assay is able to reliably quantify the Aβ oligomers in human CSF. In addition, the correlation between MMSE scores and Aβ oligomer counts suggests that the quantity of Aβ oligomers in CSF correlates with the severity of the disease. This will allow to evaluate and to monitor anti-Aβ-targeted therapies based on the Aβ oligomer counts in treated individuals.

Title: Real-time *In vivo* imaging reveals the ability of monocytes to clear vascular amyloid beta

Authors: *J.-P. MICHAUD, M.-A. BELLAVANCE, P. PRÉFONTAINE, S. RIVEST; CHUL Res. Ctr., Sainte-Foy, QC, Canada

Abstract: Cerebral amyloid angiopathy has a prevalence of more than 90% in patients with Alzheimer’s disease (AD) and correlates with cognitive deficits. Although the contribution of monocytes has yet been restricted of being macrophage precursors in AD, we aimed to investigate whether monocytes could play a role in the elimination of vascular Amyloid Beta (Aβ). By live intravital two-photon microscopy, we demonstrate that monocytes are attracted and crawl onto Aβ-positive blood vessels of APPswe/PS1 mice. Furthermore, we report the presence of crawling monocytes carrying Aβ and their ability to circulate back into the bloodstream. These observations uncover the ability of monocytes to naturally eliminate vascular Aβ and constitute a potential new therapeutic target in AD.

Title: Analysis of TREM2 expression in APPPS1 transgenic mouse brain

Authors: A. ARRANZ[1,2], *B. G. DE STROOPER[3,2];
[1]VIB Ctr. for the Biol. of Dis., Leuven, Belgium; [2]Ctr. for Human Genet. and LIND, KU Leuven, Leuven, Belgium; [3]K.U.Leuven, Leuven, Belgium

Abstract:
Rare variants in the TREM2 (triggering receptor expressed on myeloid cells 2) gene are associated with an increased risk of late-onset
Alzheimer disease (AD).
TREM2 is an immune phagocytic receptor expressed on the cell membrane of immature dendritic cells, osteoclasts, tissue macrophages and brain microglia. TREM2 on microglia is critical for the clearance of neuronal debris and has an anti-inflammatory role in the brain. Therefore, impaired function of the TREM2 protein may affect inflammatory processes and lead to a decline in cognitive function through the
inability of the brain to clear amyloid plaques.
In mouse models of AD, TREM2 is expressed in microglia surrounding
amyloid plaques however full characterization of TREM2 expression in these mouse models is lacking. Therefore, by using qPCR, immunohistochemistry and western blotting we have analyzed the expression of TREM2 gene and protein in APPPS1 transgenic mice and we have compared it with their control littermates.
Our results might provide insight into how TREM2 impairment leads to the CNS symptoms of AD.

Title: IL-1β mRNA expression, circadian rhythms, and nest building in an hAPP/ApoE4 late-onset mouse model of Alzheimer’s disease

Authors: *P. BOZZELLI, J. J. GRAYBEAL, L. L. GRAYBEAL, D. N. COX, J. M. FLINN; George Mason Univ., Fairfax, VA

Abstract: Inflammation is one of the hallmarks of Alzheimer's disease (AD). The majority of AD studies of inflammation use mouse models carrying genes associated with early-onset AD. These early-onset genes however only account for about 5% of AD cases. In order to study the more prevalent form of AD we crossed animals carrying an early-onset gene (APP) with a late-onset gene (ApoE4). Recent evidence suggests that in spite of conferring a significant risk of developing AD later in life, the ApoE4 gene may be protective in young mice (Marchant et al., 2010). Behavioral assays were conducted at 4 months and mice were then sacrificed at 7 months. RT-PCR was performed to evaluate gene expression for the inflammatory cytokine IL-1β. Mice carrying the single transgene APP had significantly higher expression of IL-1β compared to wildtype controls (Mann-Whitney U test, $p<.001$). The APP/ApoE4 mice were not significantly different from wildtype controls (Mann-Whitney U test, $p<.201$). The levels of IL-1β gene expression were then correlated with wheel-running activity variables, which are a measure of circadian rhythm. Significant correlations were observed in average bout length ($r=.509$, $p<.05$), average number of counts per bout ($r=.573$, $p<.05$), average peak rate during a bout ($r=-.509$, $p<.05$), and the average number of counts per bout-minute ($r=-.647$, $p<.01$). A nest building assay was also performed by introducing a cotton square into the wheel-running cages during the last 48 hours of circadian rhythm testing. Wildtype mice built nests while APP mice did not. IL-1β expression levels were significantly correlated with scores of nest building ($r=-.812$, $p<.000$). The APP/ApoE4 mice showed intermediate ability in constructing nests which parallels their intermediate IL-1β levels. These data indicate that ApoE4 status may be protective against disruptions in circadian rhythms, nest building, and cytokine levels in young mice.

Title: Human RAGE expressed in endothelial cells exacerbates blood-brain barrier dysfunction

Authors: *S. V. REGE[1], E. HATCH[2], M. WANG[1], N. K. CHUQUI[1], Z. ZHAO[1], A. P. SAGARE[1], B. V. ZLOKOVIC[1,2];

[1]Physiol. and Biophysics, USC, Los Angeles, CA; [2]Ctr. for Neurodegenerative and Vascular Brain Disorders, Univ. of Rochester, Rochester, NY

Abstract: The receptor for advanced glycation end products (RAGE) is responsible for the recognition of a diverse array of ligands and this interaction activates the receptor resulting in an inflammatory response. RAGE is present mainly at the luminal, or blood-facing side, of the brain endothelium at the blood-brain barrier (BBB) and mediates the influx of amyloid β-peptide (Aβ), Alzheimer's disease neurotoxin, into the brain parenchyma. Altered activity of RAGE in the BBB endothelium may contribute to the Aβ accumulation leading to uncoupling of cerebral blood flow and metabolism, neuronal injury, as well as inflammation. In diabetes, hyperglycemia stimulates the production of ligands that interact with RAGE and activate inflammatory signaling mechanisms. To study the influence of RAGE in vascular pathology at the BBB, we have generated a transgenic mouse model overexpressing human RAGE (hRAGE) in endothelial cells under the control of the Tie-2 promoter. The expression of hRAGE was confirmed by quantative real-time PCR, Western blotting, immunohistochemistry, and mass spectrometry analysis. We observed age-dependent changes in basement membrane and tight junction proteins, decreased pericyte coverage and BBB breakdown associated with accumulation neurotoxic/vasculotoxic serum proteins in brain of hRAGE expressing mice. The transgenic expression of hRAGE in vascular endothelial cells leads to these pathological changes in the BBB by 14 months of age. Thus, this model can be used to determine the RAGE mediated progression of vascular pathology associated with hyperglycemia, specifically at the BBB. In addition, newly developed RAGE inhibitors by our group (J Clin Invest. 2012; 122(4):1377-1392) could be used with this model as a rescue for the observed pathology.

Abstract: We have previously reported the temporal progression of microglial activation in the hippocampus of a PS1/APP transgenic model of Alzheimrer's disease, however the microglial phenotypes in the human pathology have not been determined yet. We have here characterized the microglial response during disease progression using hippocampal samples from human autopsies of middle-age controls, Braak II, Braak III-IV and Braak V-VI Alzheimer patients using RT-PCR, western blots, immunostainings and cell systems.
Clear microglial activation was identified on BraakV-VI samples. Using the same cohort, we tested the microglial differentiation state (M1 or M2) by determining the expression of several key factors. No changes in the expression of the murine alternative marker Arg-1 was observed. However, we detected a slight decrease in of, at least, three putative human alternative markers (mannose-receptor 1, IGF-1 and folate-receptor-2). In the same samples, the classic markers TNF-alpha, FASL and CH3CL1 displayed a clear increase. This cytotoxic inflammatory environment is coincident with a significant decline of the neuronal marker NeuN. Interestingly, a profound reduction in the expression of SOM, NPY and PV interneuronal markers was found. Furthermore, we have also tested the stimulatory capacity, in vitro using microglial cultures, of soluble extracts (S1 fractions), prepared from the same cohort of human samples. Using these preparations, the S1 derived from Braak V-VI samples produced a M1 stage whereas the S1 from Braak II induced a M2 polarization.
In conclusion, similar to animal models, aged non-demented human samples displayed a non-classic partially-alternative microglial polarization whereas demented Alzheimer samples displayed a more pronounced classic activation. We are now characterizing the human derived soluble S1 fractions trying to identify the putative mediators of the microglial activation.

Title: Prominent loss of adaptive immune responses to Aβ in perimenopausal women who carry an apoe-ε4 allele

Authors: *A. N. BEGUM[1], C. CUNHA[1], E. R. ROSARIO[2], J. SCOLNICK[3], D. W. ETHELL[1]; [1]Mol. Neurobio. Group, Col. of Biomed. Sci., Western Univ. of Hlth. Sci., Pomona, CA; [2]Casa Colina Hosp. for Rehabilitative Med., Pomona, CA; [3]Neurosurg., Arrowhead Regional Med. Ctr., Colton, CA

Abstract: Alzheimer's disease (AD) is the most common causes of dementia in the elderly, with >5.2 million cases in the US, a number that will exceed 13 million by 2030. Disappointing results in recent clinical trials that targeted immune responses to Aβ has shifted strategies toward slowing AD progression at the earliest stages possible. Identifying subjects in the early prodromal stages of this disease currently rely on measures that require at least some pathological changes in the brain. Our lab has taken a different approach by evaluating adaptive immune responses to Aβ that may be useful as early indicators of changes in the handling of Aβ as it is cleared from the brain. To achieve this goal we developed a novel platform that allows for the characterization of Aβ-specific CD4+ T cell responses using a small sample of human blood, referred to as CD4see. Notably, the immune responses evaluated by CD4see are similar, if not identical, to those elicited by Aβ vaccination. Aβ vaccination attenuates AD pathology and cognitive impairment in mice, suggesting a protective role for Aβ-specific CD4+ T cells. CD4see employs stem cell-derived dendritic cells (DC) that are engineered to present highly specific fragments of Aβ to CD4+ T cells isolated from whole blood, using HLA fusion proteins that span Aβ1-42. Blood samples that contain CD4+ T cells showed T cell proliferation in response to one or more of these probes, which is detected by flow cytometry. In our analysis of >75 human subjects we found that most young and middle-aged people have Aβ-specific CD4+ T cells, demonstrating a capacity for an adaptive immune response to Aβ. Alternatively, Alzheimer's subjects had few Aβ-specific CD4+ T cells. Women who carried at least one copy of the ApoE-ε4 allele showed few Aβ-responsive CD4+ T cells over the age of 52, which is a perimenopausal period for most women. Interestingly, these women are at very high risk for AD with a more rapid progression of dementia. Age-dependent reductions of Aβ-specific CD4+ T cell responses were not as distinct in men who carried an ApoE-ε4 allele, or in non-carriers of both genders. CD4see may provide an important early measure of changes in adaptive immune responses to Aβ that could aid in identifying subjects in the prodromal stages of AD, which could be beneficial in clinical trials that target Aβ-specific immune responses to treat AD.

Title: Determining the effects of neuroinflammatory phenotypes on amyloid deposition in APP/PS1 transgenic mice

Authors: *E. M. WEEKMAN, T. L. SUDDUTH, A. GREENSTEIN, D. M. WILCOCK; Physiol., Univ. of Kentucky, Lexington, KY

Abstract: The polarization of neuroinflammatory phenotypes has been described in early Alzheimer's Disease (AD), yet the impact of these different phenotypes on the pathology of AD remains unknown. The goal of the current study was to determine whether an M1 neuroinflammatory phenotype affects amyloid pathology in a different manner than an M2a phenotype. To address this we injected Adeno-Associated Virus serotype 8 (AAV-8) expressing either IL-4 or TNFα and IFNγ into the frontal cortex and hippocampus of both the right and left hemispheres of the brain in wildtype and APP transgenic mice. Mice receiving IL-4 AAV-8 were sacrificed at 4 to 6 weeks due to mortality. Mice injected with TNFα and IFNγ AAV-8 were sacrificed at 4 months or 6 months. The neuroinflammatory phenotype and microglial activation were measured by qPCR and immunohistochemistry, respectively.

We found that AAV-8 expressing IL-4 led to an M2a biased neuroinflammatory phenotype while TNFα and IFNγ led to an M1 biased phenotype. This was determined by qPCR for the M1 markers IL-1β, TNFα, IL-6 and IL-12 and the M2a markers Ym-1, IL-10 and IL-1Ra. Microglial activation assessed by CD11b and CD45 showed increased activation with both IL-4 and TNFα/IFNγ. However, it was noted that plaque-associated microglial activation was more intense in the mice receiving TNFα/IFNγ AAV-8. Amyloid-beta quantification is currently in progress.

Overall, we found that IL-4 AAV-8 promotes an M2a phenotype while TNFα and IFNγ AAV-8 promotes an M1 phenotype. Also, microglial activation showed a higher degree of plaque association in mice receiving TNFα and IFNγ AAV-8.

Title: MyD88 and the inflammasome are both involved in the activation of microglia by amyloid-β(1-42) protofibrils

Authors: *S. TERRILL, M. MOHAN, M. R. NICHOLS;
Univ. of Missouri St. Louis, Saint Louis, MO

Abstract: Neuroinflammation is a well-defined element of Alzheimer's disease (AD). The brains' of AD patients contain senile plaques composed of aggregated amyloid-β protein (Aβ). Surrounding these plaques are activated microglia which secrete a variety of proinflammatory cytokines and create an inflammatory environment involving both innate and adaptive immune responses in the central nervous system. Data has shown that several multi-protein receptor complexes mediate the microglial immune response to Aβ and suggest that multiple innate immune components work together for Aβ recognition. Previous work in our lab has identified Toll like receptors (TLRs) as having a role in mediating Aβ-induced inflammatory responses. The activation of TLRs leads to the recruitment of the TLR adaptor protein MyD88 and the expression of many different innate immune genes. We have previously shown that Aβ(1-42) protofibrils are potent activators of primary murine microglia. Therefore we utilized primary microglia from both wild type (WT) and MyD88 knockout ($MyD88^{-/-}$) mice to investigate the involvement of MyD88 in the Aβ-induced inflammatory response. Our data shows that WT primary microglia treated with Aβ(1-42) protofibrils significantly increased mRNA and protein levels of tumor necrosis factor alpha (TNFα) and interleukin-1beta (IL-1β) compared to buffer controls. $MyD88^{-/-}$ primary microglia treated with protofibrils produced <1% of the WT primary microglia TNFα and IL-1β mRNA after two hours. However, while secreted TNFα protein for $MyD88^{-/-}$ microglia was <20% of the WT microglia, secreted IL-1β protein was observed at 1 hour of treatment and did not show a decrease through 6 hours. Furthermore, the IL-1β protein response was comparable between WT and $MyD88^{-/-}$ microglia at all-time points suggesting that reduction of IL-1β mRNA by knockdown of MyD88 does not diminish mature IL-1β protein production. The findings herein demonstrate that the TLR-MyD88 pathway plays a significant role in mediating the Aβ(1-42) protofibril-induced proinflammatory response but is not

necessarily linked to protofibril activation of the inflammasome.

Title: Participation of Scavenger Receptor A (SR-A) in the inflammatory activation pattern of glial cells in an Alzheimer's disease new transgenic model

Authors: *R. VON BERNHARDI, F. CORNEJO, G. RAMIREZ;
Dept Neurol, Pontificia Univ. Catolica De Chile, Fac Med., Santiago, Chile

Abstract: Scavenger receptors appear to participate in β-amyloid (Aβ) uptake and the inflammatory activation of glia. We propose that binding to specific ligands can mediate neuroinflammatory processes that are characteristic in neurodegenerative diseases. In APP/PS1 transgenic mice, we observed that young animals had an increased percentage of astrocytes and microglia expressing SR-A compared with WT mice. However, the number of cells was reestablished at 6 months of age. We developed a triple-transgenic mice overexpressing Aβ and KO for SR-A (APP/PS1/SR-$A^{-/-}$), in which we observed an increased production of Nitric Oxide (NO) by microglia, and a decreased release of IL1β by astrocytes and microglia in response to inflammatory stimuli such as LPS, whereas a reduction of TNFα release was observed in stimulated astrocytes. Furthermore, triple-transgenic astrocytes showed an increased phagocytosis of Aβ, whereas microglia showed an apparent reduction in the induction of phagocytic activity in response to LPS. Trimeric SR-A receptor was expressed by WT astrocytes, whether KO cells only expressed the monomeric protein, which is not functional. We also evaluated the participation of SR-A on astrocytes and microglial cell activation as well as on the ability of astrocytes to regulate microglia. Astrocytes regulate neuroinflammation through the production of several soluble molecules, including IL1β, which is capable of regulating microglial cell activation. In astrocyte cultures obtained from WT and SR-$A^{-/-}$ mice, we analyzed the activation of MAPKs and IκB/NFκB signaling pathways and the production of NO, TNFα and IL1β in response to SR-A ligands (LPS and Poly I). LPS was capable of inducing activation

of ERK in WT and KO cells, but activation lasted longer in KO astrocytes. In WT but not KO cells, LPS induced phosphorylation of JNK and p38. Similarly, IκB/NFκB pathway was active both in WT and SR-A$^{-/-}$ cells, but activation of IκB/NFκB was delayed in KO astrocytes. LPS increased production of NO in a time dependent manner, but levels of NO were higher in KO than in WT astrocytes. In contrast, whereas SR-A ligands increased TNF-α release in WT and KO astrocytes, IL1β release was undetectable in stimulated KO cells. Our results suggest that SR-A participates in several phenomena associated to Alzheimer's disease, such as the activation of signaling pathways involved in the production of soluble molecules mediating the inflammatory activation of glial cells, and is needed to modulate neuroinflammatory cell activation.

Title: Early increase in TNF-alpha in a prodromal model of Alzheimer's disease

Authors: *C. CAVANAGH, R. QUIRION, T. WONG;
Psychiatry, Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: An enormous effort is directed at targeting amyloid-beta (Abeta), the main constituent of senile plaques, to treat Alzheimer's disease (AD). Unfortunately, all clinical trials with this approach have failed, leading to alternative hypotheses of causative agents in AD. The focus has also shifted to the prodromal stages of the disease to identify the earliest alterations contributing to AD in hopes to improve intervention. Inflammatory mediators, such as pro-inflammatory cytokines, are present from early to late stages of AD pathology and can have neurotoxic effects. For example, tumor necrosis factor-alpha (TNF-alpha) is upregulated in both humans with AD and transgenic mouse models of the disease. So far, inhibition of TNF-alpha signaling has been beneficial in mouse models (Gabbita et al., J. Neuroinflammation, 2012) and has even led to cognitive improvement in an AD patient (Tobinick et al., J. Neuroinflammation, 2008). Despite these studies, the mechanism by which TNF-alpha may exacerbate AD pathology is unknown,

however, it is possible that TNF-alpha is affecting synaptic function. Although TNF-alpha is a well-known immune mediator, increasing data indicates that TNF-alpha has functions in the brain as well. Here, the role of TNF-alpha is thought to be regulatory or neuroprotective at physiological levels, however at increased levels, TNF-alpha may become neurotoxic (Santello and Volterra, Trends in Neurosci., 2012, Cavanagh et al., Future Neurology, 2011). We hypothesize that increased levels of TNF-alpha at early stages of AD-like pathology may become pathogenic and lead to deficiencies in synaptic function. We use the TgCRND8 mouse model of AD, which overexpresses a double human mutation of the precursor to Abeta, the amyloid precursor protein (APP) to show that 1-month-old mice display both a significant increase in TNF-alpha (Cavanagh et al., J. Alzheimer's disease, 2013) and alterations in synaptic function. This time point is well suited for the study of prodromal AD, since it occurs before the development of cognitive deficits and the appearance of amyloid plaques. Our findings may provide insight on TNF-alpha as a potential therapeutic target in the prodromal stages of AD and will help elucidate the effects of TNF-alpha on synaptic function.

Title: An acute lps-induced inflammatory response in a diabetic model of alzheimer's disease

Authors: *A. S. MURTISHAW[1], C. F. HEANEY[2], J. W. KINNEY[2], M. M. BOLTON[2];
[1]Psychology/Neuroscience, UNLV Neurosci. Doctoral Student, Las Vegas, NV;
[2]Psychology/Neuroscience, UNLV, Las Vegas, NV

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder of unknown etiology. AD is characterized by cognitive and behavioral impairments in addition to pathological features that include amyloid plaques, neurofibrillary tangles and neuronal loss. Only a small proportion of AD cases are due to genetic mutations whereas the vast majority of cases are late onset and sporadic in origin. The cause of sporadic AD (sAD) is likely multifactorial, with interactions of external factors, biological, and genetic susceptibilities that contribute to the onset and and progression of the disease. Diabetes Mellitus (DM) and neuroinflammation are two of the most common risk factors that have been implicated in sAD. Considerable progress has been made to understand the involvement of each of these risk factors in isolation but limited data exist on the

combination of the two. In the below studies we investigated the effects of neuroinflammation in a diabetic-model of sAD on behavioral and pathological markers of AD. For the present study, we infused streptozotocin (STZ; a compound used to model sAD in animals) directly into the lateral ventricles to dysregulate insulin signaling within the brain. This initial investigation was directed at determining the effects of an acute inflammatory response on STZ-induced deficits relevant to AD. Lipopolysaccharide (LPS) was utilized to acutely activate the immune system one week following the STZ infusion. Learning and memory was examined in the Morris water maze (MWM), following which hippocampal tissue was examined for pathological markers of AD. Results indicate that STZ-induced deficits consistent with other reports in both behavioral tasks as well as an increase in oligomeric beta-amyloid consistent with AD. Interestingly, the acute inflammatory response significantly reduced both the behavioral deficits and the increase in oligomeric beta-amyloid. These data demonstrate a beneficial effect of an acute inflammatory response in this model (STZ+LPS).

Title: Epigenetic regulation of aging microglia in Alzheimer’s Disease and neurodegeneration

Authors: *E. M. YORK[1,2,4], A. PETIT[1,4], A. CHOU[3], A. J. ROSKAMS[1,4];
[1]Zoology, [2]Neurosci., [3]Cell. and Physiological Sci., Univ. of British Columbia, Vancouver, BC, Canada; [4]Intl. Collaboration On Repair Discoveries, Vancouver, BC, Canada

Abstract: In a healthy brain, microglia are neuroprotective; however with age, they become senescent and lose their regulative, proteolytic, and neuroprotective functions. Dystrophic microglia appear in the Alzheimer’s disease (AD) brain before tau pathology becomes apparent and may be present in other forms of cognitive dementia. We are interested in whether chromatin dysregulation contributes to the senescence of microglia, making them inefficient at performing their normal scavenging function in the aging brain. Aging of peripheral immune cells can be

directly modulated by histone deacetylase inhibitors (HDACis). HDACis can also shift glia and neurons into a more developmental state to promote or aid CNS repair, and alter microglia activation and macrophage recruitment after spinal cord injury.
We hypothesize that aging, cellular damage, and epigenetic factors cause microglia to become dystrophic, which decreases their ability to neuro-protect and respond to injury. This facilitates more long-term damage and progression of neurodegenerative disease. We have found that dystrophic microglia - identified morphologically and by enhanced expression of L-ferritin - are more numerous in the human AD neocortex compared to controls. In addition, we have observed that microglia are dysregulated with aging in the PSEN mouse model of AD. In our experiments, HDACis do appear to alter the mitotic abilities of both young and aged primary microglia cultures from adult mice in vitro, and we are currently testing if this is reflected in morphology and ability to respond to stimuli, in vitro. If so, this, coupled with approaches to produce and better characterize dystrophic microglia in vitro, will allow us to assess the ability of HDACis to revert a dystrophic microglia phenotype to that of a younger cell. We will then screen for changes in the expression and activity of individual HDACs so that highly targeted HDACis in microglia can be tested to limit off-target effects. These results will allow us to test if dystrophic microglia may malfunction as part of aging and neurodegenerative disease or neurodegeneration after injury, and if HDAC inhibition may be an appropriate approach to restore their protective functions. These results will be important in understanding and treating brain injury across the lifespan, and in developing novel approaches to mobilize microglia in the context of neurodegenerative diseases.

Title: Characterization of caspase-4 in inflammation and Alzheimer's disease

Authors: Y. KAJIWARA, N. DORR, G. VOLOUDAKIS, M. GAMA-SOSA, G. ELDER, D. L. DICKSTEIN, *O. BOZDAGI, J. D. BUXBAUM;
Dept Psychiatry, Icahn Sch. of Med. At Mount Sinai, NEW YORK, NY

Abstract: Caspase-4 has been proposed to be a primate-specific member of the inflammatory caspases. We have previously reported that caspase-4 mRNA is significantly upregulated in the brain of Alzheimer's disease (AD) subjects. However, due to the absence of the gene in the mouse genome, physiological function of caspase-4 has remained unknown. We therefore generated transgenic mice expressing human caspase-4 and characterized them in the context of innate immune response and AD pathogenesis.

Consistent with its inflammatory role, in response to lipopolysaccharide caspase-4 transgenic mice rapidly secreted higher levels of proinflammatory cytokines including interleukin-1β (IL-1β) and interleukin-18 (IL-18), both of which are known substrates of caspase-1. In addition, bone marrow derived macrophages from caspase-4 mouse secrete IL -1β and IL-18 in response to TLR ligand alone. IL-1β and IL-18 hyper-responsivity was abolished in caspase-1 deficient mice, supporting the role for caspase-4 as an upstream activator of caspase-1.

The role for caspase-4 in AD was investigated by crossing caspase-4 mice with APPsw/PS1deltaE9 mice. Caspase-4 expression was upregulated in male APPsw/PS1deltaE9/CASP4 mice and this upregulation was specific to brain regions relevant to AD. Caspase-4 did not affect either amyloid volume in the hippocampus or the level of soluble Abeta in the brain. Electrophysiological analysis showed a decrease in synaptic plasticity measured by long-term potentiation in caspase-4 mice at 14 month-old but not in 4 week-old mice. When spatial learning ability was tested by Barnes maze, all mice showed normal acquisition at 7 and 13 month. However, male APPsw/PS1deltaE9/CASP4 mice showed significant impairment upon reversal of target compared to all other genotypes at both ages.

Title: Glatiramer acetate induces cerebral infiltration of osteopontin-expressing monocytes that facilitate Aβ clearance

Authors: *A. RENTSENDORJ[1], B. SALUMBIDES[1], J. SHEYN[1], Y. KORONYO[1], D. LOPES[1], D.-T. FUCHS[1], A. WOLF[2], K. L. BLACK[1], M. KORONYO-HAMAOUI[1,3];
[1]Dept. of Neurosurg., [2]IBRI/GI, [3]Biomed. Sci., Cedars Sinai Med. Ctr., Los Angeles, CA

Abstract: Previously, we reported that immune modulation with glatiramer acetate (GA; also called Copaxone®) reduces neuropathology and cognitive impairments associated with Alzheimer's disease (AD) in transgenic murine models (ADtg mice). These effects were associated with cerebral recruitment of bone marrow (BM)-derived monocytes/macrophages inducing a local anti-inflammatory response, via IL-10 and MMP-9 secretion, and amyloid β-protein (Aβ) plaque clearance. However, the exact mechanism by which GA induces peripheral monocyte recruitment to the brain and alleviates AD progression in mice is still unclear. Osteopontin (OPN) is a glycoprotein highly expressed by BM-derived monocytic cells that serves as a modulator of immune cell migration, communication, and overall response, partly via induction of MMP-9 and by shifting helper T cell populations. To understand the role of OPN in GA-immunized ADtg mice and how GA affect OPN levels in myelomonocytic cells, OPN expression in GA-immunized bigenic APPSWE/PS1dE9 mice was studied. Further, the extent by which GA impacts OPN expression in macrophage and their phagocytic capacity to uptake fibrillar Aβ, were evaluated in primary BM-derived cultures. We found distinctive elevated OPN expression patterns in different brain regions, such as entorhinal and cingulate cortex and hippocampus, following GA immunization. A combined treatment of GA with i.v. infusion of BM-monocytes (GABM) indicated even higher OPN levels surrounding Aβ plaque sites with increased monocytic infiltration. OPN colocalized with and around Iba1+CD45high macrophages that were associated with the plaques. Correlogram analysis of quantitative immunohistochemical data from these brain regions indicated a significant linear association between OPN and infiltrating monocytes/macrophages, as well as inverse correlation between OPN levels and Aβ plaque burden. In vitro analyses, using western blot, ELISA and immunocytochemical assays, revealed that GA modulates OPN expression in BM-macrophages concomitant to enhanced cellular uptake of fibrillar Aβ1-42. These in vitro results mirror our in vivo data reinforcing the notion that OPN mediates migration of BM-monocytes to the diseased brain and affect macrophage behavior. Overall, these studies suggest that reduced cerebral Aβ burden achieved by GA immunization is mediated at least in part through increased recruitment of OPN-secreting monocytes/macrophages with enhanced ability to clear Aβ.

Title: Diet-induced obesity and low testosterone interact to promote Alzheimer- and diabetes-related pathologies: A central role of inflammation

Authors: *J.-W. LEE[1], H. WRIGHT[2], C. J. PIKE[1];
[1]Davis Sch. of Gerontology, [2]Neurosci., USC, Los Angeles, CA

Abstract: Obesity, type 2 diabetes (T2D) and low testosterone are common health issues in aging men and independent risk factors for Alzheimer's disease (AD). Epidemiological studies suggest bidirectional associations between these factors, linking low testosterone with increased risk of obesity and T2D and vice versa. In this study, we investigated whether these factors interact in regulating AD development and, if so, what pathway(s) contribute to the interaction. To accomplish this goal, we compared the effects of diet-induced obesity in male mice with normal and low levels of testosterone on metabolic and Alzheimer-related endpoints. Since chronic inflammation is a common feature in AD, obesity, and T2D, we also examined neural and peripheral metabolic inflammatory responses as a potential contributing pathway to hypothesized interactions. Specifically, young adult male, C57BL/6J mice were maintained for four months on diets containing either 10%, 45%, or 60% fat. Separate groups of mice under each diet had normal testosterone, low testosterone (orchiectomy, ORX) or ORX with testosterone treatment. At the end of the treatment period, mice were behaviorally assessed and various tissues were collected and analyzed for levels of factors associated with AD, T2D, and inflammation. We observed that high fat diet resulted in significantly increased bodyweight, fat mass, and indicators of T2D including fasting glucose and insulin levels. Obese mice also exhibited significant increases in soluble β-amyloid protein and decreased expression of the β-amyloid degrading enzyme neprilysin. Further, obese mice exhibited increased levels in brain and adipose tissues of pro-inflammatory genes such as TNFα, IL-1β and IL-6. Each of these outcomes was exacerbated in ORX mice. Importantly, the deleterious effects of ORX were prevented by testosterone treatment. Low testosterone even in the absence of high fat diet had negative effects on expression of metabolic, AD, and inflammatory factors. This study demonstrates independent and interactive effects of low testosterone and obesity on indices of AD and T2D. Notably, low testosterone and obesity also cooperatively promoted inflammatory pathways, which are implicated in the pathogenesis of both AD and T2D, suggesting that

inflammatory responses may be a central part in this interrelationship. These findings demonstrate significant beneficial roles of testosterone in neuronal and metabolic conditions that may provide insight into effective therapeutic strategies for AD and metabolic disorders.

Abstract: Most just over 6,000 million people who inhabit the planet today have a longer life expectancy than did their counterparts half a century ago and these, in turn, much larger than their ancestors had done tens of thousands of years ago. In our species is seated a biological tendency consisting of the gradual increase of life and are, therefore, a propensity to undergo degenerative processes themselves senescence. Parkinson's disease (PD) and Alzheimer's disease (AD) is the most prevalent neurodegeneration contemporary human societies and have started to become a high impact epidemiological problem by the progressive deterioration of motor and cognitive skills that characterize them. In the world literature there are many mentions of association of a number of signs that determine metabolic syndrome (MetS) with the degenerative processes mentioned, but still difficult to make categorical statements of a cause-

effect relationship. The alarming increase in the incidence and prevalence of overweight/obesity, MetS and diabetes mellitus in the world's population, can presume to observe any link with the increased prevalence of neurodegenerative diseases. Target. To determine the presence of oxidative stress-related factors and metabolic syndrome in patients with PD and AD. Methods. We compared three groups of elderly patients drawn from the general population who come to consult to Neurodiagnostics Unit and Nervous System Diseases Research, Faculty of Medicine, Universidad Autonoma of Queretaro: the first group consists of individuals diagnosed with PD, the second by individuals diagnosed with AD, and the third by individuals without such neurodegeneration or demonstrated signs of MetS. All three groups are different biochemical procedures are applied (curve glucose tolerance, glycosylated hemoglobin, fasting serum glucose, insulin determination and calculation of insulin resistance), neuropsychological performance (test for depression, drug addiction, alcoholism neurocognitive status), neurodiagnostic studies (conventional and quantitative electroencephalography, visual and auditory evoked potentials) and are being applied a questionnaire to determine your lifestyle (exercise, diet). The criteria for defining the PD, AD and MetS variables were the established by the World Health Organization. Results. At this time, partial results have different procedures. State conclusions. Because it is an ongoing investigation, the findings and results will be presented at the meeting in San Diego, CA.

Abstract: The accumulation of amyloid β-protein (Aβ) in the brain is postulated to be a primary etiologic event leading to dementia of Alzheimer's disease (AD). Fibrillar Aβ deposits are accompanied by activated microglia and increased levels of cytokines. Many lines of evidence support the notion that activated microglia, innate immune cells in the central nervous system, play pivotal, dual roles in AD progression: either clearing Aβ deposits by phagocytosis and promoting neuron survival and plasticity or releasing cytotoxic chemicals, inflammatory cytokines, exacerbating Aβ load and neurodegeneration. Aβ aggregates/deposits can activate microglia through a receptor complex that contains toll-like receptor 4 (TLR4) as one of its essential components. To investigate the role of TLR4 signaling in the pathogenesis and progression of AD, we have produced three groups of AD model mice, which differed in TLR4 copy number: 1) 6 copies of the TLR4 gene (overexpression), 2) 1 copy, and 3) no copy (TLR4-deficient). These model mice were produced by repeated mating between Tg390 mice carrying 6 copies of the TLR4 gene on the C57BL/10ScNCr background and TgAPPswe/PS1dE9 mice on the C57BL/6J background. TLR4 overexpression (6 copies) and deficiency did not influence Aβ load in the brain of an AD mouse model at 5 months of age. We are currently investigating the effects of TLR4 overexpression and deficiency on β-amyloidosis and neuroinflammation in these animal models at 10 months of age.

Title: A role for thrombin as a mediator of cerebrovascular abnormalities in Alzheimer's disease and diabetes

Authors: *P. GRAMMAS, A. SANCHEZ, J. LUO, X. YIN;
Garrison Inst. on Aging, Texas Tech. Univ. Hlth. Sci. Ctr., LUBBOCK, TX

Abstract: Alzheimer's disease (AD) and diabetes are two of the most common and devastating health problems in the elderly. Epidemiological evidence indicates that diabetes is associated with an increased risk for the development of AD. Vascular abnormalities are important features of both AD and diabetes, thus the brain vasculature is a likely nexus for the convergence of diabetic and AD pathogenic mechanisms. In the cerebromicrovasculature we have previously demonstrated oxidative injury as well as elevated expression of numerous inflammatory/neurotoxic proteins, including thrombin and amyloid beta. In the periphery, high glucose, a critical factor in the development and progression of diabetic complications, evokes vascular oxidative stress To explore the effects of high glucose on brain endothelial cell function, cultured brain-derived endothelial cells, with and without high glucose pretreatment (25 mM, 48 h), were exposed to oxidative stress induced by H2O2 (0.5 mM), menadione (25 µM), or SNP (5 mM). Thrombin activity was measured, levels of thrombin and amyloid beta quantitated by ELISA, and indices of cell injury determined by MTT assay and staining for caspase 3 and superoxide. The results indicated that high glucose pretreatment potentiated oxidant-mediated increase in levels of thrombin and thrombin activity as well as Abeta levels. Oxidative stress-induced indices of cell injury were all exacerbated in cultures exposed to high glucose, compared to cultures not treated with glucose. Treatment of cultured endothelial cell cultures with the thrombin inhibitor dabigatran diminished glucose-induced increase in thrombin, Abeta, caspase 3 and superoxide. Finally, examination of transgenic AD mice made diabetic by treatment with streptozotocin (STZ) showed that AD+STZ mice expressed higher cerebrovascular levels of thrombin compared to non-diabetic AD mice. Taken together these data suggest that glucose-induced microvascular injury may be mediated, in part, by thrombin and that therapeutic targeting of this inflammatory protein may hold promise in mitigating cerebrovascular abnormalities in both in AD and diabetes.

Title: Intracerebral microinjection of interleukin-4/interleukin-13 reduces β-amyloid accumulation in the ipsilateral side and improves cognitive deficits in young APP23 mice

Authors: *K. KAWAHARA, M. SUENOBU, Y. SUGIMOTO, H. NAKAYAMA;
Fac. of Life Sci. Kumamoto Univ., Kumamoto, Japan

Abstract: We previously reported that the anti-inflammatory cytokine interleukin (IL)-4 induced selective clearance of oligomeric β-amyloid (Aβ1-42) in rat primary type 2 microglial cells. For the present study, we investigated whether IL-4 and IL-13 could activate microglial cells to induce Aβ clearance in vivo and improve cognitive deficits in APP23 mice, which are amyloid precursor protein transgenic mice. We administered an intracerebral microinjection of a mixture of IL-4 and IL-13 or of saline vehicle into one hemisphere of APP23 mice and their wild-type littermates, 4.5 and 9 months old, after which we evaluated the effects of these treatments on spatial learning and memory by Morris Water Maze test and on accumulated amounts of Aβ. The cytokine injection significantly improved memory deficits of 4.5-month-old APP23 mice, but did not do so in 9-month-old APP23 mice, even though similar Aβ reductions were observed in both age groups of APP23 mice in the ipsilateral neocortex. The cytokine injection improved memory impairment of 9-month-old WT mice in the probe trial. Immunohistochemical analysis of the 4.5-month-old APP23 mice revealed the presence of increased numbers of microglial cells at 2 days after the cytokine injection. In addition to induced CD36 expression in the activated microglia, increased expression of neprilysin, mainly in neurons, suggested that the cytokines improved the cognitive deficits via degradation and clearance of intra- and extraneuronal Aβ peptides, of buffer-extractable nonplaque form. Double immunostaining also revealed that most of the activated microglia had the M2-like phenotype. This unique mechanism of IL-4/IL-13-induced clearance of Aβ may provide an additional strategy to prevent and/or cure Alzheimer's disease at early stage.

Title: Nuclear receptor agonists increase Aβ mediated microglial phagocytosis and influence microglial activation status in a mouse model of AD

Authors: *J. SAVAGE, G. E. LANDRETH;
Case Western Reserve Univ., Cleveland, OH

Abstract: Alzheimer's Disease is a neurodegenerative disease characterized by accumulation of amyloid beta (Aβ) within the brain and appearance of fibrillar amyloid beta (fAβ) plaques. These plaques arise from the imbalance of production and clearance of Aβ. Microglia migrate to and invest processes into fAβ plaques. This interaction leads to microglial activation, expression of proinflammatory cytokines, and reactive oxygen species. The chronic inflammatory response within the AD brain renders microglia incapable of phagocytosing and degrading fAβ. Other tissue-specific macrophages are capable of resolving inflammation, repairing damaged tissue, and phagocytosing cellular debris by converting to an "alternatively activated" M2 state. We hypothesize that conversion of microglia to an M2 state could be of benefit in AD due to their anti-inflammatory and phagocytic capabilities. However, M2 activation in microglia has not been well studied.
Activation of the peroxisome proliferator-activated receptors (PPARs) and liver x receptors (LXRs) drive M2 macrophage polarization and enhance phagocytosis. Treating AD model mice with LXR, PPAR, or retinoid X receptor (RXR) agonists improves cognition and decreases plaque load. The loss of Aβ plaques is coincident with the appearance of phagocytically active, amyloid-laden microglia. However, the mechanism of fAβ clearance has not been established. We hypothesized that treatment with nuclear receptor agonists drives M2 polarization of microglia and increases phagocytosis and degradation of fAβ. We report that treatment of the microglial cell line N9 with synthetic agonists of RXRs (bexarotene) increases their phagocytic capacity, and treatment of primary microglia with bexarotene increases expression of phagocytic receptors MerTK and Axl. Bexarotene treatment of microglia also suppresses TNF, iNOS, and Cox2 expression in response to LPS treatment. Bexarotene treatment of 5XFAD mice decreases plaque burden, and increases microglial expression of the phagocytic machinery genes Thbs1, Ly9, and clec4e. Surprisingly, bexarotene treatment increases microglial expression of both proinflammatory cytokines including IL-1 and IL-6 and anti-inflammatory cytokines and markers including IL-10, arginase, and IL1R2. These data show nuclear receptor agonist treatment of AD animals causes functional changes in microglial phenotype, including increased phagocytosis of amyloid.

Title: LXR and PPARγ agonists modify inflammation differentially in a mouse model of Alzheimer's disease

Authors: *R. SKERRETT[1], M. P. PELLEGRINO[2], G. E. LANDRETH[1];
[1]Neurosciences, Case Western Reserve Univ., Cleveland, OH; [2]Sch. of Med., Univ. of Campinas, Campinas, Brazil

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by a decreased ability to clear amyloid β from the brain. Previous work has shown that this clearance is linked to the cholesterol carrier Apolipoprotein E (Apo E) and its lipidating proteins ABCA1 and ABCG1. The expression of these proteins is regulated by the transcription factor liver X receptor (LXR) and, through a complex metabolic pathway, with peroxisome proliferator-activated receptor (PPARγ). Our studies show that treatment of aged APPswe/PS1dE9 mice with either an LXR or PPARγ agonist results in increased protein expression of ABCA1, ABCG1, and ApoE, a reduction in soluble species of amyloid β as well as in cortical plaque load, and improved performance in the contextual fear conditioning test. Activation of LXR and PPARγ can also decrease inflammatory gene expression by transrepression of inflammatory genes at NFκB promoters, and PPARγ is involved in modulating the activation state of microglia into an "alternative" activation state. Modifying harmful neuroinflammation, which is a characteristic of AD, could therefore be a further benefit of LXR and PPARγ agonists. In vitro treatments of microglia with LXR agonists, PPARγ agonists, or a combination of both results in activation of different sets of genes. Alternative activation genes such as arg1, ym1, fizz1 and TGFβ are differentially regulated by each treatment. However, treating with LXR and PPARγ agonists together appears to reduce the inflammatory markers IL6, TNFα and IL1β most efficiently. Combination therapy with these agonists might therefore be therapeutically valuable in an AD model. In vivo, 6 month old mice treated jointly with LXR and PPARγ agonists show a reduction in inflammatory markers in the brain similar to that achieved in mice treated with either LXR or PPARγ agonists alone. Regulation of genes

associated with alternative activation widely varied between treatments. However, mice treated by combination therapy showed diminished amyloid burden and behavioral performance improvements similar to those of mice treated with LXR or PPARγ agonists separately. Nuclear receptor regulation of microglial phenotype is a complex process that merits further study.

Title: Utilization of an *In vitro* model of the blood-brain barrier to study a potential Alzheimer's disease therapeutic

Authors: *D. WUEST, K. H. LEE;
Univ. of Delaware/ Delaware Biotech Inst., Newark, DE

Abstract: Numerous immunotherapeutic approaches to Alzheimer's disease (AD) have targeted the amyloid-β peptide, and the passive immunization strategy, intravenous immunoglobulin (IVIG), has been identified to contain anti-amyloid-β antibodies as well as antibodies that provide immunomodulatory effects to reduce the negative consequences of chronic inflammation in AD. Mechanisms of action of IVIG are likely multifaceted and complex, and because IVIG is currently under investigation for AD in clinical trials, a deeper understanding of how IVIG works in AD is highly valuable. Important questions about IVIG transport into the central nervous system and any impact on this transport as a function of amyloid-β may be best provided with the use of in vitro models of the blood-brain barrier (BBB).
The development of in vitro experimental approaches to study the cellular constituents and the dynamic capabilities of the BBB typically rely on the growth of a monolayer of cerebral endothelial cells grown on a porous membrane submerged in the wells of a multi-well plate, allowing numerous conditions to be tested simultaneously. With its ability to exhibit transcellular and paracellular diffusion pathways, a cell-based model offers the potential to account for metabolism and active transport processes. The murine model we use has been developed and optimized to demonstrate growth of uninterrupted endothelial cell monolayers for appropriate

transport analysis.
Here, we investigate BBB phenomena occurring in AD and its treatment with IVIG therapy. Specifically, we studied the effect and transport capability of IVIG on the BBB pre-incubated with amyloid-β and the immunomodulatory effect of IVIG on cytokines released by astrocytes in response to amyloid-β. Amyloid-β[1-42], was pre-aggregated into fibrillar or oligomeric structures, and various concentrations were incubated in the abluminal side. IVIG was administered to the luminal side at different concentrations, and IgG, the principal constituent of IVIG, and astrocyte-derived cytokines were quantified in the abluminal side in all incubation combinations of amyloid-β structure, amyloid-β concentration, and IVIG dose. IVIG accumulated in the abluminal side at physiologically relevant levels, with more accumulation resulting from amyloid-β pre-incubation, and IVIG was found to affect cytokine levels. Our investigation into the transport and immunomodulatory effect of IVIG therapy across the BBB in an AD cellular model revealed a correlation of BBB loosening and inflammation in response to amyloid-β and insight into effects of IVIG in AD.

Title: Chronic lipopolysaccharide increases neuroinflammation, reduces plaque pathology and induces cognitive deficits in a mouse model of alzheimer’s disease

Authors: *D. Y. LO[1,2], P. E. SAWCHENKO[1];
[1]Salk Inst., La Jolla, CA; [2]Biol., Coe Col., Cedar Rapids, IA

Abstract: Accumulating evidence supports a role for inflammation in the pathogenesis of Alzheimer’s Disease (AD). Peripheral infectious/inflammatory challenges can impact the inflammatory state of the brain and accelerate disease onset and/or progression. The underlying pathways by which systemic inflammation impact the progression and severity of AD are undefined, and the effects of systemic inflammation over the course of AD have not been characterized. Addressing these issues may lead to improved therapeutic management of AD. We have begun to investigate the effects of systemic inflammation on neuropathological processes in AD, and have undertaken parallel behavioral analyses in order to relate

neuropathological changes to deficits in cognitive function. Transgenic mice that express mutant human amyloid precursor protein (APP) and presenilin 1 (PS1) and their wild-type littermates were treated twice weekly with lipopolysaccharide (LPS; 0.5 mg/kg, ip) or saline for 6 weeks prior to sacrifice at 6, 10 or 14 months of age. Quantitative analysis of amyloid pathology through amyloid immunolabeling (4G8 antibody) revealed that LPS treatment resulted in a significant decrease in cortical, but not hippocampal, plaque load in cohorts of PS1/APP mice sacrificed at 14 months. LPS treatment also significantly increased the number of cyclooxygenase (COX-2)-immunoreactive endothelial cells, a marker of vascular inflammatory activation, in 14-month-old animals compared to the 6- and 10-month-old PS1/APP mice. Morphological indices of LPS-induced microglial activation (Iba-1 staining) were also reliably elevated in 14-, relative to 6- and 10-, month-old PS1/APP mice. To associate our histochemical findings with alterations in cognitive function, mice were tested on the Barnes and Y-mazes. Assessing performance through measures of latency and number of errors, performance on the Barnes maze revealed LPS treatment-induced deficits in learning and memory in 14-month-old PS1/APP mice compared to wild-type saline controls. Spontaneous alternation performance in the Y-maze showed similar deficits in 14-month-old PS1/APP mice treated with LPS. Overall our results show that chronic inflammatory challenge exaggerates CNS inflammation in aged AD mice, which is associated with decreased amyloid plaque pathology and deficits in cognitive function. These results support a role for inflammatory activity in limiting beta amyloid deposition. However, systemic inflammation has a net effect of worsening AD outcome, emphasizing a need to better understand the mechanisms of intercommunication between the immune and central nervous systems that mediate these effects.

Title: The role of TLR4 signaling in the mechanism of action of bexarotene for the treatment of Alzheimer’s disease pathology

Authors: *A. W. CORONA[1], M. M. LAKNER[1], K.-I. FUKUCHI[2], G. E. LANDRETH[1]; [1]Case Western Reserve Univ., Cleveland, OH; [2]Dept. of Cancer Biol. & Pharmacol., Univ. of Illinois Col. of Med. at Peoria, Peoria, IL

Abstract: Alzheimer's disease is associated with an increase in soluble Aβ in the brain, the deposition of fibrillar forms of Aβ (fAβ) into plaques, and cognitive dysfunction. In addition, this pathology is associated with an altered neuroinflammatory state. TLR4 is an important innate immune receptor and, along with its coreceptors CD14 and CD36, is an essential element of the fAβ receptor complex. Signaling through this receptor induces a pro-inflammatory reaction in microglia. Recent research has shown that the RXR agonist, bexarotene, stimulates the clearance of soluble and insoluble Aβ and improves cognitive deficits in aged APP/PS1 mice. We explored the role of microglia in bexarotene-stimulated Aβ clearance by genetically inactivating the TLR4 signaling pathway. The APP/PS1 mouse model of amyloidosis was crossed with mice that had a loss-of-function mutation of TLR4 (TLR4M Tg). TLR4M Tg mice show increased levels of soluble Aβ, increased plaque deposition, and increased cognitive impairment when compared with APP/PS1 with mice functional TLR4 receptors (TLR4WT Tg). Bexarotene treatment or vehicle was given for 8 days by oral gavage (100 mg/kg/day) to TLR4M or TLR4WT mice. Fear conditioning was performed the last 2 days of treatment, after sacrifice, half of the brain was processed for protein and Aβ analyses. Bexarotene caused a significant increase in the RXR target genes ABCA1, ABCG1, and ApoE in TLR4WT Tg mice, but only ApoE was significantly increased by bexarotene in TLR4M Tg mice. Bexarotene treatment enhanced learning in tone-based fear conditioning in the TLR4WT Tg mice, but not in TLR4M Tg mice. Levels of soluble and insoluble Aβ were determined in the cortex by ELISA. TLR4M Tg mice showed a decrease in soluble Aβ, but no change in insoluble Aβ following bexarotene treatment. In comparison, TLR4WT Tg mice showed a reduction in both soluble and insoluble Aβ. To determine neuroinflammatory changes in the brain, a panel of inflammatory markers were measured by qPCR in the cortex. The neuroinflammatory profile of the cortex was changed by bexarotene in both TLR4M and WT Tg mice, but in non-identical ways. These data indicate that TLR4 signaling is necessary for the ability of bexarotene to stimulate insoluble Aβ clearance, but not soluble Aβ clearance. In addition, functional TLR4 signaling is necessary for the cognitive benefits of bexarotene treatment.

Title: The effects of poly i:c on hippocampal amyloid-beta and cognition

Authors: *M. K. WEINTRAUB[1], D. KRANJAC[1], M. J. EIMERBRINK[1], B. T. VINSON[2], J. PATEL[2], W. SUMMERS[2], B. WOMBLE[1], G. W. BOEHM[1], M. J. CHUMLEY[2];
[1]Psychology, [2]Biol., Texas Christian Univ., Fort Worth, TX

Abstract: Alzheimer's disease (AD) currently affects 5.4 million Americans, and is the 6th leading cause of death in the United States. AD is a progressive disorder characterized by neurodegeneration in regions of the adult brain, including the hippocampus and cortex. The two hallmark pathologies of AD are amyloid-beta (Aβ) plaques and neurofibrillary tangles, and presence of these pathologies can limit cell-to-cell communication ultimately leading to learning and memory deficits. Although A plaques were originally thought to cause the detrimental effects in the brain, more simple forms of Aβ, such as monomers, dimers, tetramers and oligomers, have also been shown to be potentially neurotoxic. Chronic inflammation has been implicated in the onset and progression of these AD pathologies. Our lab has previously shown that peripheral injections of a bacterial mimetic led to increased Aβ levels in the mouse hippocampus, as well deficits in learning (Kahn et al., 2012). The current study was designed to further our understanding of peripheral inflammation-induced AD-like pathology by using polyinosinic:polycytidylic acid (poly I:C), which induces inflammation similar to that induced by double-stranded viral RNA. Mice were given intraperitoneal injections of poly I:C or saline once a day for seven consecutive days. Similar to our findings using the bacterial mimetic LPS, hippocampal tissue from animals receiving poly I:C also contained significantly higher levels of Aβ, a peptide component of AD plaques. Interestingly, we determined that animals required 48 hours following the 7th injection of poly I:C to no longer experience sickness behaviors. This was unlike LPS treatment, after which animals became tolerant to the LPS treatments midway through the injection series and no longer displayed sickness behaviors following the final LPS injection. Similar to our finding when using LPS, animals administered poly I:C also displayed significant cognitive deficits in the hippocampus-dependent contextual fear conditioning paradigm, extending our hypothesis that increased levels of Aβ can lead to cognitive deficits even when the Aβ has not aggregated into plaques.

Title: Network analysis of transcriptional changes after two anti-inflammatory pathway manipulations in the PSAPP mouse reveals Alzheimer disease neuroinflammatory targets

Authors: *K. R. DOTY[1], M.-V. GUILLOT-SESTIER[1], D. GATE[1,2], T. TOWN[1];
[1]Zilkha Neurogenetic Institute, Keck Sch. of Med. of USC, Los Angeles, CA; [2]Dept. of Biomed. Sci., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Alzheimer’s disease (AD) is characterized by extracellular deposition of amyloid-β (Aβ) peptides into β-amyloid plaques and neuronal injury and loss. In addition to these hallmark AD pathological features, neuroinflammation is established early and maintained chronically in brains of affected individuals. The etiology of brain inflammation, its role in disease progression, and the possibility of targeting beneficial forms of neuroinflammation to prevent AD initiation or promote regression have remained elusive. As the resident innate immune cells of the brain, microglia become activated in close vicinity of β-amyloid plaques. However, these mononuclear phagocytes are ineffective at clearing Aβ and preventing consequent buildup of β-amyloid plaques. While the reasons for microglial dysfunction in AD are unknown, one approach to correct this imbalance is to modulate neuroinflammation. Recently, our laboratory has knocked out two anti-inflammatory pathways in the PSAPP mouse model of cerebral amyloidosis. Promoting inflammation via genetic deletion of interleukin-10 or endorsing toll-like receptor signaling by knocking out the natural dominant-negative, interleukin-1 receptor associated kinase-M (IRAK-M), leads to mitigation of cerebral amyloidosis in vivo. We hypothesize that specific inflammatory mediators, as opposed to a general inflammatory state, are responsible for

the reduced AD-like pathology that we have observed. Using next-generation sequencing (RNAseq) and network analysis, we have uncovered differentially expressed genes in common to both genetic manipulations. Identification of these differentially expressed genes has allowed us to make predictions regarding unique neuroinflammatory signaling pathways that could be targeted to mitigate cerebral amyloidosis.

Title: Chronic systemic inhibition of interleukin-1 reduces spatial learning deficits in a mouse model of Alzheimer's disease without affecting amyloid plaque burden

Authors: *S. N. RESCH[1,2], J. LUTCHMAN[3], J. JOHNSON[1], A. ROE[3], T. MOY[2], K. SINGH[3], A. PEREZ[1], C. NAVAS[3], S. D. CROLL[1,2,3];
[1]Neuropsychology Doctoral Subprogram, The Grad. Ctr. of CUNY, New York, NY; [2]Regeneron Pharmaceuticals, Tarrytown, NY; [3]Psychology, CUNY Queens Col., Flushing, NY

Abstract: Chronic neuroinflammation, which includes elevated expression of the cytokine interleukin-1 (IL-1), is a prominent feature of Alzheimer’s disease and has been hypothesized to contribute to the neurodegeneration and cognitive dysfunction observed in patients with the disease. In this study, we used systemic administration of Regeneron's mouse IL-1 (mIL-1) Trap to inhibit interleukin-1 signaling in the swAPP-PS1 double transgenic mouse model of Alzheimer's Disease. Wild type and transgenic mice were chronically treated with either an Fc control protein or mIL-1 Trap (10mg/kg s.c. 2x/wk) starting at approximately 8 months of age to assess the effect of these reagents on hippocampally-dependent spatial learning and memory as well as Alzheimer’s-like brain pathology. During the fifth month of treatment, animals were tested in the Morris Water Maze task, in which they received three consecutive trials per trial block for two blocks per day across five days. Median latency to escape to the platform per trial block was used as a measure of acquisition. At the end of the fifth day, animals were placed back into the water maze for a 30 second spatial probe trial. Retention was measured using both the amount of time the animals spent in the goal quadrant and the number of crosses over the location of the goal platform. Animals were sacrificed 5 months after the initiation of treatment

and brains were removed and analyzed for amyloid plaque burden using Congo Red staining. As expected, the double transgenic mice showed significantly worse water maze acquisition than their wild type controls, and the mIL-1 Trap significantly improved acquisition in the double transgenic mice. In contrast, there was no significant effect on retention of the platform location during the spatial probe trial in the transgenic mice, suggesting the possibility of the use of compensatory strategies for performing the task in the treated animals. Amyloid plaque burden in the double transgenics was not significantly altered by administration of mIL-1 Trap. However, mIL-1 Trap decreased the positive relationship between plaque burden and cognitive impairment measured in the Fc-treated transgenics, suggesting that although the plaques were present, they were no longer associated with cognitive impairments in the animals. We are currently in the process of studying the effect of chronic systemic mIL-1 Trap treatment on other cells in the brain, with a special focus on cells most likely to have been exposed to systemic mIL-1 Trap such as the endothelial cells and subpopulations of microglial-like cells.

Title: Upregulation of glutamate transporter 1 (GLT1) by ceftriaxone ameliorates Alzheimer’s disease-associated cognitive impairment in 3xTg-AD mice

Authors: *J. M. ZUMKEHR[1], R. MEDEIROS[2], D. CHENG[2], Y. YANG[3], M. KITAZAWA[4]; [1]Mol. and Cell Biol., UC Merced, Merced, CA; [2]Neurobio. and Behavior, Univ. of California,

Abstract: Synaptic loss is an early pathological event in Alzheimer's disease (AD) and correlates well with the severity of cognitive decline in patients with AD as well as mild cognitive impairment. Although exact molecular and cellular mechanisms of synaptic loss have not been elucidated in AD, excitotoxicity is speculated to be one of the major mechanisms that trigger synaptic degeneration. To support this, it has been reported that high glutamate levels are found in cerebrospinal fluid from AD patients, and a loss of astrocytic glutamate transporters correlates with synaptic loss in AD. In addition, reduced glutamate transporter 1 (GLT1) expression in a mouse model of AD shows an early and accelerated cognitive deficit. GLT1 or its human ortholog Excitatory Amino Acid Transporter 2 (EAAT2) prevents the over stimulation of the post synapse by removing 90% of glutamate levels from the synaptic cleft. Therefore, we hypothesized that a loss of GLT1/EAAT2 is one of the early pathological changes in AD and mediates synaptic degeneration and cognitive decline associated with AD neuropathology. We found that fibrillar amyloid-beta (Aβ) reduced GLT1 levels in primary astrocyte culture. In 3xTg-AD mice, GLT1 expression was significantly decreased with age and a buildup of AD-like pathology in the brain. We next pharmacologically upregulated GLT1 using ceftriaxone, a beta lactam antibiotic known to up regulate GLT1, in 3xTg-AD mice. Two-month treatment with ceftriaxone significantly ameliorated a cognitive decline in 3xTg-AD mice. Synaptic density was restored by the treatment as well. Interestingly, both Aβ burden and tau pathology were not significantly altered by the ceftriaxone treatment in 3xTg-AD mice, suggesting that a beneficial effect on cognition was mainly mediated by a restoration of synaptic density. Together, these results show promising evidence that a functional upregulation of GLT1 plays an important role in delaying the synaptic degeneration and cognitive decline in AD.

Title: Role of the pro-inflammatory transcription factor, NFATc2, in regulating Aβ stimulated microgliosis

Authors: *A. GHATAK, K. L. PUIG, C. K. COMBS;
Pharmacology, Physiol. & Therapeut., Univ. of North Dakota, Grand Forks, ND

Abstract: Alzheimer's disease (AD) is characterized by formation of amyloid β (Aβ) peptide containing plaques and neurofibrillary tangles in the brain. Reactive microglia, the resident phagocytes of the brain, are often hypothesized to be interacting with Aβ. Our prior work has demonstrated a role for the transcription factor, NFAT (Nuclear Factor of Activated T Cells) in regulating microglial activation. In this study we hypothesized that NFAT activity would be particularly important for the phenotype change stimulated by microglia-Aβ interaction. Using primary mouse cultures we observed that NFATc2 is the most abundantly expressed isoform in microglia. Moreover, NFATc2 levels were highest in microglia compared to neuron and astrocyte cultures. Consistent with this expression pattern, Aβ 1-42 stimulation of microglia increased activity of NFATc2, but not NFATc1. Inhibition of NFAT activity with a cell permeable inhibitory peptide, 11R-VIVIT, or the small molecule, FK506, attenuated the Aβ stimulated increase in TNFα and IL-6 secretion by microglia. To validate a role for particularly NFATc2 in regulating Aβ stimulated activation, microglia from NFATc2 knockout and wild type mice were compared. Both Aβ and the bacterial endotoxin, lipopolysaccharide, had decreased ability to stimulate TNFα and IL-6 secretion from NFATc2 knockout microglia compared to controls. In addition, both 11R-VIVIT and FK506 demonstrated attenuated ability to inhibit Aβ-stimulated cytokine secretion in the NFATc2 knockout microglia compared to controls. These data demonstrated that NFATc2 activity was required for Aβ stimulated activation. Importantly, intraperitoneal injection of the 11R-VIVIT peptide was sufficient to inhibit NFATc2 activity in the brains and spleens of wild type mice. However, NFATc1 activity was inhibited in spleen but not in brain. This suggests that brain selective inhibition of NFATc2 activity is feasible. In order to begin identifying a relevant AD mouse model for assessing the role of NFAT-mediated microgliosis *in vivo*, we examined 12 month old male transgenic (APP/PS1) mouse brains to observe elevated brain protein levels of NFATc2 compared to wild type male C57BL/6 mice. This was consistent with the increased microglial activation characteristic of the AD model suggesting that these mice will be useful for examining NFAT-mediated inflammation during disease. As a whole, our findings indicate the possibility of developing anti-inflammatory drugs for AD that selectively target the proinflammatory transcription factor, NFATc2.

Title: Reelin immunoreactivity in neuritic varicosities in the human hippocampus

Authors: *T. F. NOTTER, I. KNUESEL;
Univ. of Zurich Inst. of Pharmacol. and Toxicology, Zurich, Switzerland

Abstract: By activating its receptors ApoER2/VLDL, Reelin modulates actin and microtubule cytoskeleton dynamics, thereby regulating neuronal migration/positioning during development and glutamatergic synaptic plasticity in cortical regions in the adult brain. Age-dependent reduction in Reelin levels has been suggested to contribute to Alzheimer's disease (AD) pathophysiology by increasing amyloid precursor protein (APP) proteolytic processing and Tau phosphorylation, as well as by altering NMDA receptor activation and their synaptic availability via an ApoE-dependent mechanism. We have previously reported a reduction in Reelin levels in aged mice and its accumulation in neuritic varicosities in olfactory and limbic system pathways, which correlated with cognitive impairments. Here, we aimed to investigate whether a similar Reelin-associated neuropathology is observed in aged human hippocampal formation and whether it is correlated with dementia. Using 8 specimens of AD patients and 8 of non-demented age-matched controls provided by the Netherland Brain Bank, we observed strong immunoreactivity for N- and C-terminus-containing Reelin fragments in corpora amylacea (CAm), spherical glycoprotein inclusions associated with aging and chronic neurological diseases. Stereological analysis showed that the density of these deposits was increased in the molecular layer of the subiculum of AD patients compared to non-demented individuals. Further, we detected several neuronal but no astrocytic/microglial markers co-localized with Reelin-immunoreactivity in CAm, suggestive of aging-associated impairments in neuronal transport machinery, leading to formation of neuritic varicosities and CAm. Therefore, the presence of Reelin in CAm provides a novel indicator for aging and AD-related neuronal damage and degeneration.

Title: Reduction of Alzheimer's disease related neuroinflammation induced by trans-stillbenes

Authors: *N. O. SOLBERG[1], J. VIGIL[2], V. SEVERNS[3], L. O. SILLERUD[2];
[1]UCSD, San Diego, CA; [2]Biochem. and Mol. Biol., [3]Pathology, Univ. of New Mexico, Albuquerque, NM

Abstract: Alzheimer's disease is associated with a microglia-dependent neuroinflammatory response against plaques containing the fibrous protein B-amyloid. Activation of microglia, which closely associate with amyloid plaques, engenders the release of pro-inflammatory cytokines and the microglia mediated internalization of B-amyloid plaque. Since the pro-inflammatory transcription factor NF-kB is one of the major regulators of B-amyloid induced inflammation, we treated transgenic Amyloid Precursor Protein/Presenilin-1 (APP/PS1) mice with either of two *trans*-stilbene analogs, resveratrol or its synthetic analog LD-55, which prior work had shown to inhibit NF-kB in vitro. Amyloid plaques were measured *ex vivo* by quantitative anti-APP conjugated SPION-enhanced MRI of intact brains and by optical microscopy of thioflavin-stained brain tissue sections. The regional distribution of microglial activation was measured *ex vivo* by Iba-1 immunofluorescence of brain tissue sections. We developed 3D numerical models of both plaque and microglial areal density distributions that describe the data. It was found that treatment with either resveratrol or LD-55 *concomitantly* decreased both B-amyloid plaque and activated microglial areal densities by 3 to 6-fold in a region dependent manner. We have concluded that both resveratrol and LD-55 are efficient at reducing B-amyloid plaque burden and are highly effective at reducing neuroinflammation *via* a reduction in number of activated microglia.

Title: The immune inhibition effect of DcR3 on modulating microglia activation phenotypes, neuronal plasticity and cognitive functions in Alzheimer's disease

Authors: *Y. LIU[1], I.-J. CHENG[1,2];
[1]Natl. Yang-Ming University/ Inst. of Brain Sci., Taipei, Taiwan; [2]Natl. Yang-Ming University/ Brain Res. Ctr., Taipei, Taiwan

Abstract: The complex inflammatory responses drive series of neurodegeneration and cognitive decline in the course of Alzheimer's disease (AD). Microglia is the major immune regulator in the brain. The ratio of M1/M2 subtypes can either turn to the neurotoxic or neuroprotective processing. Decoy receptor 3 (DcR3) is able to skew the macrophages differentiation into anti-inflammatory subtypes by the neutralization ability under inflammation reaction. We hypothesize that overexpressing DcR3 may reduce Aβ-induced neuroinflammation and ameliorate AD-like neuropathology *in vitro* and in APP transgenic mouse. Female pPGK-DcR3 transgene mice were crossed to male APP transgenic mice (J20 line, PDGF-APPsw,ind) to get four genotypes of mice offspring for further biological analysis at 6-month old and 12-month of age. To identify the role of DcR3 in amyloidopathology, we examined the changes in Aß level, synaptic physiology, inflammation status, microglia phenotype and histological variations in six-month old APP/DcR3 transgenic mice. To determine functional deficits in DcR3/APP double transgenic mouse, we performed behavioral tests and electrophysiology in these transgenic mice. Results showed that Aβ increased neuroinflammation and activated microglia. DcR3/APP double transgenic mouse showed decrease total Aß level than APP transgenic mice, and showed improvement on cognitive function. The immune inhibition role of DcR3 on Aß clearance, microglia phenotype changes, and functional amelioration may be a potential therapeutic target for AD-like pathogenesis.

Title: The effects of estradiol on lipopolysaccharide-induced neuroinflammation in rat mixed glial cultures

Authors: *J.-Y. WANG[1], C.-L. CHEN[2], S.-Y. CHEN[1];
[1]Dept Nursing (Basic Med. Sci), Hungkuang Univ., Taichung, Taiwan; [2]Li-Shin Hosp., Tao-Yuan, Taiwan

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder. It is associated with relevant neuroinflammatory response. The microglial cells, kind of glial cells, are the resident inflammatory cells in the brain that promote brain inflammation in response to stimuli. Astrocytes, another kind of glia, also can produce mediators that involve in neuroinflammation. The processes accompany with inflammatory response are increasing in the expression of transcription factor NFκB, inducible nitric oxide synthase (iNOS) and the release of inflammatory mediators (ex. nitric oxide (NO) and cytokines). Ultimately, these events may create a vicious cycle to induce neuronal injury.
The prevalence of AD - is recognized to be higher in women - increases with age and life expectancy is constantly increasing in civilized countries. Menopause is a natural condition of female aging in which reduction in plasma levels of estrogens lead to a variety of metabolic and physiological changes. The increase in female life expectancy during the past century has meant that women now live one-third of their lives beyond cessation of their ovarian function. And the reduction of estrogens may have important influence on elder women's life. It is known that estrogens are not only involved in reproduction, but can also modulate the central nervous system (CNS). There are many studies to investigate the relationship between estrogens and AD. But the role of estrogens in neurodegeneration has not consensus. In this study, we selected to test the influence of 17β-estradiol (E2), the predominant circulating estrogen, on lipopolysaccharide (LPS)-induced neuroinflammation in mixed glial cells.The *in vitro* experiment: rat cortical mixed glial cultures will be subjected to (1) control; (2) LPS treated with 1, 10, 100, 500, 1000 ng/ml; (3) E2 treated with 10, 100 nM, 1, 10, 100 μM ; (4) pretreatment of E2 following LPS treatment; all of above were treated for 1, 3 or 5 days. Cell density and morphology will be observed by phase-contrast microscopy. Cell injury will be assessed by MTT reduction. The production of NO will be measured to estimate the inflammatory responses. The expression of NFκB and iNOS will be estimated by western blot analysis and immunohistochemical staining. Our data indicated that the cell viability significantly decreased in LPS treatment for 1 day, but the MTT reduction (% of control) was about 90 %. The accumulation of nitrite, the expression of NFκB and iNOS were significantly increasing in 1, 3 or 5 days. Pretreatment with E2 at 100 μM significantly decreased the LPS-induced NO production and iNOS expression. We suggested that E2 can attenuate the neuroinflammatory response.

Title: Role of TNF in modulation of immune cell traffic to the CNS by peripheral inflammation in a mouse model of Alzheimer's disease

Authors: *K. P. MACPHERSON[1], M. TANSEY[2];
[1]Emory Univ., Atlanta, GA; [2]Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Epidemiological studies have found older people who use anti-inflammatory drugs regularly have significantly lower incidence of Alzheimer's disease (AD); and newly identified AD risk factors include obesity and diabetes, conditions associated with chronic low-grade systemic inflammation. Clinically, systemic infection is associated with development of dementia in elderly patients and increased cognitive decline in AD patients. These observations support the hypotheses that (1) the peripheral immune system plays an active role in AD and (2) targeting specific elements of peripheral inflammation could be useful in treating disease. In support of this, chronic peripheral administration of lipopolysaccharide (LPS) in rodent models of neuroinflammatory disease increases central markers of inflammation (including Tumor Necrosis Factor, TNF) both acutely and chronically, is associated with enhanced cognitive decline, and correlates with primed microglia. LPS is unable to penetrate the blood brain barrier (BBB), thus peripheral inflammatory signals, such as TNF, are likely important mediators of these central effects. Evidence of increased BBB permeability is present in brains of AD patients and soluble TNF is known to increase BBB permeability. Increased BBB permeability may accelerate AD-like pathology in 5xFAD mice through increased peripheral immune signaling and traffic to the CNS in conditions of chronic systemic inflammation. Targeted neutralization of soluble TNF signaling in the CNS and inhibition of TNF synthesis can ameliorate pathology induced by systemic inflammation. However, the specific role of soluble TNF in systemic circulation and its contribution to peripheral immune cell infiltration in AD pathogenesis has not been explored. To test this, we first characterized the inflammatory profile of 5xFAD mice, a transgenic (Tg) mouse with early onset of amyloid plaques, memory impairment, and neurodegeneration. In the CNS we detected increased levels of CD45 at 4 and 6 months of age

and increased CCL2 and TNF by real-time PCR at 6 months of age in 5xFAD mice versus non-Tg mice, suggesting there is immune cell activation and neuroinflammation in the 5xFAD by 4 months of age. Studies are now in progress to determine the extent to which chronic systemic inflammation promotes peripheral immune cell traffic to the CNS in 5xFAD and non-Tg mice. Our short-term goal is to evaluate the efficacy of the novel brain-permeant soluble TNF inhibitor XPro1595 in delaying or attenuating progression of cognitive deficits and AD-like pathology.

Title: Dendritic spine pathology in the primary motor cortex (M1) of MPTP-treated parkinsonian monkeys

Authors: *Y. SMITH[1], R. M. VILLALBA[2], J. F. PARE[2], T. WICHMANN[1];
[1]Yerkes Res. Ctr., Udall Ctr. Excel. For Parkinson's Dis. and Dept. of Neurol., Atlanta, GA;
[2]Yerkes Resch Crt. and Udall Ctr. of Excellence for Parkinson's Disease, Emory Univ., Atlanta, GA

Abstract: Anatomical and functional studies of the mesocortical dopaminergic system have focused almost exclusively on prefrontal cortical regions. However, the primate mesocortical dopamine system extends beyond the prefrontal cortex to densely innervate the primary motor cortex (M1). In contrast to the prefrontal innervation which originates from the ventral tegmental area, a major contingent of dopaminergic fibers in the primate M1 arises from the substantia nigra pars compacta (SNc) and retrorubral area (RRA). In MPTP-treated parkinsonian monkeys, M1 corticospinal neurons decrease their firing rate and display abnormal discharge patterns,

while corticostriatal neurons are not affected (Pasquereau and Turner, 2011, Cerebral Cortex 21:1362). These functional changes are usually interpreted as secondary to altered functions of basal ganglia-thalamocortical circuits, but they may also arise from the loss of dopamine in M1 itself. Anatomical and PET imaging data in PD patients have, indeed, shown partial degeneration of the dopamine input to M1, consistent with biochemical studies showing a 30-60% decrease of dopamine levels in M1 of MPTP-treated monkeys. Findings from our laboratory have recently shown a dramatic loss of tyrosine hydroxylase (TH)-positive innervation of M1 in parkinsonian monkeys (Weinkle et al., 2011, Soc. Neurosci. Abstr. 883.2).
Dopamine loss leads to significant spine pruning in the striatum and prefrontal cortex. The goal of the present study was to determine if dopamine denervation also induces spine loss on M1 pyramidal neurons in parkinsonian monkeys. Using Golgi impregnation, we found that M1 pyramidal neurons display as much as 40-45% loss of spines on their apical dendrites in parkinsonian animals (9.75 spines/10 µm vs 5.25 spines/10 µm of dendritic length). On the other hand, no significant spine loss was found in the cingulate cortex, a neighboring cortical region that does not display any significant dopaminergic denervation in parkinsonian monkeys (10.61 spines/10 µm vs 9.88 spines /10 µm of dendritic length). Potential changes in the extent glutamatergic inputs to M1 in parkinsonian monkeys are currently under study. Our results demonstrate significant spine loss on M1 pyramidal neurons of MPTP-treated monkeys, thereby suggesting that M1 pathology may underlie parkinsonian motor features in primates.

Title: Preferential loss of thalamostriatal over corticostriatal glutamatergic synapses in parkinsonian monkeys

Authors: *R. M. VILLALBA[1], T. WICHMANN[2], Y. SMITH[2];
[1]Yerkes Resch Ctr. and Udall Ctr. of Excelence For Parkinson's Disease, Emory Un, Atlanta, GA; [2]Yerkes Res. Ctr., Udall Ctr. Excel. for Parkinson's Dis. and Dept. of Neurol., ATlanta, GA

Abstract: It is well known that striatal projection neurons undergo a significant loss of dendritic spines in animal models of Parkinson's disease (PD) and in PD patients. These spines are the termination targets of glutamatergic inputs to the striatum. It remains unclear whether the apparent pruning of glutamatergic synapses affects preferentially cortical or thalamic afferents. To address this issue, we determined the extent of thalamic and cortical terminals loss in the sensorimotor striatum (i.e., postcommissural putamen) of MPTP-treated parkinsonian monkeys. Striatal tissue from 10 adult Rhesus monkeys (5 controls and 5 MPTP-treated) was used for electron microscopic studies. Three-dimensional reconstruction of synapses and unbiased stereology methods were applied to estimate the total number of asymmetric synapses formed by vGluT1- (from cortex) or vGluT2- (from thalamus) immunoreactive terminals per unit striatal tissue volume. The total volume of tissue analyzed was 1080 μm^3 in control and 1066 μm^3 in parkinsonian animals. Overall, there was a ~40% reduction in the number of asymmetric synapses (axo-dendritic + axo-spinous) in the postcommissural putamen of MPTP-treated monkeys (compared to normal animals). We found that 74% of all asymmetric axo-dendritic synapses were lost. A subsequent analysis of this axo-dendritic synaptic pruning based on the sources (ie cortex vs thalamus) of the presynaptic terminals revealed that 80% of axo-dendritic asymmetric synapses formed by vGluT2-positive terminals and ~16% of axo-dendritic synapses formed by vGluT1-positive terminals were lost in parkinsonian animals. On the other hand, 26% of total asymmetric axo-spinous synapses were lost in MPTP-treated monkeys. Further analysis based on their vGluT content showed that the total number of asymmetric axo-spinous synapses formed by vGluT2-positive terminals was decreased by 29%, while no significant effect was noticed for the vGluT1-immunoreactive terminals. These results suggest that most of the glutamatergic denervation of the sensorimotor striatum in MPTP-treated parkinsonian monkeys is accounted for by a loss of thalamostriatal inputs, with much less degeneration of the corticostriatal system. These findings are consistent with the significant degeneration of thalamostriatal neurons in the caudal intralaminar thalamic complex, centre median/parafascicular (CM/Pf) described in PD patients and MPTP-treated monkeys (Henderson et al., 2000, Ann. Neurol. 47:345; Villalba et al., 2013, BSF, doi:10.1007/s00429-013-0507-9).

Abstract: In healthy neurons, multiple mechanisms ensure fast restoration of calcium concentration in the cytosol following dynamic signaling events. In brain disease, however, calcium homeostasis can be disrupted resulting in catastrophic downstream effects on the integrity of neuronal networks. Recently, using conventional (fluorescence intensity) 2-photon calcium imaging in vivo in the mouse model of neurodegeneration overexpressing the human variant of synaptic protein α-synuclein (1), we demonstrated long-lasting neuronal calcium transients characterized by considerable deviation from the exponential decay in the presence of normal spiking (2). The most evident pathology was observed in response to a repetitive stimulation when subsequent stimuli were presented before relaxation of calcium signal to the baseline. A mechanistic interpretation of these findings, however, requires knowledge of the absolute intracellular calcium concentration: at the baseline and during dynamic signaling events. To this end, we have refined an existing technology, Fluorescent Lifetime Imaging Microscopy (FLIM), to enable fast and accurate estimation of intracellular calcium concentration in vivo with 2-photon resolution and applied the technology to quantify departures from normal calcium homeostasis in the α-synuclein mouse. FLIM has been utilized previously for estimation of calcium concentration in vivo and in vitro (3, 4). We took this technology a step further by introducing a fast acquisition, sufficient for resolving the time-course of dynamic neuronal calcium changes during spontaneous activity and in response to a weak electrical stimulation of the whisker pad. Our pilot results show that, in contrast to findings in APP mouse model of Alzheimer's disease (5), the baseline calcium concentration in cortical neurons in the α-synuclein mouse is normal. Further, the amount of calcium entry during the rising phase of the response to a single-shock stimulus in the α-synuclein mouse is not significantly elevated. Taken together,

these results argue in favor of specificity of the α-synuclein model and support our original hypothesis that α-synuclein promotes alterations in calcium dynamics via interference with intracellular buffering mechanisms.

Title: Synaptic transmission at cortico-subthalamic synapses

Authors: L. FROUX[1], S. MORIN[1], B. BIOULAC[1], J. BAUFRETON[1], J. LANCIEGO[2], *A. I. TAUPIGNON[1];
[1]Inst. des Maladies Neurodégénératives, CNRS Univ. Bordeaux Segalen UMR 5293, Bordeaux CEDEX, France; [2]Dept. of Neurosciences, CIMA, Pamplona, Spain

Abstract: The subthalamic nucleus (STN) is widely viewed as a relay nucleus in basal ganglia (bg). However, motor and premotor cortical inputs to STN have been demonstrated. In addition, cortical inputs arising from associative and limbic areas have recently been described, suggesting that STN integrates contextual information to set a decisional threshold (1). The cortical inputs to the STN form the so-called ‘hyperdirect pathway’ of bg.

Dopamine receptors in D1 and D2 families have been identified on afferent terminals and at post-synaptic sites within STN (2). The cortico-subthalamic (Cx-STN) transmission may therefore be modulated by dopamine and changes in dopamine at the synapses may contribute to the symptoms of Parkinson's disease and other neuropsychiatric disorders.
The data on the hyperdirect pathway and the hypothesis on its role(s) call for determining the properties of the Cx-STN synapses and clarifying the action of dopamine.
Contrary to the direct and indirect pathways of bg, the hyperdirect pathway is usually not preserved in in vitro preparations. Besides, bulk stimulations of afferent cortical fibers in the internal capsule may mask properties specific of the various cortical projections. To circumvent these two problems, we used optogenetics to specifically stimulate corticofugal axons in acute brain slices. We stereotactically delivered a viral expression vector in the motor cortex of mice in vivo, and at least 14 days later, made acute brain slices. We mostly found YFP-expressing cell bodies in cortex layer V and YFP-expressing fibers in various nuclei of bg and in the ventro-medial part of STN. We used patch clamp to probe the effects of photo-activating ChR2. A single laser blue light flash directed at YFP-expressing fibres in the STN evoked robust inward currents with graded amplitude properties in line with the duration and power of photostimuli. Average peak current amplitude and charge, were -144.41 ± 31.71 pA and -544.83 ± 93.24 pA.ms (n=7), respectively, at -80 mV. The mean delay from flash to current onset was 1.91 ± 0.11 ms (n=7), a value consistent with synaptic delay. The currents were consistently abolished by TTX (0.5 μM) or by DNQX (20 μM). Thus, light activated ChR2 which in turn elicited action potentials in ChR2-expressing pre-synaptic cortical fibres/terminals, induced glutamate release and ultimately produced AMPA/kainate EPSCs in post-synaptic STN neurons.
These results support the view that optogenetics is a valuable method to determine the properties of the motor Cx-STN pathway.

Title: L-DOPA-induced dyskinesia is associated with enhanced H2 histamine excitation of striatal cholinergic interneurons

Authors: *S. A. LIM, R. XIA, L. WON, Y. DING, D. S. MCGEHEE, U. J. KANG;
Univ. of Chicago, Chicago, IL

Abstract: Levodopa is the most effective therapy for Parkinson's disease (PD), but long term treatment leads to the development of potentially debilitating abnormal involuntary movements, or L-DOPA-induced dyskinesia (LID). Amantadine is the most effective treatment for LID at present, but its effectiveness is limited by a short therapeutic time window and worsening of LID symptoms following cessation of treatment. We recently demonstrated that striatal cholinergic interneuron (ChI) dysfunction is associated with mouse models of LID. ChI physiological changes include enhanced baseline excitability and enhanced dopamine-induced excitation. There is strong histaminergic innervation of the dorsal striatum and excitatory histamine receptors are expressed on ChIs, which lead us to test the contribution of this system to LID-induced elevation of striatal cholinergic tone. Two mouse models of PD were used, the unilateral 6-hydroxy-dopamine (6-OHDA) lesion and the Pitx3ak/ak aphakia mouse. Stepping tests were performed to determine success of the 6-OHDA lesion and the onset of Parkinsonian-like symptoms. Mice from each group were chronically treated with either vehicle or L-DOPA to induce LID. The cylinder test was performed to quantify the severity of dyskinesia. Brain slice electrophysiology was used to assess the histamine sensitivity of ChIs from dyskinetic mice as well as control mice. In cell-attached extracellular recordings, we found that H2 receptor-mediated excitation of striatal ChIs was enhanced in mice expressing LID. In the behaving animal, H2 receptor blockade by systemic administration of famotidine decreased LID expression. Similar effects of H2 antagonists were seen in both models of PD. Our data suggest that LID is associated with enhanced H2-mediated histamine signaling, and that inhibiting H2 receptors may decrease the LID-induced hypercholinergic state of the striatum. Histamine H2 receptors may therefore be a novel target for alleviating LID symptoms in humans.

Title: Dopamine D3 receptor prevents D1 receptor stimulation of [3H]GABA release in substantia nigra pars reticulata of hemiparkinsonian dyskinetic rats

Authors: *S. ALBARRAN[1], A. ÁVALOS-FUENTES[2], F. PAZ-BERMÚDEZ[1], D. ERLIJ[3], J. ACEVES[1], B. FLORÁN*[1];
[1]Physiology, Biophysics and Neurosciences, [2]Pharmacol., Cinvestav, Distrito Federal, Mexico; [3]Physiol. and Pharmacol., Sunny Downstate Med. Ctr., Brooklyn, NY

Abstract: L-DOPA remains as the most effective replacement therapy for Parkinson disease. Long term L-DOPA treatment leads to the development of dyskinesia. The mechanisms involve in dyskinesia remains unclear, but dopamine D1 receptors play a central role. Dopamine D1 and D3 receptors are coexpresed in striato-nigral neurons were dopamine D3 receptors potentiate D1 receptor stimulation of cAMP formation and GABA release. L-DOPA treatment increases the expression of D3 receptor correlating with the development of L-DOPA priming. This data originate the proposal of use dopamine D3 receptor agents as a therapeutic target for attenuation of dyskinesia but, results are still contradictory. Since GABA release in the substantia nigra reticulata (SNr) is determinant for the develop of dyskinesia, we study the effect of dopamine D3 receptor activation on D1 receptor stimulated [3H]GABA release and [3H]cAMP formation in slices and synaptosomes of SNr in the unilateral 6-OHDA lesioned rat model treated with L-DOPA divided in dyskinetic and non-dyskinetic groups. In non-dyskinetic rats, dopamine D3 receptor activation potentiates GABA release and cAMP formation stimulated by D1 receptor agonist SKF 38393. The release of GABA was similar to that observed in the control animals. In the dyskinetic rats the D3 receptor activation inhibits D1 receptor stimulation of GABA release and cAMP formation suggesting an antagonist interaction between these receptors. The total amount of GABA released by D1 receptor in this condition was higher than in the normal side. This data suggested an antagonistic interaction between D1 and D3 receptor in dyskinesia and suggested the use of agonist for the D3 receptor in the management of L-DOPA induce dyskinesia.

Title: Alpha-synuclein aggregation begins at presynaptic terminals

Authors: *K. SPINELLI, J. TAYLOR, V. OSTERBERG, C. MESHUL, V. UNNI;
Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Parkinson's Disease and Dementia with Lewy Bodies are associated with abnormal aggregation of the synaptic protein alpha-synuclein. However, the mechanisms governing aggregation in vivo are poorly understood. We have developed an in vivo multiphoton imaging paradigm to study the process of alpha-synuclein aggregation in living mouse cortex with subcellular resolution. Using in vivo multiphoton fluorescence recovery after photobleaching (FRAP), we demonstrate that somatic alpha-synuclein exists as an unbound, soluble protein. In contrast, alpha-synuclein in presynaptic terminals exists in at least 3 different pools. One pool is unbound, soluble protein, while another is bound to presynaptic vesicles, and the final pool consists of microaggregate species. Chronic imaging of terminal microaggregates over 1 week demonstrates a heterogeneous population, with likely differing levels of compaction. Using a combination of biochemical techniques, we confirm the presence of a terminal aggregate species that is resistant to Proteinase K digestion, phosphorylated at serine-129 and oxidized, and is separate from the vesicle-bound fraction by EM. In addition, we have used multiphoton FRAP to measure, for the first time in vivo, the specific binding constants for alpha-synuclein's binding to synaptic vesicles and its effective diffusion coefficient in the soma and axon. Collectively, this paradigm introduces powerful new tools for studying protein aggregation in living mouse brain, and suggests that under moderate overexpression conditions mimicking human disease, alpha-synuclein aggregation begins first at presynaptic terminals in vivo. Ongoing experiments investigate the ability of curcumin, a natural anti-aggregate found in turmeric spice, to decrease aggregation of alpha-synuclein in vivo.

Title: Effect of subthalamic stimulation on nonmotor symptoms of advanced Parkinson disease

Authors: *Y. MIYAGI[1,2], T. OKAMOTO[2], K. SAMURA[3], Y. OHYAGI[2], H. HONDA[2]; [1]Dpt.Stereotactic and Functional Neurosurg., Kaizuka Hosp., Fukuoka, Japan; [2]Kyushu Univ., Fukuoka, Japan; [3]Dpt. Neurosurg., Fukuoka Univ., Fukuoka, Japan

Abstract: Most patients with advanced Parkinson disease (PD) have nonmotor symptom (NMS). NMSs are not life-threatening but considerably affect their quality of life, therefore the management of NMS is one of the top agendas in PD. Chronic subthalamic stimulation (STN-DBS) improves the "off"-related motor symptoms but its effect on "off"-related NMS (nonmotor fluctuation, NMF) is still unclear. We have developed an online questionnaire of NMS of PD on the basis of the report by Witjas et al. (2002), which included 54 symptoms classified into categories; 26 dysautonomic, 21 psychiatric/cognitive and 7 sensory symptoms. The presence, timing ("on"- or "off"-related, "on/off"-unrelated) and severity (0, absent; 1, slightly uneasy; 2, moderately uneasy; 3, severely uneasy; 4, intolerable) of each symptom were collected from 34 PD patients before and after 6 months of STN-DBS. Among NMFs ("off"-related NMS), the top 10 rankings of decreased prevalence (prevalence before DBS minus that after DBS) of NMF were; sadness 33%, slowness of thinking 30%, fatigue 24%, urinary urgency 21%, irritability 21%, abulia 21%, sensation of injustice 18%, dyspnea 18%, self-withdrawal 18%. All severities of these NMFs and akathisia were significantly alleviated after STN-DBS ($p<0.05$, Wilcoxon paired signed rank test). The alleviated NMFs included 8 psychiatric, 2 dysautonomic and 1 sensory symptoms. Among "on/off"-unrelated NMSs, 4 NMSs were significantly alleviated after STN; mental hyperactivity, constipation, hallucination and flatulence. STN-DBS alleviates not only "off"-related NMS but also some of "on/off"-unrelated NMSs probably through the improvement of motor function and/or the decrease of dopamine replacement therapy.

Title: Aging exacerbates motor deficits in a parkinsonian mouse model

Authors: *T. A. ANSAH, T. NAYYAR;
Neurosci. and Pharmacol., Meharry Med. Col., Nashville, TN

Abstract: Parkinson's disease (PD) is characterized by degeneration of nigrostriatal dopamine (DA) neurons and a decrease in striatal DA concentration. The decrease in striatal DA levels is thought to underlie the motor symptoms of PD. Majority of PD cases is idiopathic, affecting 1 - 2% of persons over the age of 65 years. Data suggesting that striatal DA concentrations decline as a function of age has led to the hypothesis that PD arises from the effects of some acute event, such as exposure to a neurotoxicant, superimposed on the age-related decline in striatal dopamine, ultimately reaching a threshold for manifestation of symptoms. Evidence in support of this hypothesis comes from studies showing that the environmental neurotoxicant, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) produces more severe nigrostriatal dopamine neuron degeneration in older than young animals. Assessment of motor function in MPTP-treated mice has yielded inconsistent results. Some of the variance across reports probably reflects differences in age at the time of MPTP treatment and the survival time leading up to behavioral testing. In the current studies we investigated whether aging will exacerbate motor deficits produced by MPTP treatment. Mice were treated with MPTP or saline and striatal DA and motor function were assessed three weeks or 18 months after MPTP treatment. MPTP treatment resulted in 80% reduction in striatal DA at three weeks survival time. At 18 months after MPTP treatment the striatal DA was found to be 50% of that observed in saline treated mice. MPTP treatment had no effect on locomotor activity as well as performance on the rotarod apparatus when measured three weeks after MPTP treatment. In contrast significant impairments in motor function were observed 18 months after MPTP treatment. The data suggest that aging plays a significant role in interacting with environmental toxicants to produce parkinsonian motor symptoms.

Title: L-DOPA-induced dyskinesia involve structures outside the basal ganglia

Authors: *M. BASTIDE, G. CHARRON, S. DOVERO, C. E. GROSS, P.-O. FERNAGUT, E. BEZARD;
Gironde, Instute of Neurodegenerative Dis., BORDEAUX, France

Abstract: The most effective symptomatic therapy for Parkinson's disease (PD) remains the dopamine precursor L-3,4-dihydroxyphenylalanine (L-DOPA). Long-term treatment leads to involuntary aimless movements called L-DOPA-induced dyskinesia (LID). The stimulation of the dopamine D1 receptor pathway results in increased expression of several molecular markers, in particular the members of the immediate-early gene (IEG) family, a class of genes rapidly transcripted in response to an external stimulus. As the primary target of nigral DA neurons, the striatum has received most attention to understand the pathophysiology of LID. However, the myriad of dopaminoceptive structures in the brain that are likely to be affected by the exogenously produced DA have received little, if any, attention although they might play a key role in mediating those L-dopa-induced abnormal behaviours.
Therefore, we here characterized ΔFosB, ARC, Fra2 and Zif/268 IEGs expression in the whole brain of dyskinetic and non-dyskinetic rats to identify brain nuclei displaying a transcriptional response specifically related to LID and not to the treatment itself. For this mapping, we quantified the number of positive IEGs-cells using unbiased stereological methods. Within the basal ganglia, the striatum and the substantia nigra reticulata showed an increased expression for all the IEGs between the dyskinetic and non-dyskinetic rats on the lesioned side. Outside the basal ganglia, there was an increased expression of the 4 IEGs in the Motor Cortex, 3 nuclei of the bed nucleus of the stria terminalis, the hippocampus, the pontine nuclei and the cuneiform nucleus. Moreover, the Zona incerta and the lateral habenula displayed an overexpression of ΔFosB, ARC and Zif268. These results illustrate a global transcriptional response to a dyskinetic state in the whole brain suggesting the possible involvement of these structures in LID.

Title: Nicotinic receptor drugs reduce L-dopa-induced dyskinesias in a nonhuman primate model of Parkinson's disease

Authors: *M. QUIK[1], D. ZHANG[1], D. SOHN[1], F. I. CARROLL[2], M. DECKER[3];
[1]Ctr. for Hlth. Sci., SRI Intl., Menlo Park, CA; [2]RTI Intl., Research Triangle Park, NC; [3]AbbVie, Inc., North Chicago, IL

Abstract: L-dopa is one of the primary therapies for Parkinson's disease. However, its long term use results in the development of abnormal involuntary movements or dyskinesias for which there are currently few treatment options. Accumulating data now indicate that nicotine treatment results in a decline in L-dopa-induced dyskinesias in several parkinsonian animal models, suggesting that this may represent a useful treatment approach. However, nicotine may act at multiple sites yielding beneficial results but also side effects. The goal of the current study was to determine whether selective nicotinic receptor drugs reduce L-dopa-induced dyskinesias in parkinsonian nonhuman primates, a model that resembles Parkinson's disease. Monkeys were given MPTP over several months until parkinsonian. They were then gavaged with L-dopa (10 mg/kg) plus carbidopa (2.5 mg/kg) twice daily, with dyskinesias scored every 30 min throughout the course of the day. We first examined the effect of varenicline, a drug that interacts with multiple nicotinic receptors, to test the hypothesis that the effect of nicotine is receptor-mediated. Varenicline (provided by F.I.C.) reduced L-dopa-induced dyskinesias in a dose dependent manner by ~50%. ABT-089 (provided by AbbVie, Inc.), an agonist that interacts selectively with β2* nicotinic receptors, also decreased L-dopa-induced dyskinesias by ~50%. This compares well to the effect of nicotine which reduced dyskinesia by 55%. The effect of these drugs persisted for the entire length of the study (several months). Parkinsonism was not modified with drug treatment. These data suggest that β2* nicotinic receptor subtype drugs may be useful for the treatment of L-dopa-induced dyskinesias in Parkinson's disease patients. Importantly, varenicline has been approved for use in humans as a smoking cessation aid and ABT-089 has been evaluated in phase 2 clinical trials for other indications. These drugs could thus rapidly be repurposed and approved for clinical studies to test their ability to reduce L-dopa-induced dyskinesias in Parkinson's disease.

Title: Rats that self-administer methamphetamine show Parkinson's disease-like inflammation and α-synuclein pathology in the brain and colon

Authors: *T. NAPIER, S. M. KOUSIK, L. P. KELLY, S. M. GRAVES, A. L. PERSONS; Rush Univ. Med. Ctr., CHICAGO, IL

Abstract: Methamphetamine (meth) is a potent psychostimulant, and abuse of meth is associated with an increased risk for developing Parkinson's disease (PD) (Callaghan *et al. Drug Alcohol Depend* 120:35, 2012). Underlying mechanisms may include oxidative stress, mitochondrial dysfunction and inflammation (Yamamoto *et al. Ann. NY Acad. Sci.* 1187:101,2010), factors that are also believed to be involved in PD pathology and disease progression. Studies of meth-induced toxicity are largely based on *in vivo* experiments using acute, high doses of non-contingently administered meth. It is unknown if similar outcomes occur with protocols that better emulate human drug-taking, e.g., self-administration of more "physiologically relevant" doses of meth. The current study determined if meth self-administration increased markers of inflammation i.e., glial fibrillary acidic protein (GFAP; a marker of glial cell activation) in the rostral striatum and substantia nigra, the terminal and cell body regions (respectively) of dopaminergic projections that are most severely affected in PD. To validate the concept that meth abuse enhances vulnerability for PD, we then assayed the substantia nigra for α-synuclein, a neuropathological hallmark for the disease. Accumulating evidence in the PD field suggests that peripheral factors may contribute to central degenerative processes; specifically, α-synuclein aggregates have been identified in the enteric nervous system of the colon of PD patients prior to the onset of motor symptoms (Shannon *et al. Mov Disord.* 27:709,2012). Thus, we also assayed the gut for α-synuclein and GFAP. Male Sprague-Dawley rats were trained to self-administer meth for 14 days; controls were saline-yoked. Tissue was harvested on day 15 and prepared for Western blotting (brain) or immunohistochemistry (colon). Meth self-administration increased GFAP expression in the rostral striatum and nigra ($p<0.01$). In the nigra, α-synuclein levels were also increased ($p<0.01$). Quantitative assessments of α-synuclein and GFAP optical density in the colon revealed increased staining in meth-treated rats compared to controls ($p<0.05$). Collectively, these results provide the first evidence for PD-like pathology in the brains and colon of meth self-administering rats, and therefore offer insights into mechanisms that underlie the enhanced vulnerability of meth abusers to develop PD later in life. It is of great interest to

ascertain if detection of α-synuclein in the colon can serve as a biomarker that predicts PD in meth abusers.

Title: Methamphetamine self-administration reduces dopamine in the nigrostriatal and mesolimbic pathways in association with ischemia suggesting methamphetamine abuse as a risk factor for Parkinson's disease

Authors: *S. M. KOUSIK[1], T. C. NAPIER[1,2], P. M. CARVEY[1];
[1]Pharmacol., [2]Psychiatry, Rush Univ. Med. Ctr., Chicago, IL

Abstract: Methamphetamine (meth) causes excess dopamine (DA) release and can be neurotoxic. Meth abuse may be a risk factor for Parkinson's disease (PD); an alarming event as worldwide meth abuse is about 26 million. Meth abusers display reduced DAergic function and some motor deficits similar to PD patients. Laboratory animal models suggest these DA losses result from increased DA-quinones, reactive oxygen species and/or hyperthermia, but were based on extremely high levels of meth that would not likely be self-administered by humans. We focused on patterns of DA neurotoxicity in male SD rats following meth self-administration for 14 days (rats self-titrated in the 3hr/day sessions to about 4mg/kg/day) followed by forced abstinence for 1, 14, 28, or 56 days. Saline-yoked rats served as controls. Tyrosine hydroxylase (TH) was used to identify DA terminals and neurons. In the dorsal striatum, there was a 17% TH reduction ($p<0.05$) at 14 days withdrawal, and a 50% reduction ($p < 0.001$) at 28 and 56 days. TH+ cells stereologically counted in the substantia nigra, the bed nucleus of striatal terminals, revealed a 22% loss ($p < 0.05$) of TH+ cells at both 28 and 56 days withdrawal. To verify that TH reductions represented actual DA terminal and cell loss and not suppression of the TH

phenotype, a retrograde tracer (Fluorogold (FG)) was injected into the striatum and evaluated in the nigra to indicate active connections. FG imaging revealed a reduction in FG transport to the nigra at 28 and 56 days withdrawal suggesting actual terminal and cell loss within the nigrostriatal pathway. These DA losses were associated with significant vasoconstriction of small-diameter vessels (0.01-0.03 mm) in the dorsal striatum at 1 and 14 days but not 28 and 56 days (assessed using micro-computed tomography) suggesting dysfunction of the neurovascular unit. TH was also reduced (50%; $p<0.001$) in the nucleus accumbens (NAc)-core at 28 and 56 days withdrawal, but not the NAc-shell. Accordingly, FG transport from the lateral ventral tegmental area to the NAc-core was reduced at 56 days withdrawal. In summary, meth self-administration resulted in early dysfunction within the nigrostriatal sensorimotor pathway, similar to PD pathology. This was followed by dysfunction within the NAc-core, i.e., the "limbic-motor interface." The NAc-shell, which mediates reward-seeking behavior, maintained normal DA function. These data reveal a meth-induced dysfunction in the neurovascular unit producing initial ischemia which results in actual DA losses consistent with PD pathology.

Title: The anti-dyskinetic effects of serotonin transporter blockade are partially reversed by 5-HT_{1A} receptor antagonism

Authors: *M. CONTI, P. SINGH, C. BISHOP;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Dopamine (DA) replacement therapy with L-DOPA is standard treatment for Parkinson's disease (PD), but chronic treatment usually leads to the development of abnormal involuntary movements (AIMs) referred to as L-DOPA-induced dyskinesia (LID). Accumulating work has shown that compensatory plasticity in serotonin (5-HT) neurons contributes to LID leading researchers to directly target serotonin autoreceptors to attenuate LID. Treatment with 5-HT_{1A} agonists inhibits L-DOPA-derived DA release from 5-HT neurons thus alleviating LID but chronic treatment may increase motor disability. Recent evidence has indicated that 5-HT transporter (SERT) blockade with selective 5-HT reuptake inhibitors (SSRIs) also provides anti-

dyskinetic protection without interfering with motor performance. A possible mechanism underlying anti-dyskinetic effects of SSRIs may be indirect activation of 5-HT_{1A} receptors. The current investigation sought to test this mechanism using unilateral 6-OHDA medial forebrain bundle lesions in Sprague-Dawley rats. After a 3 week recovery period, rats were primed with L-DOPA (6 mg/kg + benserazide 15 mg/kg; s.c.) and monitored for AIMs expression. Using a within subjects design, rats received the following treatment across 10 test days spaced 3-4 days apart: vehicle or the 5-HT_{1A} antagonist WAY100635 (0.5 mg/kg) was administered 5 min prior to vehicle or SSRI treatment with either citalopram (3 or 5 mg/kg) or paroxetine (0.5 or 1.25 mg/kg) which was administered 30 min prior to L-DOPA. Rats were tested for ALO AIMs for 3 h immediately following L-DOPA treatment. Behavioral results indicated that blocking 5-HT_{1A} receptors partially reversed SSRIs attenuation of LID. Findings indicate that SSRIs benefits as co-treatment with L-DOPA are in part mediated by indirect stimulation of 5-HT_{1A} receptors.

Title: L-dopa induced dyskinesias in Parkinsonian mice

Authors: *B. J. HOFFER[1], L. OLSON[2], C. BACKMAN[3];
[1]Scientist Emeritus, NIDA/NIH, Lyndhurst, OH; [2]Karolinska Inst., Stockholm, Sweden;
[3]Intramural Res. Program, NIDA, Baltimore, MD

Abstract: In Parkinson's disease (PD), the efficacy of L-dopa treatment is gradually lost over time, as dyskinesias emerge in response to previously beneficial doses of the drug. Using MitoPark mice, a transgenic model that closely mimics the gradual loss of dopamine (DA) neurons observed in PD, we found that the level of DA denervation and associated adaptations in striatal neurotransmission at the time of L-dopa treatment determines the development and escalation of L-dopa-induced dyskinesias. MitoPark mice show a slow progressive loss of DA afferents in limbic areas starting in adulthood, in which nigrostriatal dopaminergic projections innervating the dorsal striatum are strongly affected, while mesolimbic projections innervating the ventral striatum are relatively spared, a pattern that closely mimics the progression of PD in humans. In this study we chronically treated 20-week old (moderate DA loss), and 28-week old

(severe DA loss) Mitopark mice with L-dopa (10 mg/kg i.p. twice a day). The locomotor response after the first and subsequent L-dopa treatments differed significantly between 20-week and 28-week old MitoPark mice. While all MitoPark mice developed locomotor sensitization to L-dopa treatment over time, 28-week old mice showed a decreased latency and increased response duration to the first and subsequent L-dopa injections. In parallel with this data, MitoPark mice with a high degree of DA striatal denervation (28-week old) developed abnormal involuntary movements (AIMs) rapidly and severely after starting L-dopa treatment, as compared to the more gradual escalation of AIMs in animals that started treatment at earlier states of the degenerative process (20-week old). Our data suggests that it is the loss of DA innervation and subsequent adaptations in the striatum that may set up the tone in the limbic system for how motor complications develop with L-dopa treatment. PCR array studies of striatal neurotransmitter receptors revealed profound changes in the mRNA expression levels for various DA, serotonin, glutamate and GABA receptors in the striatum of 30-week old Mitopark mice. While, chronic L-dopa treatment starting at 20 weeks of age normalized the expression pattern of some neurotransmitter receptors, it exacerbated, or in cases inverted, the expression of others. This study highlights the relevance of this newly developed mouse model as an enhanced platform that offers clinically relevant similarities to the manifestation of L-dopa induced motor complications during PD, and therefore could be utilized in the preclinical development of new pharmacological and gene therapies aimed at correcting the manifestation of motor complications in PD.

MJFF The Role of LRRK2 in Neurotransmission

LRRK2 in neuronal architecture and membrane dynamics

Title: The interplay between LRRK2 and the striatal DA system influences behavior in genetic animal models

Authors: *M. VOLTA[1], D. A. BECCANO-KELLY[1], L. N. MUNSIE[1], P. CHOU[1], S. BERGERON[1], S. CATALDI[1], I. TATARNIKOV[1], K. CO[1], L. TAPIA[1], H. MELROSE[3], A. J. MILNERWOOD[2], M. J. FARRER[1];

Abstract: Genetic variability in leucine-rich repeat kinase 2 (LRRK2) is a major risk factor for sporadic and familial Parkinson's disease (PD). In LRRK2 transgenic mice neuronal microarchitecture is perturbed and several studies have reported age-associated dysfunction in nigrostriatal dopamine (DA) signalling reminiscent of late-stage PD; Yue and Lachenmayer, 2011). Nevertheless, early albeit subtle deficits in neuronal physiology, and associated behavioural correlates, warrant further investigation. Herein we report a detailed behavioural characterization of several LRRK2 lines (vs. non-transgenic littermates) focused on motor and non-motor phenotypes relevant to the symptomatology of patients with PD. We observe DA-dependent behavioural alterations at 3-6 months in LRRK2 knockout (KO) and BAC hWT-LRRK2 mice supported by aberrant striatal DA signalling. Based on these observations we have broadened our study to include a recently developed LRRK2 G2019S knock-in (KI) line. In these animals expression of endogenous albeit mutant LRRK2 protein facilitates physiologic investigation of the effects of the pathogenic mutation. Initial data in heterozygous KI animals point to a trend for increased spontaneous locomotor activity in the open field at young age-points (3 and 6 months). In parallel, we report on subtle cognitive abilities (puzzle box test), spatial orientation and stereotypies (Y-maze test). To investigate the interplay between LRRK2 and the DA system across different models, KI mice have been challenged with DA receptor ligands and tested in the open field. At the same time, the expression levels of DA-related proteins has been assessed in the striata, including quantitative analyses of DN neurone (SNc) number, striatal axon terminal density, DA receptor and DA-related signalling proteins and their localization. Based on preliminary findings we hypothesize that early, altered DA signalling in striatal cells (rather than nigral neuronal death) heralds the initial pathophysiology of LRRK2-parkinsonism. The data suggest that LRRK2-parkinsonism is a developmental disorder that necessitates compensatory synaptic and circuitry changes for successful aging. Our result provides a comparative report of LRRK2's in vivo role, revealing several neuronal mechanism(s) underlying PD-relevant behavioural phenotypes. Ultimately, this data and these animals may inform therapeutic efforts aimed at disease modification (neuroprotection), to slow or halt disease progression.

Title: Early synaptic alterations in LRRK2 G2019S Knock-In mice

Authors: *D. A. BECCANO-KELLY[1], M. VOLTA[1], L. MUNSIE[1], I. TATARNIKOV[1], P. CHOU[1], K. CO[1], S. BERGERON[1], L. TAPIA[1], H. L. MELROSE[4], L. A. RAYMOND[2], A. J. MILNERWOOD[3], M. J. FARRER[1];
[1]Med. Genet., [2]Psychiatry, [3]Neurol., Univ. of British Columbia, Vancouver, BC, Canada; [4]Neurosci., Mayo Clin., Jacksonville, FL

Abstract: Parkinson's disease (PD) is the most prevalent neurodegenerative movement disorder in the world, affecting ~2% of the population. Current therapeutic research focuses on late-stage clinical phenotypes which, at best, only alleviate symptoms rather than prevent the disease progression. In order to design preventative therapies it is crucial to determine early pathophysiological changes in PD models.
Mutations in the gene encoding the Leucine-Rich Repeat Kinase 2 (LRRK2) protein cause the highest morbidity in familial and idiopathic PD cases, with the G2019S mutation alone accounting for ~2% of PD cases.
The neuronal function of LRRK2 is still unknown, although recent research has implicated it in glutamate release in simple model systems and dopamine transmission in the striatum of aged transgenic mice. Many current investigations use BAC mice overexpressing (OE) human LRRK2 to draw conclusions about PD; however results are difficult to interpret due to higher expression levels, species-irrelevant expression patterns and random insertion events.
In this study we characterize early synaptic alterations in Knock-In (KI) mice carrying the

G2019S mutation in the LRRK2 murine homologue with endogenous control of expression. Whole-cell electrophysiological recordings revealed alterations in glutamatergic transmission onto striatal medium spiny neurones in acute brain slices from 1 month old KI mice. Spontaneous excitatory postsynaptic currents display increased frequency and decreased amplitudes furthermore, this effect is related to allelic copy number with homozygous mice having a more pronounced effect than heterozygous mice.
Preliminary data also suggest altered dopamine transmission at this age in KI mice as assayed by fast scan cyclic voltammetry.
Western blotting further revealed altered levels of numerous striatal receptors and signal transduction proteins pertinent to dopamine transmission including LRRK2 itself. The data suggest a consequence of the G2019S mutation is altered LRRK2 auto-regulation.
The data show that a single point mutation, mimicking a PD risk factor, results in early synaptic phenotypes in mice in a manner distinct from those seen in either OE or knock-out mice. Thus G2019S KI mice reveal differences in LRRK2 physiology induced by mutations that are neither simplistic loss nor gain of function. We demonstrate that early stage alterations precede late stage deficits and provide a target for preventative therapeutics against onset and progression of PD.

Title: Morphological adaptations of 'direct pathway' spiny projection neurons in experimental parkinsonism and L-DOPA-induced dyskinesia

Authors: T. FIEBLINGER[1], C. ALCACER[1], L. ZANETTI[1], S. M. GRAVES[2], J. L. PLOTKIN[2], D. J. SURMEIER[2], *M. A. CENCI[1];
[1]Dept of Exp. Med. Sci., Lund Univ., Lund, Sweden; [2]Dept. of Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: The dendrites of striatal spiny projection neurons (SPN) are the principal anatomical site where dopaminergic and glutamatergic inputs to the striatum functionally interact to control movement (Gerfen and Surmeier, Annu. Rev. Neurosci. 34: 441-66, 2011). Previous studies have shown that SPN forming the 'indirect pathway' (iSPN) undergo dendritic spine pruning and loss of corticostriatal synapses in rodent models of Parkinson´s disease (PD). In this study, we set out to examine the dendritic adaptations of 'direct pathway' SPN (dSPN), which play a pivotal role in the development of motor complications during the treatment of PD with L-DOPA (Cenci, Trends Neurosci 30:236-243, 2007). BAC transgenic mice expressing TdTomato under the control of the D1 receptor promoter sustained unilateral 6-OHDA lesions of the medial forebrain bundle followed by a 10-day treatment with either L-DOPA or vehicle (saline). L-DOPA was given at dose inducing severe dyskinesia (6-12 mg/kg/day i.p.; Francardo et al. Neurobiol. Dis. 42:327-40, 2011). TdTomato-positive neurons were patched and filled with Alexa-488 in corticostriatal slices. Dendritic morphology and spine numbers were examined in optical z-stacks acquired with a two-photon laser microscope. Following 6-OHDA lesions, dSPN showed a significantly reduced total dendritic length, fewer branch points, and lower numbers of Sholl intersections ($p < 0.05$ vs normal controls on all parameters). This dendritic regression was accompanied by a significant increase in intrinsic excitability, as determined from current-voltage plots. Subsequent dyskinesiogenic treatment with L-DOPA did not significantly modify the dendritic regression of dSPN, nor their intrinsic excitability. However, it produced an approximately 30% reduction in spine density ($p < 0.05$ vs both controls and 6-OHDA-saline treated mice). These results show that dSPN undergo dendritic regression following dopamine denervation. This regression is neither aggravated nor alleviated by a short course of dyskinesiogenic treatment with L-DOPA. The treatment however results in a significant loss of spines. Ongoing studies are examining the possible significance of these dendritic adaptations to the pathophysiology of L-DOPA-induced dyskinesia.

Abstract: Research aimed at developing new therapies for Parkinson's disease (PD) critically depend on valid animal models of the disease that allows for repeated testing of motor disabilities over extended time periods. We here present a through characterization of a wide range of motor symptoms in the 6-OHDA marmoset model of PD when tested over several months. Severity of motor deficits were quantified both through manual scoring protocols appropriately adapted to include species specific motor behavior, through the use of automated quantitative motion tracking procedures based on mathematical image analysis of digital video

recordings and recordings by actimetry sensor. Analyses show that the automated methods allow for rapid and reliable characterization of changes in motor behavior matching the manual scoring procedures and that robust motor symptoms lasting for several months could be induced when using a two-stage neurotoxic lesioning procedure involving one hemisphere at a time (Mitchell et al. 1995). This non-human primate model of PD may therefore be well suited for long-term evaluation of novel therapies for treatment of PD.

Abstract: The development of therapies to improve the quality of life of people suffering from different types of body paralysis through the reestablishment of its sensory and motor functions

is a major medical challenge. Brain-machine interface (BMI) emerges as a potential answer, by allowing the control of paralyzed body parts directly by brain activity. The chronic implant of multielectrodes, employed to record neural activity directly from the brain parenchyma, is a fundamental component of an invasive BMI. However, before this technique can be effectively available to human clinical trials, it is necessary to comprehensively characterize its impact on the nervous tissue. In the present work we evaluated the impact of chronic implanted tungsten multielectrode arrays on the distribution and morphology of calcium-binding protein (CBP) neurons (CB), calretinin (CR), and parvalbumin (PV) across rat's motor cortex. In addition, to estimate the impact of post-implant elapsed time on neuronal recordings, we also correlated the cell distribution with their electrophysiological signals, which were assessed by comparing the total number of neuronal units observed in the first and last recording sessions, in order to evaluate their signal-to-noise ratio (SNR). Our results point out that chronic electrode arrays were well tolerated by the nervous tissue, with recordings remaining viable for up to 6 months after implantation, presenting a peak of signal quality around 3 months of implant. In addition, both morphology and distribution of CBP neurons were not broadly affected. Moreover, both a restricted neuronal loss and glial activation were observed on the implanted sites. Altogether, our results suggest that tungsten multielectrodes can be deemed as a feasible candidate to future human clinical interventions involving BMI.

Title: Effects of spinal cord stimulation on the neuronal population dynamic of the cortico-basal ganglia-thalamic circuit in a primate model of Parkinson´s disease

Authors: *P. HALJE[1], M. SANTANA[2,3], H. SIMPLÍCIO[2,4,5], M. NICOLELIS[2,6], R. FUENTES[2], P. PETERSSON[1];
[1]Lund Univ., Lund, Sweden; [2]Edmond and Lily Safra Intl. Inst. of Neurosci. of Natal (ELS-IINN), Natal, Brazil; [3]Psychobiology, Federal Univ. of Rio Grande do Norte, Natal, Brazil; [4]Hlth. Sci., State Univ. of Rio Grande do Norte, Natal, Brazil; [5]Neurosurgical Team, NEURON, Natal, Brazil; [6]Duke Univ., Durham, NC

Abstract: Spinal cord stimulation (SCS) has been proposed as a novel therapy for symptomatic treatment of Parkinson's disease (PD) based on rodent experiments and a few clinical case reports. We here show that dorsal SCS at the thoracic level reduce PD symptoms in unilaterally 6-OHDA lesioned marmosets and normalize neural activity in some - but not all - structures in the cortex-basal ganglia system.
The animals (n=2) were implanted with chronic epidural stimulation electrodes with the anode and cathode on different sides of the midline. We also implanted chronic 64-channel microwire electrodes positioned bilaterally in motor cortex, somatosensory cortex, putamen, subthalamic nucleus and the ventral lateral and ventral posterolateral thalamic nuclei.
The analyses of the local field potentials (LFPs) in the different structures showed that activity specific to the PD state, such as cortical over-expression of beta oscillations, was effectively normalized by the SCS. A comparison of the activity during SCS with the activity during levodopa treatment revealed several similarities but also a few remarkable differences in the spectral profile of the LFPs in the different structures; motor cortex, putamen and subthalamic nucleus showed similarities, while somatosensory cortex and thalamus (ventral lateral and ventral posterolateral nuclei) showed differences compared to the levodopa treated state.
Also, we evaluated the effect of different stimulation frequencies on behavior and electrophysiology. Tested stimulation frequencies ranged from 4 Hz to 300 Hz and behavioral effects were quantified offline using video tracking software. We found that the optimal stimulation frequency varied greatly between individuals. In motor cortex the resemblance of the spectral profile to the levodopa treated state correlated with symptom relief. In contrast, the spectral profile in putamen primarily showed a higher degree of resemblance to the levodopa state as stimulation frequency increased, but did not directly correlate to reduction of symptoms

Title: Functional coupling in the cortico-basal ganglia-thalamic loop in a primate model of Parkinson's disease

Authors: *U. RICHTER[1,2], P. HALJE[2,3], M. SANTANA[4,5], M. NICOLELIS[4,6,7,8,9], R. FUENTES[4], P. PETERSSON[2,3];
[1]Lund University, Neuronano Res. Ctr., Lund, Sweden; [2]Dept. for Exptl. Med. Sci., [3]Neuronano Res. Ctr., Lund Univ., Lund, Sweden; [4]Edmond and Lily Safra Intl. Inst. of Neurosci. of Natal, Natal, Brazil; [5]Psycobiology, Federal Univ. of Rio Grande do Norte, Natal, Brazil; [6]Biomed. Engin., [7]Ctr. for Neuroengineering, [8]Dept. of Neurobio., [9]Dept. of Psychology and Neurosci., Duke Univ., Durham, NC

Abstract: The cerebral cortex, the basal ganglia, and thalamus together constitute an anatomically distributed but strongly interconnected neuronal network that is known to play a crucial role for motor behavior. A deeper knowledge of the relevance of functional coupling within this neural network is of crucial interest for a better understanding of both normal and pathophysiological behavior, in particular in Parkinson's disease.
We have here studied functional coupling in terms of coherence between the motor cortex (MI), somatosensory cortex (SI3a), putamen (Put), subthalamic nucleus (STN) and the ventral lateral (VL) and ventral posterolateral (VPL) thalamic nuclei of unilaterally 6-OHDA lesioned marmosets (n = 2). The animals were bilaterally implanted with chronic 64-channel microwire electrodes, and neuronal recordings were obtained in the freely moving animals during a Parkinsonian baseline period and following therapeutic levodopa treatment. Time-resolved coherence was calculated for all available pairs of local field potential signals. Video recordings were employed to quantify the overall motor activity, which was correlated to the mean coherence in frequency bands of interest.
In subject 01 an intermittent narrowband oscillation in the 10-Hz band could be observed in the Parkinsonian state in several structures of the lesioned, but also in a number of channels of the intact hemisphere. The mean coherence around this oscillation frequency (8-12 Hz) was significantly increased in the Parkinsonian compared to the levodopa-treated state. Furthermore, in the Parkinsonian state the strength of the coherence was significantly modulated with motor activity, such that it decreased at the occasions when the animal displayed relatively normal motor activity.
In subject 02 a more broadband intermittent oscillation in the 10 to 20-Hz band was observed in the Parkinsonian state, where it was most prominent in MI and Put of the lesioned hemisphere. Similar to subject 01 the mean coherence between MI and Put was stronger in the lesioned compared to the intact hemisphere and was negatively correlated to motor activity. A similar trend could also been seen between MI and VL as well as Put and VL of the lesioned hemisphere, and levodopa treatment effectively reduced coherence between all structures.
These findings are in line with a pathophysiological role of low-frequency oscillations causing excessive synchronization and functional coupling between MI, Put, STN and VL in the cortico-basal ganglia-thalamic loop, thereby potentially preventing functional information processing and resulting in motor disturbances.

Abstract: Epidural electrical stimulation of the spinal cord (SCS) for chronic pain dramatically improves tremor, rigidity, posture and gait in Parkinson´s disease (PD), as reported in 18 patients from four different clinical studies (Parkinsonism Relat Disord. 2012; 18:213-4; Neurol Med Chir (Tokyo). 2012, 52(7):470-4; Neuromodulation 2012 Dec 10; J Clin Neurosci. 2013 pii: S0967-5868(13). Nonetheless, the neural mechanisms underlying these effects are largely unknown. We hypothesize that SCS alleviates the motor symptoms by modulating the activity of supraspinal structures related to sensory and motor function.
Objective: To study the effect of spinal cord stimulation in the neuronal activity of the cortico-basal ganglia-thalamic circuit in a primate model of PD.
Methods: Adult males marmosets (Callithrix Jacchus) received unilateral or bilateral medial forebrain bundle 6-OHDA lesions and were later chronically implanted with a spinal cord bipolar stimulation electrode at high thoracic level, EMG wires in the deltoid muscles, and two 32-channel microelectrode arrays bilaterally targeting the 6 following structures: primary motor cortex, somatosensory cortex, putamen, ventral lateral and ventral posterior lateral thalamus, and

subthalamic nucleus. Electrophysiological and video recordings were obtained from marmosets with different levels of dopamine depletion while freely moving in an open field.
Results: SCS caused alleviation of parkinsonian symptoms. Analysis of the firing rate showed that SCS consistently modulated the neuronal firing in all the structures recorded, mainly in the ventral lateral thalamus, ventral posterior lateral thalamus, and subthalamic nucleus. Additionally, in the parkinsonian condition, nearly one third of the recorded neurons showed oscillatory activity in the beta range, which was reduced while SCS was on.
Conclusion: The firing rate modulation and the disengagement of neuronal activity from pathological beta rhythm in most of the supraspinal structures recorded may represent important physiological changes induced by SCS that lead to alleviation of motor symptoms.

Title: A method for characterization of activity patterns in cortico-basal ganglia-thalamic structures related to reaching in a primate model of Parkinson’s disease

Authors: *P. PETERSSON[1,2], P. HALJE[1], M. SANTANA[2], R. FUENTES[2], M. A. L. NICOLELIS[2,3,4,5,6];
[1]Lund Univ., Lund, Sweden; [2]Edmond and Lily Safra Intl. Inst. of Neurosci. of Natal, Natal, Brazil; [3]Biomed. Engin, Durham, NC; [4]Ctr. for Neuroengineering,, Durham, NC; [5]Dept. of Neurobiol, Durham, NC; [6]Dept. of Psychology and Neurosci., Duke Univ., Durham, NC

Abstract: During behavioral tests, 6-OHDA lesioned marmosets commonly show difficulties in controlling skilled limb movements and may sometime display motor freezing at the moment of movement initiation when trying to reach for food rewards.

In order to further characterize these types of motor deficits in this primate model of Parkinson's disease and to investigate the associated neurophysiological processes in the cortico-basal ganglia-thalamic loop, we have here characterized reaching behavior in two unilaterally 6-OHDA lesioned adult male marmoset monkeys that were trained in a skilled reaching task requiring the use of both forelimbs (adapted from Campos-Romo et al. 2009).
Animals were trained over a period of several weeks to reach and grasp small pieces of marshmallow through holes in a vertical wall. When the task was fully learnt the animals would normally collect all food rewards within less than 5 min. Both animals were exposed to neurotoxic lesions affecting the medial forebrain bundle according to previously described protocols (adapted from Annette et al. 1992) and eight weeks later, were implanted with bilateral 64-channel wire electrode arrays targeting primary motor cortex and parts of somatosensory cortex, putamen, the subthalamic nucleus and the ventral lateral and ventral posterolateral thalamic nuclei in both hemispheres. Two weeks after implantation, the animals were tested in the reaching set-up and it was confirmed that the animals had retained the ability to perform the task.
Preliminary analyses of the recorded data from these two subjects indicate that parallel single unit recordings could be obtained from the different structures of the cortico-basal ganglia-thalamic loop in all recording sessions during the performance of the task and that freezing events could easily be identified from the digital video recordings.
By analyzing neuronal unit activity specifically related to periods of behavioral freezing as well as other detailed aspects of normal reaching behavior a more comprehensive understanding of neuronal dynamics in the cortico-basal ganglia-thalamic circuit related to voluntary skilled motor control of the hand will be obtainable.

Title: Chronic Spinal Cord Stimulation alleviates motor asymmetry in an Alpha-synuclein animal model of Parkinson Disease

Authors: *I. BRYS[1,3], B. SCHNEIDER[4], M. M. FREIRE[2,1], M. NICOLELIS[1,5,6,7,8], R. FUENTES[2,1];
[2]Neuroengineering Grad. Program, [1]Edmond and Lily Safra Intl. Inst. of Neurosci. of Natal, Natal, Brazil; [3]Psychobiology, Federal Univ. of Rio Grande do Norte, Natal, Brazil; [4]École Polytechnique Federale de Lausanne, Lausanne, Switzerland; [5]Dept. of Biomed. Engin., [6]Ctr. for Neuroengineering, [7]Dept. of Neurobio., [8]Dept. of Psychology and Neurosci., Duke Univ., Durham, NC

Abstract: Parkinson Disease (PD) is associated with progressive loss of dopaminergic neurons in the nigrostriatal pathway and aberrant low-frequency synchronous corticostriatal oscillations. Electrical Spinal Cord Stimulation (SCS) is a minimal invasive neuromodulation method that showed to be effective in alleviating parkinsonian motor symptoms in 6-hydroxydopamine lesioned rats, dopamine depleted mice and PD patients. The mechanisms underlying the pro-kinetic effects of SCS remain poorly understood. Alpha-synuclein overexpression provides a progressive model of dopaminergic destruction, suitable for both testing potential therapies and study the underlying mechanisms.
Objective: To conduct a behavioral, electrophysiological and immunohistochemical characterization of the AAV6 alfa-synuclein rat model of PD and to test the chronic effects of SCS in this model.
Experiment 1) 2 µl of empty vector suspension AAV6 (Control) or of the vector carrying the gene for wild type human alpha-synuclein (Unil, Unil+SCS Groups) were injected stereotaxically in the right substantia nigra of Sprague-Dawley male rats. Animals were tested for asymmetry in the Cylinder test one week before and weekly from 4th to 10th week after injection. SCS groups were submitted to stimulation sessions once a week from 6th to 10th week in an Open Field.
Experiment 2) Electrode arrays were implanted in both hemispheres in motor cortex and dorsolateral striatum of rats injected with vector suspension AAV6 alpha-synuclein in the right substantia nigra and empty viral suspension in the left. Electrophysiological recording was performed during the behavioral tests from 1th to 10th week following the viral injection. Brains were collected and submitted to basic histology and immunohistochemistry.
Results: There is no difference between groups in the distance walked during the Open Field Test ($p>0.05$). Animals from Unil and Unil+SCS groups showed a significant decrease in the use

of the forepaw contralateral to the lesion (left) four weeks after viral injection in the Cylinder Test [$F(3,23)=5.2$, $p<0.05$]. However, animals treated with chronic SCS (Unil+SCS) recovered the ability to use the left paw after the SCS sessions. In the 6th week after the viral injection the mean percentage of left forepaw use in the Unil Group was 15.17%, while in the SCS Group was 39.04%.
Conclusion: Chronic SCS alleviates motor asymmetry in an animal model of PD based on the overexpression of the protein alpha-synuclein in the substantia nigra. Chronic epidural stimulation showed to be an effective treatment to motor PD symptoms and might become an alternative neuromodulation option to treat PD.

Abstract: The development of animal models through protein expression by viral infection is an attractive approach for neuropathology studies. The recombinant adeno-associated viral (rAAV) vectors provide a novel tool to study the neurodegeneration observed in Parkinson's disease (PD). Different rAAV serotypes differ in their expression efficiency. In the current study, we compared the expression in the primate ventral midbrain of two different viral strains, AAV6 and AAV9, using as model common marmosets (Callithrix jacchus). Both vectors carried Green Fluorescent Protein (GFP) as a marker for viral efficacy. The injections were conducted in three marmosets weighing 300g-400g according to a modified protocol from Brain 2007. 130:799-815. Briefly, 2 injections of 2µL of virus per hemisphere were performed, both targeting ventral midbrain. The animals received an injection of the AAV6 strain on the right hemisphere and one of AAV9 strain in the left hemisphere. Before and after the lesions, the animals were evaluated using a rating scale of motor impairment adapted from UDPRS. After 8 months the animals were perfused (0.9% warm heparinized saline solution and 4% cold paraformaldehyde) and the brain tissues were processed for histological analyses. Representative slides of the putamen and substantia nigra were stained with GFP immunohistochemistry. Subsequently, images were captured in a confocal microscope (Zeiss LSM 710, 40x objective) and cell count was done in the substantia nigra images. After the injection the animals did not present any behavioral change, asserting that GFP can be used as a control marker protein in the marmoset brain. There was a difference of GFP expression between the hemispheres, indicating a difference in the viral efficiency and suggesting that AAV9 is more efficient than AAV6 for viral injection. Accordingly, AAV9 might be a better prospective to be used as a viral carrier for a disease model in future studies, such as studies with PD models in the common marmoset.

Title: Analysis of local field potentials in a common marmoset (Callithrix jacchus) during rest and locomotion

Authors: *M. F. P. ARAUJO[1], R. C. MOIOLI[1], F. L. BRASIL[1], R. FUENTES[1], M. A. L. NICOLELIS[1,2,3,4,5];
[1]Neuroengineering Grad Program, Edmond and Lily Safra Intl. Inst. of Neurosci. of Natal, Natal, Brazil; [2]Biomed. Engineering, Duke Universiy, Durham, NC; [3]Ctr. for Neuroengineering, Duke Univ., Durham, NC; [4]Dept. of Neurobio., [5]Dept. of Psychology and Neurosci., Duke Univ., Durham, NC

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder in which the most striking symptoms are related to motor impairments. Traditionally, rodents are used as animal models to study the mechanisms and possible treatments of PD. Recently, common marmosets (Callithrix jacchus) have been increasingly used in PD research. So far, however, the neurophysiological processes related to locomotor behavior in this primate species are still not well established. The aim of this work was to investigate the neurophysiological processes at the cortico-basal ganglia-thalamic loop related to rest and spontaneous locomotion periods.
To examine locomotor network activity we implanted 64 microeletrodes bilaterally to record neuronal spike and local field potentials (LFP) in 4 regions of a female marmoset monkey: primary motor cortex, putamen, internal globus pallidus and external globus pallidus. At each recording session, the monkey was placed inside a plexiglass box (40 cm x 40 cm), where she was allowed to freely move for 10 min. The monkey behavior was recorded by 2 video-cameras: top and frontal. LFPs during movement and rest period were successfully recorded from the 4 structures in all recording sessions.
Preliminary analyses indicate that LFPs successfully relate to locomotor acitivity in all video analyses in this species. Together, this experimental setup and the resulting data will provide a better understanding of the functioning of the cortico-basal ganglia-thalamic circuit of common marmosets during rest and spontaneous locomotion periods. In addition, these results provide the grounds for the analysis of this circuit in different marmoset models of PD.

Title: Prefrontal dopamine is essential for temporal control

Authors: *K. L. PARKER, N. S. NARAYANAN;
Neurol., Univ. of Iowa, Iowa City, IA

Abstract: Parkinson's disease is a devastating neurodegenerative disorder that impairs movements. However, PD patients also suffer significant morbidity from cognitive symptoms of this disease. Temporal control of movement, or how movements are guided in time to achieve behavioral goals, is one such cognitive deficit. One contributor to these symptoms may be dysfunctional dopamine signaling in cognitive brain regions such as the prefrontal cortex. We have previously shown that disrupting prefrontal D1 dopamine signaling impairs interval timing and conversely, optogenetic stimulation facilitates temporal control. Here, we record from prefrontal neuronal ensembles in awake, behaving rats performing an interval timing task while pharmacologically manipulating dopamine signaling within these brain regions. We trained rats to perform an interval timing task with a 12 second interval. Once well trained, an injection cannula and electrode arrays were implanted in the prelimbic cortex. Prelimbic neuronal activity and local field-potentials were analyzed during interval timing performance, and while D1 antagonists (SCH 23990) and D1 agonists (SKF 81297) were infused. We found three major patterns of prefrontal neuronal activity: 1) timing-encoded ramping activity, 2) reward-acquisition-related activity, and 3) motor-related activity. Following D1 blockade, animals' interval-timing performance was impaired. Furthermore, ramping activity among prefrontal neurons was less prominent in sessions with D1 blockade, while neuronal activity related to movement and reward-acquisition was preserved. Finally, time-frequency analysis revealed that task-modulated low-frequency rhythms were altered. Taken together, these data suggest that D1 dopaminergic systems within prefrontal cortex are critical to temporal control, and suggest that manipulating D1 systems may be a useful target of novel pharmacological agents that treat cognitive symptoms of Parkinson's disease.

Title: Dorsal raphe serotonergic neurons and levodopa-induced dyskinesia in Parkinson's disease

Authors: *V. CERPA, A. D. MILLER, G. B. RICHERSON, N. S. NARAYANAN;
Neurol., Univ. of Iowa, Iowa City, IA

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder involving degeneration of midbrain dopaminergic neurons. L-3,4-dihydroxyphenylalanine (Levodopa; L-Dopa) is an effective treatment for the motor symptoms of PD; however, L-Dopa therapy commonly leads to disabling side effects including motor fluctuations and dyskinesias. L-Dopa does not induce dyskinesias in humans without PD. In primate models of PD, dyskinesias require dopaminergic denervation. Prior work has demonstrated that dyskinesias can be modulated by 5-HT1a/5-HT1b receptor agonists; however, it is unclear which serotonin neurons, projections, and striatal circuits are involved. Serotonin nuclei do degenerate in PD, although much less than monoaminergic nuclei. Here we use tract tracing, in-vivo microdialysis, optogenetics, and electrophysiology to map the influence of serotonin signaling on L-Dopa-induced dyskinesias in a mouse 6-OHDA model of PD. First, using retrograde tracers in Pet1-YFP mice, we identified a population of neurons in the dorsal raphe that directly project to the dorsal striatum. We found that both dorsal raphe serotonin and non-serotonin neurons monosynaptically project to the striatum. Next, we found that dyskinesia severity correlated with dopaminergic damage, and dyskinesias were diminished after co-administration of L-Dopa and administration of the 5-HT1a receptor agonist 8-OH-DPAT. We used in vivo microdialysis to analyze striatal neurochemistry during L-Dopa-induced dyskinesias and administration of 5-HT1a receptor agonists. Future directions will explore L-Dopa-induced dyskinesias with optogenetic stimulation of serotonin neurons in the dorsal raphe, as well as with striatal electrophysiology. Our results describe a direct projection between serotonin projections from the dorsal raphe nucleus to the striatum. This projection could be targeted by future therapies aimed at reducing L-Dopa-induced dyskinesias.

Col. of Med., Busan, Korea, Republic of; [5]Dept. of Psychology, Univ. of Memphis, Memphis, TN

Abstract: Deep brain stimulation (DBS) within the basal ganglia complex is an effective neurosurgical approach for treating a variety of neurological and psychiatric disorders, including Parkinson's disease (PD). Despite well-established clinical efficacy, the mechanism of DBS remains poorly understood. To help elucidate the mechanism of action of DBS, we performed 3T functional magnetic resonance imaging (fMRI) in a Rhesus monkey. We stereotactically implanted a miniature 6 contact DBS electrode into the subthalamic nucleus (STN), passing through zona incerta, dorsal STN, medial STN, ventral STN and to substantia nigra. We tested the proportional effects of each contact DBS by manipulating current spread and varying stimulation contacts in a within-subjects design. The fMRI examinations were performed using a simple block-style paradigm that alternated between the stimulator-off condition and the stimulator-on condition using DBS parameters (1-6V, 0.15 msec pulse width at 130 Hz) similar to those used clinically. High frequency stimulation of the STN in anesthetized monkey induced local blood oxygenation level dependent (BOLD) effect in the ipsilateral motor cortex, ipsilateral caudate, and contralateral cerebellum. Importantly, stimulation of both STN and SN resulted in intensity-dependent activations of the BOLD signal. Our results demonstrate that DBS activates areas of the brain, distal to the electrodes, suggesting that DBS activates a diffuse neural network that may be involved in alleviating motor dysfunction in PD patients. Taken together, our results

show that the nonhuman primate model for DBS fMRI, which conforms to human implanted DBS electrode configurations and human neuroanatomy, may be a useful platform for translational studies investigating the global neuromodulatory effects of DBS.

Title: Dopamine depletion results in altered frequency dependent striatal responses to cortical stimulation

Authors: *V. R. JAYASINGHE[1], D. R. THOMASES[2], A. R. WEST[3], K. Y. TSENG[2]; [2]Cell. and Mol. Pharmacol., [3]Neurosci., [1]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Parkinson’s disease is a common neurodegenerative disorder. It is characterized by the loss of dopamine (DA) neurons in the substantia nigra that project primarily to the striatum. Despite the well-defined motor deficits in Parkinson’s disease, the neurobiological mechanisms underlying such impairments are not clear. Recent studies revealed that the emergence of the parkinsonian state is often associated with an increased synchronous activity at beta frequencies (15-30 Hz) between the basal ganglia and cortex. These excessive oscillations are thought to disrupt cortico-striatal transmission and thereby result in the motor symptoms characteristic of Parkinson’s disease. Here we employed *in vivo* local field potential recordings to determine if striatal processing of synchronous cortical inputs at high frequencies is impaired following chronic DA depletion. Towards this goal, we used the 6-hydroxydopamine rat model of parkinsonism and assessed the pattern of striatal response to motor cortex stimulation using trains of pulses delivered at 10, 20, or 40 Hz. In control/DA-intact animals (sham-lesioned rats), we found that motor cortex stimulation at 10 and 20 Hz typically elicited a marked inhibition

local field potential response in the dorsal striatum. Interestingly, such suppression of striatal local field potential responses is lacking in the DA-depleted group. In contrast, striatal response to 40 Hz stimulation appears to remain intact following DA depletion. Thus, an intact DA system within the striatum is required for the normal suppression of cortical inputs at 10 and 20 Hz, but not at 40 Hz. Together, these results are indicative of an impaired inhibitory control of cortical inputs in the DA-depleted striatum, and suggest that the augmented cortico-basal ganglia synchronization observed in the parkinsonian state is not restricted to beta oscillations.

Title: Characterization of four stages of neural changes in parkinsonism using cross-frequency-coupling analysis of subthalamic nucleus local field potentials

Authors: *T. H. SANDERS[1], A. DEVERGNAS[2], M. A. CLEMENTS[1], T. WICHMANN[2,3]; [1]Georgia Inst. of Technol., Atlanta, GA; [2]Udall Ctr. of Excellence in PD Res., Atlanta, GA; [3]Dept. of Neurology, Emory Univ., Atlanta, GA

Abstract: The progression of Parkinson's disease (PD) can be modeled in primates with repeated small injections of the dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Much has been learned about PD using this model. However, we have insufficient knowledge regarding the link between dopamine loss, altered brain activities and parkinsonian motor signs. To address this issue, we analyzed subthalamic nucleus (STN) local field potentials (LFPs) recorded in monkeys before, during, and after induction of parkinsonism with MPTP injections.

The analyzed data were recorded in two rhesus monkeys rendered parkinsonian with weekly i.m.

injections of MPTP. STN-LFPs were recorded with bipolar recording methods as the monkeys progressed from baseline to moderate parkinsonism. An observational rating scale was used to quantify the level of parkinsonism.
We used phase-amplitude cross frequency coupling (CFC) features extracted from the STN LFP data for the analysis. We found that, while beta power was not changed consistently in these animals, ANOVA showed in both monkeys statistically significant increased beta phase modulation compared to baseline conditions for slight to mild parkinsonism, followed by decreased beta phase modulation for the moderate parkinsonism conditions. Analysis of the relationship between parkinsonism and the relative magnitude of 36 phase-amplitude CFC features (delta through gamma bands) over increasing severity of motor signs revealed several discernible stages of parkinsonism, each with a characteristic pattern of phase-amplitude modulation. The progression for each monkey was statistically similar. The data suggest that worsening parkinsonism is associated with predictable patterns of brain activity changes.

Title: Causal role of striatal cholinergic system in generating parkinsonian beta oscillations

Authors: *X. GU[1], M. MCCARTHY[2], N. KOPELL[2], X. HAN[2];
[1]Biomed. Engin., [2]Boston Univ., Boston, MA

Abstract: Enhanced beta oscillations (15-30Hz) are found in the cortical-basal ganglion-thalamic neural circuit of parkinsonian brains and correlate with motor dysfunction in Parkinson’s disease. However, it remains unclear how the loss of dopaminergic neurons in the substantia nigra in Parkinson’s disease leads to pathologically enhanced beta oscillations. Dopamine neurons in the substantia nigra primarily project to the striatum, and among their

broad effects on various striatal neuronal types, they inhibit striatal cholinergic interneurons. Our computational models have suggested that elevated cholinergic tone can turn a normal striatum into a beta oscillation pacemaker, primarily through elevating the firing rate of medium spiny neurons in the indirect pathway. Direct infusion of the cholinergic agonist carbachol into the striatum of normal mice elicited profound beta oscillations, suggesting that normal striatum contains sufficient neural elements to generate beta oscillations and that acetylcholine is a potent modulator of striatal beta rhythms. To further examine the causal role of the striatal cholinergic system in generating beta oscillations in Parkinson's disease, we used optogenetics to directly modulate striatal cholinergic interneurons. Direct optogenetic activation of striatal cholinergic neurons lead to enhanced beta oscillations similar to that induced with striatal carbachol infusion but with much more precise temporal control over their onset and offset. In addition, optogenetic silencing of striatal cholinergic neurons in 6-hydroxydopamine parkinsonian mice models restored parkinsonian motor deficits. Together, our results provide direct evidence for the causal role of cholinergic interneurons in generating parkinsonian beta oscillations and related motor deficits.

Title: Deep brain stimulation control of beta oscillations through the indirect pathway: A computational study

Authors: *M. M. MCCARTHY, N. KOPELL;
Boston Univ., BOSTON, MA

Abstract: Deep brain stimulation (DBS) of the subthalamic nucleus (STN) can be highly effective in alleviating movement disability in Parkinson's disease. However, its therapeutic mechanism of action is unknown. DBS is most effective at reducing motor pathology if the stimulation frequency is high (~130 Hz). Beta frequency DBS is either ineffective or may worsen motor symptomatology. These findings suggest that interruption of beta rhythms in basal

ganglia networks may be instrumental in the therapeutic action of DBS. Previously we have shown that robust beta oscillations can be generated in the striatum of normal mice under a condition relevant to Parkinson's disease: high cholinergic tone. Computational modeling suggests that robust beta rhythms can emerge in networks of striatal medium spiny neurons (MSNs) in the presence of high cholinergic tone due to increased interaction between the synaptic GABAa current and the intrinsic membrane M-current. Here we extend our models to study how DBS may be working to interfere with the production of exaggerated beta rhythms in striatal networks. We find that a subset of neurons in the external segment of the globus pallidus (GPe) which projects to the striatal MSNs is capable of normalizing the MSN network when driven to spike at high frequency (~ 130 Hz). Specifically, with high frequency input from this subset of GPe neurons, the parkinsonian MSN network returns to a normal baseline spiking rate and the beta power within the network returns to normal levels. Conversely, we find that input to the striatum from the GPe neurons at beta frequency increases the beta power in MSN networks. We show that beta frequency GABAergic input to the MSN network creates resonance within the network, increasing beta frequency spiking of the population of MSNs, whereas high frequency (130 Hz) input to the MSN network creates a condition similar to static inhibition of the network, which opposes the increased excitation due to high cholinergic tone. These findings suggest the therapeutic mechanism of DBS to the STN may work through network dynamics in the indirect pathway of the basal ganglia.

Title: A direct relationship between parkinsonian rest tremor and oscillatory coupling in a distributed subcortico-cortical network

Authors: *J. HIRSCHMANN[1], C. J. HARTMANN[1], M. BUTZ[2], N. HOOGENBOOM[1], T. E. ÖZKURT[3], S. ELBEN[1], J. VESPER[1], L. WOJTECKI[1], A. SCHNITZLER[1];

[1]Heinrich Heine Univ., Düsseldorf, Germany; [2]Univ. Col., London, United Kingdom; [3]Middle East Tech. Univ., Ankara, Turkey

Abstract: Electrophysiological studies on parkinsonian rest tremor revealed that neuronal oscillations and muscle activity are synchronized at tremor frequency, suggesting that oscillatory coupling might underlie tremor manifestation. However, it has not been demonstrated so far that the strength of oscillatory coupling is indeed related to the presence and severity of tremor. To shed light on the relationship between tremor and coupling, we took advantage of naturally occurring spontaneous tremor fluctuations and measured oscillatory coupling both during the presence and absence of rest tremor.
We simultaneously recorded local field potentials (LFPs) from the subthalamic nucleus (STN), the magnetoencephalogram (MEG) and the EMG of forearm muscles in 11 patients with Parkinson's disease. Recordings took place the day after surgery for deep brain stimulation, following withdrawal of anti-parkinsonian medication. We selected epochs containing spontaneous rest tremor and tremor-free epochs, respectively, and compared power and coherence between STN, cortex and muscle across conditions. Tremor-induced increases in coherence were localized by Dynamic Imaging of Coherent Sources (Gross et al., PNAS 2001). Subsequently, cortico-cortical coupling was investigated by reconstruction of the time domain activity of selected sources and computation of the imaginary part of coherency, a coupling measure insensitive to volume conduction (Nolte et al., Clin. Neurophysiol. 2004).
Following tremor onset, LFP power decreased in the beta band (13-30 Hz) and increased at double the individual tremor frequency. Sensor level STN-cortical, cortico-muscular and STN-muscular coherence increased during tremor specifically at individual tremor frequency. The increase in STN-cortical coherence correlated with the increase in EMG power. On the source level, we observed tremor-induced increases in cortico-muscular coherence in primary motor cortex, premotor cortex and posterior parietal cortex contralateral to the tremulous limb. Analysis of the imaginary part of coherency revealed tremor-dependent coupling between these cortical areas at individual tremor frequency and double tremor frequency.
This study demonstrates that the STN is a part of a distributed subcortico-cortical tremor network (Timmermann et al., Brain 2003). Furthermore, it reveals that spontaneous tremor manifestation is associated with characteristic changes in STN power and intra-network oscillatory coupling.

Abstract: Parkinson's disease (PD) patients experience progressive motor symptoms that become associated with medication-induced motor complications, including motor fluctuations and dyskinesia. The past 2 decades have seen unprecedented preclinical and clinical efforts towards identifying and validating putative targets to establish novel antiparkinsonian therapies. While a multiplicity of therapeutic interventions has been developed in rodent models, only a few were tested in MPTP-treated monkeys, which remain the gold standard for modelling PD in non-human primates. The lack of consensus on a methodology, and the almost exclusive reliance upon the sole clinical rating of PD symptoms in the MPTP-treated monkeys, have been among the major roadblocks that have hindered successful translation to clinical settings. Consequently there is a critical need to develop high-resolution translational methodologies to evaluate safety and optimize efficacy of therapeutic interventions developed in rodents before clinical applications. Here, we leveraged our newly established translational analysis platform to characterize alteration of whole-body kinematic, muscle activity, and motor cortex neuronal modulations during unconstrained locomotion in MPTP-treated monkeys. The animals were trained to perform a range of natural walking tasks designed to evaluate the contribution of specific neural pathways to gait control. Using principal component analysis applied on a large number of multifaceted parameters, we could uncover the patterns of gait features associated with increasing PD severities. This analysis also provided an unbiased and quantitative ranking of the degree of locomotor deficits in MPTP-treated monkeys, which could be readily exploited to assess the beneficial impact of therapeutic interventions such as L-Dopa administration. Our combined results highlight the striking sensitivity and rich information content of our recordings and analytic tools. This neuromotor analysis platform establishes the settings to evaluate safety and efficacy of therapeutic interventions to restore locomotion after PD and other neuromotor disorders.

Title: Modulation of primary motor cortex neurotransmitter signaling by dopamine lesion and L-DOPA therapy using a rat model of Parkinson's disease

Authors: *D. LINDENBACH, A. GOLDENBERG, C. OSTOCK, M. CONTI, C. BISHOP; Psychology, Binghamton Univ., Binghamton, NY

Abstract: Parkinson's disease (PD) is typically viewed as a movement disorder resulting from the death of cells that supply dopamine (DA) to the striatum. However, many aspects of motor cortex function are abnormal in PD patients and animal models of PD, implicating motor cortex involvement in disease symptoms and their treatment. We sought to characterize changes in primary motor cortex (M1) neurotransmitter signaling using the rat unilateral 6-hydroxdopamine model of PD. Animals were studied in their "off-drug" state as well as after treatment with the DA precursor L-DOPA (6 mg/kg). The first experiment investigated changes in tissue concentrations of M1 monoamines. At least 3 weeks after DA lesion surgery, tissue from striatum and M1 was dissected for analysis of dopamine, serotonin, and norepinephrine using high performance liquid chromatography. In the second set of experiments, we performed in vivo microdialysis of M1 to analyze extracellular concentrations of glutamate and GABA in real-time. Consistent with prior literature, treatment with L-DOPA improved movement in hemiparkinsonian rats, but caused the gradual development of L-DOPA-induced dyskinesias. Results from experiment 1 show that M1 tissue levels of DA are not reduced after 6-hydroxydopamine lesions despite a severe (~99%) loss of striatal DA. Preliminary data from experiment 2 suggest that L-DOPA increases M1 glutamate levels concomitant with L-DOPA-induced dyskinesia in DA-lesioned rats. Together, the data suggest that M1 neurotransmitter levels are dynamically modulated in the PD brain. Further investigations will shed light on the role of each system in controlling motor output.

Title: Cerebellar recruitment by subthalamic nucleus deep brain stimulation for Parkinson's disease

Authors: *A. C. SUTTON[1], J. G. PILITSIS[2,1], D. S. SHIN[1];
[1]Ctr. for Neuropharm. and Neurosci., Albany Med. Col., Albany, NY; [2]Neurosurg., Albany Med. Ctr., Albany, NY

Abstract: Deep brain stimulation (DBS) surgery for advanced Parkinson's disease (PD) has been performed nearly 100,000 times and is effective in managing motor symptoms of PD in well-selected individuals. However, expanding the patient population suitable for DBS and minimizing stimulation-induced side-effects are unmet needs which continue to encourage research into understanding the therapeutic effects of DBS; at present, the mechanisms of DBS remain unknown. Recently, efforts to examine circuit mechanisms of DBS have extended beyond the traditional basal ganglia (BG)-thalamus loop to include cortical and cerebellar circuits. Functional imaging has shown changes in cerebellar activity due to PD and DBS, yet the cerebellum has an intricate and complex microcircuitry that cannot be parsed by conventional imaging techniques. DBS for PD is most commonly applied to the subthalamic nucleus (STN), a BG nucleus that has recently been shown to have a disynaptic connection with the cerebellum. In our study, we assess whether STN-DBS provides efficacy by recruiting cerebellar activity and connected brain regions by applying STN-DBS in hemiparkinsonian rats and simultaneously recording from the STN, pedunculopontine tegmental nucleus (PPTg), Purkinje layer of cerebellar cortex, deep cerebellar nuclei (DCN), and ventromedial nucleus of the thalamus (VM). While STN neurons decreased spiking activity during DBS, a concomitant decrease was also noted in most PPTg and Purkinje neurons, presumably from reduced STN glutatmatergic signaling. In contrast, activity in the DCN and VM increased during DBS, which likely resulted from reduced inhibitory input from Purkinje cells. Then, as a proof-of-concept that STN-DBS recruits cerebellar activity to contribute to efficacy, we apply STN-DBS with sub-therapeutic current amplitude with a co-stimulation of the cerebellum to see if we can elicit similar improvement in forelimb akinesia as seen in hemiparkinsonian rats with supra-threshold current

stimulation alone. Notably, we found that this was the case and this novel finding demonstrates that STN-DBS modulates cerebellar activity to modify motor function. Our study is the first to characterize the changes in cerebellar activity in response to STN-DBS using electrophysiology and unmask a potential for stimulating the cerebellum to potentiate STN-DBS efficacy and/or minimize stimulation-induced adverse effects.

Title: Human intraoperative fMRI during STN DBS for Parkinson's Disease reveals BOLD activation in motor circuitry

Authors: *E. KNIGHT[1], K. M. WELKER[1], J. HUSTON, III[1], J. P. FELMLEE[1], D. A. CLAYTON[1], I. KIM[1], K. E. BENNET[1], C. D. BLAHA[2], K. H. LEE[1], S. CHANG[1]; [1]Mayo Clin., Rochester, MN; [2]Univ. of Memphis, Memphis, TN

Abstract: Although Deep Brain Stimulation (DBS) is widely performed for a variety of movement and psychiatric disorders, the effect of this therapy on the global neural circuitry is as yet poorly understood. fMRI has emerged as a powerful technique to visualize these circuitry effects; however, fMRI has traditionally not been performed in patients undergoing DBS due to safety concerns. Development of this technique would allow for visualization of the global circuitry responsible for the therapeutic effect of DBS, as well as potentially allow for the development of the use of fMRI as a biomarker of effective electrode placement and stimulation parameters. Therefore, we present the development of a methodology to allow for safe intraoperative fMRI during DBS surgery. This approach involves externalization of the DBS lead and application of 6 second periods of stimulation with 60 second rest periods using an external pulse generator while simultaneously acquiring gradient echo (GRE) echo planar imaging (EPI). All combinations of sequences and MR coils were first tested for safety by measurement of temperature change in an anthropomorphic phantom. Temperature increase was less than 0.2ºC. We then demonstrate the efficacy of this approach for obtaining functional

images during subthalamic nucleus (STN) DBS in patients with Parkinson's Disease to test the hypothesis that STN DBS would lead to blood oxygen level dependent (BOLD) signal increase in motor cortices. Consistent with our hypothesis, with left unilateral STN DBS at 2V 185Hz 90us, contact 0 negative and 3 positive, there was BOLD signal increase in the ipsilateral motor cortex as well as the ipsilateral thalamus, caudate, and cerebellum. Our results suggest that STN DBS results in modulation of motor circuitry, which may underlie the therapeutic effect of STN DBS in Parkinson's Disease.

Title: A model of how transmission delays inside the basal ganglia proper cause beta-band oscillations in Parkinson's desease

Authors: *B. GIRARD[1], J. LIÉNARD[2,3];
[1]CNRS / UPMC, Paris Cedex, France; [2]ISIR, CNRS / UPMC, Paris, France; [3]Washington State Univ., Vancouver, WA

Abstract: In a previous study [1], we presented a mean-field model of the whole basal ganglia of monkeys, defined by a hundred parameters half of which where set according to experimental measurements from the literature, while the remaining ones were optimized in order to fit to both anatomical and electrophysiological data. We obtained a large set (more than one thousand) of relatively similar parameterizations compatible with all these constraints. The structure of these models does not rely on a strict segregation between direct/indirect pathways, as anatomical data suggest it is not the case in monkeys (e.g. [2]).
In these models, the transmission delays between basal ganglia nuclei were simplified. Here, we present a procedure by which we extract from the experimental literature (e.g. [3-8] and more) the delay configuration which is the most plausible. We then show that using this delay configuration with the previously obtained models, β-band oscillations appear when the activity of the STN, GPe, GPi and SNr increases (as a consequence of the decreased effect of their

inhibitory dopamine D2 receptors), while an imbalance in the direct indirect pathways is not necessary.
A sensitivity analysis on the critical pallido-subthalamic delays around their optimal values, shows that the slower θ-band oscillations can not possibly emerge in these basal ganglia proper models. This leads to the hypothesis that they could be caused by the longer delays of the cortico-baso-thalamo-cortical loops.

Title: Mapping DNA double-strand breaks in human and mouse brains

Authors: *G. TORRES[1], J. R. LEHESTE[2];
[2]Biomed. Sci., [1]NYIT COM, OLD WESTBURY, NY

Abstract: Neurons of the mammalian brain are susceptible to DNA damage following external (e.g., γ-radiation) and internal (e.g., α-synuclein deposit) insults. Indeed, it is thought that neuronal DNA damage may be responsible for the pathology often seen in neurodegenerative diseases such as Parkinson's disease (PD). Here we have mapped the parkinsonian brain and the brains of animal models of PD (e.g., Pit X3-1) with specific markers of DNA double-strand breaks. To accomplish this experimental goal, we have used two cellular markers of DNA damage: anti-phospho-histone H2A.X (Ser139) and 53BP1 (P-53 binding protein). Both of these markers label DNA damage in post-mitotic cells and can be used in brain pathology contexts. For labeling of neurons, we performed immunocytochemistry and Western blotting on human PD brains and adult PitX3-1 mouse brains. We report here that human and mouse brains show a significant number of labeled neurons positive for DNA double-strand breaks. Areas of the brain showing DNA double-strand breaks included the cortex, the hippocampus, the hypothalamus, the midbrain and cerebellum. Immunoreactivity focus for both markers (i.e., anti-phospho-histone H2A.X and 53BP1; P-53 binding protein) was exclusively nuclear and could easily be identified through light and confocal microscopy. This pattern of DNA labeling was also reproducible in vitro studies using human neuro-blastoma and neural-progenitor cells. It appears, therefore, that histone and chromatin modifications can accurately be identified and experimentally used for assessing neuronal DNA damage in the mammalian brain.

Title: Corticostriatal synapses on striatopallidal neurons are lost in a mouse model of Parkinson's disease and restored in mice exhibiting L-DOPA-induced dyskinesia

Authors: *S. M. GRAVES[1], L. E. SEBEL[1], J. L. PLOTKIN[1], T. FIEBLINGER[2], M. A. CENCI[2], D. J. SURMEIER[1];
[1]Physiol., Northwestern Univ., Chicago, IL; [2]Dept of Exp. Med. Sci., Lund Univ., Lund, Sweden

Abstract: A hallmark of Parkinson's disease (PD) is dopamine depletion of the striatum. L-DOPA, the dopamine precursor, treats the motor symptoms of PD but long-term therapy is complicated by L-DOPA-induced dyskinesia (LID). Numerous reports indicate an involvement of direct pathway spiny projection neurons (dSPNs) in LID (Cenci, *Trends Neurosci* 30: 236-43, 2007; Guigoni and Bezard, *Parkinsonism Relat Disord*. 3:S64, 2009) but it is unclear whether there also is participation of indirect pathway spiny projection neurons (iSPNs). To examine this issue, hemizygous BAC-D2-eGFP mice were unilaterally lesioned using 6-OHDA injections into the medial forebrain bundle and then administered L-DOPA (6-12 mg/kg/day i.p.) or saline on alternate days for 10 days. This L-DOPA regimen rendered mice dyskinetic. As previously described (Day *et al.*, *Nat Neurosci.* 9(2): 251, 2006), iSPNs from lesioned mice that were not given L-DOPA lost spines. However, in iSPNs from dyskinetic mice treated with L-DOPA, spine density was elevated and near normal levels. In contrast, iSPN dendrites in lesioned mice were fewer in number and shorter, regardless of whether mice were saline and L-DOPA treated. To determine the identity of the synaptic connections lost with lesioning and restored by L-DOPA treatment, optogenetic circuit mapping was employed in transgenic mice expressing channel rhodopsin 2 in the cortex. After 6-OHDA lesioning, iSPNs lost cortical axospinous synapses (~70% in control *vs*. ~50% in dopamine depleted). The percent of cortically responsive spines rose in dyskinetic mice (~70%), suggesting that the newly formed spines received cortical input. These results suggest that the loss of cortical connectivity with iSPNs following 6-OHDA lesioning is restored following L-DOPA treatment. The association of this restoration in connectivity with dyskinesia could mean that this connectivity is abnormal and leads to inappropriate indirect pathway activity and the failure to appropriately suppress unwanted dyskinetic movements.

Title: Striatal projection neurons of the D1 and D2 types are differentially altered in a mice model of Parkinson's disease

Authors: M. G. SÁNCHEZ, C. BORIES, D. GAGNON, Y. DE KONINCK, J. M. BEAULIEU, A. PARENT, *M. PARENT;
Psychiatry and Neurosci., Laval Univ., Quebec City, QC, Canada

Abstract: The main neuropathological hallmark of Parkinson's disease is a progressive neuronal loss of the substantia nigra pars compacta, which causes a marked decrease of the striatal dopaminergic innervation. The activity of striatal projection neurons expressing dopaminergic receptors of the D_1 type is known to be decreased as a functional consequence of such dopaminergic depletion compared to striatal neurons expressing D_2 receptors. However, the specific consequences of a dopaminergic striatal denervation on fine dendritic and spine processes belonging to striatal neurons remains poorly known. Therefore, we looked for possible morphological changes at the level of three different types of striatal projection neurons: the D_1+, the D_2+ and the D_1+/D_2+ medium spiny neurons, after dopaminergic denervation. We used double transgenic BAC mice *Drd1a*-tdTomato/*Drd2*-EGFP, a model that allows a clear identification of the direct and indirect striatal projection neurons based on their dopamine receptor content. Striatal dopaminergic denervation was induced by unilateral injections of 6-hydroxydopamine in the medial forebrain bundle. Cylinder test and immunohistochemistry staining of tyrosine hydroxylase and dopamine transporter confirmed the extent of the lesion. Subsequently, the D_1+, D_2+ and the D_1+/D_2+ striatal neurons were subjected to single-cell intraneuronal injections of Lucifer yellow combined to immunohistochemistry. Detailed morphometric analyses of dendritic trees and spines as well as their glutamatergic afferents were performed on high-resolution images acquired from a confocal microscope. Our results indicate that the dopaminergic denervation causes a decrease in the total dendritic length of the D_1+ and D_2+ medium spiny projection neurons analyzed. On the lesioned side of the brain, spine density was increased along the dendrites of the D_1+ striatal neurons and decreased on the D_2+ neurons, compared to the intact side. No significant changes of spine density were detected along the dendrites of the D_1+/D_2+ medium spiny neurons. These results provide direct evidence for differential morphological alterations of D_1+ and D_2+ striatofugal neurons involved in the direct and indirect pathways, respectively, following dopaminergic denervation of the striatum. Our preliminary results indicate that other factors, such as a reorganization of the corticostriatal glutamatergic projections might also contribute to the neuroadaptative changes reported above.

Title: Disturbed development and stability of dendritic spines of adult-born olfactory bulb neurons in A30P α-synuclein mice

Authors: *J. NEUNER[1], S. V. OVSEPIAN[2], S. FILSER[2], M. DOROSTKAR[1], J. HERMS[2]; [1]Ludwig-Maximilians-University, München, Germany; [2]DZNE, München, Germany

Abstract: Impaired olfaction is an early symptom in Parkinson disease (PD) with yet unknown underlying mechanisms. Here, we examined the possible link between the PD-related α-Synuclein (α-SYN) pathology, olfactory deficits and the integration of adult-born granule cells (GC) into the neuronal circuitry of the olfactory bulb (OB), using A30P α-SYN mice. We report that accumulation of α-SYN in mitral cells (MC) strongly interferes with the olfactory discrimination as well as integration of the adult-born GCs into the neuronal networks, with detrimental effects on the survival of new arrivals. Through combining chronic in vivo two-photon imaging with time-coded labelling of newborn GCs, we demonstrate for the first time a considerable impairment of the development and stability of dendritic spines of adult-born GCs, resultant in a significantly decreased lifespan of the nascent spines with an overall reduction of their density in the adult OB of α-SYN mice, as compared to wild-type controls. Impaired spine development of GCs is maturation stage-dependent, progresses with age and appears to be contributed by the occurrence of the α-SYN pathology in MCs. Our data suggest the impaired signalling between α-SYN enriched MCs and adult-born GCs as principal causative to the compromised integration of the latter into the pre-existing networks of the OB and to their decreased survival. Hence, important novel clues are provided on the role of dendrodendritic synapses between MCs and GCs in the maintenance and plasticity of existing circuits in the adult brain, in addition to their well recognized functions in olfactory discrimination via lateral inhibition.

Title: Physiological changes in the PPN in a normal and parkinsonian non-human primate during rest and gait

Authors: *H. M. HUDSON[1], A. T. CONNOLLY[2], J. ZHANG[1], K. B. BAKER[1], J. L. VITEK[1]; [1]Neurol., [2]Biomed. Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: The pedunculopontine nucleus (PPN) is being investigated in patients with Parkinson's disease (PD) as a potential therapeutic target for the treatment of gait and posture impairments that are refractory to current medical and surgical interventions. Recent trials of PPN deep brain stimulation (DBS) have been inconsistent, however. In contrast to the higher pulse frequencies used during therapeutic globus pallidus (GPi) or subthalamic nucleus (STN) DBS, PPN DBS typically involves the application of lower frequencies (~10 - 20 Hz). While the therapeutic benefit of high frequency GPi and STN DBS, as well as levodopa replacement therapy, is thought to derive at least in part from the disruption of excessive and pathological low frequency oscillations present in the basal ganglia-thalamo-cortical loop, the benefits of low frequency stimulation of PPN are thought to arise from the augmentation of physiological synchronizations that contribute to normal movement. This study was undertaken to characterize the changes in neuronal activity (single unit and local field potentials) in the PPN in the parkinsonian state, with and without dopamine, and assess the effect of PPN DBS on gait mechanics using our treadmill-based model of the ambulating non-human primate. Additionally, we report here local field potential data recorded from an 8-channel, scaled DBS lead implanted in the area of the PPN of one non-human primate. Recordings were taken with the animal at rest and during ambulation on a motorized treadmill in the naïve as well as the moderate parkinsonian state (induced by systemic injections of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), with and without levodopa replacement medication. We will elucidate the relative changes in spectral content across the primary electroencephalographic frequency bands (i.e., delta, theta, alpha, beta and gamma) as a function of parkinsonian state and address the hypothesis that low frequency oscillations are associated with normal movement and are reduced in a parkinsonian state.

Title: Low frequency stimulation of pedunculopontine nucleus modulates hyperactivity of basal ganglia in the parkinsonian rat models

Authors: *E. PARK[1], I. SONG[2], D. JANG[1], I. KIM[1];
[1]Biomed. engineering, Hanyang Univ., Seoul, Korea, Republic of; [2]Med. Device Develop. Ctr., Osong Med. Innovation Fndn., Chungwon-gun, Korea, Republic of

Abstract: Deep brain stimulation (DBS) is an established therapy for movement disorders. The subthalamic nucleus (STN) or globus pallidus internus (GPi) is considered an effective therapeutic target for Parkinson's disease. Although STN or GPi DBS produce clinical improvement in motor symptoms such as tremor, rigidity and bradykinesia, it responds less in gait disturbance and postural instability for advanced Parkinson's disease. Recently, the pedunculopontine nucleus (PPN; the equivalent of the pedunculopontine tegmental nucleus (PPTg) in rodent) has been introduced as an alternative therapeutic target for advanced Parkinson's disease with severe and medically intractable axial symptoms like gait and postural impairment. The PPN is reciprocally connected to the basal ganglia such as STN, GPi and substantia nigra, and projected to the thalamus and spinal cord. Specially, the PPN receives GABAnergic afferents from output structures of basal ganglia such as the substantia nigra par reticulate (SNr), entopeduncular nucleus (EP; GPi in primates) and striatum as well as glutamatergic afferents from the STN and frontal cortex. The PPN also sends excitatory efferents to the substantia nigra pars compacta (SNc), SNr, EP and STN. Therefore, the PPN performs the potential role of controlling the basal ganglia output and plays an important role in the initiation, maintenance and modulation of gait and postural stability. The current study aims to investigate the synchronized changes in neuronal activity of both STN and SNr with low frequency stimulation of PPTg in intact as well as in rat models of Parkinson's disease, and to provide a comparison of analyzed data from both intact and rat models with Parkinson's disease. Thirty male Sprague-Dawley rats (180-200 g) were used in this study. The animals were randomly divided into 2 groups: intact control group and 6-OHDA lesioned group. The 6-OHDA lesioned group was treated with unilateral 6-OHDA injections. The implantation of electrodes was performed 4 weeks after 6-OHDA lesion of SNc under anesthesia. The stimulation electrode was implanted into the PPTg and the two microelectrodes were used for electrophysiological recordings. In this research, we found that the two major structures of the basal ganglia, which are STN and SNr, has hyperactivity after 6-OHDA lesion. However, low frequency stimulation

of PPTg reverses the firing rate of two structures into normalization. These results can be used to evaluate the role of low frequency stimulation of PPTg with the recorded responses in basal ganglia.

Title: Selective inactivation of FosB expressing neurons in the juxtacapsular BST decreases L-Dopa induced dyskinesia

Authors: *P.-O. FERNAGUT[1,2], M. BASTIDE[1,2], C. GLANGETAS[3], C. GROSS[1,2], F. GEORGES[3], E. BEZARD[1,2];

Abstract: The most effective symptomatic therapy of Parkinson's disease (PD) remains the dopamine precursor L-3,4-dihydroxyphenylalanine (L-DOPA). Long-term treatment leads to involuntary aimless movements called L-DOPA-induced dyskinesia (LID). Accumulation of the truncated splice variant of FosB (ΔFosB) in the striatum has been established as a surrogate marker of LID in rodent and primate experimental models. Other dopaminoceptive structures however also display an L-dopa-driven overexpression of ΔFosB. The juxtacapsular part of the Bed Nucleus of the Stria Terminalis (jBST) is a limbic relay of basal ganglia information that display dramatic increase in immediate-early gene expression in response to L-dopa only in dyskinetic animals. Furthermore, the BST was found to be metabolically active in dyskinetic monkeys and not in non-dyskineic ones, rasing the possibility that this nucleus plays a role in LID manifestation.
To assess if ΔFosB expressing neurons in the jBST have an impact on LID, we thus targeted these neurons using the selective Daun02/β-galactosidase inactivation method. β-galactosidase expression, driven by a FosB promoter, was achieved using a FosB-Lacz lentiviral vector injected in the jBST of unilaterally 6-hydroxydopamine lesioned rats. Following chronic L-Dopa treatment (6mg/kg) and the induction of LID, rats were injected with Daun02 in the jBST. Three days after Daun02 administration, animals were tested daily with L-Dopa to assess LID and L-

Dopa-induced rotations. Inactivation of FosB-expressing neurons significantly reduced LID (-20,3%, P<0,05) but had no impact on L-Dopa-induced rotations. This study is the first showing the impact of selective inactivation of ΔFosB expressing neurons in LID outside the basal ganglia.

Title: Impact of phosphodiesterase 9A and 10A inhibition on aberrant cortically-evoked spike activity in the striatum of transgenic rats that model Huntington's disease

Authors: *A. R. WEST[1], S. CHAKROBORTY[1], A. M. DEC[1], C. J. SCHMIDT[2];
[1]Rosalind Franklin Univ. Med. Sci., NORTH CHICAGO, IL; [2]Pfizer Inc., Cambridge, MA

Abstract: Huntington's disease (HD) is an autosomal dominant disorder associated with abnormal expansion in CAG trinucleotide repeats within the HD gene and degeneration of striatal medium-sized spiny projection neurons (MSNs). Recent studies indicate that the metabolism of cyclic nucleotides by phosphodiesterases (PDEs) is likely to be perturbed in MSNs in the HD striatum. Studies providing evidence for both decreased cAMP/cGMP production and deficits in corticostriatal transmission in advanced HD suggest a link between cyclic nucleotide signaling and disrupted MSN network activity. The current study assessed cortically-evoked firing in aged (8-10 months old) wild-type (WT) and full-length BAC transgenic line 5 HD rats (TG5) treated with vehicle, the PDE9A inhibitor PF-4447943, or the PDE10A inhibitor PF-2545920. WT and TG5 rats were anesthetized with urethane and single-unit spike activity was isolated during low frequency electrical stimulation (0.5 Hz, 0.5 msec, 0.4-1.0 mA) of the ipsilateral motor cortex. Compared to WT rats, TG5 animals exhibited decreased spike probability during cortical stimulation delivered at lower stimulation intensities

(0.6 mA). No differences in cortically-evoked spiking were observed at higher stimulus intensities (≥ 0.8 mA) and spike onset latency was similar across groups and intensities. Systemic administration of both the PDE9A inhibitor PF-4447943 (3.2 mg/kg, s.c.) and the PDE10A inhibitor PF-2545920 (1 mg/kg, s.c.) significantly decreased the onset latency of cortically-evoked spikes at all stimulation intensities in WT rats as compared to vehicle-treated controls. Systemic administration of PF-4447943 also decreased the onset latency of cortically-evoked spikes in TG5 rats and reversed deficits in spike probability observed in these animals. Interestingly, PF-2545920 administration had only modest facilitatory effects on onset latency in TG5 rats and no effects on spike probability. Robust increases in cortically-evoked spike activity were observed in MSNs recorded in WT rats, thus it is likely that PDE10A function is compromised in the HD striatum. Given that PDE10A metabolizes both cAMP and cGMP, while PDE9A is specific for cGMP, it is possible that MSNs in the aged HD rat striatum lose their ability to respond to transmitters that signal through the cAMP/PKA pathways (e.g., dopamine, adenosine) but not cGMP (e.g., nitric oxide). Thus, drugs such as PF-4447943 which act to facilitate cGMP signaling could be useful therapeutic agents for restoring corticostriatal transmission in HD, and potentially, alleviating motor and cognitive symptoms of this disease.

Abstract: Chorea in Huntington's disease (HD) patients might be due in part to a dysfunction of the indirect pathway (IP) of the basal ganglia. D2-expressing striatal medium spiny neurons (MSN), giving rise to IP projections, appear more vulnerable to expression of mutant huntingtin (mHtt). A consequence of the preferential loss of striato-external pallidal (GPe) projections in HD patients would be expected to result in increased GPe firing rate, reduced STN firing rate, reduced activity of GPi, and ultimately overactivity of the thalamus, resulting in chorea. Previous studies in the mouse BACHD model (6 month old), reported an age-dependent increase in mean firing rate of GP neurons and decrease in the mean firing rate of STN neurons in vitro (D.J. Surmeier, Northwestern Univ.) and in vivo (James Tepper, Rutgers Univ.). The current study, using dual simultaneously recording from GP and STN, demonstrated that comparable alterations in firing rates was also detected in 8 to 15 months old BACHD full length transgenic rats. Mean spontaneous firing rates showed a significant increase in GPe (22.2±2.0 Hz in WT vs. 30.4±2.5 Hz in BACHD, $P<0.02$) and a significant decrease in STN (10.8±1.1 Hz in WT vs. 6.7±1.0 Hz in BACHD, $P<0.005$). The phosphodiesterase 10 (PDE10) is highly expressed within dopaminoreceptive MSNs of the striatum and PDE10 inhibitors have been viewed as a potential treatment for schizophrenia. To provide a rationale for developing PDE10 inhibitors as a therapy for HD, we evaluated whether MP-10, a specific and potent PDE10 inhibitor, would be able to reverse the altered firing rate observed in BACHD rat. A single bolus IV injection of MP-10 at all doses studied (0.18, 0.52, and 1.5 mg/kg) produced a clear increase in the firing rate of STN neurons in both WT and TG rats. Surprisingly, MP-10 effect on the GP firing rate was modest. PK/PD relationship was studied by collecting blood samples at 5, 30, 60, and 120 minutes after compound administration. The earliest effect on firing rates was observed at 3 to 5 minutes post MP-10 administration, which may reflect the time needed for cAMP/cGMP to reach a critical level. The magnitude of firing rate increase in STN was not dramatically different across doses, but the 0.52 and 1.5mg/kg doses produced longer lasting effects than the 0.18mg/kg dose. Our data provide evidence that are complementary to the prevailing hypothesis in HD patients; expression of mHtt in rats alters the firing properties of neurons in the "indirect" pallidosubthalamic pathway. MP-10 restored the low STN firing rates in BACHD rats, which is consistent with a potential therapeutic action of PDE10 inhibitors for the treatment of HD.

Abstract: Huntington's disease (HD) is a devastating, genetic neurodegenerative disease caused by a tri-nucleotide expansion in exon 1 of the huntingtin gene. HD is clinically characterized by chorea, mood and psychiatric disturbance and cognitive deficits with later symptoms including rigidity and dementia. Pathologically, the cortico-striatal pathway is severely damaged, resulting in striatal and cortical atrophy in late-stage disease. Brain-derived neurotrophic factor (BDNF) is a neuroprotective, secreted protein which binds with high affinity to the extracellular domain of the tropomyosin related kinase B (TrkB) receptor promoting neuronal cell survival by activating the receptor and its down-stream signaling cascade. Reduced levels of BDNF produced by cortical neurons and released in the striatum have been implicated in the pathogenesis of Huntington's disease (HD) and therefore, the ability to enhance TrkB signaling using a BDNF mimetic may slow or reverse HD onset. Using recombinant and native assay formats, we have evaluated a panel of small molecules and functional antibodies, reported to be TrkB agonists, and identified the best candidate for future *in vivo* proof of concept studies in HD models.

Title: Atg4b-dependent autophagic flux alleviates huntington's disease progression

Authors: *C. C. PROENCA, N. STOEHR, M. BERNHARD, T. BOUWMEESTER, I. GALIMBERTI;
Novartis Pharma NIBR, Basel, Switzerland

Abstract: Huntington's disease (HD) is characterized by an abnormal accumulation of mutant huntingtin protein (mHtt) in inclusion bodies, leading to a selective degeneration of striatal and cortical neurons. Despite the ubiquitous expression of Htt throughout the body, the reason for this selectivity remains elusive. Here we have developed a new model to study medium-sized spiny neuron (MSN) degeneration in the context of HD. We produced organotypic cortico-striatal slice cultures (CStS) from HD transgenic mice mimicking specific features of HD progression. We were able to rescue HD progression and MSN degeneration in vitro by inducing autophagy using a catalytic inhibitor of the mTOR pathway. On the other hand, blocking autophagy by manipulating Atg4b accelerated disease progression. Finally, catalytic mTOR inhibition was inefficient in the presence of Atg4b overexpression, indicating that Atg4b is a key downstream player of mTOR.
These results establish modulators of Atg4b-dependent autophagic flux as new potential targets in the treatment of HD.

Title: Cerebral cortex develops normally in mice with early embryonic deletion of huntington from cortical pyramidal neurons

Authors: *I. DRAGATSIS[1], P. DIETRICH[1], Y. DENG[2], N. DEL MAR[2], J. ROGERS[2], M. J. IRUDAYAM[1], K. R. JONES[3], A. REINER[2];
[1]Physiol., [2]Anat. & Neurobio., Univ. of Tennessee/Health Sci. Ctr., Memphis, TN; [3]Molecular, Cellular, & Developmental Biol., Univ. of Colorado, Denver, CO

Abstract: Understanding the normal function of the Huntingtin gene is important in elucidating how its mutation leads to Huntington's disease. Studies have suggested that the wild-type huntingtin (htt) protein plays a critical role in neurogenesis and neuronal migration during cortical development (Godin et al., Neuron, 2010; Tong et al., J Neurosci, 2011). We therefore evaluated the impact of early embryonic deletion of htt from cortical pyramidal neurons, by using the cre-loxP system to inactivate the mouse htt gene (Hdh) in Emx1-expressing cell lineages. Since Emx1 is expressed in the pallial proliferative zone beginning at about E8, Emx1-Cre/+; Hdh flox/- mice sustain htt deletion from cortical pyramidal neuron and glial precursors and their progeny. Western blot analysis confirmed reduction of htt expression in the cortex of Emx1-Cre/+; Hdh flox/- mice, with residual cortical htt expression in all likelihood restricted to cortical interneurons of the subpallial lineage and/or endothelial cells of the vasculature. Histological analyses showed that despite the loss of htt from early in development, cortical thickness and lamination were normal. Immunocytochemical evaluation of layer-specific cell populations such as calbindinergic neurons in layers 2-3, VGLUT2+ fibers in layer 4, SMI32+ and CTIP2+ neurons in layer 5, and FoxP2+ neurons in layer 6 revealed no obvious laminar abnormalities. Control and Emx1-Cre/+; Hdh flox/- mice were studied behaviorally and histologically over a 7-24 month age range to determine if absence of htt from cortical pyramidal neurons yields progressive abnormalities. Emx1-Cre/+; Hdh flox/- mice were slightly impaired in rotarod performance, and hyperactive compared to WT in an open field test at all ages. Emx1-Cre/+; Hdh flox/- mice also showed a greater age-related decline in locomotor speed in open

field than WT mice. The only progressive neuropathology observed in cortex was increased astrocytic GFAP labeling in cortical layer 4. The striatum, globus pallidus and striatal projection systems were normal in morphology and neurochemistry. Our results show that embryonic deletion of huntingtin from developing pallium does not alter cortical neurogenesis or neuronal migration of cortical neurons to their correct laminar destinations, or yield major progressive pathology in adult mice. Early deletion of huntingtin from cortical neurons does, however, cause developmental or functional abnormalities that manifest as hyperactivity and modest motor impairments.

Title: Post-translational modifications of huntingtin protein in HD brain

Authors: *T. RATOVITSKI[1], E. CHIGHLADZE[1], A. ZAVALA[1], E. WATKIN[1], N. ARBEZ[1], R. CHAERKADY[2], X. WANG[1], O. PLETNIKOVA[3], J. C. TRANCOSO[3], R. N. COLE[2], C. A. ROSS[1];
[1]PSYCHIATRY, [2]Mass Spectrometry and Proteomics Core, [3]Neuropathology, Johns Hopkins Univ., BALTIMORE, MD

Abstract: Post-translational modifications (PTMs) of expanded Htt are likely to be important mediators or modulators of HD pathogenesis. A number of PTMs of Htt have been identified, mainly within its N-terminal region. However, huntingtin is a very large multifunctional protein, providing a scaffold for regulated binding of other proteins. It is highly likely to have many sites of PTM. While there are a number of groups studying PTMs using cell models, there has been considerably less attention to identification of such modifications in HD mouse models and in human post-mortem HD brain. None of the previous studies were designed to characterize Htt PTMs systematically in the context of full-length normal and polyQ-expanded Htt endogenously expressed *in vivo* in HD mouse models and in HD human brain.

Here we used immunoprecipitation to purify full-length Htt from brain of homozygote HD KI175Q mice and human post-mortem brain and employed mass spectrometry to identify Htt PTMs, especially phosphorylation.
We have developed a large-scale Htt purification procedure to obtain sufficient amounts of purified Htt from mouse and human brain, detectable on the gel using protein stains. Quality control of samples showed the preservation of S13/S16 phosphorylation during the procedure. We were able to identify 25 Htt PTMs in the brains of either/or both KI 175Q and WT mice at 6 months of age. Among these, there are 3 lysine acetylation sites and 2 threonine phosphorylation sites. Out of 20 serine phosphorylation sites, 15 are novel, and 5 have been previously reported. In a parallel study we have identified a novel phosphorylation site S116 using HEK293 cells transiently transfected with human Htt (first 511 amino acid). This site was functionally validated in primary neurons: the S116A alteration showed significant and reproducible protection in the nuclear condensation assay.
For our studies in human brain, we have selected 3 HD cases and 3 controls based on an adequate purification of intact full-length Htt, and on the preservation of known S13/S16 phosphorylation sites in post-mortem material. We have achieved 56% coverage of WT Htt sequence, and 68% coverage of expanded Htt using trypsin for digestion, and have identified 11 Htt PTMs from the frontal cortex of human brain Among these are the previously reported S419/ S421 phosphorylation sites, which we had not detected in mouse brain. The other 9 PTMs are novel, and include 3 lysine acetylation sites and 6 phosphorylated serines.

Title: Pattern of premanifest loss of thalamostriatal and corticostriatal input to striatal projection neuron types in Q140 Huntington’s disease knock-in mice

Authors: *Y. DENG, T. WONG, A. REINER;
Univ. of Tennessee HSC, MEMPHIS, TN

Abstract: Motor slowing, forebrain white matter loss, and striatal shrinkage have been reported in premanifest Huntington's disease (HD) prior to overt striatal neuron loss. These findings raise the possibility that the earliest motor defects in HD victims may be related to the loss of excitatory cortical and thalamal afferent connectivity of motor striatum. In a prior study, we showed that in premanifest Q140 heterozygous HD knock-in mice not yet showing striatal projection neuron pathology, a 20% loss of thalamostriatal axospinous terminals is evident by 4 months of age, and a 30% loss of corticostriatal axospinous terminals is evident by 12 months of age. In the present study, we characterized the relative loss of thalamostriatal and corticostriatal axospinous terminals from direct pathway (D1+) and indirect pathway (D1-) striatal projection neurons, using immunolabeling to identify thalamostriatal (VGLUT2+) and corticostriatal (VGLUT1+) axospinous terminals. Measuring the size and abundance of such terminals on D1+ versus D1- spines to construct terminal size frequency distributions, we found that in wildtype mouse, VGLUT1 axospinous terminals on direct pathway neurons (D1+) showed a unimodal distribution with a peak at 0.5 µm (presumed to be IT-type corticostriatal terminals), while those on indirect pathway neurons (D1-) showed a mixture of small presumptive IT-type (≤0.6 µm) and large presumptive PT-type (>0.6 µm) axospinous terminals (Reiner et al., Frontiers 2010). The loss of corticostriatal terminals at 12 months of age in Q140 mice was preferentially on D1+ spines (70% reduction), and especially included small terminals (≤ 0.6 µm). Indirect pathway D1- spines showed slight loss of 0.6 µm terminals, and a mild loss of 0.9 µm terminals. For the thalamostriatal projection in WT mice, VGLUT2 terminals on D1+ spines showed a unimodal distribution with a peak at 0.4 µm, while those on D1- spines showed peaks at 0.3 µm and another at 0.5 µm). Thalamostriatal terminal loss in Q140 mice for both D1+ and D1- spines was comparable at 4 months and 12 months of age, and involved smaller terminals. Regression analysis showed that numerous open field motor parameters such as speed and length of locomotor segments were highly correlated with the spatial abundance of VGLUT1+ terminals on D1+ spines at 12 months, indicating the loss of corticostriatal terminals to D1 direct pathway neurons appeared to drive motor impairments in the Q140 mice at this age. Our results in general raise the possibility that cortical and thalamic input loss is an early event in human HD and contributes to early HD symptoms.

Abstract: A delicate balance between the activities of kinases and phosphatases is required to maintain normal memory and plasticity processes. cAMP-dependent protein kinase (PKA) promotes the formation and maintenance of long-term memory (LTM) but an aberrant and sustained activation of this pathway can lead to memory dysfunction and alterations in long-term potentiation (LTP) in the hippocampus. We have previously shown that increased PKA activity is implicated in the cognitive impairment observed in Huntington's disease (HD) and that its regulation could be a promising therapeutic approach. Dopamine D1 receptor (D1R) and adenosine A2A receptor (A2AR) are G protein coupled receptors that stimulate PKA activity via cAMP production. Although we found that these receptor levels remain unchanged in the hippocampus of the R6/1 mouse model of HD, higher receptor sensitivity in the presence of mutant huntingtin could lead to increased PKA signaling. Here, we pharmacologically antagonized these receptors in order to regulate PKA signaling in the hippocampus. Twelve-week-old wild-type (WT) and R6/1 mice were chronically treated (daily intraperitoneal injections) with vehicle or SCH23390 (D1R antagonist) + SCH58261 (A2AR antagonist). Mice performed the novel object recognition test (NORT) at 13 weeks of age, the T-maze spontaneous alteration test (TSAT) at 14 weeks of age, and the passive avoidance (PA) task at 15 weeks of age. R6/1 mice treated with D1R and A2AR antagonists showed a significant improvement in cognitive performance whereas cognitive function was not altered in WT mice. This improvement correlated with a decrease (to WT levels) of the phosphorylation level of PKA substrates in the hippocampus of R6/1 mice while no changes were detected in WT mice. In contrast, chronic treatment with D1R or A2AR antagonist alone did not improve learning and memory in R6/1 mice. Interestingly, an acute blockade of these receptors 90-120 min before

training lead to significant LTM deficits in WT mice as assessed using the NORT, TSAT and PA tasks, but had no further effect on R6/1 mice. In conclusion, our results indicate that a combined chronic inhibition of hippocampal D1R and A2AR is necessary to achieve cognitive improvement in HD mice. Thus we demonstrate that regulation of PKA signaling in the hippocampus is a therapeutically relevant approach in HD.

Title: Dysregulated behavioral modulation of striatal neuronal processing in the YAC128 mouse model of Huntington's disease

Authors: E. S. ZHANG, S. J. BARTON, *G. V. REBEC;
Program Neurosci & Dept. Psychological & Brain Sci.,, Indiana Univ., Bloomington, IN

Abstract: Transgenic mouse models of Huntington's disease (HD), a dominantly inherited neurodegenerative condition, have been instrumental in identifying the changes in neuronal function that appear to underlie the onset and progression of the behavioral phenotype. R6/2 mice, a widely used model expressing a truncated toxic fragment of the mutant huntingtin gene, develop robust neurological signs early in life and, relative to control mice, show corresponding neuronal changes in several forebrain areas, including the striatum, which shows the first signs of HD neuropathology (Estrada-Sanchez and Rebec, Basal Gang., 2:57-66, 2012). When these mice are symptomatic and behaving freely, striatal neurons are hyperactive and display a firing pattern very different from control (Miller et al., J. Neurophyiol.,100:2205-2216, 2008). Most notable is an R6/2 decrease in striatal burst firing (e.g., fewer bursts/min, a lower percentage of spikes that participate in a burst, and a longer interval between bursts). Because burst activity is a critical component of neural processing, the bursting deficits in the R6/2 striatum likely play an important role in modulating HD behavioral signs. Here, we assessed striatal neuronal activity in behaving YAC128 mice, a full-length transgenic HD model in which the behavioral phenotype develops later than in R6/2s. This later-onset feature allows us to examine striatal activity before and after symptom expression. Like R6/2s, YAC128 mice show many of the same deficits in

striatal bursting, including fewer bursts/min. But when we assessed striatal firing across an age range from pre-symptomatic (10 weeks) to symptomatic (up to 90 weeks), YAC128s differed from control in some but not all aspects of burst firing. For example, some burst parameters changed as the behavioral phenotype developed, while others were present before symptom onset. Thus, although striatal firing changes as symptoms emerge, activity in HD striatum may differ from control even before symptom development.

Title: Role of cortical mutant huntingtin in the aberrant behavioral modulation of striatal neuronal activity in the BACHD model of Huntington´s disease

Authors: *A. M. ESTRADA SANCHEZ[1], C. BURROUGHS[1], S. CHEN[1], S. J. BARTON[1], S. CAVALIERE[1], X. W. YANG[2], G. V. REBEC[1];
[1]Program Neurosci & Dept. Psychological & Brain Sci., Indiana Univ., Bloomington, IN;
[2]Psychiatry & Biobehavioral Studies, Geffen Sch. of Med., Univ. of California, Los Angeles, CA

Abstract: Early signs of neuropathology in Huntington's disease (HD), a dominantly inherited neurodegenerative condition, occur in the striatum, which receives major glutamate input from cerebral cortex. In transgenic mouse models of HD, ample evidence indicates a dysregulation of information processing in medium spiny neurons (MSNs), which account for >90% of the striatal neuronal population (Estrada-Sanchez and Rebec, Basal Ganglia, 2:57-66). A critical issue is whether abnormalities in behavioral modulation of striatal signaling can be explained by the presence of the mutant huntingtin gene (mhtt) in MSN neurons, a cell-autonomous process, or by the interaction of cortical and striatal neurons, both of which express mhtt. To address this issue, we used the BAC-Emx1Cre (BE) conditional HD transgenic mouse model, in which mhtt is suppressed in forebrain glutamate projecting neurons, including the cortical pyramidal neurons that project to striatum. We recorded neuronal activity in primary motor cortex and dorsal striatum while the animals behaved spontaneously in an open-field arena and plus maze. Neurobehavioral data also were obtained from BACHD mice, a commonly used transgenic model that expresses full-length mhtt, and wild-type strain controls (FvB/N). Animals ranged in

age between 19 and 60 weeks, which for BACHD mice includes both pre-symptomatic and symptomatic periods. Relative to wild-type, BACHD mice showed characteristic changes in striatal activity similar to those reported for other HD models (Miller et al., J. Neurophysiol. 100:2205-2216), including: changes in burst firing such as decreases in the number of spikes/burst and the percentage of spikes in a burst. These striatal changes were accompanied by characteristic signs of behavioral inflexibility such as increased open-field grooming and decreased turning probability in the plus maze. BE mice, in contrast, showed intermediate changes in burst firing and behavior that were often significantly different from BACHD. Surprisingly, however, cortical neurons in BE mice show increased bursting activity, suggesting possible compensatory effects in response to neuronal inputs containing mhtt. Collectively, our results argue against the cell-autonomous model of HD and support a role for cell interactions in the abnormal firing patterns of striatal MSNs.

Title: Turnover of mutant huntingtin in different neuronal compartments

Authors: *T. ZHAO, Y. HONG, S.-H. LI, X.-J. LI;
Human Genet., Emory Univ., Atlanta, GA

Abstract: Huntington’s disease (HD) is an autosomal dominant, neurodegenerative disease that affects one in every 10,000 Americans. About 200,000 Americans are at risk of inheriting the disease from affected parents. HD patients are characterized by motor, cognitive and neuropsychiatric abnormalities. HD is caused by the expansion of the trinucleotide CAG (>37 units) encoding an expanded stretch of polyglutamine (PolyQ) in the N terminal region of mutant huntingtin (mhtt). Mhtt is neurotoxic and induces neuronal death by disturbing gene expression,

axonal transport, and mitochondrial function. Mhtt is prone to form insoluble aggregates. Appearance of mhtt aggregates is indicative of the accumulation of mhtt. In HD, progressive emergence of mhtt aggregates in neurons is observed. Strikingly, the mhtt aggregates preferentially form in neuronal neurites and nuclei, and few aggregates form in the cytosol of soma. Based on these observations, we hypothesize that the degradation of mhtt is slower in neuronal neurites and nuclei than in cytosol of soma. In order to study degradation rates of mhtt in different neuronal compartments, we conjugate dendra2, a photoconvertible fluorescent protein, to the N-terminal fragmented mhtt (Htt230-130Q) and wild-type htt (Htt230-23Q) that is used as the control. Dendra2 is irreversibly photoconverted from a green to a red fluorescent state with 405nm light in the neuronal compartments. After photoconversion, decline of red signal over time is used to measure the degradation rates of Htt230(130/23Q)-dendra2 in the subcellular compartments. Our results showed that Htt230(130Q)-dendra2 was degraded faster than Htt230(23Q)-dendra2 in the cytosol of soma in primary hippocampal neurons. However, mhtt was stable in the neurites. No difference in degradation rate was seen in neuronal nucleus between mhtt and wild-type htt. Furthermore, turnover of mhtt was faster in the cytosol of soma than in the nucleus and neurites in neurons. Compared to neurons, astrocytes show faster degradation of mhtt than wild-type htt in each compartment. Our data supports the hypothesis that few mhtt aggregates in the cytosol of soma is due to efficient turnover of mhtt in this compartment and that astrocytes are capable of degrading mhtt fast and efficiently to avoid mhtt toxicity.

Title: Expression of mutant huntingtin in mouse brain astrocytes suppresses BDNF secretion

Authors: *Y. HONG, T. ZHAO, X.-J. LI, S.-H. LI;
Human Genet., Emory Univ., Atlanta, GA

Abstract: Huntington's disease (HD) is an inherited neurological disorder caused by a polyglutamine (polyQ) expansion in the N-terminal region of the protein Huntingtin (htt), and is characterized by the preferential loss of striatal medium-size spiny neurons (MSNs) in the brain. Symptoms usually consist of body weight loss, cognitive deficits, and movement disorders. Previous studies have been mainly focused on the neuronal cells in the brain, as the neuronal cell death in the brains of patients with HD is the most prominent pathology. However, the brain consists of a large number of glial cells, including astrocytes, which support neuronal function and survive. Astrocytes have functions that include promoting neuronal survival, removing toxic materials, and providing neurotrophic factors to neurons. Many studies show that brain-derived neurotrophic factor (BDNF) levels are decreased in the brains of HD patients and animal models, especially in the striatum, leading to the idea that reduced BDNF levels may be responsible for the selective neuronal vulnerability in HD. In this study, we used transgenic mice (Htt-160Q mice) that express N-terminal mutant huntingtin (mhtt) only in astrocytes to study the effect of mhtt on BDNF secretion. Western blotting and q-PCR results show no significant difference of BDNF level in astrocytes between WT and Htt-160Q mice. However, ELISA results demonstrate that the secretion level of mature BDNF decreases in the culture medium of astrocytes from Htt-160Q mice. These results indicate that mhtt may impair secretion of BDNF from astrocytes, which might contribute to the neuronal dysfunction and degeneration in HD. The mechanism of decreased BDNF secretion is under investigation.

Title: Altered dopamine release dynamics correlate with behavioral alterations in the YAC128 mouse model of Huntington's disease

Authors: *K. D. BUNNER, A. M. ESTRADA SANCHEZ, G. V. REBEC;
Program in Neurosci. & Dept. Psychological & Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder characterized by cognitive and motor deficits. Few studies have examined changes in neurotransmission during the initial hyperkinetic motor period of HD. In part, this is due to the rapid symptom onset seen in certain mouse lines. However, because HD is known to be caused by expansion of the CAG repeat on the huntingtin gene, multiple animal models have been developed. One such model, the YAC128 mouse, has slow disease progression. As is the case with humans, YAC128 mice show striatal and cortical atrophy as well as a hyperkinetic followed by a hypokinetic phenotype. Because dopamine (DA) is known to innervate the striatum as well as play a critical role in movement, striatal DA release and uptake in the YAC128 mice were assessed at 3, 6, 9, and 12 months of age. Using fast scan cyclic voltammetry (FSCV), electrically evoked DA release was monitored in vivo via medial forebrain bundle stimulation. Our results indicate an increase in DA release from 3 to 6 months of age, followed by a decrease in DA during the 9th and 12th month. These results demonstrate changing DA release dynamics, which parallel the biphasic (hyper- and hypo-) phenotype expressed in YAC128 mice. Interestingly, while significantly lower in YAC218 mice compared to wild-type (WT) controls, the rate of DA uptake showed no change throughout the progression of the disorder in the YAC128 mouse. Preliminary immunoblotting data indicates a decrease in the amount of DA transporter present in YAC128 compared to WT control.
Nest building behavior has also been linked to DA and was analyzed throughout disease progression in YAC128 mice. Results revealed YAC128 mice displayed nest building similar to WT controls until 9 months of age, after which YAC128 mice show a progressive decline in nest building activity. These data parallel the decline in DA release during the hypokinetic phenotype. Collectively, our results have important implications for understanding the progression of HD and the mechanisms by which HD pharmacotherapies focused on DA (e.g. tetrabenazine) exert their therapeutic effects.

Title: Altered neuronal activity in-vivo in subthalamic nucleus but not globus pallidus in the heterozygous z_Q175 mouse model of Huntington's disease

Authors: H. LIN[1], S. ZHONG[1], S. BENT[1], *H. S. HAIN[2], V. BEAUMONT[3], A. GHAVAMI[1]; [1]Preclinical Testing Group, [2]Behavioral Pharmacol., PsychoGenics, Tarrytown, NY; [3]CHDI Mgmt. / Fndn. Inc, Los Angeles, CA

Abstract:
Huntington's disease (HD) is a lethal autosomal dominant neurodegenerative disease that leads to deficits in motor control and cognitive/psychiatric functions. Chorea, a loss of motor control that is characteristic of HD physical symptoms, is thought to reflect a dysfunction of the indirect pathway (IP) drive arising from a deficit of striatal output to globus pallidus (GP), which in turn innervates subthalamic nucleus (STN). Due to the inhibitory GABAergic projections from GP to STN, it is expected that an increase in GP activity would lead to a decrease in STN neuronal discharge. Electrophysiological studies in basal ganglia slices from symptomatic transgenic BACHD rats carrying full length mutant huntingtin has shown increased GP and decreased STN firing consistent with this hypothesis[1].
We have evaluated spontaneous single unit discharges in GP and STN *in-vivo*, in heterozygous (HET) and homozygous (HOM) z_Q175 mice, a knock-in mouse model of HD which carries either one normal Htt allele and one mutant htt allele with an expanded CAG tract (HET), or two mutant Htt alleles (HOM)[2,3]. Six month-old HET, HOM and WT littermate mice were anesthetized using urethane, and extracellular single unit spikes were recorded in GP or STN. The firing rate of STN neurons appeared to be more sensitive to the presence of mHtt, with lower firing rates in HET and HOM mice compared to WT counterparts; however there was no change in mean firing rate difference found for GP neurons between WT and HET. The lack of rate difference in GP could either stem from less sensitivity of GP neurons to IP dysfunction, or could be due to GP heterogeneity in firing rate and pattern that makes detection of abnormalities in single unit activity harder in GP than STN. Alternatively, an impairment of the hyperdirect pathway
(excitatory glutamatergic cortico-STN projection) could result in a hypoactive STN with minimum impact in GP activity, at least during the early stage of HD neurodegeneration in the z_Q175 mouse model.

Title: Characterization of endogenous BDNF isoforms, secretion and signaling in a mouse model of Huntington's disease

Authors: Q. MA, *B. L. HEMPSTEAD;
Weill Cornell Med. Col., NEW YORK, NY

Abstract: Huntington's disease (HD) is a neurodegenerative disease that features striatal cell loss, leading to involuntary movements, cognitive decline, and psychiatric manifestations. Brain-derived neurotrophic factor (BDNF) has been shown to have protective roles for primary striatal neurons expressing mutant huntingtin in vitro, and the primary source of BDNF in the striatum is from anterograde transport from the cortex. A significant decrease of BDNF protein has been reported in the striatum of both HD patients and transgenic animal models. However, the mechanisms underlying the reduction of striatal BDNF and the subsequent selective neuronal atrophy are largely unknown.

To analyze alterations in BDNF levels and downstream signaling cascades in the cortex and striatum of HD knock-in mice, we utilized the zQ175 knock-in mouse model of HD, which has ~190 CAG repeats inserted in human/mouse chimeric exon 1. We demonstrate that mature BDNF levels and TrkB activation are both significantly reduced in the striatum of 9-month-old zQ175 mice, with more modest decreases in the levels in the cortex and the hippocampus. Interestingly, total p75NTR expression is significantly decreased in both the cortex and the striatum of zQ175 mice, but localized induction of p75NTR is observed in the astrocytes within these two brain regions in 12 month old zQ175 mice. Sortilin, a member of Vps10p-domain receptor family that can regulate intracellular trafficking of proBDNF and proBDNF-mediated cell death, is modestly increased. However, SorCS2, another Vps10p family member that interacts with proBDNF, is selectively downregulated in the medium spiny neurons, but its levels are unchanged in the cortex and the hippocampus.

These data suggest that in addition to a decrease of BDNF protein in the striatum, expression of mutant Htt leads to alterations in the level of BDNF receptors, that could contribute to the dysfunction of medium spiny neurons, and the pathogenesis of HD. Ongoing studies are evaluating the processing, trafficking and release in endogenous BDNF, utilizing bdnf-HA knock-in mice to facilitate quantification of BDNF isoforms in the striatum in models of HD.

Title: Ubiquilin suppresses accumulation of mutant Huntingtin and motor deficits in HD mice

Authors: C. L. HETTINGER[1], G. DONG[2], Y. LIU[1], L. LU[3], M. J. WATT[1], G. L. FORSTER[1], X. WANG[1], *H. WANG[1];
[1]Univ. of South Dakota Sanford Sch. of Med., Vermillion, SD; [2]Dalhousie Univ., Halifax, NS, Canada; [3]Sun Yat-sen Univ., Guangzhou, China

Abstract:
Huntington's disease (HD) is pathologically characterized by loss of neurons in the striatum and cortex, leading to motor, cognitive and psychiatric impairments, and by the formation of intra-neuronal aggregates in both the cytoplasm and nucleus. Ubiquilin (Ubiquilin 1, Ubqln) is a ubiquitin-like protein and is associated with mutant huntingtin (mHtt) in the aggregates. Our previous studies using cell culture models of HD have indicated that Ubqln facilitates the degradation of mHtt protein and protects cells against mHtt-caused cytotoxicity, suggesting that Ubqln may be a potential therapeutic target for HD. However, this has not been determined in a vertebrate animal model. To further understand the role of Ubqln *in vivo*, we generated Ubqln transgenic (Tg) and conditional knockout (cKO) mice. By crossing Ubqln Tg and cKO animals with HD mice, we generated the HD/Ubqln double transgenic mice and the HD mice deficient for the Ubqln gene, respectively. Compared to the HD single transgenic animals, overexpression of Ubqln in the Ubqln/HD double Tg mice prevents accumulation and aggregation of mutant Htt and attenuates HD motor deficits. In contrast, knockout of Ubqln gene in the HD mouse exacerbates the accumulation of mHtt and HD motor behavior deficits. These observations not only support that enhancement of mHtt degradation is a therapeutic strategy but also indicate that Ubqln is a potential therapeutic target for treating HD.

Title: Utilization of an In-Cell Western™ assay to evaluate putative SIRT1 pathway modulators: PARP inhibition leads to increased SIRT1 activity in an oxidative stress paradigm

Authors: *D. F. FISCHER[1], J. BATE[2], S. DOWLER[2], V. LAZARI[2], S. DIJKSTRA[3], G. MCALLISTER[2], J. WITYAK[4], I. MUNOZ-SANJUAN[4];
[1]BioFocus / Galapagos, Leiden, Netherlands; [2]BioFocus, Saffron Walden, United Kingdom; [3]Galapagos, Leiden, Netherlands; [4]CHDI Management/CHDI Fndn., Los Angeles, CA

Abstract: Overexpression of SIRT1 is reported to be neuroprotective in a range of preclinical models, including multiple Huntington's disease (HD) mouse models. Therefore, small molecules that are able to modulate SIRT1 activity may lead to neuroprotection in HD. There remains significant controversy over recently identified SIRT1 "activator" molecules, which appear to require fluorescent tag-containing peptide substrates to show SIRT1 "activation." Additionally, there may be less direct, pathway-mediated ways to modulate SIRT1 activity in cells that are not amenable to a biochemical assay using cell-free readouts.
We have therefore developed an In-Cell Western™ assay with the ability to detect modulation of SIRT1 activity in a cellular context, focusing on acetylation of the well-characterized SIRT1 substrate, p53K382. Assay development experiments have shown the ability of this assay to detect both pharmacological inhibition and overexpression of SIRT1. Experiments performed using this system reveal a significant increase of p53 acetylation upon acute challenge with oxidative stress. Further experiments reveal that the DNA damage response caused by oxidative stress results in a rapid depletion of intracellular NAD+ and ATP, consistent with activation of the PARP (poly ADP-ribose polymerase) resulting in a reduction of NAD+ dependent SIRT1 activity and subsequent increase in p53 acetylation. Treatment of cells with PARP inhibitors, such as olaparib, leads to protection from the NAD+/ATP depletion caused by oxidative stress and may represent alternative methods of activating the SIRT1 pathway leading to neuroprotection. The significance of this pathway in a Huntington's disease context is being investigated.

Title: To fold or not to fold? Novel methods for identification of modifiers of mutant huntingtin conformation

Authors: *R. KUHN[1,2], A. WEISS[2], M. VERANI[2], L. AZZOLINI[2], V. FODALE[2], H. PARK[3], A. CARICASOLE[2];
[1]Redbark Gmbh, Riehen, Switzerland; [2]IRBM PROMIDIS, Pomezia, Italy; [3]CHDI Fndn., Los Angeles, CA

Abstract: Huntington's disease is caused by a CAG triplet repeat expansion in exon 1 of the huntingtin gene, encoding an abnormal expanded polyglutamine (polyQ) tract. The expanded polyQ alters protein folding and leads to aggregation and accumulation in the nucleus and cytoplasm with consequent disturbance of many cellular processes, which ultimately result in neuronal cell death. Recent evidence highlights a potential role of post-translational modifications (PTMs) in the N-terminal 17 amino acids (N17) and neighboring regions of the polyQ domain. Also, X-ray crystallography and studies with conformation-specific antibodies indicated that N17 sequences adopt multiple conformations and strongly influence aggregation and toxicity properties of mutant huntingtin.
Our studies with huntingtin-specific TR-FRET assays (sensitive for conformational changes) also suggest that wild type and mutant huntingtin can adopt different conformations when the purified proteins or cell lysates are incubated at different temperatures prior to TR-FRET assays. Specifically, we observed that temperature changes in huntingtin FRET signals are strongly and progressively modulated by the polyQ length of the protein, i.e. the huntingtin TR-FRET signal is low with long polyQ and high at short polyQ length suggesting that increasing polyQ length restricts the conformational flexibility of the huntingtin protein. This observation was reproduced with purified huntingtin fragments, cell lysates of huntingtin fragments and full-length huntingtin. Interestingly, the conformational flexibility of the mutant protein is strongly reduced above polyQ lengths of >35-40, namely the threshold above which the disease invariably

develops. Clearly, these assays represent potentially valuable tools, and require further studies to validate their relevance to other mutant huntingtin properties and to different translationally and clinically relevant biological matrices, such as tissues from animal models and human HD samples.

Title: The effects of resveratrol on mitochondrial function mechanism in Huntington’s disease model mice

Authors: *J. JEON, H. SEO;
Dept. of Mol. and Life Sci., Hanyang Univ., Ansan, Gyeonggi, Korea, Republic of

Abstract: Huntington's disease (HD) is a neurodegenerative disease, which leads to progressive disability with both psychiatric and cognitive impairment. HD is caused by a cytosine-adenine-guanine (CAG) repeat expansion in the huntingtin gene. The mutant huntingtin protein induces neuronal dysfunction and eventual cell death. It was reported that mitochondrial dysfunction and morphological dysregulation in HD impacted on neuronal cell death. In this study, we administrated resveratrol (RSV) that functions as antioxidant and sirtuin1 (Sirt1) activator to HD model mice of YAC128. We determined the epigenetic controls of mitochondrial function in HD. In addition, we checked the changes of progressive pathology in HD mice brain. We detected that the function of mitochondria was improved by RSV through ATP elevation and attenuation of cellular oxidative stress levels. In addition, we detected the improved motor ability by RSV administration in HD mice model. These results suggest that the mitochondrial regulation can control not only mitochondrial function, but also HD motor impairment.

Abstract: Autophagy is an essential degradation pathway conserved in all eukaryotes that controls cellular homeostasis by eliminating protein aggregates and damaged organelles. Induction of macroautophagy through pharmacological or genetic means has been shown to to enhance clearance of aggregated huntingtin and to reduce toxicity of huntingtin in cells. However, knowledge of neuronal macroautophagic process is still largely inferred upon findings in non-neuronal contexts.
We have developed quantitative, specific and sensitive immunoassays that are independent of reporter constructs to interrogate macroautophagy at multiple levels in cells,neurons and in vivo model-derived material to characterize the autophagic process in disease-relevant Huntington’s disease models and to identify novel neuronal autophagy inducers. We present novel

immunoassays that are sufficiently robust and scalable for high throughput screening and applicable to monitoring autophagic activities in preclinical and clinical HD samples.

Title: Impairment of parkin-mediated mitophagy in Huntington’s Disease

Authors: M. SACINO, N. LAMBRINO, C. ERIE, M. LU, *J. WEI;
Florida Atlantic Univ., BOCA RATON, FL

Abstract: Mitochondrial dysfunction has emerged as a key pathogenic mechanism in the progression of Huntington’s Disease (HD). Damaged mitochondria are accumulated in HD, suggesting impairment in the removal of dysfunctional mitochondria in these cells. The interaction between mitophagy, the macro-autophagic removal of damaged mitochondria, and mitochondrial dynamics has been linked to the removal of dysfunctional mitochondria. Strong evidence supports the role of parkin in mediating mitophagy. In this study, we sought to investigate the functional impairment of the Parkin-mediated mitophagy in two HD cell lines. We overexpressed EYFP-parkin in striatal cell line (STHdhQ7 and STHdhQ111), or a PC12 huntingtin-inducible cell line (htt23Q and htt145Q). Using Carbonyl cyanide 3-chlorophenylhydrazone (CCCP) to depolarize mitochondria, we showed that parkin translocated to depolarized mitochondria and ubiquintinated mitochondria proteins in both cells expressing wild type or mutant huntingtin (mhtt) by immunofluorescence. However, we noticed that

damaged mitochondria formed larger perinuclear aggregates in mhtt cells while they appeared smaller and isolated in normal cells. We reasoned that cells expressing mhtt exhibited decreased levels of mitochondrial clearance compared to wild type cells because of the formation of larger dysfunctional mitochondrial aggregates. Consistently, we showed that mitochondrial clearance was decreased by ~50% in Hela cells overexpressing N-terminal htt103Q compared to Hela cells with N-terminal htt23Q after a 24-hour CCCP treatment. Immunoblotting assay and immunofluorescence data confirmed disregulated proteasomal degredation of Mitofusin 1 and 2, outer mitochondrial membrane proteins essential to mitochondrial fusion, in PC12 htt145Q cells. Our data suggest impairment in the canonical pathway of linking the Ubiquitin-Proteasome System (UPS) activation with mitophagy in HD cells. Subsequently, depolarized mitochondria may not be able to enter autophagosomes for lysosomal fusion and degradative clearance.

Title: Bidirectional control of PSD-95 clustering by non-pathogenic huntingtin

Authors: *M. P. PARSONS, R. KANG, L. A. RAYMOND;
Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Decreasing expression of the huntingtin protein (htt) is a promising strategy for the treatment of the neurodegenerative disorder Huntington disease (HD). In HD, the presence of mutant huntingtin (mhtt) results in synaptic alterations and subsequent cell death. Particularly vulnerable are the striatal spiny projection neurons (SPNs), whose dysfunction and eventual degeneration result in severe motor symptoms that are the hallmark of HD. Unfortunately, many of these htt-lowering strategies are not necessarily specific for mhtt over htt and the lowering of the non-pathogenic protein could be detrimental to cellular function. However, the role of htt in

synaptic communication is unknown. Here, we used immunohistochemical analyses and electrophysiological measurements in co-cultures of striatum and cortex to show that htt plays an important role in protein organization in the SPN postsynaptic density. Specifically, we found that htt overexpression resulted in an increase in the palmitoylation and synaptic clustering of the integral scaffolding protein PSD-95. Surprisingly, this effect was dependent on presynaptic, not postsynaptic htt overexpression and was mimicked and occluded by the addition of the trophic factor BDNF to the culture media. Despite the enhanced clustering, we saw no associated increase in the amount or composition of NMDA or AMPA glutamate receptors at cortico-striatal synapses. Conversely, htt knockdown decreased the size of PSD-95 clusters and preliminary electrophysiological data suggests an associated reduction in AMPA receptor currents at these synapses. In all, our results demonstrate that wild-type htt can influence the organization of synaptic proteins and cautions the use of non-specific htt-lowering strategies for the treatment of HD.

Title: Characterization of autophagy in a Huntington’s disease mouse model

Authors: *J. LIM, Z. YUE;
Biol., Mount Sinai Sch. of Med., New York, NY

Abstract: Huntington's disease (HD) is a devastating neurodegenerative movement disorder characterized as one of the polyglutamine (polyQ) disease family. Huntingtin (Htt) protein with polyQ expansion leads to accelerated protein aggregation that is causal to the disease. Emerging evidence has shown that mutant Htt can be degraded by autophagy, which is a catabolic pathway responsible for the turnover of long-lived proteins, damaged organelles and large protein aggregates that cannot be degraded by the ubiquitin proteasome system. Therefore enhanced autophagic degradation of polyQ-expanded Htt protein is expected to be beneficial, while impairment of its degradation would accelerate the disease progression. Other evidence suggests that mutant Htt impairs autophagy in an HD cell model. It remains to be examined, however, whether autophagy is altered in the CNS of the HD animal model. In this study we characterized

autophagic activity using a knock-in mouse model expressing mutant Htt with an 175 glutamine repeat (Q175). First we examined the expression levels of numerous autophagy-related proteins in the cortex and striatum including LC3, p62, Vps34, Atg14L, p-mTOR, p-ULK1 and Beclin 1 at multiple ages of Q175 mice. Second, we crossed transgenic GFP-LC3 reporter mice to Q175 HD mice and analyzed autophagic activity by monitoring GFP-LC3 distribution in the striatum. Furthermore, we carried out lipid kinase assays monitoring the Atg14L-associated Vps34 complex, which is a class III phosphatidylinositol-3 kinase involved in the regulation of autophagy induction, in HD brain lysates. We will report our findings from the above studies and discuss the implication of the results in the development of autophagy-modulating drugs to treat HD.

Title: Region-specific effects of huntingtin overexpression on the palmitoylation and clustering of PSD-95

Authors: *C. BUREN, M. P. PARSONS, R. KANG, L. WANG, L. A. RAYMOND; Psychiatry, The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Huntington disease (HD) is caused by a polyglutamine (polyQ) expansion in the N-terminal region of the huntingtin protein (Htt). This mutation results in synaptic dysfunction and eventual neurodegeneration that particularly influences the spiny projection neurons (SPNs) of the striatum. While it is clear that a toxic gain-of-function of mutant Htt contributes to disease pathogenesis, many lines of research suggest that a loss of wildtype Htt function may also play a significant role in HD progression. Despite this, we know little regarding the role of Htt in synaptic function. By comparing cortico-striatal co-cultures from FVB/N wildtype (WT) versus YAC18 mice, which overexpress non-pathological human Htt, we have found that Htt

overexpression increases synaptic clustering of the important scaffolding protein PSD-95, thereby suggesting a role for Htt in synaptic function. Importantly, this effect was observed in SPN dendrites receiving excitatory input from cortical neurons. Here, we examined PSD-95 palmitoylation - a post-translational modification that promotes PSD-95 clustering - in different brain regions from WT and YAC18 mice. Consistent with enhanced PSD-95 clustering, we observed an increase in PSD-95 palmitoylation in striatal tissue from YAC18 mice compared to WT mice. Interestingly, this effect was not a global phenomenon as we found no evidence for enhanced PSD-95 palmitoylation in cortical tissue, nor any change in PSD-95 clustering in the dendrites of YAC18 cultured cortical neurons. As in the striatum, increased palmitoylation of PSD-95 was also observed in YAC18 hippocampal tissue. Studies of PSD-95 cluster size in cultured hippocampal neurons are ongoing and will be presented at the meeting. Finally, we have previously published that YAC18 striatal neurons are protected from NMDA-induced apoptosis, compared with WT, and we have recently found an increase in basal levels of nuclear phospho-CREB in co-cultured YAC18 SPNs. Experiments to determine whether Htt overexpression protects cortical or hippocampal neurons from NMDAR-mediated death, or alters basal levels of nuclear pCREB are underway. Together, our data suggest that huntingtin can influence synaptic protein localization in a region-specific manner.

Title: Differential effects of a neuroprotective selenium dose on selenoprotein transcripts levels in brains of wild-type and transgenic Huntington’s disease mice

Authors: *Z. LU[1,2], J. CHEN[1,2], E. MARKS[1,2], J. MOLINE[1], M. RAISBECK[1], L. F. BARROWS[1], I. VOLITAKIS[3], A. BUSH[3], J. H. FOX[1,2];
[1]Dept. of Vet. Sci., [2]Interdepartmental Grad. Neurosci. Program, Univ. of Wyoming, Laramie, WY; [3]Mental Hlth. Res. Institute, Univ. of Melbourne, Parkville, Australia

Abstract: Huntington's disease (HD) is a progressive neurologic disorder caused by polyglutamine-expanded mutant huntingtin protein (mhtt) which misfolds and accumulates in neurons resulting in selective brain degeneration. Selenium is an essential nutrient that is required for normal brain function. Defects of brain selenium metabolism can induce neurodegeneration. We have found that selenium supplementation provides neuroprotection in N171-82Q HD mice, including improved motor endurance on Rota-rod, increased brain mass and decreased amounts of mutant huntingtin aggregates. Understanding the mechanism(s) of protection by selenium supplementation is important as it may provide avenues for treatment optimization and reveal peripheral treatment biomarkers. The function of selenium in brain is mainly mediated by selenoproteins, therefore we are investigating whether selenium supplementation increases expression of selenoprotein-encoding genes in the brains of N171-82Q HD mice. Female mhtt (+/-) and mhtt (-/-) mice were provided with selenite in drinking water and / or control water, from 6-14 weeks of age. All 24 selenoprotein transcripts are being analyzed by quantitative real-time PCR. Results show that selenium supplemented N171-82Q mice have a significant increase in brain glutathione peroxidase 3 (GPX3) mRNA. Further, for several of the genes studied (e.g. thioredoxin reductase 1, 2 and 3, selenoprotein S) the effect of selenium supplementation is genotype dependent (significant genotype x treatment interaction effect). Our findings show differential transcriptional responses to selenium supplementation between wild-type and HD mice and suggest that some selenoprotein-encoding genes could be mediating the protective effect of selenium supplementation in HD mice.

Title: Golgi protein ACBD3 mediates neurotoxicity associated with Huntington's Disease

Authors: *J. I. SBODIO, B. D. PAUL, C. E. MACHAMER, S. H. SNYDER;
Johns Hopkins Univ., Baltimore, MD

Abstract: Huntington's disease (HD) is an autosomal dominant neurodegenerative condition characterized by emotional disturbances, motor dysfunction and neuronal loss. Mutations in the gene encoding the protein huntingtin results in an expansion of CAG codon generating an extension of glutamines responsible for misfolding and aggregation. Mutant huntingtin (mHtt) is expressed throughout the brain and the peripheral tissues, however, HD patients show a predominant degeneration of the corpus striatum and lesser damage to the cortex. The striatal association of the disease can be explained by the binding of the striatal-specific protein Rhes (Ras Homolog Enriched in Striatum) to mHtt, which enhances mHtt toxicity. Here we report that the Golgi protein ACBD3 (Acyl-CoA binding Domain Containing 3) interacts with Rhes and mutant Huntingtin to mediate toxicity. We observe elevated levels of ACBD3 in the striatum of HD patients, in a neuronal cell line with extended glutamine repeats, as well as in the brain of HD mouse models. ACBD3 levels are upregulated by Golgi stress, ER stress and mitochondrial stress, suggesting that the stress induced by mHtt can elicit neurotoxicity through ACBD3-Rhes-mHtt.

Title: Altered Rpt6 proteasome function in S. cerevisiae

Authors: *E. M. MARQUEZ-LONA;
Biol. Sci., UCSD, La Jolla, CA

Abstract: The inherent turnover rate (half-life, t ½) for any given protein is determined by a combination of its synthesis and degradation. Importantly, cell biological signals are capable of altering rates of synthesis, degradation or both. Protein degradation via the ubiquitin proteasome system has proven to play a fundamental role in the central nervous system for the development, maintenance and remodeling of synaptic connections. Examining the mechanisms underlying synaptic plasticity, which alter the signaling dynamics of a synapse, we have recently found that the 26S proteasome, is itself regulate in a dynamic fashion (Djakovic et al., 2009). We have also

identified a specific phosphorylation event on the 19S ATPase subunit, Rpt6, which controls the activity and distribution of proteasomes in neurons (Djakovic-MarquezLona, 2012). Since UPS dysfunction is attributed to the pathogenesis of several neurodegenerative diseases (e.g. Alzheimer Disease, Huntington Disease, and Parkinson Disease), using a yeast model of altered Rpt6 phosphorylation (S120A, S120D) and proteasome function we have evaluated the functional relevance of proteasome phosphorylation in various stress-response and disease-related pathways. We find that mutations preventing Rpt6 phosphorylation, are susceptible to proteotoxic stress and protein aggregate formation.

Title: L-12/15 lipoxygenase (L-12/15 LO) null mutant mice show enhanced motor behavioral deficits and increased moribundity in response to 3-nitroproprionic (3-NP) acid treatment

Authors: *R. C. AKUMUO, Y. YANG, Y. HE, S. J. HEWETT;
Biol., Syracuse Univ., Syracuse, NY

Abstract: Oxidative stress results from an imbalance in the production and/or removal of reactive oxygen species resulting in DNA, protein and lipid peroxidation. Recent studies demonstrate an increase in L-12/15 LO immunoreactivity in pathologically affected Alzheimer's disease (AD) brains, that correlated with the extent of lipid peroxidation, suggesting that increased L-12/15 LO activity may contribute to the pathogenesis of AD (Pratico et al 2004, *Am J Pathol* 164:1655-62; Yao et al 2005, *Ann Neurol* 58:623-6). Additionally, mice null for the L-12/15 LO isoform have been reported to be less susceptible to cerebral ischemic damage, an acute neurological injury also associated with oxidative stress (Khanna et al 2005, S*troke* 36:e144-52; van Leyen et al 2006, *Stroke* 37:3014-8). In keeping with these *in vivo* results, we and others determined that when L-12/15 LO activity is disrupted, either genetically or pharmacologically, neurons are less susceptible to oxytosis ─ a non-receptor-mediated glutamate-induced oxidative cell death. Herein, we compared the behavioral motor function between L-12/15 LO null mutant mice (JAX: Strain B6.129S2-Alox15^{tm1Fun}/J) and wild-type littermate control mice that followed systemic injection of 3-NP, a succinate

dehydrogenase inhibitor that produces energy depletion, oxidative stress and striatal lesions. To induce injury, male L-12/15 LO null mutant animals (n = 18) and male wild-type littermate control mice (n = 15) received two i.p. daily injections (8-12 h apart) as follows: 20mg/kg x 2d, 30mg/kg x 2d, 50mg/kg x 1d and 60mg/kg x 4d (total cumulative dose = 780 mg/kg in 9 days). A three level scale assessed the severity of the following five items (maximal score=10): hindlimb clasping, reduced locomotor activity, hindlimb dystonia, truncal dystonia and balance adjustments to a postural challenge. Mice were rated before each injection during the intoxication procedure. Surprisingly, we found that severity of the motor system deficits at days 7 and 9 following systemic 3-NP in the L-12/15 LO knockout cohort was greater than in wild-type littermate controls. Additionally, nearly twice the number of the L-12/15 LO null mutant mice (9/18) became moribund when compared to their wild-type littermate control mice (4/15), necessitating sacrifice. This could not be explained by differential metabolism of 3-NP between the different groups as striatal succinate dehydrogenase activity was inhibited by a single acute dose (200mg/kg) to the same extent in both genotypes. Overall, we conclude that animals null for the L-12/15 LO gene are more susceptible to the toxic effects of 3-NP treatment.

Title: Mutant huntingtin transcriptionally represses the cholesterol biosynthetic pathway in striatal astrocytes

Authors: *A. BENRAISS, A. CORNWELL, D. CHANDLER-MILITELLO, M. J. TONER, S. WANG, S. A. GOLDMAN;
Ctr. for Translational Neuromedicine and Dept. of Neurol., Univ. of Rochester Med. Ctr., ROCHESTER, NY

Abstract: Huntington's disease (HD) is caused by an expansion of the CAG trinucleotide repeat of the first exon of the gene encoding huntingtin (Htt). Although striatal neuronal death is a hallmark of HD, the extent to which neuronal death is cell-autonomous or is instead dependent upon paracrine interactions with affected astrocytes has been unclear. To address the specific role of astrocytic pathology in the pathogenesis of HD, we investigated mutant Htt-associated changes in gene expression by striatal astrocytes. To this end, we studied astrocytes acutely isolated from the R6/2 mouse model of HD, using Glt1-based fluorescence activated cell sorting (FACS) followed by mRNA expression profiling by Affymetrix Mouse-430 2.0 microarrays. In particular, striatal tissue from 12 week-old R6/2 mice (150 CAG; n = 6; 5-9 mice/sort) and their wild-type littermate controls (n = 5; 4-9 mice/sort) was dissected and sorted by 2-color FACS using antibodies directed against the astrocytic glutamate transporter 1 (Glt1) and the microglial ectodomain CD11b, so as to isolate microglia-free striatal astrocytes. Analogous sorts were obtained from wild-type age- and strain-matched control mice as well. Differential gene expression analysis revealed profound mHtt-associated changes in the gene expression patterns of both astrocytes and microglia. Among Glt1-defined astrocytes, 619 transcripts were up-regulated and 591 were suppressed as a function of mutant Htt expression ($p<0.01$). In particular, functional enrichment analysis on Gene Ontology terms revealed the sharp down-regulation of transcripts encoding essentially every single transcript within the cholesterol biosynthetic pathway, including: Cyp51a1; Dhcr7; Dhcr24; Fdft1; Hmgcr; Hmgcs2; Lss; Msmo1; Mvd; Mvk; Nsdhl; Sc5dl; Sqle; Tm7sf2 (FDR cut-off $p<0.01$). These data suggest the mHtt-dependent perturbation in astrocytes of a transcriptional regulator common to the entire family of cholesterol pathway genes. Together, these results highlight the potential contribution of glial dysfunction to HD pathology, and suggest that the coordinated inhibition of cholesterol synthesis may be important to HD pathogenesis, while its targeted reversal may have therapeutic potential.

Title: Role of vesicular glycolysis in fast axonal transport

Authors: *M. V. HINCKELMANN[1], D. ZALA[1], C. NIEHAGE[2], B. HOFLACK[2], F. SAUDOU[1];
[1]Inserm U1005, CNRS UMR3306, Inst. Curie, Orsay, France; [2]Biotech. Ctr., Dresden, Germany

Abstract: Impairments in fast axonal transport (FAT) are a common feature in many neurodegenerative diseases, highlighting the importance of transport in neurons. FAT is an active process that occurs via the consumption of ATP by molecular motors. We have previously shown that FAT does not depend on mitochondrial ATP, but on glycolytic ATP produced on vesicles, due to the presence on vesicles of the glycolytic enzyme GAPDH.
Here we demonstrate that all of the components of the glycolytic machinery are specifically associated to motile vesicles. These enzymes were detected by mass spectrometry analysis of purified motile vesicles and further validated by immunoblotting. Indeed, immunofluorescent staining in cortical neurons, show that glycolytic enzymes colocalise with BDNF containing neurons. Using live imagining of BDNF-mCherry vesicles in cortical neurons grown in microfluidic chambers, we were able to show that Pyruvate Kinase (PK), one of the two ATP producing glycolytic enzymes, is essential for axonal transport. Knockdown of this enzyme reduces the velocity of BDNF-mCherry vesicles. Furthermore, addition of PK's substrate, rescues the transport deficit caused by the knocking down of GAPDH, which is upstream PK. This suggests that all of these enzymes are needed on vesicles to efficiently sustain these chained reactions that generate ATP locally to support FAT.
This study on the energetic independence of transport could give a new insight into the mechanisms regulating axonal transport and have an impact in the study of neurodegenerative diseases.

Abstract: Accumulating evidence from mice expressing ALS-causing mutations in SOD1 has implicated pathological immune responses in motor neuron degeneration. This includes microglial activation, lymphocyte infiltration and induction of C1q the initiating component of the classic complement pathway that is part of the protein-based arm of the innate immune response. Our previous studies using laser-microdissection based gene expression profiling have identified C1q induction in motor neurons of different ALS mouse models expressing dismutase active or inactive SOD1 mutants. Robust induction early in the ALS disease course is now identified for multiple complement components (including C1q, C4 and C3) in spinal cords of SOD1 mutant expressing mice. These findings are consistent with initial intraneuronal C1q induction, followed by global activation of both classic C1q- and alternative C3-dependent complement pathways, potentially adding to an ongoing deleterious neuroinflammatory response in ALS. We now tested if global complement activation are mechanistic contributors to ALS disease by genetic deletion of C1q and C3 in SOD1 mutant ALS mice. Elimination of C1q induction and classic complement cascade activation that follows from it produced changes in microglial morphology and synaptic densities during disease. Nevertheless and in contrast to expectations, in C1q-deleted ALS mice global onset and progression of disease are unaffected and survival is unchanged in both C1q and C3-deleted ALS mice. These results establish that C1q induction and global complement activation do not contribute significantly to SOD1 mutant-mediated ALS pathogenesis in mice.

Title: The c-Abl tyrosine kinase is activated in amyotrophic lateral sclerosis motor neurons and participates in transgenic SOD1(G86R) mice neurodegeneration

Authors: *A. MARTINEZ[1,2], C. VALLS[1,2], C. HETZ[3], A. R. ALVAREZ[1,2];
[1]Cell Signaling Lab, Cell. & Mol. Biology, Biol. Sci. Faculty., [2]CARE-Chile-UC, Pontificia Univ. Catolica de Chile, Santiago, Chile; [3]Inst. of Biomed. Sci., Univ. de Chile, Santiago, Chile

Abstract: The c-Abl tyrosine kinase is a ubiquitous protein that participates in the response to cellular stress, regulating apoptosis in neurons. c-Abl has been implicated in neurodegenerative disorders such as Alzheimer, Parkinson and Niemann Pick diseases. The Amyotrophic Lateral Sclerosis (ALS) is a lethal neurodegenerative disease in which the oxidative and endoplasmic reticulum (ER) stress are associated to the loss of motor neurons. Accumulation of mutant forms of the superoxide dismutase 1 (SOD1) has been proposed as one of the causes of this disease; however, the molecular mechanisms involved in the motor neuron loss are not completely understood. We hypothesized that c-Abl is activated in the SOD1 model and it participates in motor neurons neurodegeneration.
To analyze the role of c-Abl in ALS, we first evaluated the activation of c-Abl (through its Tyr412 phosphorylation) under experimental ER stress, by tunicamycin or thapsigargin treatment of primary cultured cells derived from rat spinal cord. We found that c-Abl was early activated under ER stress induction in spinal cord-cultured cells. Also, overexpression of mutant SOD1 in NSC34 cells, a motor neuron-like cell line, induced c-Abl activation. Concordantly to our *in vitro* data, we found increased levels of activated c-Abl in symptomatic transgenic ALS mice, SOD1(G86R), what was specifically localized in motor neurons of the spinal cord. Moreover, the treatment of ALS mice with the FDA-approved inhibitor of c-Abl Imatinib, delayed the paralysis and weight loss. Furthermore, ALS mice exposed to Imatinib treatment exhibited a significant increased survival rate.
Our results suggest a role of c-Abl tyrosine kinase in ALS associated neurodegeneration. Thus, c-Abl inhibition could be a therapeutic target to ameliorate the disease progression.

Title: Ischemia-like conditions *In vitro* damage rat spinal cord via complex cell death mechanisms

Authors: E. BIANCHETTI[1], M. MLADINIC[2], *A. NISTRI[1];
[1]Neurobio., SISSA, Trieste, Italy; [2]Biotech., Univ. of Rijeka, Rijeka, Croatia

Abstract: New spinal cord injury (SCI) cases are frequently due to non-traumatic causes, including vascular disorders. To develop mechanism-based neuroprotective strategies for acute SCI requires full understanding of the early pathophysiological changes to prevent disability and paralysis. The immediate damage spreads from the initial site through excitotoxicity and metabolic dysfunction (ischemia, free radicals and neuroinflammation) to surrounding tissue (secondary damage). The aim of our study was identifying molecular and cellular mechanisms underlying this process and triggered by a pathological medium (PM) mimicking ischemia in the neonatal rat spinal cord in vitro. We previously showed that extracellular Mg2+ (1 mM) worsened PM-induced damage and inhibited locomotor function. The current study sought to identify the cells affected by PM with Mg2+, and the associated molecular death pathways. Our focus was on the spinal lumbar region which contains the locomotor networks for the hindlimbs. The present study indicated that 1 h PM+Mg2+ application induced delayed pyknosis chiefly in the spinal white matter via overactivation of poly (ADP-ribose) polymerase 1 (PARP1), suggesting cell death mediated by the process of parthanatos that was largely suppressed by pharmacological block of PARP-1, and also via caspase 3-dependent apoptosis. Grey matter damage was less intense and concentrated in dorsal horn neurons and motoneurons that became immunoreactive for the mitochondrial apoptosis-inducing factor (the intracellular effector of parthanatos) translocated into the nucleus to induce chromatin condensation and DNA fragmentation. Immunoreactivity to TRPM ion channels believed to be involved in ischemic brain damage was also investigated. TRPM2 channel expression was enhanced 24 h later in dorsal horn and motoneurons, while TRPM7 channel expression concomitantly decreased. Conversely, TRPM7 expression grew earlier (3 h) in white matter cells, while TRPM2 remained undetectable. Our results show that extracellular Mg2+ amplified the consequences of dysmetabolic SCI to comprise not only white matter parthanatos and apoptosis, but also motoneuronal degeneration via PARP1-dependent pathways with distinct changes in their TRPM expression. Title: TDP-43 and translational control in neurodegenerative disorders

Authors: *K. MILLER[1], K. DUNCAN[2];
[1]Ctr. For Mol. Neurobiology, Hamburg (ZMNH), Hamburg, Germany; [2]ZMNH, Hamburg, Germany

Abstract: TDP-43 is an RNA-binding protein (RBP) implicated in etiology of several neurodegenerative diseases, including amyotrophic lateral sclerosis (ALS), the most common motor neuron disease, and frontotemporal lobar degeneration (FTLD). In diseased cells, TDP-43 frequently redistributes from the nucleus to the cytoplasm, where it has been found to form inclusions. Additionally, numerous TDP-43 patient mutations have been identified. Model organism studies have shown that misregulated TDP-43 causes motor deficits and motor neuron degeneration, and that TDP-43's RNA-binding ability is necessary to incur these defects. Transcriptome-wide RNA interaction studies revealed that TDP-43 binds to thousands of mRNAs and regulates splicing of a large subset of these. Nevertheless, how TDP-43 contributes to disease remains unclear. TDP-43's relocalization from the nucleus to the cytoplasm in disease-affected neurons raises a fundamental, unanswered question: is disease due to a loss of nuclear function, gain of cytoplasmic function, or both? Important cytoplasmic functions have been described for other nuclear RBPs that shuttle between nucleus and cytoplasm. Moreover, TDP-43 binds to a subset of mRNA 3'UTRs, a common binding region for RBPs that regulate translation, and TDP-43 protein was found to associate with polyribosomes under certain conditions (e.g. stress). Thus, TDP-43 might conceivably promote disease by directly affecting either general translation rates or the translation of specific mRNAs. To explore this possibility, we first examined the impact of altered TDP-43 expression on general translation in motor neuron-like cells. Using polysome profiling and nascent protein synthesis measurements, we found no effect on general translation after TDP-43 knockdown. Additionally, no effects on general translation were found upon expression of human TDP-43 (hTDP-43), hTDP-43 targeted to the cytoplasm or specific mutant variants of hTDP43. To investigate possible effects on translation of specific mRNAs, we used qRT-PCR to analyze the distribution of candidate TDP-43 targets across polysome profiles generated from either TARDBP or control siRNA treated

motor neuron-like cells. For the subset of mRNAs that we analyzed, including several mRNAs bound at the 3'UTR by TDP-43, no alteration was detected. Taken together, our results imply that neither loss nor gain of TDP-43 function has a significant impact on general translation in motor neuron-like cells under standard conditions. If TDP-43 does alter translation and thereby contribute to disease, the conditions under which this occurs and the specific mRNAs involved remain to be identified.

Title: Motor function deficits identified in motor neurons of the spinal cords of mice infected with West Nile virus and other encephalitic viruses using optogenetic photoactivation

Authors: *J. D. MORREY, H. WANG, V. SIDDHARTHAN, J. O. HALL, K. K. KESLER; Inst. for Antiviral Reseach, Sch. of Vet. Med., Utah State Univ., LOGAN, UT

Abstract: Acute flaccid paralysis, limb weakness, respiratory insufficiency, and long-term motor function deficits are serious outcomes of human West Nile neurological disease (WNND) and of other viral encephalitides. Mouse models would be particularly useful in determining the physiological and cellular mechanisms of these motor function deficits; however, the development of such rodent models has been difficult due to the confounding effects of lethargy, neurocognitive or memory deficits, or otherwise a lack of motivation by animals to perform behavioral tests. These limitations have been overcome with the use of optogenetic transgenic mice expressing channelrhodopsin 2/EYFP fusion protein from the choline acetyltransferase promoter. Electromyography (EMG) of muscles of the diaphragms, forelimbs, and hind limbs have been activated by photoactivation of these transgenic mice in the C3-4 cervical cord, C4-5 cervical cord, and in the lumbosacral/cauda equina cord, respectively. Photoactivation-induced EMGs at these locations were markedly suppressed when these mice were infected with WNV. Suppression of diaphragmatic EMGs was associated with infection of ventral neurons, and loss of phrenic neurons in the cervical cord. Using a cannula mount on the lumbosacral cord,

hindlimb weakness can be monitored longitudinally. Transgenic mice infected in the cerebral spinal fluid with WNV, Japanese encephalitis virus, or neuroadapted Sindbis virus develop hindlimb motor function deficits as measured by optogenetic photoactivation. This optogenetic model will allow investigations into the mechanisms of viral induced motor function deficits, and for the evaluations of amyotrophic lateral sclerosis or spinal cord injury drugs for treatment of WNND and other viral encephalitides.

Title: The ALS disease associated mutant TDP-43 impairs mitochondrial dynamics and function in motor neurons

Authors: *W. WANG, L. LI, W. LIN, X. WANG;
Case Western Reserve Univ., Cleveland, OH

Abstract: Mutations in TDP-43 lead to familial ALS. Expanding evidence suggest that impaired mitochondrial dynamics likely contribute to the selective degeneration of motor neurons in SOD1-associated fALS. In this study, we investigated whether TDP-43 mutations may impact mitochondrial dynamics and function. We demonstrated that overexpression of wild type TDP-43 reduced mitochondrial length and density in neurites of primary motor neurons which was further exacerbated by ALS associated TDP-43 mutants Q331K and M337V. In contrast, suppression of TDP-43 significantly increased mitochondrial length
and density in neurites, suggesting a specific role of TDP-43 in regulating mitochondrial dynamics. Surprisingly, both TDP-43 overexpression and suppression impaired mitochondrial movement. We further showed that abnormal localization of TDP-43 in cytoplasm induced devastating and widespread abnormal mitochondrial dynamics. TDP-43 co-localized with mitochondria in motor neurons and their colocalization was enhanced by ALS associated mutant. Importantly, co-expression of Mfn2 could abolish TDP-43 induced mitochondrial dynamics

abnormalities and mitochondrial dysfunction. Taken together, our data suggested that mutant TDP-43 impairs mitochondrial dynamics through enhanced localization on mitochondria, which causes mitochondrial dysfunction. Therefore, abnormal mitochondrial dynamics is likely a common feature for ALS and might be potential new therapeutic targets for ALS.

Ctr., Toronto, ON, Canada; [4]Psychiatry and Neurosci., Laval Univ., Laval, QC, Canada; [5]Ctr. de Recherche du Ctr. Hospitalier Universitaire de Quebec, Laval, QC, Canada

Abstract: Amyotrophic lateral sclerosis (ALS), is an adult-onset neurodegenerative disease caused by the progressive loss of motor neurons in the CNS. A major feature of degenerating motor neurons in ALS is the mislocalization of the transactive response DNA-binding protein of 43kDa (TDP-43) from the nucleus to the cytoplasm, forming ubiquitinated inclusions. Mutations in TDP-43 account for a small portion of ALS cases, however, TDP-43 pathology is observed in over 90% of cases, indicating that abnormalities in TDP-43 are an important contributor to ALS pathogenesis.
Since TDP-43 is a nuclear DNA and RNA binding protein that has known functions in regulating RNA metabolism it is likely that abnormalities in TDP-43 will be reflected in changes in RNA processing and expression. Our objective is to identify these changes as a means to understanding how abnormal TDP-43 contributes to ALS pathogenesis.
Typical approaches to identifying changes in RNA expression (transcriptional profiles) rely on

analyzing total mRNA pools from a tissue region or cell type. We used a novel technique entitled Translating Ribosome Affinity Purification (TRAP) to obtain mRNA directly being translated from spinal cord motor neurons of TDP-43A315T mice. Mice expressing an EGFP-tagged ribosomal protein, L10a under control of the choline acetyltransferase promoter were crossed with TDP-43A315T mice to facilitate affinity purification of translating mRNAs from motor neuron polysomes. Translational profiles were obtained via microarray analysis in symptomatic mice and compared to wildtype (WT) littermates. The Biological Networks Gene Ontology Tool (BiNGO) plugin in Cytoscape was used to identify overrepresented GO terms. Genes with a ≥ 2 fold change between TDP-43A315T and WT were validated using immunofluorescence. Translational profiles showed that 28 genes were significantly misregulated. BiNGO analysis demonstrated that there was overrepresentation of genes involved in RNA metabolic process (GO-ID 0016070, p=3.27E-02), immune response (GO-ID 0006955, p=3.39E-02), and regulation of mitotic recombination (GO-ID 0000019, p=3.27E-02) in the TDP-43A315T mice, all which are highly implicated in ALS pathogenesis and other neurodegenerative diseases. Of the 28 misregulated genes, 20 are mapped and 7 had a fold change of ≥ 2. Immunofluorescence in TDP-43A315T motor neurons was indicative of microarray and will be validated in patients samples. This discovery-based approach has, for the first time revealed translational changes in motor neurons of a TDP-43 mouse model and will provide a greater understanding of the mechanistic basis of ALS.

Title: The involvement of Notch in the non-cell autonomous pathogenesis of amyotrophic lateral sclerosis

Authors: A. H. NONNEMAN[1,2], T. PHILIPS[3], C. EYKENS[1], *R. R. VANDENBERGHE[4], W. ROBBERECHT[1,2,5];
[1]Lab. of Neurobiology, Vesalius Res. Centre, VIB, Leuven, Belgium; [2]Leuven Res. Inst. for Neurosci. and Dis. (LIND), Univ. of Leuven (KU Leuven), 3000 Leuven, Belgium, Leuven, Belgium; [3]Johns Hopkins University, Sch. of Medicine, Brain Sci. Inst., Baltimore, MD; [4]Univ. Hosp Gasthuisberg, Leuven 3000, Belgium; [5]Neurology, Univ. Hosp. Leuven, Leuven, Belgium

Abstract: Amyotrophic lateral sclerosis (ALS) is a late-onset progressive neurodegenerative disease, mainly but not exclusively affecting the motor neurons in the spinal cord, brain stem and cortex. This degeneration results into fasciculations, progressive muscle weakness and atrophy, and ultimately paralysis. The course of disease is typically between 1 and 5 years after onset of symptoms and the denervation of the respiratory muscles and the diaphragm is in most cases the fatal event.
Studies using the mutant SOD1 G93A mouse model have shown that the pathogenesis of ALS is non-cell autonomous, meaning that non-neuronal cells contribute to motor neuron degeneration. Typically for ALS is the presence of very reactive microglia and astrocytes, the so-called microgliosis and astrocytosis respectively, determining disease progression. Recently, oligodendrocytes are found to actively contribute to the pathogenesis of ALS. Oligodendrocytes degenerate and are replaced by newly differentiated oligodendrocytes. However, these new oligodendrocytes appear to be dysfunctional, as a decrease in Myelin Basic Protein (MBP) indicates failure of myelination, and a reduced expression of Monocarboxylate Transporter-1 (MCT1) shows impairment of proper neurotrophic support.
As the Notch signaling pathway is known to regulate cell-cell communication, the aim of this study was to investigate the involvement of Notch in the context of non-cell autonomous glial cell contribution to motor neuron degeneration.
We modulated the Notch signaling pathway in the SOD1 G93A mice by means of tamoxifen-induced Cre-Lox mediated recombination. Tamoxifen was administered via oral gavage at the age of 60 days for 4 consecutive days. We found that modulating the Notch signaling pathway affects the reactivity of both astrocytes and microglia. In addition, modulation of Notch rescued the expression levels of both MBP and MCT1, suggesting that the Notch pathway is involved in proper functioning of oligodendrocytes in the mutant SOD1 G93A mice.
In conclusion, our data suggest that the Notch signaling pathway may play an important role in the non-cell autonomous component of the pathogenesis of ALS.

Title: Cytoprotective effect of Rho guanine nucleotide exchange factor (RGNEF)

Authors: K. CHEUNG, C. DROPPELMANN, K. VOLKENING, I. CAMERON, *S. H. PASTERNAK, M. J. STRONG;
Univ. of Western Ontario, London, ON, Canada

Abstract: Background: Rho guanine nucleotide exchange factor (RGNEF) is a dual-functionality protein having an RNA-binding domain and a GEF domain. Similar to other ALS-related RNA-binding proteins such as TDP-43 and FUS/TLS, RGNEF can form pathological neuronal cytoplasmic inclusions in ALS spinal motor neurons. It is unknown whether RGNEF inclusions lead to a loss of the normal function of RGNEF including a failure of RhoA activation and the accompanying response to cellular stress. In order to understand this, we are first characterizing the activity of RGNEF in response to cellular stress, including its ability to become incorporated in stress granules.
Methods: HEK293T cells were transfected (both as a transient and stable transfection) with myc-tagged RGNEF or empty vector (pcDNA myc-HisA). Cells were plated in 96-well plates, and then, 24 hours post plating, time-course experiments (ranging from 6 to 24 hours post-treatment) were conducted using heat shock (42.5^{o}C), sodium arsenite treatment (0.5mM) or sorbitol treatment (400mM). Cell viability was examined using the MTT assay and the formation of either stress (TIA-1 immunoreactive) or transport (staufen immunoreactive) granules visualized by confocal microscopy.
Results: For each of the three stressors examined, HEK293T cells over-expressing RGNEF showed increased survival when compared to pcDNA myc-HisA transfected cells. This cytoprotective effect was observed in both stable and transient transfections of myc-tagged RGNEF. At 2 and 4 hours post stress (sodium arsenite and sorbitol, respectively), stress granule formation was markedly up-regulated compared to non-stressed cells. In neither scenario was RGNEF observed to be associated with TIA-1 immunoreactive stress granules. In contrast, RGNEF did co-localize with transport granules.

Conclusion: These results suggest that in response to cellular stress, RGNEF expression is associated with cytoprotection and is not incorporated into stress granules, but rather into transport granules. These observations have important implications for our understanding of the consequences of sequestration of RGNEF within pathological neuronal cytoplasmic inclusions in ALS, where we hypothesize that it will be unavailable to participate in the physiologic stress response.

Title: Reduced levels of a glycosylated species of the insulinoma-associated protein 2 (IA2) in ALS spinal cord: Evidence of dysregulated endosomal trafficking in ALS

Authors: *R. P. BOWSER, D. M. RIASCOS;
Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Several mutations linked to ALS implicate dysregulated endosomal trafficking as an important pathophysiological mechanism. Neurotransmission in motor neurons relies on normal functioning of transport of neuropeptides and active cell membrane components. We recently used unbiased proteomics methodologies to identify proteins that exhibit abnormal levels in the CSF of ALS patients. We detected a decrease of the Insulinoma-Associated protein 2 (IA2) in the CSF of ALS patients. IA2 is a transmembrane protein belonging to the protein tyrosine phosphatase superfamily and appears enriched in secretory vesicles and dense-core granules of various neuroendocrine cell types including central nervous system neurons. IA2 is processed to mature form via known posttranslational modifications. Thus, we characterized the expression, distribution, and biochemistry of IA2 in ALS by using three antibodies that bind distinct epitopes to recognize all IA2 species. Spinal cord, hippocampus and frontal cortex tissue sections from ALS, FTLD and age-matched controls were subjected to IA2 immunohistochemistry (IHC). Snap frozen tissue from ALS and control subjects were used for western blot analysis. We also

compared IA2 expression between human tissue and Neuro2A, SH-SY5Y, and HEK-293 cell lines. We observed reduced levels of IA2 immunoreactivity in the ALS spinal cord and different IHC patterns when using the 3 IA2 antibodies. Subsequently, we demonstrated that IA2 also underwent posttranslational modifications in spinal cord in agreement to prior reports in neuroendocrine tissues. However, only the high molecular weight (130 kDa) species of IA2 was reduced in ALS when compared to controls. The 130 kDa IA2 species results from glycosylation of specific resides in the pro-IA2 species. Thus, our data indicate altered processing and metabolism of IA2 during ALS. Our findings suggest reduced IA2 function in ALS, since glycosylation is a critical posttranslational modification involved in the protein-protein interactions and function of IA2. Therefore, decreased levels of this particular species may indicate dysfunction in intracellular sorting of cargoes and instability of specialized membrane domains (such as neuromuscular junction) which in turns contributes to motor neuron vulnerability in ALS.

Title: Dysregulation of neurofilament composition underlies disease-causing SOD1-mediated motor neuron degeneration

Authors: *H. CHEN[1], K. QIAN[1], Z. DU[2], J. CAO[2], L. W. BLACKBOURN, IV[2], A. ERRIGO[2], H. CINDY[2], Y. YIN[2], J. LU[2], M. AYALA[2], S.-C. ZHANG[2];
[1]Waisman Ctr., Madison, WI; [2]Waisman center, Madison, WI

Abstract: Neurofilament (NF) tangle is a pathological hallmark of amyotrophic lateral sclerosis (ALS), including that caused by mutations in the Cu/Zn superoxide dismutase (SOD1) gene. Transgenic expression of multiple copies of the mutant forms of SOD1 in animals indeed leads to aggregation of proteins including neurofilaments (NF) and motor neuron degeneration although mechanisms underlying NF aggregation and selective motoneuron degeneration remain unknown. Here we show that NF aggregation appeared progressively in spinal motor neurons but rarely in non-motoneurons that were derived from induced pluripotent cells (iPSCs) from

patients with SOD1 (D90A and A4V) mutations at a time when glial cells have not developed. This pathological change was accompanied by reduced expression of neurofilament-low (NF-L) and altered proportion of NF subunits. Such motoneuron NF changes were mimicked by expression of a single copy of the same mutant SOD1 in human embryonic stem cells (ESCs) and prevented by genetic correction of the SOD1 mutation in the patient's iPSCs. Importantly, conditional expression of NF-L in the SOD1 iPSC-derived motor neurons corrected the NF composition and mitigated NF aggregation. These results indicate that the mutant SOD1 alters the NF composition and results in NF aggregation in motor neurons and that the degenerative process can occur in a cell-autonomous manner. The faithful modeling of ALS pathology highlights the utility of the stem cell strategy for revealing pathological processes of neurological conditions under the human genetic background.

Title: Serum ferritin is elevated in amyotrophic lateral sclerosis patients

Authors: *J. R. CONNOR[1], X. W. SU[1], S. L. CLARDY[2], R. J. LAWSON[3], H. E. STEPHENS[2], Z. SIMMONS[2];
[1]Neurosurg., [2]Neurol., Penn State Col. of Med., Hershey, PA; [3]Northeast ALS Consortium, Boston, MA

Abstract: Background: Dysregulated iron metabolism contributes to ALS pathophysiology. HFE iron regulatory gene polymorphisms may increase ALS risk, and iron dyshomeostasis negatively impacts pathways implicated in ALS, including oxidative stress.
Objectives: To analyze levels of serum ferritin, a marker of iron metabolism, in ALS patients as

well as healthy and diseased controls, and to determine if ferritin impacts survival.
Methods: An IRB-approved, retrospective analysis was performed of data from 137 ALS patients, 152 healthy controls, and 80 patients with other neurological diseases seen at a university-based multidisciplinary ALS clinic or who provided samples to the Northeast ALS Consortium. Gender, age, site of onset, and, for select patients, dates of symptom onset and death were recorded. Survival time was defined as the duration from symptom onset to death. Serum ferritin levels were measured using standard clinical laboratory procedures. Ferritin levels between groups was compared using ANOVA. Spearman correlation was used to analyze the association between ferritin and survival time. Ferritin levels were categorized into high and low groups, and survival was analyzed using Kaplan-Meier logrank statistics and Cox proportional hazards regression.
Results: Age differed in ALS patients (mean 60.5 years) compared to healthy (mean 44.1) and diseased controls (mean 52.1). However, age was not associated with serum ferritin levels (R-squared 0.063). Gender proportions differed in ALS patients (65.3% males) compared to healthy (32.5% males) and diseased controls (38.5% males), and gender significantly affected ferritin levels (mean 224.8 ng/ml, males; mean 90.0 ng/ml, females; $p < 0.001$). Gender stratification was performed. In males, ferritin was significantly higher in ALS patients (mean 286.6 ng/ml) than either healthy (mean 160.8 ng/ml, $p < 0.001$) or diseased controls (mean 164.5, $p = 0.003$). In females, ferritin was significantly higher in ALS patients (mean 142.6 ng/ml) than either healthy (mean 69.3 ng/ml, $p < 0.001$) or diseased controls (mean 77.5, $p < 0.001$). Ferritin was not associated with survival time in either males (R-squared 0.001) or females (R-squared 0.069). ALS patients were categorized into low and high ferritin groups by median values (200.0 ng/ml, males; 123.0 ng/ml, females). Ferritin status did not significantly impact survival by Kaplan-Meier logrank tests or Cox regression in either gender.
Conclusions: These results suggest altered iron metabolism in ALS patients, an effect not simply due to neurological disease. However, serum ferritin alone may be insufficient to reflect or predict disease progression and survival.

Title: Phenotypic analysis of neurodegeneration induced by codon optimized wild type TDP-43 in a *Drosophila* model of ALS

Authors: *T. YUSUFF, S. CHATTERJEE, G. R. JACKSON;
Univ. of Texas Med. Br., Galveston, TX

Abstract: TAR DNA Binding Protein-43 (TDP-43) is known to mediate neurodegeneration associated with amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD). The exact mechanism by which TDP-43 exerts toxicity in patient brains remains unclear. In a Drosophila model, we have identified robust gain of function phenotypes produced by misexpression of insect codon-optimized wild type TDP-43 in retina using the binary GAL4/UAS system, as well as direct promoter fusion constructs. Compared to human transgenic flies, the codon optimized flies express more protein. We were able to detect higher molecular weight species in SDS-PAGE under non-denaturing conditions in the codon-optimized lines. Both nuclear and cytoplasmic expression of TDP-43 were detected along with cytoplasmic aggregation. Our observation led us to believe TDP-43 has the propensity to form toxic protein aggregates when too much protein is present via a gain of function mechanism. Using the direct promoter fusion constructs, we identified that in adult retina TDP-43 misexpression causes strong depigmentation, disruption of polarity in interommatidial bristles, and apparent necrotic patches or hypermelanization that worsen with age. Specifically, the photoreceptor neurons appear flattened and shorter in length with failure of rhabdomere separation; they contain large vacuole-like structures that are morphologically similar to autophagic intermediates. Furthermore, misexpression of TDP-43 in the CCAP expressing neurons in ventral nerve cord leads to wing expansion defects and swelling. When expressed in the Drosophila notum using Eq-GAL4, TDP-43 causes loss of bristles. Based on our observation, we believe that TDP-43 is exerting its toxicity via gain of function mechanism. Further investigation will help us identify and better understand the exact disease mechanism of TDP-43 proteinopathies and find potential therapeutic targets.

Title: Cognitive phenotype in a mouse model of Familial Dysautonomia: Spatial memory

Authors: S. POWELL[1], F. LEFCORT[2], *J. L. WIESELER[3], A. BABCOCK[1];
[1]Psychology, [2]Cell Biol. and Neurosci., [3]Dept. of Psychology, Montana State Univ., Bozeman, MT

Abstract: Familial dysautonomia (FD) is a Hereditary Sensory and Autonomic Neuropathy (Type III) marked by a mutation within the IKBKAP gene encoding the IKAP protein. IKAP is an essential component in growth and development of the sensory and autonomic nervous systems. This protein is widely expressed throughout the nervous system including the hippocampus. Symptoms of FD are progressive and include delayed motor development, psychological disorders, and mild cognitive impairment (Axelrod, 2006). The Lefcort lab group has generated a mouse model of FD in which *Ikbkap* was selectively deleted from CNS neurons. The present study assessed spatial memory of FD mice using an object location task. FD mice and age-matched controls were tested in a task that included habituation, acquisition, and testing phases. Mice were habituated to the apparatus in the absence of the test objects for 10 mins. During acquisition, mice were exposed to two identical objects for 10 mins. One hr after acquisition, animals were reintroduced to the apparatus with one of the object placed in a different location (testing phase). Exploration of the moved object during the testing phase represented a measure of recognition and memory of the spatial change. Time spent within one cm of the moved object in proportion to total object exploration was used for analysis. Other behaviors were recorded and analyzed separately (ie., locomotor activity, mobility and total object exploration).
There was no significant difference in the proportion of exploratory behavior for the novel location object between FD and control groups. However, FD subjects explored objects significantly more than controls. Additionally, FD mice spent significantly less time immobile (e.g. FD mice were more active). Taken together, these data suggest that FD mice are not impaired in object spatial memory, but exhibit behaviors indicative of decreased anxiety response to novelty. Further research is under way to characterize the behavioral phenotype of this model of FD.

Title: Pathogenic FUS mutations retain spliceosomal snRNPs in the cytoplasm

Authors: V. GERBINO[1,2], A. MIRRA[3], *N. CANU[4], M. CARRÌ[1,2], M. COZZOLINO[5], T. ACHSEL[6];

Abstract: Motor neuron diseases such as Amyotrophic Lateral Sclerosis (ALS) and Spinal Muscular Atrophy (SMA) are associated with defects in proteins involved in RNA metabolism (TDP43 and FUS, and SMN, respectively). SMN, the causative factor in SMA, is crucial for the biogenesis of the spliceosomal snRNPs. FUS is a nuclear protein which has been implicated in alternative splicing or mRNA localisation; it forms cytoplasmic aggregates, as a consequence of disturbed nuclear import due to disease-causing mutations. It is extremely likely that the cytoplasmic aggregates are cytotoxic because they trap important factors; the nature of these factors, however, remains to be elucidated. Based on our previous findings, showing that FUS and SMN associated with each other, and that FUS binds to spliceosomal snRNPs, we investigated whether aggregation-prone FUS mutants might interfere with the localisation and biogenesis of snRNPs. Indeed, in transfected mouse motoneuronal-like NSC34 cells, mutations in FUS do not affect its association to the snRNPs. However, mutant FUS and SMN co-localise in multiple cytoplasmic aggregates, and snRNAs are retained into the cytoplasm. As a result, alterations in the alternative splicing of a reporter plasmid are observed. Alternative splicing defects as well as alterations in SMN sub-cellular distribution are also observed in cells depleted of FUS by RNA interference, suggesting that aggregated mutant FUS might disturb the nuclear import of SMN, thus reducing the availability of functional snRNPs in the nucleus. Experiments are undergoing to further characterise this issue. Overall, our observations indicate that FUS mutations and genetic depletion of SMN converge onto the same pathway, i.e. alternative splicing changes, that might represent a unifying theme in the FUS-related ALS and SMA.

Title: Lis1 and Ndel1 regulate dynein-dependent mitochondria traffic in mature neurons

Authors: *L. SHI[1], J. PANDEY[2], D. SMITH[1];
[1]Univ. of South Carolina, Columbia, SC; [2]Harvard Med. Sch., Boston, MA

Abstract: Lissencephaly (smooth brain), caused by Lis1 haploinsufficiency, is a rare brain malformation characterized by defective neuronal mitosis and migration during the early weeks of gestation. The disorder results in increasingly severe seizures and ultimately childhood lethality. If the well-characterized developmental defects are solely responsible for the seizures and lethality, then treatment options are limited. However, Lis1 expression remains high in the adult nervous system. Lis1 binds to cytoplasmic dynein, a microtubule motor critical for retrograde axonal transport. In earlier studies, we demonstrated a role for Lis1 and its interacting partner, Nudel, in dynein-dependent lysosome transport in adult rat sensory neurons. Because mitochondria play important role in cell survival and energetics, we have now addressed the question of whether Lis1 and Nudel also regulate dynein-dependent mitochondria transport in mature axons. As with lysosomes, Lis1 overexpression increased in the percentage of mitochondria moving in a retrograde direction, while Lis1 knockdown reduced retrograde motility. Similarly, loss of both Lis1 and Nudel dramatically reduced motility of both organelle types. However, there were major differences in the impact of Lis1 point mutants on mitochondria transport compared to lysosome transport. A Lis1 mutant that blocks dynein binding had severe effects on motility in both organelle systems, while a Nudel-binding mutant had a much more severe phenotype with respect to mitochondria. Our current model is that while Nudel and Lis1 must both be present for efficient lysosome and mitochondrial transport, a direct interaction between Lis1 and Nudel is more important for the larger mitochondria. From a disease standpoint, disruption of the Lis1/Nudel dynein regulatory pathway could result in post-developmental defects associated with faulty mitochondrial distribution.

Title: Study of mitochondria quality control in the G93A-SOD1 mouse model for ALS

Authors: G. M. PALOMO, J. MAGRANE, B. SIDER, *G. MANFREDI;
Weill Med. Col. Cornell Univ., NEW YORK, NY

Abstract: Amyothropic lateral sclerosis (ALS) is a progressive and fatal neurodegenerative disease caused by specific degeneration of motor neurons. Familial forms of ALS represent a 10% of the all the cases of this disease and mutations in the gene Cu-Zn superoxide dismutase (SOD1) account for a 20% of these. Several mechanisms have been proposed to explain the pleiotropic pathogenic effects of mutant SOD1, among which mitochondrial dysfunction is considered a central component of the pathogenic mechanisms underlying motor neurons degeneration. Mitochondria quality control in neurons is a tightly regulated and critical pathway, whose ultimate purpose is the specific degradation of damaged mitochondria. Elimination of damaged mitochondria occurs largely through the mitophagy pathway, and deregulation of this process can lead to accumulation of dysfunctional mitochondria. We studied mitochondria quality control in the G93A-SOD1 mouse model of ALS using either enriched-mitochondria fractions from spinal cord or primary cortical neurons obtained from E18 embryos. On mitochondria fractions, at disease end stage, we found increased levels of several markers of autophagy in mutant samples compared to non-transgenic littermates: LC3-II protein levels were markedly higher and p62 was accumulated on mitochondria. At disease onset, the increase in LC3-II associated with mitochondria was less marked, suggesting a progression of this molecular phenotype. In SOD1 mutant primary cortical neurons in basal conditions we also found an increase in LC3-II protein levels. To evaluate the autophagy flux in this system, neurons were exposed to bafilomycin A1 (vacuolar ATPase inhibitor). The results indicated a robust increase

in autophagy flux in mutant cells, measured as the rate of accumulation of p62. Also, the different steps of the autophagy process are currently being examined in cortical neurons by using fluorescent-labeled proteins and live-cell imaging techniques. The presence of dysfunctional mitochondria in neuromuscular junctions and motor neurons of ALS models has been extensively described and could be caused by accumulation of damaged organelles that fail to be turnover correctly. Further studies to assess the efficiency of autophagy at these target sites of neurodegeneration are needed in order to determine if the accumulation of damaged mitochondria is the consequence of defective autophagy machinery or of excessive mitochondrial damage that saturates the system.

Title: Studying the function of Fused in sarcoma (FUS) at the presynaptic terminal of the neuromuscular junction: Implications for FUS-mediated ALS

Authors: *K. KRISHNAMURTHY, M. SHAHIDULLAH, I. LEVITAN, D. TROTTI, P. PASINELLI;
NEUROSCIENCE, THOMAS JEFFERSON UNIVERSITY HOSPITAL FOR NEUROSCIENCE, PHILADELPHIA, PA

Abstract: Amyotrophic lateral sclerosis (ALS) is an adult-onset neurodegenerative disease that leads to fatal paralysis. About 10% of ALS cases are familial (fALS), and are associated with mutations in one or another of several genes, while the remainder are sporadic (sALS). FALS and sALS are clinically indistinguishable, suggesting that the different forms of the disease converge on common pathways. Destruction of the neuromuscular junction (NMJ) is a hallmark (and converging point) of all forms of ALS. One gene associated with fALS encodes the DNA/RNA binding protein Fused in Sarcoma (FUS), and FUS-related *Drosophila* models of ALS show early functional NMJ abnormalities as in human disease. In particular loss of the FUS homologue Cabeza disrupts the NMJ suggesting a role for FUS in formation of synapses at the neuromuscular junction (NMJ). In this study, we investigated the role of FUS at mammalian NMJ using a co-culture of rat motor neurons with myotubes. We first examined the localization

of endogenous FUS with pre-and-postsynaptic markers. We find FUS primarily express at the presynaptic terminal of the NMJ with a striking co-localization to a presynaptic marker, synaptic vesicle 2 (SV2), in motor neurons. FUS levels at postsynaptic densities associated with PSD-95 are significantly lower. Studies are underway to characterize the functional consequences of presynaptic FUS at the NMJ as well as the mechanisms by which disease-causative mutant FUS, through perhaps a dominant-negative mechanism, impairs the normal function of FUS and neurotransmitter release at NMJ, thereby triggering atrophy on the contacted muscle cells.

Title: Muscle fiber-type regulation of maintenance of neuromuscular junction innervation

Authors: *C. MILLIGAN[1], J. STRUPE[2], C. MANSFIELD[2], M. ROBINSON[2], R. OPPENHEIM[2], A. ZAIA RODRIGUES[2], R. KUDO[2];
[1]Wake Forest Sch. Med., WINSTON SALEM, NC; [2]Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Motoneurons (MNs) are the largest and maybe the most complicated neurons. They must coordinate interactions of the soma and dendrites with the CNS environment and those of the axon and terminals exposed to the peripheral environment. Much amyotrophic lateral sclerosis (ALS) research has focused on pathology in the spinal cord; however, effective treatment strategies for ALS will involve targets in the spinal cord and at the neuromuscular junction (NMJ). In cultured MNs the JNK signaling pathway appears to contextually regulate both survival and degeneration. To further investigate how JNK may regulate MN development and survival in vivo, we utilized JNK isoform knock-out (KO) mice. We found no difference in MN cell death or innervation between KO and non-transgenic, wild-type (WT) mice. In JNK1 KO mice, however, we found deficits in motor behavior accompanied by muscle denervation

beginning at postnatal day (P) 180. We examined denervation in the tibialis anterior (TA) muscle that is composed of fast fatigue resistant fibers [type 2a (F)] and fast fatigable [type 2b (FF)] fibers and the soleus muscle that is composed of slow [type 1 (S)] fibers. The NMJs of the TA had significant denervation at P180 while denervation in the soleus muscle was not significant until 1.5 years. Interestingly, in the SOD1 mouse, MNs that innervate FF fibers denervate NMJs first, whereas those that innervate S fibers do not appear to undergo denervation until very late stage of the disease. Both results are intriguing when we consider the following: 1) both TA and soleus motor pools in JNK1 KO mice are deficient in JNK1 signaling and appear to develop and innervate their target muscles normally; 2) in the SOD1G93A mouse model of ALS both TA and soleus motor pools exhibit mitochondrial pathology, altered afferent input and a decreased capillary density in the spinal cord; 3) yet, in both mouse models, MNs innervating the TA denervate their NMJs significantly before denervation by the soleus MNs. This striking difference in target denervation may suggest that differing muscle physiologies influence the rate, extent, and stability of innervation with age. We have preliminary data that suggest differences in expression of MN survival promoting factors (BDNF and heat shock protein (Hsp) 70) have decreased expression in fast muscles as compared to slow muscle fibers. If and how expression of MN survival promoting factors is altered in JNK1 deficient animals is under investigation. Understanding the molecular differences of these peripheral (muscle derived) signals in the pathology of MN disease may provide a foundation for therapeutic development.

Technol., Genoa, Italy; [5]Ctr. of Excellence for Neurodegenerative Dis., Milan, Italy; [6]Ctr. of Excellence for Biomed. Res., Genoa, Italy

Abstract: Glutamate (Glu)-mediated excitotoxicity plays a major role in the degeneration of motor neurons in amyotrophic lateral sclerosis (ALS) and reduced astrocytary glutamate transport, which in turn increases the synaptic availability of the amino acid neurotransmitter, was suggested as a cause. Alternatively, here we report our studies on the exocytotic release of glutamate as a possible source of excessive glutamate transmission.
We have studied the release of [3H]D-aspartate and of endogenous Glu induced by depolarizing and non depolarizing stimuli, known to induce exocytotic neurotransmitter release, in mice expressing human SOD1 with the G93A substitution [SOD1G93A], a transgenic model of ALS, respect to mice expressing the unmodified human SOD1 and to non transgenic littermates. Exposure to 15 or 25 mM KCl or to 0.3 or 1 μM ionomycin provoked an almost complete Ca2+-dependent release of Glu from spinal cord synaptosomes. The exocytotic release of Glu induced by KCl or ionomycin was dramatically increased in symptomatic SOD1G93A mice than in controls. The higher glutamate release in mutant animals was already present in early-symptomatic 70-90 and pre- symptomatic 30-40 day-old mice. Noticeably, the stimulus-evoked release of [3H]GABA or [3H]Glycine in spinal cord of SOD1G93A mice did not differ from controls
As to the molecular determinants of this abnormal glutamate exocytosis, increased Ca2+ levels were detected in SOD1G93A mouse spinal cord nerve terminals, accompanied by increased activation of Ca2+/calmodulin-dependent kinase II and increased phosphorylation of synapsin I. In line with these findings, release experiments suggested that the glutamate release augmentation in SOD1G93A mice involves the readily releasable pool of vesicles and a greater capability of these vesicles to fusion upon stimulation. Modifications of the SNARE complex and of release proteins were also observed.
Our in vitro results show that the exocytotic release of Glu is enhanced in mutant SOD1 mice. If it occurs in vivo, the different modulation of Glu, GABA and glycine release here reported could induce an unbalance between spinal inhibitory and excitatory transmission in ALS.

Title: The RNA binding protein RBM45 associates with nuclear stress bodies during cellular stress events

Authors: *M. A. COLLINS[1], R. RICE[2], R. BOWSER[2];
[1]Neurosci., Univ. of Pittsburgh, Phoenix, AZ; [2]Neurol., Barrow Neurolog. Inst., Phoenix, AZ

Abstract: The RNA binding protein RBM45 is a component of the inclusion bodies found in neurons and glia in neurodegenerative disorders such as amyotrophic lateral sclerosis (ALS), frontotemporal lobar degeneration (FTLD), and Alzheimer's disease (AD). In human neurodegenerative disease post-mortem tissue, RBM45 also exhibits a speckled nuclear staining pattern that is independent of inclusion bodies. To investigate the mechanisms of inclusion formation and the biological function of RBM45-positive nuclear granules, we performed immunocytochemistry and co-immunoprecipitation experiments in cultured cells. A variety of subnuclear structures exhibit speckled nuclear staining patterns and we used a combined iterative digital deconvolution/quantitative immunocolocalization analysis to characterize the presence or absence of RBM45 in these structures. We found that RBM45 does not colocalize with markers of nuclear speckles (SC35), Cajal bodies (coilin), or nuclear gems (SMN) and likewise is not a component of cytoplasmic stress granules. In untreated cells, RBM45 was diffusely localized throughout the nucleus, with few granules present. In contrast, when cells were subjected to heat shock or genotoxic stress, the number and size of RBM45-positive granules significantly increased ($p < 0.05$). We identified significant colocalization of RBM45 and the nuclear stress body-associated proteins HSF1 and SAM68 in stressed cells ($p < 0.05$). Co-immunoprecipitation experiments demonstrated that RBM45 could be pulled down using anti-HSF1 antibodies and HSF1 could be pulled down using anti-RBM45 antibodies. Collectively, these results demonstrate that RBM45 is a new component of nuclear stress bodies and identify a new potential therapeutic target for neurodegenerative disorders such as ALS, FTLD, and AD.

Title: Broker genes in the skeletal muscle of SOD1G93A amyotrophic lateral sclerosis mouse model

Authors: *J. R. MAXIMINO[1], G. P. OLIVEIRA[1], M. MASCHIETTO[2], D. M. CARRARO[2], E. ZANOTELI[1], G. CHADI[1];
[1]Univ. of Sao Paulo - Sch. of Med., São Paulo, Brazil; [2]Intl. Ctr. of Res. and Teaching, AC Camargo Hosp., São Paulo, Brazil

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease characterized by the loss of motor neurons (MN). The events regarding MN death are still unknown. Evidences point to skeletal muscle as a primary target of ALS, however little is known about the signaling mechanisms of the disease. In a previous study, the web tool http://bioinfo.lbhc.hcancer.org.br/interactomegraph/ was used to obtain the interactome, and mathematical analysis was applied in order to find broker genes from a gene expression microarray analysis of Wnt and related pathways in gastrocnemius from SOD1G93A mouse model and its age-paired wild-type controls in the age of 40 and 80 days. The network based on the genes was composed by 251 genes from the 40 days and 531 genes from 80 days, where the Grb2 and Src were key genes for the construction of both networks.
In order to better understand the involvement of Grb2 and Src in the presymptomatic phases of ALS, RNA and total protein of gastrocnemius of SOD1G93A mice at presymptomatic ages of 40 and 80 days and wild-type were extracted and the qPCR and western blotting were conducted. The results were analyzed by Student t-test.
Up regulations of the gene expression of Src (1.6 fold, $p<0.05$) and Grb2 (1.3 fold, $p>0.05$) were seen in 80 days old ALS mice compared to wild-type controls. The western blotting showed significant increases of the Src (9.6%) and Grb2 (42.6%) protein levels in the 80 days old ALS mice. Above described, changes in the gene expression and protein levels were not found in the 40 days old ALS mice.
These results showed that already in presymptomatic periods, there are important changes in gene expression and protein levels of skeletal muscle from ALS mice. The Src is important to stabilize the neuromuscular synapse and is considered as a hub for glutamate receptors regulation leading a modulation of synapse. Grb2 is involved in cell proliferation and transformation and via Erk is thought to influence the volume and number of cells, neuritis, and synapses.
Further studies are needed to better characterize whether signaling pathways of Src and Grb2 are involved in the physiopathology of ALS or in the responses to maintain muscular function in the presymptomatic phase of ALS.

Abstract: Amyotrophic Lateral Sclerosis (ALS) is an adult-onset and fast progression neurodegenerative disease that leads the loss of motor neurons. Familial ALS is manly linked to dominant mutations in the gene for Cu/Zn superoxide dismutase (SOD1). Toxic signs from non neuronal cells, mainly astrocytes and microglia, have been proposed to be involved in the rapid evolution of the disease. However, little is known about the related signaling mechanisms.
In order to better understand the triggering events of ALS, RNA of lumbar spinal cords of transgenic SOD1G93A ALS mice at pre-symptomatic ages of 40 and 80 days and age-paired wild type controls was extracted and the microarray analysis of the whole mouse genome was performed. Differentially expressed genes were identified by means of the Bioconductor packages “Agi4x44Preprocess” and “limma”. Gene Ontology analyses of differentially expressed mRNAs were conducted using the NCBI's online DAVID bioinformatics interface. qPCR was conducted in order to validate microarray data. Ventral horn astrocytes from 40 and 80 old days mice, labeled by immunofluorescence, were submitted to laser microdissection, the RNA was extracted and amplified for further evaluation of a selected gene by qPCR.
Statistical analysis has pointed to 492 differentially expressed genes (155 up and 337 down regulated) in 40 days old ALS mice and 1105 (433 up and 672 down regulated) in 80 days old ALS mice. At the age of 40 days, the main biological process regarding down regulated genes was synapse organization, while the up regulated process were fructose metabolism and regulation of neuronal synaptic plasticity. In 80 days old ALS mice, the main down regulated processes were mRNA metabolism, ribonucleoprotein complex biogenesis and blood circulation. Also, the up regulated genes were related to actin filament based process, vesicle mediated transport, protein modification by small protein conjugation, acetyl-coA metabolism and aerobic

respiration. qPCR have confirmed the microarray results. The appearance of protein modification process in 80 days old ALS mice motivated the evaluation of Ube2i gene expression in astrocytes of both ages. Ube2i was found up regulated both in 40 (5.52 fold, $p<0.05$) and 80 days (1.77 fold, $p <0.05$).
Preliminary results indicate important processes occurring in astrocytes of ALS mice since early 40 days. The Ube2i gene encodes the Ubc9 protein, an enzyme of sumoylation pathway. SUMO1-conjugated proteins are reported to promote astrogliosis in symptomatic ALS due to their accumulation in astrocytes nuclei. Further studies are being conducted in order to identify related processes that could clarify the ALS mechanisms.

Title: Propagation of misfolded SOD1 in mouse models of ALS; Implications for mechanism of disease pathogenesis

Authors: *M. A. O'NEILL, L. I. GRAD, A. PETIT, A. J. ROSKAMS, N. R. CASHMAN; Univ. of British Columbia, Vancouver, BC, Canada

Abstract: ALS is a fatal neurodegenerative disease caused by the loss of motor neurons, leading to progressive paralysis and muscle atrophy. Familial cases of ALS (FALS) account for ~10% of all cases, defining the remaining 90% as sporadic (SALS). Mutations in superoxide dismutase 1 (SOD1), occurring in ~2% of all cases of ALS, cause the protein to misfold resulting in a cytotoxic gain-of-function. Although the exact mechanism is unknown, cytotoxic misfolded SOD1 is involved in disease pathogenesis, with a remarkable specificity for motor neurons, even though SOD1 is ubiquitously expressed in many cell types. Excluding *de novo* events, ALS cases don't have mutations in the SOD1 gene, yet the clinical and europathological similarities to FALS suggest a common mechanism of disease pathogenesis. Previous work has shown that under oxidizing conditions, wild type SOD1 misfolds, and acquires the same cytotoxic properties as mutant SOD1. Distinct cell types have different sensitivities to oxidizing events, which could have significant implications in disease onset and pathogenesis. Since pathogenic SOD1 is

misfolded, our laboratory developed antibodies that specifically recognize epitopes only exposed if the protein is misfolded. Using these antibodies, we analyzed spinal cord from control, FALS and SALS patients. Our data clearly shows the presence of misfolded/oxidized SOD1 in the spinal cords of both FALS and SALS patients, and remarkably, the amount detected in SALS is tantamount to that in SOD1 FALS. This data strongly implicates misfolded SOD1 as a marker in all cases of ALS. To analyze this further, we are currently analyzing for the cell-type distribution (motor neurons, astrocytes, microglia, and oligodendrocytes) of misfolded SOD1 in mouse models of ALS and human ALS spinal cord to localize site of misfolding. *In vitro* experiments with conditioned media and serial passaging have shown that the misfolding of SOD1 can be propagated from one source of cells, through the media, to recipient cells. *Ex vivo* studies with spinal cord organotypic slice cultures aim to address the notion of cell-to-cell propagation of misfolded SOD1. And by applying the insights from the cell-type specific analysis to the *ex vivo* experimental paradigm, cell-type specific primary cultures may be applied to *ex vivo* tissue to analyze the relative importance of each cell type to disease pathogenesis and disease progression.

Title: FUS regulates alternative splicing patterns of Mapt by cooperating with PSF/SFPQ: a novel link between FUS and Tau in the pathogenesis of ALS and FTLD

Authors: *S. ISHIGAKI, Y. FUJIOKA, T. UDAGAWA, D. HONDA, M. KATSUNO, G. SOBUE;
Dept. of Neurol., Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan

Abstract: FUS is linked to the pathogenesis of amyotrophic sclerosis (ALS), which is one of the most cruel neurodegenerative diseases. Mutations in FUS gene cause familial ALS/FTLD and the protein mislocalization to the cytoplasm in the affected neurons, which is also observed in

sporadic cases of ALS/FTLD. We found that FUS made a high-molecular weight complex in the nucleus of neurons and that was uncompleted in the ALS-associated FUS mutants. We identified splicing factor, proline- and glutamine-rich (PSF/SFPQ) as a component of the high-molecular complex of FUS and found that the interaction between FUS and PSF/SFPQ was affected by disease-associated mutation in FUS. These findings suggested that loss of FUS function on alternative splicing could lead to neuronal degeneration in FUS-associated ALS/FTLD. We next established the FUS-regulated transcriptome profiles of primary neurons using exon-sensitive microarrays and identified that FUS regulated the alternative splicing of Mapt exon10. This alternative splicing event results in three-repeats (RD3) and four-repeats (RD4) Tau isoform production and the ratio of RD4/RD3 was increased when FUS was silenced in neurons. Morphological abnormality of neurite was observed in FUS-silenced primary neurons and it was rescued by silencing of RD4. FUS-knock-down mice were generated by injecting adeno-associated virus (AAV) encoding shRNA against FUS into bilateral hippocampus. The mice showed obvious reduction of FUS and increased ratio of RD4/RD3 in bilateral hippocampus. Abnormal anxiety behavior was observed in FUS-knock-down mice compared to the control. Pathological specimen analysis showed the change of the ratio of RD4/RD3 in FTLD and other tauopathies such as progressive supranuclear palsy (PSP). Thus, our findings suggest a pathophysiological link between FUS and Tau in ALS/FTLD.

Title: Comparison of action potential evoked dendritic calcium entry in SOD1G93A and non-transgenic spinal motor neurons

Authors: *K. A. QUINLAN, J. B. LAMANO, J. SAMUELS, D. L. WOKOSIN, C. J. HECKMAN;
Physiol., Northwestern Univ. Feinberg Sch. of Med., CHICAGO, IL

Abstract: In amyotrophic lateral sclerosis (ALS), the largest (fast fatiguable) motor neurons which lack Ca2+ buffering proteins are the most vulnerable to degeneration. Previous studies in mutant SOD1 mouse models have shown that spinal motor neurons have significantly more dendritic branching than age-matched counterparts. Whether these added dendrites have similar levels of activity has not yet been examined. Therefore, in this study we characterized action-potential-evoked dendritic Ca2+ entry in juvenile (P4-11) motor neurons in transverse slices of lumbar spinal cord. Whole cell patch was performed with both Ca2+ Green-1 and Texas Red dextrans diluted in the standard internal solution of the electrode. Once a stable patch configuration had been established for 20 minutes, 2 photon Ca2+ imaging was implemented using line scans across the dendritic arborization. The Texas Red was included to control for variations in dye transport throughout the processes, and the peak signal of the averaged Ca2+ transient was collected for locations throughout the dendritic field. Over all the neurons recorded, dendritic diameter and path distance from the soma were significant factors related to the observed Ca2+ transients. More robust Ca2+ transients were observed in the proximal dendrites, with decreasing Ca2+ transients observed distally along the process. As dendritic distance from the soma is inversely correlated with dendritic diameter, Ca2+ transients were found to be largest in the proximal processes with greatest dendritic diameter and decreased in the distal processes where dendritic diameter is reduced. Within individual neurons, there was significant variation between processes in 8 of 9 neurons, suggesting that in Ca2+ entry is not uniform throughout motor neuronal compartments but rather is independently regulated. Finally, dendrites of SOD1G93A motor neurons had significantly smaller Ca2+ transients than non-transgenic motor neurons (N = 4 & 5, respectively). In conclusion, action-potential-evoked dendritic Ca2+ transients were highly variable from dendrite to dendrite, potentially due to localized regulation of ion channel expression or neuromodulation. Within the expanded dendritic field of SOD1G93A motor neurons, there was an overall reduction in Ca2+ transients, perhaps a mechanism to equalize overall calcium entry from the expanded dendritic arborization.

Title: Non-proteolytic ubiquitination of glycogen phosphorylase by the malin-laforin complex regulates glycogen metabolism

Authors: *M. S. GENTRY[1], V. DUKHANDE[2], B. PAASCH[2];
[1]Biochem., Univ. of Kentucky, LEXINGTON, KY; [2]Univ. of Kentucky, Lexington, KY

Abstract: Autosomal recessive mutations in genes encoding malin or laforin cause Lafora disease (LD). LD is a progressive myoclonic epilepsy characterized by pathological aberrant glycogen accumulations in brain and various other organs. Our group identified laforin as a novel glycogen phosphatase essential for maintaining glycogen in a soluble form. Additionally, we discovered that malin is a RING-type E3 ubiquitin ligase and demonstrated that it ubiquitinates proteins involved in glycogen metabolism such as laforin, glycogen synthase, protein targeting to glycogen and glycogen debranching enzyme. However, malin's role in LD pathogenesis is not completely understood. In this study, we aimed to discover substrate/s of malin and its function in LD pathogenesis. We utilized malin- and laforin-knockout mice, immunoprecipitations, Western analyses, immunocytochemistry, glucan-binding assay, PAS staining, and enzyme activity measurements. We discovered glycogen phosphorylase as a novel substrate of malin ubiquitination, but malin does not target glycogen phosphorylase for degradation. Glycogen phosphorylase is vital in the catabolism of cellular glycogen. The expression of glycogen phosphorylase was decreased in liver and skeletal muscle tissues from malin knockout mice. Similarly, overexpression of LD mutations of malin in HEK-293 cells decreased glycogen phosphorylase expression. In addition, overexpression of malin in HEK-293 cells increased the endogenous expression of glycogen phosphorylase. Malin interacted with and ubiquitinated glycogen phosphorylase, and the presence of malin increased the nuclear localization of glycogen phosphorylase. Malin also altered glucan-binding and phosphorylation of glycogen phosphorylase. Thus, glycogen phosphorylase is a novel substrate of malin. Further exploration into the mechanisms of this regulation will unravel insights in glycogen metabolism, physiological functions of the malin-laforin complex and will aid in betterment of LD pharmacotherapy.

Title: Bringing light on to the corticospinal motor neurons: Mehr licht bitte

Authors: *P. OZDINLER;
Dept. of Neurol., Northwestern University, Feinberg Sch. of Med., CHICAGO, IL

Abstract: Corticospinal motor neurons (CSMN) have a unique executive function in the brain. They receive, integrate, translate and transmit cerebral cortex's input to spinal targets, acting as the "spokes person" for the cerebral cortex especially for the motor neuron circuitry. Even though it is the pre-motor neurons that determine CSMN function, it is CSMN that connects the brain and the spinal cord for the execution and modulation of most of the voluntary movement in humans. Therefore, understanding mechanisms that underlie their selective vulnerability and progressive degeneration is critically important for building effective treatment strategies in ALS. However, studying the details of CSMN biology has been limited due to the complexity of the cerebral cortex and the limited numbers of CSMN. However, recent developments allow their visualization, isolation and detailed investigation at different stages of the disease. We found that CSMN show varied transduction efficiency to different AAV serotypes, and that it can be retrogradely transduced by AAV2-2 in the most effective way. Most importantly, introduction of eGFP gene into exposed the cytoarchitectural details of CSMN and revealed that the apical dendrite degeneration is an early event in CSMN degeneration and lack of spines especially on apical dendrites suggest early cortical modulation defects in ALS. Generation of a novel reporter line, ¬ the UCHL1-eGFP mice¬, in which CSMN are genetically labeled now allows their detailed cellular analysis in vivo. Such studies uncovered autophagy as an intrinsic mechanism involved in CSMN apical dendrite degeneration. Our on going studies will reveal the intrinsic and extrinsic factors that are involved in CSMN vulnerability and progressive degeneration, and will help develop effective treatment strategies for ALS and related motor neuron diseases.

Title: *In vitro* characterization of RBM45, a new RNA-binding protein implicated in ALS and FTLD

Authors: *Y. L. LI[1], R. BOWSER[2];
[1]Neurol., [2]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD) are closely related neurodegenerative diseases with overlapping clinical, pathological and genetic characteristics. A major advancement to our understanding of the pathogenesis was the identification of mutations in the RNA-binding proteins TDP-43 and FUS in familial cases of ALS and FTLD, and the observation of cytoplasmic aggregates of these proteins in familial and sporadic ALS and FTLD. However, the motor neuron degeneration mechanism remains unknown. Our lab has recently identified a new RNA-binding protein, RBM45, with pathologic alterations in ALS and FTLD. RBM45 containing cytoplasmic inclusions were observed in both ALS and FTLD patients. RBM45 also co-localized with TDP-43 and ubiquitin inclusions in affected neurons. However, very little is known about the physiological functions and RNA-binding targets of RBM45.

We have used in vitro cultured cells to characterize the structural functions of RBM45. Domain analysis shows that RBM45 contains 3 RNA-recognition motifs, sharing similar structural elements with TDP-43 and FUS. Immunolocalization showed RBM45 is a nuclear protein, and the disruption of its nuclear localization signal (NLS) mis-localizes RBM45 to the cytoplasm. Reciprocal co-immunoprecipitation assays indicated physical interactions between RBM45 and TDP-43 and FUS. RBM45 domains responsible for these protein-protein interactions were determined using truncation analysis. We also discovered that RBM45 can self-aggregate and determined the domain required for self-aggregation. To study the RNA-mediated pathways of neurodegeneration in cultured neurons, we have developed a novel CLIP-seq (Crosslinking and Immunoprecipitation coupled RNA-seq) approach to identify the RNAs bound and regulated by RBM45. The CLIP-seq data and the genes jointly regulated by RBM45, TDP-43 and FUS will be presented.

Our results demonstrate that RBM45 is a new RNA-binding protein implicated in ALS and

FTLD. We propose that RBM45 is a nuclear protein that functions in RNA splicing and transport. Nuclear import defects and environmental stress mis-localize RBM45 to the cytoplasm, where cytoplasmic aggregation can occur. The accumulation of cytoplasmic RBM45 disrupts normal RNA processing, contributing to cell death. Future mechanistic studies of RBM45 are warranted to further define the roles of RBM45 in neurodegeneration, which will broaden therapeutic options for ALS and FTLD.

Title: Xenopus tadpole model for valproate-induced neurodevelopmental disorders

Authors: *E. J. JAMES, J. GU, C. RAMIREZ, A. S. KHAKHALIN, C. D. AIZENMAN; Brown Univ., Providence, RI

Abstract: Prenatal exposure to valproic acid (VPA), a commonly prescribed anticonvulsant, is known to increase the risk for autism spectrum disorder (ASD) in children. Rodents exposed to VPA in utero, have been utilized to generate VPA-induced rodent models of autism that show significant behavioral and electrophysiological phenotypes, for example cortical pyramidal neurons show significant increases in the probability of local connectivity and reductions in cell excitability. Here we develop a Xenopus tadpole model of VPA-induced neurodevelopmental disorders.

Xenopus laevis tadpoles are an easily manipulated and efficient model organism for studying neural development and function. In particular, the optic tectum has been used to study a wide variety of neurodevelopmental phenomena ranging from synaptogenesis, process outgrowth and neural circuit formation and plasticity. We tested whether exposing tadpoles to VPA during a critical neurodevelopmental time period would result in a similar neuronal phenotype to what has been described in rodents. We chronically exposed Xenopus tadpoles to VPA for 8-10 days, from stage 41, when retinal inputs innervate the tectum, to stages when the retinotectal map refines (48/49). We then recorded intrinsic excitability and connectivity of tectal neurons

utilizing whole-cell patch clamp recordings. We measured various electrophysiological properties related to synaptic transmission and membrane excitability, such as voltage-gated currents, excitatory and inhibitory synaptic transmission, and spike output. We found that chronic exposure to VPA increased the frequency and duration of spontaneous excitatory synaptic activity, increased network connectivity and excitability within the tectum, while reducing intrinsic excitability of tectal neurons compared to matched controls. These results mirror the electrophysiological findings in the valproate-treated mice studies.
Behavioral research has shown that autistic children and VPA-induced models of ASD have an increased sensitivity to sensory stimuli. Consistently, we also conducted behavioral assays on the VPA-treated tadpoles and observed an increased response to sensory stimuli, expressed as decreased habitutation and enhanced sensitization to a startle stimulus.
Xenopus tadpoles are a high-throughput model organism with well-understood neural organization useful for studying mechanisms that govern development of neural circuits. When these attributes of Xenopus are combined with our findings, we demonstrate that Xenopus tadpoles are a viable and efficient model to study the mechanisms by which VPA-induced ASD occurs.

Abstract: Valproic acid (VPA) is a first-line therapy for epilepsy. Recently, the FDA warned that children born to mothers treated with VPA are at an increased risk of developing cognitive deficits. Indeed, some studies have highlighted a relationship between these cognitive deficits and autism spectrum disorders (ASDs). It is widely accepted that disruptions to excitatory/inhibitory (E/I) balance and communication alterations between different brain areas are important factors in the etiology of ASDs. In other words, ASDs are "circuit disorders" that are more likely caused by alterations to macroscopic neural circuit function rather than alterations to specific microscopic synapses or neurons. To date, only a limited number of methods for demonstrating alterations in neuronal circuit activity have been reported. Here, we examined alterations in neural circuit activity by using single-photon wide-field voltage-sensitive dye (VSD) imaging. Previously, we found that mice born to mother's treated with VPA on embryonic days 12, 13, and 14 showed clear deficits in learning- and memory-related behavior after postnatal day 84. In the hippocampal slice preparation of VPA-treated mice, we searched for deficits in synaptic activation patterns in the perforant (PP), mossy fiber (MF), and Schaffer collateral (Sch) pathways by using VSD imaging. Hippocampal slices (thickness, 400 μm) were prepared and stained with VSD (Di-4-ANEPPS) from adult (older than 84 days) mice treated with and without VPA. Neuronal activation patterns were recorded using CMOS high-speed imager sensor technology (MiCAM Ultima, BrainVision), and single electrical stimulation was applied to the PP, MF, and Sch pathways under wide-field optical microscopy (THT-macroscope, BrainVision). The neuronal response of VPA-treated mice, as observed using VSD imaging, was not different from that of control mice; however, the overall depolarizing activities of the circuit in the presence of the GABA(A) receptor inhibitor, picrotoxin (100 μM), were significantly lower in the VPA mice following Sch and MF stimulation. In other words, the circuit activities showed reduced sensitivity to the GABA(A) receptor inhibitor after Sch and MF synaptic activation. We hypothesize that this occurs because of reduced inhibitory activation in VPA-treated mice, accompanied by reduced excitatory activation. That is, the disruption of E/I balance in the hippocampal circuit may cause the behavioral deficits.

Title: Maternal infection perturbs fetal brain development through IL-6 signaling

Authors: *Z. YAN, W.-L. WU, E. Y. HSIAO, P. H. PATTERSON;
Div. of Biol., Caltech, Pasadena, CA

Abstract: Epidemiologic studies identify maternal infection as a risk factor for autism and schizophrenia in the offspring. To understand the mechanism of how maternal infection alters fetal brain development, we use a mouse model in which injection of the viral mimic poly(I:C) at mid-gestation elicits maternal immune activation (MIA). MIA offspring exhibit autistic- and schizophrenia-like behaviors as well as neuropathology characteristic of each of these disorders. Prior work demonstrated that maternal interleukin-6 (IL-6) is a key cytokine that mediates the effects of MIA on the fetus. The receptor for IL-6, IL-6Rα, is expressed in brain regions associated with pathology in autism and schizophrenia. To examine where this cytokine acts, we are studying patterns of activation of IL-6 signaling in the fetal brain. First, we demonstrate that IL-6 mRNA and protein increase in fetal brain 3 hours following maternal poly(I:C) injection. Second, we find that highly selective regions of the embryonic brain respond to MIA: phospho-STAT3 (pSTAT3) immunostaining is elevated in the hindbrain and cerebellar primordium, and laser capture micro-dissection analysis of the JAK/STAT signaling pathway yields results consistent with the immunostaining. To further examine the role of IL-6, we have generated tissue-specific IL-6Rα knockout mice.

Title: Modelling autism spectrum disorder through maternal immune activation in mice

Authors: I. C. XUAN[1], A. J. RAMSEY[2], *D. R. HAMPSON[3];
[1]Pharmaceut. Sci., [2]Pharmacol. and Toxicology, [3]Dept. of Pharmaceut. Sci., Univ. of Toronto, Toronto, ON, Canada

Abstract: Autism spectrum disorder (ASD) is a prevalent neurodevelopmental disorder characterized by deficits in social interaction and communication as well as ritualistic repetitive behaviours. Although a small percentage of cases are caused by genetic mutation(s), the etiology of ASD is largely unknown. Epidemiological studies have suggested that children from mothers who experienced an infection during pregnancy (i.e. maternal immune activation, MIA) may be at increased risk for this disorder. This theory is supported by reports of the presence of activated astrocytes and microglia in human post-mortem brain samples and changes in cytokine levels in the sera of ASD patients. Our objective was to assess MIA in mice. We injected mouse dams (C57BL/6) with lipopolysaccharide (LPS) or polyinosinic:polycytidylic acid (Poly I:C) during mid-gestation to mimic a bacterial or viral infection, respectively. Adult male and female offspring from injected mice were analyzed separately for ASD-associated behaviours. Pathological analyses were subsequently conducted on the cerebellum by measuring the expression of microglia, astrocyte, and mature oligodendrocyte markers using immunohistochemistry/western blots. The results indicate the presence of several ASD-like behaviours in the MIA offspring, some of which are sex-dependent.

Abstract: Prenatal exposure to valproic acid (VPA) in rodents has been used as a reliable animal model of autism. It is already known that alterations in the immune system of patients are common, indicating possible roles in the pathophysiology of autism. In addition, altered levels of different cytokines have been associated to cognitive impairments with relevance to this disorder. In this context, considering that most reports of cytokines studied in autism are limited to plasma and serum evaluation, we aimed in this study to evaluate the levels of different cytokines in cerebral cortex and hippocampus of mice prenatally exposed to VPA. Female BALB/c mice coming from the local breeding colony (FEPPS-Porto Alegre) were kept in a room with controlled temperature (22 ± 1 °C), water and food ad libitum, and a 12:12 light cycle (lights on at 7:00 and lights off at 19:00). They had their fertility cycle controlled, and, when on proestrus, mated overnight. In the morning, females that presented a vaginal plug would be considered pregnant. Pregnant animals received a single intraperitoneal injection of 600 mg/kg of VPA or saline (control) on gestational day 11. The offspring of both groups (VPA and control) were killed after 30 days of birth and had their cortices and hippocampi dissected. Tissues were homogenized and used to measure IFN, TNF, IL-6 and IL-17 by a mouse Th1/Th2/Th17 cytokine cytometric bead array kit and CBA software (BD Pharmingen, San Jose, CA). The VPA group presented higher amount of TNF (12 pg/mg ± 2.112, p= 0,048) in the cortex when compared to the control group (7.8 pg/mg ± 0.3469), with no alteration in the hippocampus (VPA, 12.7 pg/mg ± 3.579 and control, 8.25 pg/mg ± 3.746). The amount of cortical IL-6 increased 2 fold in VPA group (8 pg/mg ± 1.597, p= 0,0454) compared to the control (4 pg/mg ± 0.5270) and again, no hippocampal alteration was found. Cortical IL-17 level was higher in the VPA group (5 pg/mg ± 0.7984, p= 0,0148) in comparison to controls (2.6 ± 0.3835), and the hippocampal levels of this cytokine were similar in both groups (VPA, 3.470 ± 0.5264 and control, 4.137 ± 1.307). In summary, our results show a disbalance on cytokine levels in cortex of mice exposed to VPA in utero. These data should be examined carefully, since these alterations might be associated with autistic-like behaviors. It was already reported that abnormal amount of cytokines, such as IL-6 and TNF, and their receptors in rodents is related with depression and social withdraw, typical behaviors found in autism. In the future, the use of transgenic animals overexpressing these proteins in behavioral tests would clarify the influence of immunological factors on autism pathophysiology.

Title: Early life disruption of serotonin alters microglia expression in adult rodents

Authors: A. T. GARGIULO[1], R. D. DARLING[2], Y. LU[2], M. A. LEA[1], K. L. SIMPSON[2,3], J. C. SHIH[4,5], K. CHEN[4], I. A. PAUL[3], *R. C. LIN[2,3];

Abstract: Serotonin (5HT) has been shown to be important in neurodevelopmental processes in addition to its traditional role in adults. The 5HT system is one of the first neurotransmitter systems to appear in the brain, and it has been shown that 5HT is transiently present in non-serotonergic neurons. This early influence suggests a pervasive impact on neurodevelopment, and disruption could be long-lasting and widespread. Our laboratories and others have used a combination of techniques to better understand 5HT's role in neurodevelopment, including the use of monoamine oxidase (MAO) mutant mice and the use of rats exposed perinatally to antidepressants such as selective serotonin reuptake inhibitors (SSRIs). In these animals, we have discovered behavioral changes during sexual and social interactions, and in response to novelty and conspecifics. Anatomically, we have found a down-regulation of 5HT markers, a disruption of the interhemispheric connections between sensory and limbic cortical areas, and an up-regulation of the locus coeruleus/norepinephrine system. Importantly, most of these changes persisted in adult animals.
Because these pathological changes included altered myelin formation, oligodendrocyte morphology, and neural morphology, examination of immune responses became a next logical step. Therefore, we used immunohistochemical procedures to explore microglial expression patterns within the structures that have been shown previously to be disrupted. Male Long Evans rats were exposed intraperitoneally to either saline or to the SSRI citalopram (CTM: 20 mg/kg/day) from postnatal day 8-21. Rats and MAOA KO mice were allowed to mature to adulthood before being sacrificed. Animals were perfused and brain slices processed with CD11b or Iba1 for microglia expression, as well as various co-stains including tyrosine hydroxylase (TH), tryptophan hydroxylase (TPH), serotonin reuptake transporter (SERT),

parvalbumin, microtubule associated protein (MAP), and myelin basic protein (MBP). Increased expression patterns were noted within both white matter and gray matter areas in both rats exposed postnatally to CTM and in MAOA KO mice. Morphological changes in microglia were also noted, suggesting increased microglial activation in experimental animals. This increased expression pattern of microglia in our animals is especially relevant given the recent PET findings of increased microglia activity in young adults with Autism Spectrum Disorder.

Title: Group B streptococcus inflammatory response induced during gestation leads to perinatal injuries and subsequent behavioral impairments in male offspring mimicking autistic features

Authors: *J. BERGERON[1], M.-J. ALLARD[1], J. DESLAURIERS[2], S. GRIGNON[2], P. SARRET[2], L.-C. FORTIER[2], C. POYART[3], G. SÉBIRE[2];
[1]Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Univ. de Sherbrooke, Sherbrooke, QC, Canada; [3]Ctr. national de référence des streptocoques de groupe B, Cochin, France

Abstract: Background: The prevalence of autism increases since 1970's and the causes remain unclear. Pathogen exposures during pregnancy, including group B streptococcus (GBS) are associated with perinatal brain lesions in human. Despite GBS infection is common during pregnancy, its role on the fetal brain remains unknown. However, GBS-induced inflammation plays a noxious role in placental and perinatal brain damage, and subsequent neurobehavioral impairments including autism-like traits. The autistic features affect mostly the male progeniture.

Methods: Pregnant rats were injected every 12 hours with inactivated GBS (10^9 CFU) from serotype 1a GBS, versus saline, from gestational day 19 until the end of gestation. During the juvenile period, behavioral tests assessing exploration (Open field at post-natal day (P) 15, 20, 25), sensorimotor gating (Prepulse inhibition - PPI at P35), and social interactions (at P40) were used to detect the behavioral impairments. Additionally, anxiety-like behaviors (Elevated plus maze between P105-P115) and memory impairments (novel object recognition test at P120-150) were determined in adult rats. **Results:** Decreased ability to recognize maternal odor and increased delay to reach home-bedding compartment in GBS-exposed versus unexposed pups at P9 were observed with the nest-seeking test. Behavioral studies of exploration showed decreased motor abilities only in males - not in females - exposed to GBS compared to control pups. Duration (34.0 seconds (s) ± 7.4) and number of episodes (10.5 ± 2.5) of social interactions were significantly decreased only in male exposed to GBS compared to control animals (duration: 99.6 s ± 14.1; number of episodes: 22.0 ± 4.0). PPI disclosed - only in males exposed to GBS - sensorimotor gating deficits relevant to autistic behaviors (17% of reduction, $p<0.05$). In adulthood, male rats exposed to GBS exhibited anxiety-like behaviors and showed resistance to novelty in the novel object recognition test.**Conclusion:** Inflammatory response induced by GBS during gestation affects offspring behaviors, especially male pups which developed autistic-like behaviors. This animal model will be used to uncover the mechanistic processes linking gestational inflammation to gender-specific perinatal brain injuries and their behavioral correlates, including autistic-like symptoms.

Title: Effects of prenatal exposure to valproic acid on hypothalamic and limbic structures in the rat

Authors: Y. D. GILLES, N. L. POWELL, T. T. DANG, *E. K. POLSTON;
Dept. of Physiol. and Biophysics, Howard Univ. Col. of Med., WASHINGTON, DC

Abstract: Maternal use of valproic acid (VPA), a commonly prescribed anticonvulsant drug, is reportedly associated with an increased risk of autism spectrum disorders (ASD) in human offspring. In utero VPA administration has been shown to cause ASD like behavioral profiles in the rat which include heightened anxiety and disrupted social investigations. The specific neurodevelopmental abnormalities caused by VPA remain poorly understood in human and animal models. Behavioral phenotypes seen in autism suggest altered growth of brain areas involved with social affiliation and emotional state. Several hypothalamic and limbic nuclei are known to regulate these processes, supporting the premise that developmental perturbation of subcortical structures may contribute to autistic behavioral phenotypes. We have examined hypothalamic and limbic structures in an animal model for autism whereby rat fetuses are subjected to VPA early in gestation. The present study investigated the hypothesis that prenatal VPA exposure disrupts the formation of hypothalamic and limbic nuclei in the rat. To test our hypothesis, pregnant Sprague-Dawley rats were injected with VPA on gestational day 12.5 and offspring were raised to adulthood. Brains were stained with cresyl violet for analysis of nuclear volumes and cell numbers. Preliminary analyses reveal that sex differences that were evident in the hypothalamus and amygdala of control animals were not present in VPA treated offspring. Our findings suggest that one mechanism by which prenatal VPA contact results in ASD-like behavioral phenotypes may be through abnormal sexual differentiation of subcortical brain areas that mediate the social and emotional behaviors that are typically disrupted in autism.

Title: Valproate application to rat fetus encourages the development of Purkinje cell dendrites and network formation in cerebellar development

Authors: *S. YOSHIDA[1], H. MURAMOTO[1], M. TANOZAKI[1], N. HOZUMI[2], Y. FUETA[3], Y. SEKINO[4];

Abstract: Valproate, the popular antidepressant, is known as an inducer of autism. It has many kinds of physiological properties, including the inhibition of histone deacetylase (HDAC) and γ-amino butyric acid (GABA) transaminase. GABA plays important roles in cerebellar differentiations and functions. Recently we have developed the neurotransmitter photo assay devices for GABA, glutamate and ATP. Using these devices, we observed that GABA was much released from the glial cells in developing cerebellar external granular layer (EGL) from P3 to P7, and dropped down suddenly. ATP release to 100 μM glutamate stimulation was observed drastically at P10 in the lower molecular layer and granular layer, and decreased gradually to P14. During the first two weeks, Purkinje cells form a single layer and elongate their dendrites with synapses.

Now we investigated the effects of application of Valproate to fetus. Valproate application to embryonic day 16 p.o. increased GABA release even from early developing periods, and changed its releasing spatial pattern. ATP release was also increased from P6. In addition, Purkinje cells in the Valproate-applied rat elongate their dendrites all over the molecular layer even in P12. Figure showed anti-Calbindin D-28k antibody-stained Purkinje cells in P12. A and B is the Valproate-applied and control rat, respectively. ML: the molecular layer, PL: the Purkinje layer.

GABA would act as excitatory transmitter and/or an inducer for proliferation in developing cerebellar cortex, whereas GABA acts as inhibitory transmitter in mature brain. We suggested that Valproate application would cause precocious development of cerebellar cortex due to increase GABA release.

Title: Effects of prenatal stress, variable prenatal diet, and maternal genotype on offspring in an animal model of autism spectrum disorders

Authors: *K. L. JONES[1], M. WILL[2], K. FRITSCHE[2], P. HECHT[2], J. BROWNING[2], M. TILLEY[3], D. Q. BEVERSDORF[2];
[1]Div. of Rheumatology/Allergy and Clinical Immunology, Univ. of California - Davis, Davis, CA; [2]Univ. of Missouri, Columbia, MO; [3]Central Methodist Univ., Fayette, MO

Abstract: Multiple studies have reported that prenatal stress is a possible risk factor for the development of autism. In rodents, a significant reduction in sociability is seen in adult rats exposed to prenatal stress. Genes that contribute to stress reactivity may, therefore, exacerbate prenatal stress-mediated behavioral changes in the adult offspring. Humans with the short allele of an insertion/deletion polymorphism of the SLC6A4 gene, which reduces the expression and function of the serotonin transporter (5-HTT), display increased stress reactivity. A previous rodent study found that prenatally stressed offspring of 5-HTT heterozygous (+/-) dams displayed autistic-like sociability deficits.
An additional environmental factor that may contribute to the etiology of autism is diet. One diet variable that has received recent attention is polyunsaturated fatty acids (PUFAs), particularly the decline in omega-3 PUFAs in the modern Western diet. Currently, modern Western diets are rich in omega-6 (n-6) PUFAs and deficient in omega-3 (n-3) PUFAs. A previous rodent study found that offspring exposed to a diet rich in n-6 and deficient in n-3 PUFAs during gestation and lactation displayed autistic-like sociability deficits. In contrast to n-6 PUFAs, n-3 PUFAs are known to have neuroprotective effects.
Therefore, in our study we wished to examine the role of maternal genotype, prenatal stress, and prenatal diet in mice in order to determine whether they produce autistic-like behavior in the offspring. Pregnant C57BL/6J and 5-HTT +/- dams were placed into a chronic variable stress group or a control group. Additionally, dams received one of three diets beginning 2 weeks before breeding and lasting until offspring were weaned: a control diet, a diet low in n-3 and rich in n-6 PUFAs, and a diet rich in n-3 PUFAs. We subsequently recorded the ultrasonic vocalizations of the offspring on postnatal day 8 as a measure of social communication. Beginning on postnatal day 60, the adult offspring were tested for levels of social interaction

using the 3-chamber social approach task. Anxiety was tested using the elevated-plus maze, and general activity levels were assessed using the open field. The brains of the adult offspring were then extracted and analyzed for varying levels of PUFA in whole brain tissue, and plasma was collected for immune assay analysis. Results indicated that both prenatally stressed offspring of 5-HTT +/- dams and offspring exposed to the n-3 deficient diet display autistic-like behavioral deficits. Interestingly, a perinatal diet rich in n-3 seems to ameliorate these effects in prenatally-stressed offspring of 5-HTT +/- dams.

Abstract: Vitamin D deficiency/insufficiency, defined as inadequate circulating concentrations of 25-hydroxyvitamn D (25OHD), has been estimated to affect up to 75% of pregnant women in some developed nations. Multiple studies have established an associative link between low maternal 25OHD concentrations and a variety of mental health conditions, including autism spectrum disorders (ASD). The current study aimed to examine the effects of prenatal vitamin D deficiency on offspring behaviors. Female C57BL/6J mice were assigned to either a vitamin D deficient diet or a control diet two weeks prior to mating and maintained on this diet throughout pregnancy until postnatal day 7, at which point both dietary groups were switched to the control diet. We subsequently recorded the ultrasonic vocalizations of the offspring on postnatal day 8 as a measure of social communication. Beginning on postnatal day 60, the adult offspring were tested for levels of social interaction using the Crawley 3-chamber social approach task. Anxiety was tested using the elevated-plus maze, and general activity levels were assessed using the open field.

Title: Aminopeptidase P1 deficiency causes neurodevelopmental disorders in mice

Authors: *Y.-S. BAE, S. YOON, M.-S. MUN, K.-Y. PARK, W. KIM, J.-H. CHA, M.-H. KIM; Dept. of Physiol. & Biophysics, Seoul Natl. Univ. Col. of Med., Jongno-Gu, Seoul, Korea, Republic of

Abstract: Aminopeptidase Ps (APPs) catalyze the cleavage of the N-terminal amino acid residue of a peptide chain when the penultimate amino acid is proline. In mammals, there are three known isoforms of APPs (APP1-3) encoded by distinct genes (Xpnpep1-3). Many bioactive peptide hormones and neuropeptides have proline residues in their N-terminal penultimate site, and expected to be effectively degraded by the action of APPs. According to the previous report, reduced level of APP activity in humans leads to urinary excretion of imino-oligopeptides. In addition to this peptiduria, an APP-deficient human subject exhibited developmental retardation and microcephaly. However, APP isoform associated with such dysfunctions in the subject still remains unknown. In this study, we genetically disrupted APP1 function in mice and investigated the causal relationship between APP1-deficiency and developmental dysfunctions. Interestingly, urinary excretion of undigested imino-oligopeptides was observed in APP1 knockout mice, which was consistent with human subjects with reduced APP activity. In addition, APP1 deficiency in mice caused severe developmental retardation and microcephaly. These dysfunctions were associated with hippocampal pathology and abnormal synaptic transmission. These results indicate that APP1-dependent peptide metabolism is important for brain development and synaptic function.

Sch. of Med., Cleveland, OH

Abstract: Early brain overgrowth is a hallmark phenotype of autism, but the mechanisms linking regulation of brain size with social behavioral defects are unknown. The development of the neocortex is regulated by the highly conserved wingless/Wnt developmental pathway. A key component of Wnt pathway, the Dishevelled (Dvl) family of proteins, relays Wnt signals from receptors to downstream effectors. *Dvl1*-null mice exhibited abnormal social interaction however no gross brain pathological abnormalities were seen in these mice (Lijam et al., 1997; Long et al., 2004). This suggests that redundancy of *Dvl* genes may mask subtle brain abnormalities. Thus we generated *Dvl1-/-3+/-* mice and tested the development of the neocortex in these mice. We found that Dvl mutant mice displayed early embryonic brain overgrowth associated with induced proliferation and early expansion of basal neural progenitors *in vivo* and *in vitro*. In addition, brain overgrowth was associated with expansion of deep layer neurons but not superficial layer neurons. NPC expansion was caused by deregulation of a previously uncharacterized transcriptional cascade downstream of the canonical Wnt pathway. Reduced β-catenin transcriptional activity in the $Dvl1^{-/-}3^{+/-}$ NPCs resulted in down-regulation of Brn2. This relieves the repression of Brn2 on the Tbr2 promoter, which increased Tbr2 expression and the production of basal NPCs. Moreover, Brn2-/- embryos recapitulate the brain overgrowth phenotype. Importantly, preliminary results using pharmacological induction of the Wnt canonical pathway in a short
window during embryonic development rescued the embryonic brain overgrowth phenotype. The rescue of the social behavior phenotypes is currently being tested. These results support a model that spatiotemporal regulation of the β-catenin/Brn2/Tbr2 transcriptional cascade is critical for

brain development and may contribute to the social behavioral phenotype in the *Dvl* mutant mice.

Title: Specific gene and prenatal stress interaction in the development of autism spectrum disorder

Authors: *P. HECHT[1], M. TILLEY[3], K. JONES[4,1], D. Q. BEVERSDORF[2];
[2]Radiology, Neurology, Psychology, and Thompson Ctr. for Neurdevelopmental Disorders, [1]Univ. of Missouri, Columbia, MO; [3]Central Methodist Univ., Fayette, MO; [4]Univ. of California- Davis, Davis, CA

Abstract: Our previous research has shown a significant increase in prenatal stress in mothers of children with ASD with a peak at weeks 21-32 of gestation. However, not all mothers that encounter stressful situations during pregnancy have children with ASD. It is possible that genetics may play a role in stress tolerance in the development of ASD. The serotonergic system holds particular interest in this regard. An insertion/deletion polymorphism in the promoter region of the serotonin transporter (5-HTT) gene, SLC6A4, has been associated with anxiety and stress reactivity, and some studies have suggested an association with ASD in carriers of the short allele. Additionally, the 3' polyadenylation site of the serotonin transporter has been shown to have a polymorphism that has a stronger association with panic disorder than the insertion/deletion polymorphism in the promoter. Our aim is to discover which of these stress-reactive polymorphisms found on the serotonin transporter gene may interact with environmental stressors during the pregnancy to produce a higher risk for the development of ASD. Blood was collected from families with children diagnosed with ASD for genetic testing and mothers were asked to complete questionnaires regarding their history of stress exposure during pregnancy. Early evidence suggests that the 44 base-pair deletion in the 5-HTTLPR is the critical polymorphism interacting with environmental stressors to increase the risk for ASD in the

developing child. Mothers with the 5-HTTLPR short allele have higher numbers of stressors and stressor severity during pregnancy, predominantly during the critical period of pregnancy identified in our previous work, when compared to carriers of the long allele. Furthermore, when compared to the polyadenylation polymorphism, the short allele in the 5-HTTLPR is associated with more stressors and stress severity. This study is beginning to suggest a gene and environment interaction in the development of ASD. Our study continues to show the significance of stress during gestation in the etiology of ASD particularly during weeks 21-32. More importantly, this evidence further identifies a specific gene that appears to interact with prenatal stress exposure in association with this risk. While the polyadenylation site is linked with panic disorders it does not appear to be interacting with environmental stressors to increase the risk for ASD in the child. Any marginal effect shown with the polyadenylation polymorphism may be a result of the polyadenylation site being in linkage disequilibrium with 5HTTLPR. Further analysis needs to be conducted to completely understand this gene and environment interaction.

Title: Benzyl butyl phthalate (bbp) treatment induces alterations in estrogen responses, synaptic plasticity regulation, and neuronal development in rodents

Authors: D. DEBARTOLO[1], S. JAYATILAKA[2], E. GALLAGHER[2], M. ROSE[2], *A. J. BETZ[2], E. EMERY[2];
[1]Mol. and Cell Biol., [2]Psychology, Quinnipiac Univ., Hamden, CT

Abstract: Benzyl Butyl Phthalate (BBP) is an industrial plasticizer that has an unknown action in the central nervous system. Phthalates have recently been associated with behavioral actions that are linked to their endocrine disrupting properties. The purpose of this study was to investigate the behavioral and molecular effects of neonatal exposure to BBP. We administered BBP (2.5 and 10.0 μg/ml) in sweetened food pellets to pregnant rats until post natal day 23 until pups were weaned. We found increased serum levels of 17β-Estradiol in male offspring at PND63 suggesting BBP can invoke changes in the endocrine system. There was a significant

decrease in brain weights suggesting processes regulating brain development and function such as synaptic plasticity, neuronal growth and organizing the neural circuit are influenced by the deleterious effects phthalate exposure. Lastly, animals showed decreased freezing in tests of fear conditioning and no gross motor changes. Additionally, we found BBP altered protein levels of synaptic plasticity markers such as estrogen alpha receptors, MeCP2, UBEA3, VGLUT, and gephyrin in the amygdala, distinct hippocampal compartments and the prefrontal cortex. In a separate study, anogenital distance, a hormonally sensitive developmental measure, was decreased in both male and female offspring at PND23. Lastly, embryonic primary cortical neurons were exposed to BBP in concentration of 10nM and1000nM and immunolabled. BBP exposure in these cells altered synaptic development and the amount of inhibitory synapses. We suggest that BBP administration disrupts normal learning and social behavior, and that these effects could be related to alterations in brain development and could result in a phenotype similar to what is observed in autism spectrum disorders. These findings indicate a compelling need for evaluation of acceptable levels of exposure to phthalates present in the environment.

Abstract: Benzyl butyl phthalate (BBP) is a widely used industrial plasticizer which, if ingested, appears to have endocrine disrupting properties and may have deleterious consequences on the developing nervous system. In the present study, pregnant Sprague-Dawley rats were fed sweetened food pellets containing 10ug/ml of BBP. This dose was continued up until post-natal day 23 at which time the rat pups were sacrificed. Pregnant control rats received sweetened food

pellets with no BBP. All brains were fixed in 10% neutral buffered formalin. Coronal blocks incorporating the parietal cortex and underlying hippocampus of 4 BBP-treated and 4 control 23 day-old male rats were Golgi stained. From coded slides camera lucida drawings of randomly selected granule cells of the dentate gyrus were prepared and evaluated for extent, complexity, and distribution of the dendritic arbor. Granule cell morphology was largely unaffected by this pre-weaning BBP exposure. Layer V pyramids, conversely, were significantly impacted by BBP. Analysis of the basilar dendritic tree showed that the BBP-exposed pups had significantly larger and more complex dendritic trees of the cortical pyramids. Dendritic spine density on the layer V pyramids was not significantly altered, but greater branching indicates that there was an overall increased synaptic presence in the layer V basilar tree. The present findings suggest that pre-weaning BBP exposure - e.g., during the period of the rodent brain growth spurt - may contribute to either additional cortical dendritic growth or diminished dendritic pruning in the course of the maturation of cortical circuits. Additional studies will determine if this is a transient or long-lasting phenomena, and if additional cell populations are also at risk from BBP exposure. Regardless, there is now evidence that environmental BBP may have deleterious consequences on neuronal development which could influence brain circuitry and, ultimately, behavior.

Title: Prostaglandin E2 alters the differentiation of neuroectodermal stem cells

Authors: *C. WONG[1], H. LI[1], D. A. CRAWFORD[1,2];
[1]Kinesiology and Hlth. Sci., [2]Biol., York Univ., Toronto, ON, Canada

Abstract: Background: The naturally occurring prostaglandin E_2 (PGE_2) is a bioactive lipid derived from membrane phospholipids that acts as a signalling molecule, mediating

physiological processes in early neuronal development including the neuroimmunological response and synaptic plasticity. Abnormalities in the PGE_2 signalling pathway have been linked to the neuropathology of autism. We previously showed that PGE_2 can increase the amplitude of calcium transients in growth cones of Neuro-2a cells and reduce neurite outgrowth. Studies in various non-neuronal cells have found that PGE_2 can alter cell growth, migration, and adhesion. However, the effect of PGE_2 on neuronal cell motility in the developing nervous system is poorly understood.

Objective: The goal of this study is to investigate the effect of PGE_2 on neural stem cell movement. We examined the effects PGE_2 has on the behaviour of mouse neuroectodermal stem cells (NE-4C) and its differentiation into neurons.

Methods: NE-4C stem cells were differentiated into neurons via a serum-free media protocol containing vehicle, 0.1μM, or 1μM PGE_2. Time-lapse microscopy was used to collect images over a 6-8 day differentiation period. Cell migration (final distance from original, path length, and average speed), proliferation, and the formation of neurosphere were quantified. Quantitative RT-PCR was used to measure expression of EP receptors and developmental target genes.

Results: Our study shows that undifferentiated NE-4C stem cells express all EP receptors and upon differentiation into neurons, the expression profile changes significantly. We established that *in vitro* NE-4C cells normally undergo distinct stages of differentiation that are time-specific, including proliferation followed by inward migration and aggregation, neurosphere formation, and lastly, outward migration and neurite extension. 0.1μM and 1μM PGE_2 treatment alters these stages of differentiation by varying aggregation timelines and neurosphere characteristics (i.e. size and quantity).

Conclusions: Our *in vitro* results show that PGE_2 modifies the progression of NE-4C stem cell differentiation suggesting that elevation of PGE_2 during critical periods of early neuronal development may contribute to pathologies of the central nervous system.

Title: Prenatal domoic acid exposure as an animal model of autism: Selective disruption of male pro-social behavior

Authors: *B. D. MILLS, H. PEARCE, J. TURNER, D. ZULOAGA, J. RABER, G. LAHVIS; Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Domoic acid (DA) is an algal neurotoxin that accumulates in marine fish and shellfish. When consumed DA can cause memory loss, seizures, and death. DA is hydrophilic and thus rapidly excreted so traditional epidemiology studies examining the effects of prenatal exposure cannot be employed. Although limits on DA have been imposed, rodent experiments suggest that these limits do not protect an exposed fetus or infant from subsequent impairments. Further, animal models reveal that the effects of exposure to DA bear a striking resemblance to the repetitive behaviors, social behaviors, and neuropathology of autism spectrum disorder (ASD). These similarities, combined with indications that high prevalence of ASD has been reported for coastal communities adjacent to marine environments with DA, call for further study of the effects of exposure to this algal toxin that is transiently present in our food supply. The current study examines the effects of 1.5 mg/kg DA injected into pregnant dams at E15. In order to examine the interaction between genes and behavior, two mouse strains with differing baseline levels of social behavior and seizure susceptibility were examined (FVB and B6). After 24 hours of isolation, pups were allowed to interact with a same sex litter mate where social interaction (SI) and ultrasonic vocalizations (USV) were measured. These tests were administered at PD25 and PD35. Both human studies and animal models of autism report deficits in sensorimotor gating. In order to examine the effect of DA on sensory gating, mice were tested for potential alterations in pre-pulse inhibition (PPI).
As expected, FVB mice had greater SI scores and concurrent USVs than did B6 mice. However, despite these strain differences the effects of DA on SI and USVs were comparable. Across strains, we found that mice prenatally exposed to DA had less social interaction ($p < .01$) and fewer USVs ($p < .01$) than mice prenatally exposed to saline. A sex by group interaction ($p < .01$) revealed that the main effect of social interaction could be attributed to a decrease in social interaction in male mice exposed to DA. No sex by group interaction was found for USVs showing that unlike social interaction deficits, USV deficits extend to both male and female mice exposed to DA. Unlike the effects of DA on SI and USVs, genetic background and sex-dependent effects modulated DA-induced PPI deficits. DA-exposed male FVB mice and female B6 mice showed PPI deficits. Overall, we show that prenatal exposure to DA leads to deficits in SI, USVs, and PPI, that social measures affect males more than females and that DA may have differential effects depending on genetic susceptibility.

Title: Effects of prostaglandin-E2 on expression of wnt-target genes during critical period of mouse brain development

Authors: *R. BHOGAL[1], C. WONG[2], H. LI[2], D. CRAWFORD[1,2];
[1]Biol., [2]Kinesiology, York Univ., Toronto, ON, Canada

Abstract: Background: Recent evidence suggests that defects in lipid signalling pathways contribute to the pathology of autism spectrum disorder (ASD). The plasma membrane phospholipids serve as a supply of bioactive molecules such as prostaglandin E2 (PGE2) which are important for normal function of the brain. Abnormalities in lipid metabolism that alter the level of PGE2 have been linked to ASD, but the molecular mechanisms are not well understood. We have previously shown that PGE2 increases the amplitude of calcium transients in growth cone of Neuro-2a cells and induces neurite retraction. Previous studies have also shown a cooperative regulation of PGE2 signalling with developmental signalling pathways such as wingless (wnt) in non-neuronal cells.
Objectives: Our current study aims to investigate the molecular mechanisms of PGE2 interaction with the wnt signalling pathway in the developing mouse brain.
Methods: Wild-type mice (C57BL/6) were administered subcutaneously with dimethyl-Prostaglandin E2 (dmPGE2) during the critical period of development (embryonic day 11, E11). mRNA was isolated from brain tissues at two prenatal stages (E16 and E19), and one postnatal stage (day 8 after birth, P8), and investigated for quantitative expression of wnt-target genes using Custom taqman gene expression assay and confirmed with real-time PCR using SYBR Green.
Results: Following maternal exposure of PGE2, individual embryos from the litter showed significant differences in the expression of three genes: mmp7 (matrix metalloproteinase-7, involved in synapse structure and function), wnt2 (involved in neurogenesis) and Fosl1 (Fos-like antigen-1, involved in cell proliferation and differentiation). Our results show that at E16, there is a pattern of increased expression of mmp7, and decreased expression of wnt2, and at E19, a pattern of decreased expression of mmp7, and increased expression of wnt2. We also found that in normal mouse development, the expression of mmp7 and wnt2 decreases or increases throughout normal brain, respectively.
Conclusion: In this study, we found that an increase of PGE2 level during early brain development caused changes in expression levels of crucial wnt-regulated neurodevelopmental genes including mmp7, wnt2 and fosl1. Interestingly, previous findings show that mmp7 can activate mmp9, which has been found to be associated with ASD. Wnt2 is also emerging as an

autism susceptibility gene, and may play a role in language development in ASD. In summary, this in vivo study provides molecular evidence that PGE2 can alter gene expression during early development and possibly contribute to brain pathologies associated with ASD.

Title: Development of a versatile enrichment analysis tool reveals associations between the maternal brain and mental health disorders, including autism

Authors: *B. E. EISINGER, M. C. SAUL, T. M. DRIESSEN, S. C. GAMMIE;
Zoology, Univ. of Wisconsin-Madison, Madison, WI

Abstract: In large scale gene expression studies, enrichment of disease/disorder associated gene sets is not commonly performed. Few currently available enrichment programs support this functionality, and those that do rely on a very restricted number of mainstream disease ontologies. To make enrichment analysis possible using the existing landscape of deep and varied genetic health databases, we have developed the Modular Single-set Enrichment Test (MSET). MSET is a minimal, user friendly permutation testing script that enables researchers to assess enrichment of any conceivable gene list of interest within expression results. Using nine independently curated, unique autism gene lists extracted from gene-disease databases and recent publications, a striking consensus of enrichment was detected within gene changes measured in the lateral septum (LS) of outbred postpartum mice compared to virgin. The maternal brain has translational value to behavioral disorders such as autism because both phenomena involve dramatic changes in sociability, reactivity to fear and anxiety, and affective state. A network of 160 genes identified by MSET with links to both motherhood and autism was functionally profiled, revealing that it primarily represents developmental processes such as synaptic plasticity, neuronal morphogenesis, and differentiation. In addition to autism, the maternal LS also exhibited enrichment for genes associated with bipolar disorder, schizophrenia, ADHD, and depression. Collectively, these findings suggest that plasticity of the adult brain shapes the maternal phenotype and may form the basis of sociability in natural contexts and conditions of dysregulation. The MSET approach was validated by evaluating enrichment for a battery of

twenty-nine gene lists spanning five high profile mental health disorders and one control disease (arthritis) within three sets of expression data publicly available through NCBI's Gene Expression Omnibus. It was shown that the T-box brain protein (Tbr1) knockout mouse is a promising model for autism genetics, and that methylphenidate (Ritalin) treatment specifically affects ADHD associated genes in mice. Expression data from a murine arthritis model were also analyzed, and showed high enrichment for multiple independent arthritis gene sets.

Title: Opposing effects on structural brain volumes and cortical thickness in 16p11.2 deletion and duplication carriers

Authors: *A. Y. QURESHI[1], S. MUELLER[1], A. Z. SNYDER[2], J. P. OWEN[3], W. K. CHUNG[4], E. H. SHERR[3], R. L. BUCKNER[1,5], .. AND THE SIMONS VIP CONSORTIUM[6];
[1]Harvard Univ., Cambridge, MA; [2]Washington Univ. in St. Louis, St. Louis, MO; [3]Univ. of California, San Fancisco, San Francisco, CA; [4]Columbia Univ., New York, NY; [5]Mass Gen Hosp., Boston, MA; [6]Simons Fndn., New York, NY

Abstract: Rare genetic copy number variations (CNVs) contribute to neurodevelopmental disorders including autism. Here we explored the influence of the recurrent ≈ 600 kb (BP4-BP5) 16p11.2 deletion and duplication in a large cohort of individuals enrolled as part of the Simons VIP Project (Simons VIP Consortium, Neuron 2012 73: 1063-1067). Participants and controls were scanned at 3T on matched scanners at one of two locations (UCSF and CHOP). Morphometric estimates were computed using Freesurfer software implemented with a custom atlas representing the anatomy of the target cohorts. Test-retest reliability for whole brain gray matter volume, surface area, and estimated intracranial volume (eTIV) exceeded r = 0.97 for individuals scanned on multiple occasions between the two sites. Cortical thickness and most subcortical structures showed reliability ~ r = 0.80. Comparison of children (ages 8 to 16) with 16p11.2 deletions (n=22) and matched controls (n=26) yielded a consistent pattern of enlarged brain volumes. Deletion of 16p11.2 was associated with significantly enlarged eTIV, increased

gray matter volume, increased cortical thickness , and increased volume in multiple subcortical structures (e.g., amygdala and hippocampus). In contrast, in adults (ages 25 to 63) duplication of 16p11.2 (n=16) was associated with opposing effects when compared to their age-matched controls (n=32). eTIV, gray matter, cortical thickness, and subcortical volumes were all significantly reduced. To understand whether the opposing effects of deletion and duplication were due to gene dosage or the age difference, allometric scaling lines were plotted to compare eTIV (which is fixed at a young age) against brain volumes (which display longitudinal change with age). The plots were well behaved and consistent with the genetic effects having influences on brain structure that were independent of age. These results suggest that the 16p11.2 CNV has distinct, opposing effects dependent on copy number. The observation that the effects generalize across multiple cortical and subcortical structures further suggests the effect's mechanism may stem from a central developmental process that is pervasive throughout the brain.

Title: White matter microstructure in children with 16p11.2 deletions

Authors: J. P. OWEN[1], P. BUKSHPUN[1], N. POJMAN[1], T. THIEU[1], W. CHUNG[3], E. H. SHERR[1], *P. MUKHERJEE[2], .. FOR THE SIMONS VIP CONSORTIUM[4];
[1]Univ. of California - San Francisco, San Francisco, CA; [2]Professor of Radiology & Bioengineering, Univ. of California - San Francisco, SAN FRANCISCO, CA; [3]Columbia Univ., New York, NY; [4]Simons Fndn., New York, NY

Abstract: Rare genetic copy number variations (CNVs) contribute to neurodevelopmental disorders including autism. Here we explored the influence of the recurrent ≈600 kb(BP4-BP5) 16p11.2 deletion in a large cohort of children (ages 8-16 years) enrolled as part of the Simons VIP Project [1]. We used diffusion tensor imaging (DTI) to assess changes in white matter (WM) microstructure associated with this CNV.
3T DTI of 19 child probands with 16p11.2 deletions (mean age 12.0±2.2, 10 females) and 19

controls matched for age and gender (mean age 12.7±2.5, 10 females) was acquired with 2-mm isotropic voxels and 30 directions at b=1000 s/mm^2. FSL was used to calculate fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD) and radial diffusivity (RD). Nonparametric permutation testing with tract based spatial statistics (TBSS) was used to detect group differences in whole brain WM ($p<0.05$), corrected for multiple comparisons with threshold-free cluster enhancement [2].

Widespread increases in FA and AD of children with 16p11.2 deletions compared to their matched controls were detected in the genu and body of the corpus callosum, bilateral anterior and posterior corona radiata, bilateral forceps minor, bilateral forceps major, and bilateral corticospinal tracts. MD was also increased in all these areas except for the corpus callosum (Figure).

To our knowledge, this is the first demonstration of altered WM microstructure associated with 16p11.2 deletions. Abnormally reduced FA is found in many disorders; however, abnormally elevated FA is rare. One recent example, although with much less spatial extent of increased anisotropy, is Williams syndrome [3]. Correlation with animal models of these CNVs might elucidate how genes at the 16p11.2 locus govern WM microstructure. This work also motivates further research into how these gene-brain relationships affect behavior and cognitive abilities in individuals with 16p11.2 deletions.

Title: Phenotypic variation in mouse autism models for delay eyeblink conditioning, a form of cerebellar multisensory learning

Authors: *A. D. KLOTH[1,2], L. A. LYNCH[1,2], A. LI[1,2], R. D. JONES[2], S. G. CONNOLLY[2], M. A. BANGASH[3], O. PEÑAGARIKANO[4], P. F. WORLEY[3], D. H. GESCHWIND[4], S. S.-H. WANG[1,2];

Abstract: Persons with ASD are highly variable in their behavioral phenotype. We tested two mouse autism models for variability in delay eyeblink conditioning, a form of multisensory associative learning that requires the cerebellum. This behavior is of particular interest because (1) it is well suited to quantification and neurophysiology in head-fixed mice, (2) in humans, cerebellar injury at birth increases the risk of ASD by ~30-fold, and (3) eyeblink conditioning shows defects in both syndromic and nonsyndromic ASD (Sears et al. 1994 J Aut Dev Disord 24:737; Tobia & Woodruff-Pak 2009 Behav Neurosci 123:665).
To quantify eyeblink responses we developed a quantal analysis method. Eyelid movement amplitudes were histogrammed and separated into nonresponding and responding trials to define conditioned response (CR) probability (cf. “reliability” in synaptic plasticity literature; O’Connor, Wittenberg, & Wang 2007 Synapse 61:664) and the average response amplitude (cf. “potency”). We applied this analysis to two validated ASD models of genes highly expressed in cerebellum: the Shank3ΔC mutation (Phelan-McDermid syndrome) and the knockout of the mouse ortholog of CNTNAP2. Over 12 days of training (1 session/day), we recorded the response for each presentation of a neutral stimulus (LED flash) and a corneal airpuff.

Both Shank3(+/ΔC) and Cntnap2-/- mice and littermate wild-type controls began to generate CRs in the third training sessions. However, Shank3(+/ΔC) and Cntnap2-/- showed lower response probability at the end of training. Furthermore, CRs showed timing defects including earlier peaks and faster rise times (Kloth et al. 2012 Soc Neurosci Abstr). Blink amplitude, extinction, and reacquisition were unaltered. Both mutants showed greater variation in CR probability (coefficient of variation, CV, for Shank3(+/ΔC) = 0.28, n=14; Cntnap2-/- CV=0.61, n = 11; combined wild-type CV = 0.17, n=25). This finding suggests that within-strain genetic variation and/or environmental influences are likely to drive phenotypic variation in cerebellar developmental outcomes.

Title: Maternal valproic acid treatments induce aberrant pattern of corticostriatal system in an animal model of autism spectrum disorders

Authors: *H.-Y. KUO, F.-C. LIU;
Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Autism spectrum disorders (ASDs) are severe, heterogeneous, neurodevelopmental disorder with high prevalence around 1 in 88 individuals who share the common triad of clinical features including social impairments, communication deficits and stereotypic behaviors. Maternal valproic acid (VPA)-treated mice developed ASD-like behaviors, including social impairments and stereotypic behaviors. In the present study, we examined the effects of maternal VPA injection in the corticostriatal system with respect to the striosome-matrix compartmentation in the striatum. We found that maternal VPA injection in the time window of neurogenesis of striosomal cells resulted in reduction of mu-opioid receptor 1 (MOR1)-positive striosomes without significant changes of the calbindin-positive matrix in postnatal day (P) 14 striatum. The reduction of MOR1-positive striosomes might be due to decreases of MOR1 expression in striosomal cells. To test this possibility, we performed Western blotting. The results showed that the MOR1 protein levels were comparable between vehicle and VPA-treated striatum. Alternatively, the decreases of MOR1-positive striosomes might be resulted from failure in aggregation of striosomal cells into patches. We tested this hypothesis by pulse-labeling striosomal cells with 5-bromo-2'-deoxyuridine (BrdU), and found that unlike clusters of BrdU-labeled cells in the vehicle-treated striatum, BrdU-labeled cells tended to be scattered in the VPA-treated striatum, suggesting a defective migration of striosomal cells. Because cortical cells in deep layers share neurogenesis time windows with striosomal cells and project their axons preferentially to striosomes, we also examined the maternal VPA-treated cortex. In vehicle-treated cortex, Foxp2-positive cells were restricted to layer VI. In VPA-treated cortex, some Foxp2-positive cells were ectopically located in ER81-positive layer V. Taken together, our study indicates that maternal VPA treatments results in defective neural development of the corticostriatal system in the basal ganglia, which may underlie parts of the pathogenesis of ASDs.

Title: DTI and HARDI measures of anomalous auditory and language system microstructure in 16p11 deletions

Authors: *J. I. BERMAN[1,3], M. R. LANZA[2], W. CHUNG[4], T. P. L. ROBERTS[1,3], .. SIMONS VIP CONSORTIUM[5];
[2]Radiology, [1]Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Radiology, Univ. of Pennsylvania, Philadelphia, PA; [4]Columbia Univ., New York City, NY; [5]Simons Fndn., New York City, NY

Abstract: Rare genetic copy number variations (CNVs) contribute to neurodevelopmental disorders including autism. Here we explored the influence of the recurrent 16p11.2 deletion in a large cohort of children (ages 8-16 years) enrolled as part of the Simons VIP Project (Simons VIP Consortium, Neuron 2012 73: 1063-1067). Deletion of a segment of chromosome 16 at location p11.2 has been associated with developmental disorders such as dysfunctions in language, mild to moderate intellectual disability, and autism spectrum disorders (ASD). Diffusion MR is sensitive to white matter architecture and has been previously used to detect white matter abnormalities in associated with neuropsychiatric disorders. This study uses diffusion tensor imaging (DTI) and high angular resolution diffusion imaging (DTI) to quantify alterations to the auditory and language pathways in 16p11.2 deletion.
This study included 26 healthy control (HC) children (13 male, mean age 12.1 ± 2.5 years) and 19 children (11 male, mean age 11.2 ± 2.2 yrs) with deletion of 16p11.2. Groups did not differ significantly in age or gender. MRI was performed at 3T and included a 30 diffusion gradient direction DTI and a 64 direction HARDI. DTI fiber tracking was used to identify the arcuate fasciculus (AF) and HARDI fiber tracking was used to delineate the auditory radiation. A Heschl's gyrus region of interest was identified with the Freesurfer parcellation. Voxels containing fiber tracks were used to measure tract-specific DTI parameters including fractional anisotropy (FA), mean diffusivity (MD), parallel diffusivity, and transverse diffusivity. The HARDI derived generalized fractional anisotropy (GFA) was measured in the complex white matter of the auditory radiation.
Changes in white matter microstructure were observed within the auditory and language systems. The arcuate fasciculus of deletion carriers exhibited significantly higher transverse diffusivity ($p<0.05$) and a trend toward higher mean diffusivity ($p=0.08$). The deletion group exhibited a trend toward higher mean diffusivity ($p=0.052$) in the auditory radiation. The Heschl's gyrus region contained lower FA ($p<0.01$) and higher transverse diffusivity ($p<0.02$)
The changes in diffusivity are similar to that observed in developmental disorders, particularly ASD. The present findings implicate aberrancy in WM microstructure of auditory regions in developmental and language disorders. Quantitative assessment of functionally specific regions with diffusion MR will allow us to correlate white matter microstructure with findings from electrophysical auditory and language measures (MEG) and neuropsychiatric testing.

Abstract: Rare genetic copy number variations (CNVs), specifically the recurrent ≈600 kb (BP4-BP5) 16p11.2 deletion and duplication, are known to contribute to a range of neurodevelopmental disorders, including autism. Here, we examined changes in oscillatory activity derived from magnetoencephalographic imaging (MEG-I) generated during a picture naming task in a large cohort of individuals recruited as part of the Simons VIP project (Simons VIP Consortium, Neuron 2013 73:1063-1067). We hypothesize that gene dosage in this interval is critical for the specialization of language in the left hemisphere, and that those with deletion or duplication of this locus will not develop this hemispheric dominance.
Data were acquired using 275-channel whole-head biomagnetometers (MISL; Vancouver, BC) installed at both UCSF and CHOP. During MEG recording, participants engaged in a picture naming task where an image appeared at fixation on a screen in front of the subject at the beginning of each trial (duration=1000ms), prompting the subject to respond by providing a name for the object and speaking into an optical microphone placed in front of the subject. Tomographic reconstructions of oscillatory activity across the alpha, beta, gamma and high-gamma frequency bands were locked to response onset (vocalization=0ms) and generated using an adaptive spatial filtering technique implemented in Nutmeg (nutmeg.berkeley.edu). In order to compute laterality index (LI), oscillatory activity was extracted from a pair of ROIs (frontal-temporal, temporal-parietal) in and contrasted between the left and right hemispheres.
Typically developing adults (mean age = 40.3) and children (mean age = 11.8) exhibited left-

hemisphere dominance during picture naming (LI>0.1 in 62% adults and 58% children). In contrast, in 16p11.2 child deletion carriers, 55% were right-hemispheric dominant, and 36% exhibited bilateral patterns of activity during picture naming (LI > -0.1 and < 0.1). Interestingly, in 16p11.2 adult duplication carriers only 36% were right-hemispheric dominant (LI<-0.1). A comparison between control children and 16p11.2 child deletions, LI was significantly lower in the 16p11.2 deletion group ($p<0.01$). These findings indicate that gene dosage at 16p11.2 is important for the hemispheric specialization of language.

Abstract: Rare genetic copy number variations (CNVs) contribute to neurodevelopmental disorders, including autism (Weiss et al, 2008). We explored the influence of the recurrent ≈600 kb (BP4-BP5) 16p11.2 deletion and duplication on neural function as part of a large cohort of individuals enrolled in the Simons VIP Project (Simons VIP Consortium, Neuron 2012 73: 1063-1067). Neural activity was recorded in participants with deletion or duplication of the 16p11.2 CNV and control participants matched on age, handedness and IQ using whole-head magnetoencephalography (MEG), coregistered to individual cortical anatomy. Participants performed two discrimination tasks in the auditory and visual domain: classifying spoken words

as living or non-living and visually differentiating between face and non-face stimuli. Cortical localization of induced neural oscillations was performed using adaptive spatial filtering techniques (Dalal et al, 2011) and non-parametric statistical analyses used to compare activations between matched groups, with corrections for multiple comparisons (Singh et al 2003). During the auditory task, decreased high gamma activity (63-117 Hz) was observed in bilateral auditory cortex for 16p11.2 deletion participants relative to their control group at 100 ms post-stimulus onset. Analysis of face-specific activations revealed decreased early gamma activity (30-55 Hz) in Right Fusiform for participants with 16p11.2 deletions, as well as later decreased activity in bilateral Lingual and Middle Occipital Gyri. Analysis of evoked, broadband activity to all visual stimuli revealed deletion participants with significantly longer latencies of peak response than typically observed at 170ms following stimulus onset, as well as greater amplitude of the visual evoked field. In contrast to the patterns observed in the deletion group, duplication participants showed elevated high gamma activity of auditory cortex at 100 ms post-auditory stimulus onset, and increased late gamma band activity of Right Fusiform to face stimuli, relative to their age-matched controls. Measures of visual evoked fields in duplication participants did not differ from their age-matched controls. These results suggest pervasive abnormalities in neural oscillations induced by sensory stimuli in multiple sensory systems in participants with 16p11.2 deletions.

Title: Abnormal erk signaling in 16p11.2 copy number variation

Authors: *E. H. SHERR[1,2], A. FARIDAR[1], B. FREGEAU[1], P. BUKSHPUN[1], N. POJMAN[1], T. THIEU[1], .. THE SIMONS VIP CONSORTIUM[2];
[1]Dept Neurol, UCSF, SAN FRANCISCO, CA; [2]Simons Fndn., New York, NY

Abstract: Recurrent deletion or duplication of a ≈600 kb (BP4-BP5) 16p11.2 interval is the most common chromosomal change associated with autism. There is also evidence that dysregulation of the MAPK/ERK pathway may regulate the social deficits of autism. This locus not only contains the gene MAPK3 (ERK1), but also the gene MVP (major vault protein), a critical regulator of MAPK/ERK pathway. In this study, we evaluated whether alteration of the MAPK/ERK pathway correlates with gene dosage at the 16p11.2 locus. In patients with deletion at 16p11.2 locus, the degree of phosphorylation of ERK1/2(p-ERK1/2), as observed in freshly isolated peripheral blood mononuclear cells (PBMC), was significantly increased in comparison to controls (p-ERK/ERK: $p<0.0001$), despite the observation that protein levels for ERK1/2 were significantly decreased compared to controls ($p=0.0009$). In contrast, we found that in 16p11.2 duplication patients that the degree of p-ERK1/2 was decreased compared to controls (p-ERK/ERK: $p=0.02$). Given the prior hypothesized role for MVP in regulating ERK, tested this directly in 16p11.2 patients. We compared total MVP levels in patient cells to measures of cognitive performance, observing a statistically significant correlation between FSIQ and SRS scores and MVP protein levels ($R2=0.52$, $p=0.0016$ and $R2=0.71$ $p=0.0005$). To evaluate the role of MVP more directly in this pathway, we tested both total ERK protein levels and the degree of ERK phosphorylation in response to altering MVP levels in a cell line. We first demonstrated that we could suppress MVP translation through transient transfection of MVP siRNA into human fibroblasts. We then showed that this suppression resulted in an increase in ERK phosphorylation, without affecting total ERK protein levels. These findings demonstrate that the MAPK/ERK pathway is dysregulated in ways that are the reverse of what would be expected by gene dosage of a MAP kinase, but rather may be explained by MVP levels, secondarily regulating ERK activity. Whether these biochemical findings explain the altered behavior in these patients is subject to ongoing investigation.

Title: Auditory cortex speech sound processing impairments in a rat model of autism

Authors: *C. T. ENGINEER, T. M. CENTANNI, K. W. IM, N. A. MORENO, W. A. VRANA, M. S. BORLAND, R. S. CARRAWAY, J. A. SHETAKE, K. G. RANASINGHE, J. R. RILEY, J. D. SEALE, L. G. WILSON, M. P. KILGARD;

Abstract: Although individuals with autism are known to have significant communication problems, the neural mechanisms responsible for impaired communication are poorly understood. This study documents speech sound coding in the valproic acid (VPA) animal model of autism, and quantifies the beneficial effects of a common autism therapy, auditory training. Valproic acid is an anticonvulsant that is a known risk factor for autism in children who are prenatally exposed to it. Prenatal exposure to VPA in rats causes symptoms that mimic autism. Multiunit responses to speech sounds were collected from primary auditory cortex, anterior auditory field, ventral auditory field, and posterior auditory field in VPA exposed and control rats. Speech sounds evoke precise spatiotemporal activity patterns in the auditory cortex of control rats. Our results indicate that in utero VPA exposure severely degrades the precise spatiotemporal patterns evoked by speech sounds in anterior auditory field and ventral auditory field, but not primary auditory cortex or posterior auditory field. We next tested the hypothesis that speech sound discrimination would be impaired in VPA exposed rats. Groups of VPA exposed and control rats were trained to discriminate consonants, vowels, and tones, and were tested on their ability to generalize to novel sounds. VPA exposed rats are impaired in their ability to discriminate between some consonant sounds. Multiunit responses to speech sounds were then collected from auditory cortex of VPA exposed rats that were speech trained. Our preliminary results indicate that training enhances both speech discrimination ability and anterior auditory field responses to speech sounds. Insights derived from these studies may influence the development of new behavioral and sensory techniques to treat the communication impairments in autism that result in part from a degraded representation of speech sounds.

Title: Electrophysiologic and structural markers of language impairment are seen in a genetic condition with high risk of autism spectrum disorders (ASD)

Authors: *T. P. ROBERTS[1], J. JENKINS[1], V. CHOW[1], K. HEIKEN[1], M. LANZA[1], W. CHUNG[2], J. I. BERMAN[1], .. SIMONS VIP CONSORTIUM[3];

Abstract: Introduction
Rare genetic copy number variations (CNVs) contribute to neurodevelopmental disorders including autism. Here we explored the influence of the recurrent ≈600 kb(BP4-BP5) 16p11.2 deletion in a large cohort of children (ages 8-16 years) enrolled as part of the Simons VIP Project. Deletion of this segment is known to be associated with dysfunctions such as language impairment, and diagnosis of autism spectrum disorder. Previous studies using magnetoencephalography (MEG) have demonstrated delays in early auditory evoked response components (M100 and mismatch field); Diffusion tensor MRI studies have shown abnormal microstructure in white matter language pathways with the magnitude of the difference correlating with language impairment severity.
Methods
In this study we used auditory MEG and DTI in a cohort of 21 children with 16p11.2 deletions and 28 typically developing control subjects. Stimuli included sinusoidal tones to elicit M100 responses and oddball presentation of vowels to elicit MMF. DTI was performed using a Siemens 3T Verio™ system with 2mm isotropic resolution. Reconstruction of the arcuate fasciculus was performed as described in Nagae et al. 2012, using the FACT algorithm. Dependent variables were the M100 latency, MMF latency and Mean Diffusivity (MD) of the left hemisphere arcuate fasciculus.
Results
M100 delays were observed for tones of all frequencies and in both hemispheres. As in ASD, effects were most pronounced for right hemisphere responses to tones of 300Hz and 500Hz. On average a delay of 6.1ms (128.1+/-4.9 vs. 122.0+/-4.3ms) was observed in the 16p11.2 deletion cohort (approximately 50% of the delay seen in idiopathic ASD). MMF latencies were delayed 11.2ms (214.6+/-8.2 vs 203.4+/-6.6ms), again only a fraction of the effect seen (20-50ms) in ASD. Left hemisphere arcuate fasciculus MD showed elevation in 16p11.2 deletion (0.745+/-.004x10-3mm2/s vs 0.737+/-.004mm2/s) analogous to previous findings in ASD.
Conclusion
In conclusion both auditory electrophysiologic signatures and microstructural markers from DTI show abnormalities in the 16p11.2 deletion cohort that are in the same direction as those observed in idiopathic ASD, but typically approximately 50% of the magnitude. We conclude

that either 16p11.2 deletion conveys part (but not all) of the brain-level phenotype of ASD, or that this population is divided into an ASD-like cohort and a non-ASD-like cohort, with concomitant population effect reduction through averaging. Such signatures might in future form a basis for reducing such population heterogeneity.

Title: Neural correlates of language development in infants at risk for autism and infants with cranial deformities

Authors: *P. HASHIM, M. COFFMAN, C. MUKERJI, R. TILLMAN, A. NAPLES, G. RIGHI, J. TERNER, R. TRAVIESO, D. STEINBACHER, L. MAYES, J. A. PERSING, J. MCPARTLAND;
Yale Univ. Sch. of Med., New Haven, CT

Abstract: Background:
Language delay and difficulties in communication are characteristic features of autism spectrum disorder. Atypical lateralization of neurophysiological responses to language emerge between 6 and 12 months in high-risk infants. It remains unclear whether this atypical lateralization marks a perturbation specific to autism or a general disruption in development. Comparisons to other clinical groups are essential for establishing specificity as a biomarker for autism. Non-syndromic craniosynosyosis (NSC) is a congenital craniofacial condition also associated with language delay. Despite shared deficits, there has been no previous study comparing atypical neural development in autism and NSC.
Objective:
Our goal was to contrast electrophysiological signatures of language processing in infants at high risk for autism, infants with NSC, and infants at normal risk for autism. We compared two hypotheses: If atypically lateralized event related potentials (ERPs) to language (1) are a biomarker of autism, then only high risk infants will display the atypical response; (2) reflect general disruption of brain development, then both infants with NSC and those at high risk for autism will demonstrate atypical neural response to speech.
Methods:
The study included three groups of infants under 12 months: infants at high-risk for autism by virtue of having a sibling diagnosed with the disorder, infants with NSC, and normal-risk controls. ERPs were recorded with a 128 channel HydroCel Geodesic Sensor Net during auditory presentations of native and non-native phonemes. ERP analysis contrasted amplitudes recorded over the right and left frontal scalp to evaluate hemispheric lateralization of neural response to speech, a marker of normative language development.
Results:
Preliminary analyses focused on response to the native phoneme between the three groups at an initial positive inflection (P150). Paired samples t-test revealed hemispheric lateralization over the P150 in infants at normal risk for autism ($p = 0.043$) but not in infants at high risk for autism ($p = 0.43$) or NSC ($p = 0.33$). Ongoing analyses compare neural responses to the non-native phoneme between the three groups.
Conclusions:
This study is the first to utilize a clinical control group in order to examine the specificity of atypical ERPs to language in infants at high risk for autism. We identified atypical patterns of hemispheric lateralization of neural response to speech in both high-risk infants as well as those with NSC. These shared patterns suggest that atypical ERP responses to language may reflect a general disruption of brain development rather than a specific biomarker of autism.

Title: A new computational approach, µGWAS, identifies a novel drug target for Autism

Authors: *B. BIGIO[1], V. SONAKYA[1], M. K. TONN[3], C. NASCA[2,4], K. M. WITTKOWSKI[1]; [1]Ctr. for Clin. & Translational Sci., [2]Neuroendocrinology, The Rockefeller Univ., New York, NY; [3]RheinAhrCampus, Remagen, Germany; [4]Physiol. and Pharmacol., Univ. of Rome, Sapienza, Rome, Italy

Abstract: Autistic Spectrum Disorders (ASDs) are childhood neurodevelopment diseases with complex genetic profiles and significant lifetime neuropsychiatric comorbidity. So far, there have been no major breakthroughs in uncovering a consistent map of susceptibility loci that would pave the way in understanding ASD etiology as well as in promoting appropriate medications and behavioral therapies to prevent a genetic predisposition from becoming disease. Genome wide association analysis (GWAS) based on currently used statistical approaches require thousands of subjects and produce ambiguous results when applied to heterogeneous diseases as ASD. We extended u-statistics for multivariate data from structures among phenotype characteristics to expected linkage disequilibrium (LD) from HapMap and the spatial structure of single-nucleotide polymorphisms (SNP) within an LD block. By incorporating information about the neighborhood structure of SNPs and from HapMap about their expected LD, the novel µGWAS computational biostatistic approach increases the power of GWAS, avoids unrealistic assumptions (independence and additivity of risk factors) and reduces false positives. Applying µGWAS to childhood absence epilepsy (CAE), we identified genetic variations in Ras/Ca2+ pathways as major risk factors, consistent with a Ca2+ depolarization driven mechanism resulting in an imbalance between excitatory and inhibitory signaling in the developing brain. Based on high comorbidity of epilepsy and ASD, we hypothesized these pathways might also be involved in ASD. Indeed, a remarkable number of genes involved in the RAS/Ca2+ pathway in the two stages of the Autism Genome Project (AGP) we analyzed as independent populations, confirms that CAE and Autism share major risk factors. Our results show a strong involvement of ion channels, growth factors, and effectors of Ras. For instance, we confirmed previous results on the involvement of several genes in the regulation of synaptic plasticity. We also found consistent evidence for the involvement of receptor-type tyrosine-protein phosphatase in both populations. Remarkably, we discovered a family of genes related to

Ca2+signalingand so far not know to be involved in ASD, as targets of a drug, already approved for use in humans, that could be novel addition to the current ASD treatments. Our findings strongly supports the hypothesis that the Ras-pathways play an important role in ASD, suggesting a major role for Ca2+signaling and paving the way in developing behavioral interventions and new drugs targeting networks involved in synapse development and functions.

Title: The 5HT2a receptor antagonist M100907 attenuates probabilistic reversal learning impairments in the BTBR mouse model of autism

Authors: *D. A. AMODEO[1], J. A. SWEENEY[2], M. E. RAGOZZINO[3];
[1]Psychology, Univ. Illinois, Chicago, Chicago, IL; [2]Univ. of Texas South Western, Dallas, TX; [3]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Individuals with autism spectrum disorder (ASD) exhibit cognitive flexibility impairments that include deficits in probabilistic reversal learning. The BTBR T+ tf/J (BTBR) mouse, like ASD individuals, exhibits impairments in probabilistic reversal learning. There is increasing evidence suggesting that brain serotonin (5HT) 2a receptors are involved in cognitive flexibility. Currently, it is unknown whether treatment with a 5HT2a receptor antagonist will reduce impairments in cognitive flexibility in the BTBR mouse. The present experiment examined the effect of the 5HT2a receptor antagonist, M100907, on probabilistic reversal learning in BTBR and C57BL/6J (C57) mice. Mice were tested in a spatial discrimination task using a 80/20 probabilistic reinforcement procedure. In the spatial discrimination, mice were tested on acquisition and reversal learning across two consecutive days. Mice learned to obtain a cereal reinforcement from the “correct” spatial location (reinforced on 80% of trials) compared with the “incorrect” spatial location (reinforced on 20% of trials). The learning criterion in both phases was choosing the ‘correct’ location on 6 consecutive trials. Thirty minutes prior to the reversal learning phase, mice received injections of vehicle, 0.01, or 0.1 mg/kg of M100907. BTBR mice were not impaired on initial learning of the spatial discrimination. BTBR mice were

impaired on probabilistic reversal learning compared to that of C57 mice. M100907 treatment at both doses attenuated a reversal learning deficit in BTBR mice. M100907 treatment had no effect on reversal learning in C57 mice. M100907 0.01 mg/kg administration in BTBR mice showed a trend to reduce both perseverative and regressive errors in reversal learning. M100907 0.1 mg/kg treatment in BTBR mice attenuated a reversal learning deficit by significantly decreasing regressive errors. Thus, M100907 0.1 mg/kg treatment in BTBR mice improved the ability to reliably execute a new choice pattern during reversal learning. Because individuals with ASD exhibit cognitive flexibility deficits due to an impairment in reliably executing a new choice pattern, treatment with a 5HT2a receptor antagonist may be effective in alleviating cognitive flexibility and related features in ASD.

Imaging and Neuropathology, [5]Psychiatry Developmental Neurosci., New York State Psychiatric Inst., New York, NY; [6]Neurosci., EB Sci., Oakland, CA

Abstract: The hormone oxytocin (OT) is thought to be associated with autism spectrum disorder (ASD), particularly in a subset with gut disturbance. We have demonstrated that OTR expression is developmentally regulated in rat enterocytes. Secondly, OT in combination with secretin reduces colonic inflammation in adult rats. And third, mice lacking the OTR have altered gastrointestinal motility, inflammation, macromolecular permeability, and mucosal maintenance. All of these findings suggest that understanding the function of OT in the gut could lead to an better understanding of the physiology of ASD phenotypes, and lead to new therapies. The oxytocin receptor (OTR) expression in neonatal rat enterocytes is robust from birth to weaning, but function of OTR during this period is not known. The mammalian target of rapamycin

complex1 (mTORC1) signaling is inhibited by oxytocin (OT) stimulation of Caco2BB cells (enterocytes in vitro). The unfolded protein response (UPR) protectively reduces translation during endoplasmic reticulum (ER) stress. We investigated UPR markers in OT-stimulated Caco2BB cells because of the role of mTORC1 pathway and its connection to cellular stress and ASD. We found that OT modulates several factors involved in translation and sensors of ER stress. 4E-BP1 phosphorylation (Ser65), which is known to inhibit cap-dependent translation via its rate-limiting factor eIF4E is reduced by High OT (62.5 nM). Furthermore, high OT, but not low OT (7.8 nM), increased translation elongation factor 2 (eEF2) phosphorylation (Thr56). The latter is known to inactivate eEF2. Significantly, phosphorylation of eIF2a phospho-Ser51, which inhibits eIF2a, was increased by high OT. High OT also increased PERK phosphorylation, a sensor of ER stress and a kinase of eIF2a. Finally, both high and low OT activated inositol requiring enzyme1 (IRE1), which generates the transcription factor XBP1s and induces the UPR. These findings indicate that OT modulates sensors of ER-stress and suggests that the high level of OTR expression in neonatal gut may serve a protective role during a critical post natal developmental period. These findings may contribute to understanding abnormal intracellular stress mechanisms in the autistic gut and lead to new treatments for ASD and gastrointestinal disorders.

Title: Behavioral impairments in the BTBR T+tf/J mouse model of autism are improved by perinatal choline supplementation

Authors: *E. LANGLEY, M. KRYKBAEVA, J. K. BLUSZTAJN, T. J. MELLOTT; Pathology & Lab. Med., Boston Univ. Sch. of Med., Boston, MA

Abstract: Autism is a neurodevelopmental disorder involving multiple genetic and environmental risk factors and is typically characterized by deficits in social interaction, impaired communication, and restricted, repetitive behaviors. Choline is an essential nutrient for animals and humans. Prenatal and early postnatal choline supplementation has been shown to

enhance long-term cognitive performance, improve motor deficits in a mouse model of Rett syndrome, and reduce the adverse effects of neonatal alcohol exposure. We examined the effects of perinatal choline supplementation on social behavior, anxiety, and repetitive behaviors in a mouse model of autism. The BTBR T+tf/J (BTBR) inbred mouse strain exhibits many of the behavioral irregularities observed in patients with autism, including deficits in play and social approach and excessive self-grooming behavior relative to other strains. Mice from the BTBR strain and the more "sociable" control C57BL/6J (B6) strain were either fed a control or choline supplemented diet from conception through lactation and weaning of the offspring. Locomotor function, anxiety, repetitive behaviors, and social interaction were evaluated in the offspring of both strains at two time points (postnatal days 33-36 and 89-91) using the following behavioral assays: open field (OF), elevated plus maze (EPM), marble burying (MB), and three-chamber social interaction. As expected, control-diet BTBR mice displayed increased self-grooming behavior and higher locomotor activity during the OF test, a reduction in time spent in the open arms of the EMP, impaired social preference, and increased digging behavior in the MB test compared to control-diet B6 mice. Choline supplementation during development significantly reduced the frequency of digging behavior in MB test, increased the number of open arm entries and time spent in open arms in the EPM in BTBR mice, but had no effect on locomotor activity. Choline supplementation did not alter social interaction in B6 strain mice but significantly increased the time engaged in social interaction by BTBR mice. The effects of perinatal choline supplementation observed at both ages tested show that the benefits of supplementation can persist long after dietary choline returns to control levels. We are currently examining the mechanism by which choline supplementation improves these behavioral deficits. The results of this study suggest that the availability of choline during early development can prevent or reduce deficits in social behavior and anxiety in a genetic mouse model of autism, revealing a novel strategy for the treatment/prevention of autism spectrum disorders.

Title: Enhancement of α2,3-GABAA receptor signaling rescues autistic-like behaviors in a mouse model of autism

Authors: *S. HAN, C. TAI, C. J. JONES, T. SCHEUER, W. A. CATTERALL;
Pharmacol., Univ. of Washington, Seattle, WA

Abstract: Autism spectrum disorder (ASD) may arise from increased ratio of excitatory to inhibitory neurotransmission in the brain. Many pharmacological treatments have been tested in ASD, but only limited success has been achieved. Here we report that BTBR T+tf/J (BTBR) mice, a well-established model of idiopathic autism, have reduced spontaneous GABAergic neurotransmission. Treatment with non-sedating/non-anxiolytic doses of benzodiazepines, which increase inhibitory neurotransmission through positive allosteric modulation of postsynaptic GABAA receptors, completely rescued autistic-like behaviors. Moreover, negative allosteric modulation of GABAA receptors induced autistic-like behaviors in otherwise normal C57BL/6J mice, suggesting a causal role for impaired inhibitory neurotransmission in autistic-like behaviors. The dramatic behavioral improvement after low-dose benzodiazepine treatment was subunit-specific; the α2,3-subunit-selective positive allosteric modulator L-838,417 was effective, but the α1-subunit-selective drug zolpidem exacerbated the social deficits. We propose that impaired GABAergic neurotransmission may contribute to ASD and that α2,3-subunit-selective positive GABAA receptor modulation may be an effective treatment.

Abstract: Prenatal valproic acid (VPA) exposure has been proposed as an animal model reproducing both behavioral and anatomical impairments of autism spectrum disorders (ASD). Some of the behavioral features of the model are lower sensitivity to pain and higher sensitivity to nonpainful stimuli, diminished acoustic prepulse inhibition, hyperresponsiveness to novel environment and decreased number of social behaviors. Among neuroanatomical changes that have been reported is a delay in eye opening related to impaired cerebral maturation; also, exposure to VPA causes abnormalities in tangential migration facial neurons and initial facial nucleus formation; finally, another important change linked to neural tube defects is the crooked tail phenotype, which also is a characteristic trait in these rats.
The neurotrophic peptide mixture Cerebrolysin (Cbl)has been reported to ameliorate abnormalities in models of aging and neurodevelopmental disorder such as Alzheimer, schizophrenia and brain injury. Only three studies about Cbl administration in autistic patients have been reported in literature with good results. For that reason, our aim in this study was to assess the effect of Cbl administration from postnatal day (PD) 5 to 21 on pups (age 21PD) and adult rats (age 70PD) prenatally VPA-exposed. We determined the effects of Cbl on different features including behavioral, neuromorphological and anatomical changes reported in the VPA animal model. Until now, we have found that Cbl administration reduces the delay in eye opening observed in VPA rats as well as attenuates the defect in crooked tail. Hyper-responsiveness to novel environment previously reported is also diminished. As far as morphology is concerned, we have found changes in dendritic morphology and density spines in prefrontal cortex, too after Cbl administration.

Title: Ketogenic diet attenuates behavioral abnormalities in the prenatal valproic acid rat model of autism spectrum disorder

Authors: *Y. AHN, S. T. NAKANISHI, R. TOBIAS, J. M. RHO, R. MYCHASIUK;
Pediatrics, Alberta Children's Hosp. Res. Inst., Calgary, AB, Canada

Abstract: Autism spectrum disorder (ASD) is a heterogeneous neurodevelopmental condition characterized principally by impaired social interactions. Prenatal exposure of valproic acid (VPA) has been linked to ASD symptomology in humans and has been used as a model of ASD in rodents. Although the mechanisms underlying the VPA-induced ASD phenotype are not fully understood, neurometabolic changes have been implicated in other rodent ASD models. We hypothesized that the ketogenic diet (KD) - a dietary treatment that has been shown to enhance cellular bioenergetics - might improve ASD-like behaviors in VPA-exposed rats. Using a split litter design, rats exposed to VPA or saline (SAL) prenatally were administered either the KD or a standard diet (SD) from weaning until postnatal day 35 (SAL/SD; n=18, SAL/KD; n=22, VPA/SD; n=18, and VPA/KD; n=22), at which point they underwent testing in the play behaviour paradigm and the acoustic startle test, also known as the acoustic prepulse inhibition (PPI) task. Play behavior requires that each animal understands and follows a complex set of social rules and cues that can be categorized and quantified. The play behaviours analyzed for this study included evasions, complete rotations, partial rotations, and horizontal rotations. We found that prenatal VPA treatment limited both the complexity and amount of play rats engaged in, consistent with an autistic behavioral phenotype. Furthermore, we found that after KD treatment, VPA-treated rats tended to normalize their play behaviors by increasing both the diversity of play as well as the frequency of play initiations. PPI, a phenomenon in which a weak pre-stimulus decreases the startle response to an intense stimulus, provides an operational measure of sensorimotor gating (a process by which an organism filters sensory information). Our data suggest that KD treatment can increase the peak response in habituation and PPI trials. Moreover, the PPI was independently increased by both KD and VPA treatments (SAL/SD; n=17, SAL/KD; n=18, VPA/SD; n=20, and VPA/KD; n=22). These findings indicate that KD treatment may lead to improvements in ASD-like behaviors, particularly those behaviors that can be associated with higher-order social functions such as play. That said, the limbic forebrain regions more commonly associated with the PPI task may not be affected by the KD in rodent models of ASD. Based on our preliminary results, we conclude that the KD may prove to be a clinically effective intervention for ASD, one that is readily available and accessible to patients given the growing number of clinical centers worldwide that are offering this treatment.

Paris Descartes, Paris, France

Abstract: GABAergic signals are altered in autism and GABA-acting benzodiazepines exert paradoxical effects in patients with autism suggesting that, as in epilepsies, GABA excites neurons because of elevated intracellular concentrations of chloride.
We have recently shown (Lemmonier et al, 2012) in a double-blind clinical trial on 60 children with autism (3-11 years old) that the diuretic NKCC1 chloride importer antagonist bumetanide (1mg during 3 months), that reduces intracellular chloride [Cl-]i, significantly reduced the Childhood Autism Rating Scale (CARS) and Clinical Global Impressions. Bumetanide also significantly reduced the Autism Diagnostic Observation Schedule values when the most severe cases were removed, supporting the use of bumetanide in the treatment of autism. A large multi-center European trial has been approved to be conducted soon. We have also performed in parallel an investigation on the early and late alterations of GABAergic signals and chloride homeostasis in animal models of autism (in utero valproate-treated rats (VPA), and fragile X mice). The results that confirm our working hypothesis will be presented.

Title: Effects of a beta-adrenergic antagonist on social and cognitive abilities in autism spectrum disorder

Authors: *R. M. ZAMZOW, B. J. FERGUSON, M. L. LEWIS, E. C. REZNICEK, A. S. RAGSDALE, S. E. CHRIST, J. P. STICHTER, D. Q. BEVERSDORF;
Univ. of Missouri-Columbia, Columbia, MO

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by social communication impairments and restricted, repetitive behaviors. Current pharmacological interventions for ASD focus primarily on psychiatric symptoms, such as agitation and obsessive behaviors. Few agents target core domains, such as social and cognitive functioning. It has been previously hypothesized that stress contributes to social and cognitive deficits in ASD. Accordingly, propranolol, a non-selective beta-adrenergic antagonist with known anxiolytic effects, may serve as a potential therapeutic agent for ASD, as it blocks the noradrenergically mediated sympathetic response system. The present ongoing study explores the effects of propranolol on social and cognitive abilities in ASD. Individuals with ASD participated in two study sessions in which they were given propranolol (40 mg) or placebo in a counterbalanced, double-blinded manner. 60 minutes following drug administration, participants performed several cognitive and social tasks. Preliminary analyses indicate a significant improvement in task performance on the General Social Outcomes Measure, an assessment of social functioning, as well as a trend for improved task performance on the Anagrams task, a measure of problem solving abilities, in the propranolol condition, as compared to the placebo condition. Continued data collection is necessary to further characterize the effects of propranolol on social and cognitive abilities in ASD. In addition, subsequent work will consider the role of baseline sympathetic nervous system activity in predicting which individuals will respond best to propranolol. Overall, these findings contribute to insight regarding potential therapeutic interventions for core symptomatology in ASD.

Title: Potential contribution of pitocin and/or epidurals in labor to the development of an autism phenotype

Authors: *A. SAREEN, E. BAKER, T. WILLIAMS;
Trinity Univ., San Antonio, TX

Abstract: Autism spectrum disorders (ASDs) are a fascinating, yet perplexing group of developmental disorders because we still do not know their exact etiology. ASDs diagnoses continue to rapidly increase in number, and as of current, we know that there may be a genetic component and there is a potential for environmental influences. Since the 1970s, epidural usage has noticeably increased and previous research has shown that mothers of autistic children were more likely than mothers of non-autistic children to have received epidurals. This two-part study examines the relationship between mothers who were administered pitocin and/or an epidural during labor and the development of ASD in their offspring. All surveys were verbally administered. The survey techniques consist of interviewing mothers of ASD and non-ASD children to better understand their behavior and actions during pregnancy, including whether or not they received epidural or Pitocin. The second portion of this study involved elucidating the in vivo effects of pitocin and bupivacaube on early brain development using Drosophila melanogaster. The data from this study could yield implicative results that could influence decision-making, in terms of whether or not to use Pitocin or epidural during labor. Furthermore, this study could potentially contribute to preventative measures against this increasingly diagnosed disorder.

Title: D-cycloserine improves sociability in the BTBR T+ Itpr3tf/J mouse model of autism spectrum disorders with altered Ras/Raf/ERK1/2 signaling

Authors: *J. A. BURKET[1], A. D. BENSON[1], A. H. TANG[2], S. I. DEUTSCH[1];
[1]Psychiatry and Behavioral Sci., [2]Microbiology and Mol. Cell Biol., Eastern Virginia Med. Sch., Norfolk, VA

Abstract: The genetically-inbred BTBR T+ Itpr3tf/J (BTBR) mouse is a validated model of autism spectrum disorders (ASDs). Similar to several syndromic forms of ASDs, mTOR activity may be enhanced in this mouse strain as a result of increased Ras signaling. Recently, D-cycloserine, a partial glycineB site agonist that targets the NMDA receptor, was shown to improve the sociability of the Balb/c mouse strain, another validated genetically-inbred model of ASDs. NMDA receptor activation is an important regulator of mTOR signaling activity. Given the ability of D-cycloserine to improve the sociability of the Balb/c mouse strain and the regulatory role of the NMDA receptor in mTOR signaling, we wondered if D-cycloserine would improve the impaired sociability of the BTBR mouse strain. D-Cycloserine (320 mg/kg, ip) improved measures of sociability in a standard sociability paradigm and spontaneous grooming that emerged during social interaction with an ICR stimulus mouse in the BTBR strain; however, similar effects were observed in the Swiss Webster comparator strain, raising questions about their strain-selectivity. Importantly, the profile of D-cycloserine's therapeutic effects on both measures of sociability and stereotypies is consistent with that of a desired medication for ASDs; specifically, a desired medication would not improve sociability at the expense of worsening stereotypic behaviors or vice versa. The ability of D-cycloserine to improve two prominent domains of psychopathology in ASDs in the BTBR mouse strain may be related to its ability to regulate mTOR signaling activity via stimulation of NMDA receptors.

Title: Emergence of holistic processing for neural objects in autism

Authors: E. WHYTE[1], M. BEHRMANN[2], *D. ELBICH[3], N. MINSHEW[4], S. SCHERF[1]; [1]Dept. of Psychology, The Pennsylvania State Univ., University Park, PA; [2]Dept. of Psychology, Carnegie Melon Univ., Pittsburgh, PA; [3]Penn State Univ., University Park, PA; [4]Dept. of Neurol. and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Face processing deficits for individuals with autism may stem from a general perceptual bias that emphasizes featural processing at a cost to holistic processing (Behrman et al., 2006; Happe & Frith, 2006). This visuoperceputal processing bias appears to impact recognition of faces as well as other kinds of homogenous objects, including cars (Ewing et al., 2013) and novel objects (Scherf et al., 2008). In this study, we investigated whether such a visuoperceptual bias prohibits individuals with autism from learning to recognize exemplars from a class of novel objects, which only differ with respect to holistic properties. In addition, we examined whether or not this learning influenced behavioral and neural processing of faces. We tested adolescents with high functioning autism (12-18 years) in a 2-month visuoperceptual training paradigm over the course of 20 training sessions. The paradigm was designed to train participants to recognize 20 Greebles, novel objects containing two horizontal and two vertical appendages on a body, designed to invoke holistic processing demands similar to faces (Gauthier & Tarr, 1997). Importantly, the set of Greebles that were selected for training all shared the same set of appendages and only differed from one another based on the holistic organization of the features in combination with the body. Pre- and post-testing measures included the Cambridge Face Memory Task (CFMT), a composite task measuring holistic processing of untrained Greebles, as well as an fMRI task to map face-, and Greeble-related activation. In contrast to predictions from the strong version of the visuoperceptual bias argument, all 9 adolescents with autism successfully completed the training protocol and learned to recognize the 20 training Greebles. The training also lead to the emergence of holistic processing of novel Greebles in the composite task. There was no significant change in performance on the CFMT or in the size of the individually defined face-related region in the right fusiform gyrus immediately following training. These results suggest that holistic processing abilities are spared enough in adolescents with autism to learn to recognize novel objects. In addition, the widely reported deficit in face recognition abilities is not likely to be solely based on a visuoperceptual processing bias that interferes with holistic processing. These findings may have important implications for informing intervention strategies to help reduce face-processing deficits and improve adaptive functioning for individuals with autism.

Title: Neural signatures of phonological working memory and grammatical processing in autism spectrum disorders

Authors: *Z. QI[1], T. PERRACHIONE[1], A. HARRIS[2], I. OSTROVSKAYA[1], S. BEACH[1], K. HALVERSON[1], A. CYR[1], K. SHER[1], M. KJELGAARD[1], J. D. E. GABRIELI[1], K. WEXLER[1], H. TAGER-FLUSBERG[2];
[1]MIT, Cambridge, MA; [2]Boston Univ., Boston, MA

Abstract: Language deficits are one of the core impairments of autism spectrum disorders (ASD). Behavioral studies have documented reduced phonological working memory capacity and impaired grammatical processing in children with ASD. The current study is the first to probe the neural characteristics of these two key language functions in children with ASD and their typically developing (TD) counterparts. Participants were all native English-speaking children and subject groups were matched on age, non-verbal IQ, and performance on standardized language tasks.
In Experiment 1, 19 children (7 ASD and 12 TD, mean age 12;1) completed a nonword repetition task during fMRI. Stimuli were pseudowords designed to match the phonological and phonotactic properties as real English words and ranged from two to five syllables in length. As predicted, the ASD group performed significantly worse than the TD group in overall accuracy (78.2% vs. 90.0%, $p < .05$). Imaging results revealed that repeating nonwords activated bilateral superior temporal gyri (STG) and left prefrontal areas in both groups, but that children with ASD showed a significantly greater task-induced activation in right middle temporal gyrus (FDR < 0.01, $q < .05$) as compared to TD children. As syllable length increased, both groups exhibited decreasing accuracy in performance ($r = 0.14$, $p < .05$) and a corresponding increased recruitment in left STG as syllabic length increased (FDR < 0.01, $q < .05$).
In Experiment 2, 22 children (10 ASD and 12 TD, mean age 12;0) completed an auditory grammaticality judgment task during fMRI. Children listened to short sentences, which were

either grammatically correct or contained morphosyntactic errors and decided if each sentence sounded correct or not. The type of errors was characteristic of those made by TD during initial language acquisition and children with language impairments for a protracted length of time (e.g. Every day he walk to school). As compared to the TD group, the ASD group performed marginally worse (91.5% vs. 97.1%, $p = .07$) on this task, and had significantly reduced task-induced activation in left inferior frontal gyrus, STG, and precentral gyrus (FDR < 0.01, $q < .05$). These preliminary results revealed hyperactivation in the right temporal lobe during the PWM task and reduced activation in the left hemisphere during grammaticality judgment in the ASD group. This works paves the way for understanding the neural characteristics underlying language deficits in children with ASD.

Title: Child behavior checklist dysregulation profile and the brain: A VBM analysis

Authors: *D. N. KENNEDY[1], M. E. WOOD[1], E. MICK[2], J. A. FRAZIER[1];
[1]Psychiatry, [2]Quantitative Hlth. Sci., U. Massachusetts Med., WORCESTER, MA

Abstract: Background:
Behavioral dysregulation is a hallmark feature of many neurodevelopmental disorders. We sought to examine what neuroanatomic regions were related to behavioral dysregulation, as characterized by the CBCL Dysregulation Profile (CBCL-DP), using structural MRI and voxel-based morphometry.
Methods:
We identfied 120 subjects in our cohort, aged 6-18, that had a volumetric MRI and CBCL assessment. The diagnoses of these subjects included neurotypical subjects, as well as subjects with ADHD, early-onset schizophrenia, and early onset bipolar disorder. The structural images were used in a VBM analysis (FSL) in order to observe the correlation (AFNI) of gray matter density with the individualized CBCL-DP scores. These regions were further analyzed with

covariation for age and gender.
Results:
A number of regions were identified that demonstrated negative correlation between behavioral dysregulation and gray matter density, localized to the inferior lateral parietal cortex, bilaterally; left middle temporal-fusiform cortex; right parahippocampal cortex; and left hippocampus/amygdala area. After co-varying for age and gender, the left hippocampal/amygdala region demonstrated the most robust relationship.
Conclusions:
Consistent with evidence in the structural analysis literature in these disorders, the hippocampus/amygdala region is implicated for smaller gray matter density as behavioral dysregulation increases. These results promote further study of the detailed relationship of this region with the behavioral profiles in children and adolescents with neurodevelopmental psychiatric disorders.

Psychology, Otto von Guericke Univ., Magdeburg, Germany; [6]German Ctr. for Neurodegenerative Dis. (DZNE), Magdeburg, Germany

Abstract: Novel stimuli elicit a rapid automatic orienting response relevant for adaptive behavior in a complex and changing environment. With frequent presentation, this response declines if the stimulus has no further behavioral significance. Children with attention deficit hyperactivity disorder (ADHD) have difficulties in regulating their behavior according to situational demands. So far it is poorly understood whether altered neuronal processing of novelty contributes to these problems.
We aimed to investigate the neuronal mechanisms involved in processing novel and otherwise salient (i.e. contextually rare) stimuli in children/ adolescents with and without ADHD. Each group consisted of 19 male participants between 11-16 years. Functional brain images (3T) were recorded while participants performed a visual oddball task composed of four stimulus categories: a frequent standard picture (62.5%), a task relevant target picture (12.5%), a task irrelevant repeated rare picture (12.5%) and unique novel pictures (12.5%).
For both groups novelty related activity involved bilateral temporal and occipital regions, parahippocampal gyrus, posterior cingulate and right thalamus. However, the left superior temporal as well as inferior and middle frontal gyri showed differential effects. Specifically, processing novel stimuli was associated with stronger deactivation in healthy controls in contrast to ADHD patients. Furthermore, brain regions involved in novelty processing were also activated by contextually rare items in ADHD patients but not in healthy controls.
Our results indicate similar activity patterns to novel information in children with and without ADHD. However, the observed involvement of the novelty network in processing contextually rare items and reduced deactivations in response to task-irrelevant novelty reflect inefficient use of neuronal resources and might account for the increased distractibility in ADHD patients.

Title: Atypical rich-club organization in brain connectivity as an endophenotype of attention deficit hyperactivity disorder

Authors: *M. MATTHEWS, S. RAY, J. NIGG, D. FAIR;
Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Attention deficit hyperactivity disorder (ADHD) is a prevalent and persistent psychiatric disorder that emerges early in childhood, with a current prevalence rate of 5.5% to 9.3% in children 4 to 17 years old. ADHD exhibits high heritability but despite numerous genes that have been identified that convey risk for ADHD, their collective risk explained is very small. The inability to clarify the genetic basis of this disorder may contribute to the heterogeneity in the population, but may also result from a lack of identified endophenotypes that better link the behavioral symptoms of the disorder with the genetic risks. Brain imaging may serve as a tool capable of identifying reliable endophenotypes with the capacity of improving our understanding of the underlying genetic component of the disorder. Based on current models of ADHD, it is likely that the cortical-subcortical interactions critical for typical development are atypical in children with this disorder, and thus may serve as a strong endophenotype. Additionally, it is likely that large-scale network properties with regard to cortico-cortical interactions are also atypical, which may be another endophenotype. To examine this possibility, we used resting state functional magnetic resonance imaging (rs-fcMRI) to measure specific neural circuits thought to be involved in ADHD, including areas such as the nucleus accumbens and the amygdala, along with graph theory analyses to identify atypical functional patterns in ADHD probands and their unaffected siblings (along with control siblings). We found no similarities or overlap in connectivity between probands with ADHD and their unaffected siblings when looking at connectivity between the nucleus accumbens or amygdala and the cortex, compared to control siblings. On the contrary, when examining network patterns such as rich-club organization, whereby highly connected nodes within a network (such as the brain) are also highly connected to each other, we observed atypical rich-club organization in functional networks of both ADHD probands and unaffected siblings. These data suggest that atypical rich-club patterns of connectivity may potentially serve as an endophenotype for ADHD. These findings provide new insight into the developmental pathobiology of ADHD and may assist in characterizing the genetic underpinnings of the disorder.

Title: Tracking the response inhibition network in ADHD: A joint F-MRI-DTI study

Authors: *L. K. TREMBLAY[1], M. BHAIJIWALA[1], D. MABBOTT[2], S. AMEIS[1], A. CHEVRIER[1], F. WANG[2], F. LIU[2], R. SCHACHAR[1];
[1]Psychiatry, [2]Psychology, Hosp. For Sick Children, Toronto, ON, Canada

Abstract: Purpose : Functional MRI (F-MRI) was combined with Diffusion Tensor Imaging (DTI) to explore the integrity of the response inhibition network in childhood ADHD from a functional and structural standpoint. Response inhibition represents a key and well-studied cognitive deficit in this patient population, and an appropriate focal point in terms of elucidating the neurobiology of this complex disorder.
Methods: ADHD subjects ages 8-17 were recruited through a hospital diagnostic research clinic, which includes an interview with the patient, family and teacher, a diagnostic review and consensus by two independent clinicians, administration of parent and teacher symptom scales, extensive chart review, and psychological testing. Controls were recruited by ads and word-of-mouth. Within one study session, DTI scans were acquired along with an F-MRI study (n=8 per group), interrogating activation while participants performed the Stop Signal Task (SST). The SST is an established measure of response inhibition, probing one's ability to stop an ongoing response. F-MRI activations where ADHD differed from controls were used as seeds for DTI tractography of relevant white matter pathways. Specifically, F-MRI activation maps analyzed in AFNI were co-registered with each participant's DTI and structural MRI (T1) scans using the Automated Image Registration (AIR) and ANALYZE software. Subsequently, the FSL tools were used to perform probabilistic tractography.
Results: The F-MRI component has been analyzed in a separate study within our group, establishing that ADHD and controls differentially activate a wide network of brain regions during response inhibition, spanning from the inferior frontal gyrus (IFG), the anterior cingulate, to the cerebellum. The specific brain activations of interest, areas where ADHD clearly differed from controls during the monitoring phase of the task, were used as seed points, revealing white matter tracts of interest such as the inferior fronto-occipital fasciculus (IFOF) and the inferior longitudinal fasciculus (ILF). White matter integrity between the two groups was subsequently analyzed showing higher radial diffusivity within these tracts ($p<0.05$). A trend was seen between SST performance and white matter integrity.

Conclusions: The results of this combined structure-function study help characterize the integrity and architecture of a specific and complex cognitive network relevant in ADHD.

Title: Relationship between grit, self-control and academic achievement in ADHD

Authors: K. J. RUTLEDGE, J. F. DIXON, C. FASSBENDER, T. A. HARTANTO, E. CALFEE, *J. B. SCHWEITZER;
Dept Psychiatry & Behav Scienc, Unive Calif Davis SOM, SACRAMENTO, CA

Abstract: Attention-Deficit / Hyperactivity Disorder (ADHD) is the most common childhood behavioral disorder and persists into adulthood for a majority of individuals. The disorder is characterized by cognitive impairments and behavioral problems which have been linked to underlying neurological deficits, and individuals with ADHD typically experience downstream effects on academic achievement. Outside the ADHD literature, recent research has associated achievement with “grit,” or the personality trait of persistence and perseverance toward long term goals, demonstrating that higher grit is linked to greater achievement. This research has suggested that higher levels of grit, or persistence, can enable individuals to pursue activities that may not be very intrinsically rewarding - as may be found in the academic setting - out of motivation to achieve long-term goals. Another process relevant to academic, health and occupational success is impulsivity, or delay discounting, characterized by opting for smaller, more immediately available rewards over larger, delayed rewards. Individuals with ADHD often exhibit higher levels of delay discounting. The present study sought to examine how these variables may affect academic achievement when examined concurrently in a sample including participants with ADHD. Male and female children with ADHD (of either the inattentive subtype, IA, or combined subtype, CO) and without ADHD (TD) between the ages of 12 and 17 years completed a battery of assessments including the Short Grit Scale and others assessing academic achievement, ADHD symptoms, cognitive tempo, and delay discounting. Participant scores across measures were compared categorically between participant subtypes (TD, IA, or

CO), as well as continuously in models with other variables of interest. Results demonstrated significant subtype differences with respect to grit, such that IAs is significantly associated with lower grit scores than did TDs, and delay discounting, as COs were more impulsive than TDs. Academic achievement scores were also related to subtype, ADHD symptoms, cognitive tempo, and delay discounting. These findings point to possible new avenues to consider when examining the etiology of deficits in academic performance in ADHD, as well as potential new targets related to symptoms for treatment that may alter developmental trajectories in children with ADHD.

Title: Altered connectivity in default mode and cingulo-opercular networks in children with adhd

Authors: *S. H. MOSTOFSKY[1,3], M. NEBEL[1], L. JACOBSON[1], J. WEXLER[4], B. S. CAFFO[5], J. J. PEKAR[2,3], A. D. BARBER[2,3];
[1]Neurology/Developmental Cognitive Neurol., [2]Kennedy Krieger Institute, Johns Hopkins Univ. Sch. o, Baltimore, MD; [3]Johns Hopkins Sch. of Med., Baltimore, MD; [4]Kennedy Krieger Inst., Baltimore, MD; [5]Johns Hopkins Sch. of Publ. Hlth., Baltimore, MD

Abstract: Attention Deficit Hyperactivity Disorder (ADHD) is characterized by inattentiveness, hyperactivity and impulsivity. These behavioral impairments may be associated with networks involved in sustaining task control (cingulo-opercular network: CON) and self-reflective lapses of attention (default mode network: DMN). The current study examined whether connectivity with these networks was altered in ADHD. 51 ADHD and 51 typically-developing (TD) children (ages 8-12 years) were matched for age, gender, handedness, and verbal comprehension index. All children had a five-minute resting state scan. Preprocessing included slice time correction, motion correction, co-registration, segmentation, and normalization. Nuisance variables were removed from each voxel (cerebrospinal fluid and white matter using CompCor, global mean signal, and absolute and differential motion parameters). Functional images were spatially smoothed using a 6 mm FWHM filter and then temporally filtered (bandpass 0.01-0.1Hz). 6mm

radius seeds were placed in six CON regions: bilateral dorsal anterior insula (DAI), bilateral supramarginal gyrus (SMG), and anterior cingulate cortex); and three DMN regions: medial prefrontal cortex (MPFC), posterior cingulate cortex (PCC), and lateral parietal cortex (LP). Mean time-courses were extracted and full-brain connectivity maps were created for each seed. The five CON maps were averaged to make one mean CON map and the three DMN maps were averaged to make one DMN map for each subject. Second-level t-tests were then performed to examine differential connectivity between the two groups for the CON and DMN networks. Within the DMN, a number of regions were more connected in the ADHD group, including the MPFC, bilateral LP and PCC. The left orbitofrontal cortex and left dorsolateral prefrontal cortex were also more connected with the DMN in children with ADHD. Greater connectivity with the DMN in the TD group was found in a cerebellar region and in the precuneus/superior parietal cortex. Within the CON, greater connectivity in the ADHD group was found in bilateral DAI, SMG, putamen and postcentral gyri. On the left side there was greater connectivity with the inferior frontal gyrus, inferior parietal lobule and thalamus. While prior studies have found hypo-activation or hypo-connectivity within the DMN network in ADHD, the current study finds increased within-network connectivity for both the DMN and CON. In addition, children with ADHD showed altered connectivity between DMN and other brain regions. Atypical CON and DMN connectivity may contribute to ADHD-associated impairments in attentional and behavioral control in children.

Title: EEG source imaging indices of attentional and inhibitory processing show association with dopamine system genes

Authors: *G. MCLOUGHLIN[1,2,3], S. MAKEIG[2], J. PALMER[2], D. BRANDEIS[4,6], M. LAUCHT[5];

Adolescents, [5]Dept. of Child and Adolescent Psychiatry and Psychotherapy, Central Inst. of Mental Hlth., Mannheim, Germany; [6]Dept. of Child and Adolescent Psychiatry, Univ. of Zurich, Zurich, Switzerland

Abstract: Attention deficit hyperactivity disorder (ADHD) like many psychiatric disorders is heterogeneous at the symptom level, and there is most likely further heterogeneity in the etiology and pathophysiology of the disorder. Uncertainties about phenotype definition in psychiatry may have impeded the discovery of risk factors for the development of disorders. One goal for research in psychiatry is to move beyond subjective and variable diagnoses to classify disorders based on identifiable neural circuits. Dopamine system genes have been loosely linked with attention deficit hyperactivity disorder and other psychiatric disorders that have deficits in inhibitory or attentional networks. In a targeted candidate gene approach, we hypothesize that dopamine system candidate genes, specifically DRD4 and COMT, will be related to electroencephalographic (EEG) indices of inhibition and attention respectively. We collected EEG and genotype data in a sample of 200 adolescents; 53 ADHD cases and 253 controls. We measured EEG activity both at the hypothesized scalp electrodes and also at the source level using independent component analysis (ICA). ICA is a statistical blind source separation technique that has been found to be useful for separating out independent EEG signals from many cortical and non-cortical sources. No genetic association between the genetic markers and ADHD diagnosis or channel ERPs (at expected locations) was evident. However, EEG source imaging identified a strong genetic association between the risk alleles for ADHD and attenuated amplitude in source components that relate functionally to attention and inhibition ($p<.001$). This finding indicates that the inconsistent replication between dopamine genes, in particular DRD4, and ADHD may be due to heterogeneity and lack of specificity at the neurocognitive level. The association of DRD4 and COMT with EEG source markers of inhibition and attention should be explored in other disorders and the general population. EEG source imaging may improve the functional characterization of specific genetic risk factors.

Title: Behavioral problems in preschool children relates to regional differences in cortical surface area

Authors: *A. BJØRNEBEKK[1,2], A. M. FJELL[2], V. MOE[3,2], K. J. Ø. HAABREKKE[3], T. SIQVELAND[3,2], K. SLINNING[3], K. B. WALHOVD[2];

Abstract: Behavioral problems in children are thought to reflect a dynamic interaction between maturation and environmental factors, profoundly connected to brain development. Cortical anomalies have been linked to behavioral problems in children and recently it was shown that attention deficit hyperactivity disorder reflects a developmental delay in cerebral development of cortical thickness and surface area. In a longitudinal investigation we have followed the development of children born to mothers with drug abuse- and/or psychiatric problems and mothers without such burdens since the third trimester of pregnancy. In the current study we aimed to investigate cerebral correlates of behavioral problems in these children at 4 ½ years, thus comprising a sample exposed to pre- and postnatal risk factors for child developmental problems to various degree. 36 children underwent MR scanning and their parents completed the Child Behavior Checklist (CBCL). The relations between cortical surface area and behavioral problems were investigated throughout the cerebrum. Higher score of the CBCL Total Problem Scale were associated with reduced cortical surface area in superior frontal, caudal middle frontal, pre-central and post-central areas of the right hemisphere. Posthoc analyses are indicative that externalizing rather than internalizing behavior problems may account for the observed association. Child behavioral problems constitute an important predictor of maladjustment later in life and it is possible the observed relationship between mother assessment of behavior problems and regional reductions in surface area reflects an early susceptibility marker to later maladjustment.

Title: Amygdalar and hippocampal volumetric and endocrine correlates of mood and anxiety in children with chromosome 22q11.2 deletion syndrome

Authors: *E. A. BEATON[1], N. Q. CUNG[2], M. H. CABARAL[2], D. D. STEPHENSON, Jr.[1], K. ANGKUSTSIRI[3], I. LECKLITER[3], T. J. SIMON[2];
[1]Dept. of Psychology, Univ. of New Orleans, New Orleans, LA; [2]MIND Inst. & Psychiatry, [3]MIND Inst. and Pediatrics, Univ. of California Davis, Sacramento, CA

Abstract: Background: Children with 22q11.2DS cope with serious medical, cognitive, and socioemotional challenges including a 20-30 percent increased risk for schizophrenia. Particular susceptibility to stress and anxiety stemming from atypical brain development, genetically-modulated temperament and cognitive impairments combined with early and ongoing traumatic experiences may contribute to the high risk of schizophrenia in this population (Beaton and Simon, 2011). We used structural magnetic resonance imaging (MRI) to measure amygdalar and hippocampal volumes in combination with daily measures of salivary cortisol (CORT) as a possible developmental marker of stress vulnerability.
Methods: As part of a larger ongoing study, participants were 7-14 year-old children with and without 22q11.2DS. They completed a series of psychological self-report and clinician-administered questionnaires measuring anxiety, and depression. High-resolution anatomical brain images were acquired using a 3T MRI scanner. Amygdalar and hippocampal volumes were calculated using a highly validated tracing methodology. Salivary cortisol was collected at five time points over two school days and one home day for a subset of children with imaging data.
Results: Children with 22q11.2DS reported higher levels of anxiety and depression versus TD children. Reduced Left amygdala volume was observed in the 22q11.2DS group versus TD children, in addition to reduced left versus right amygdala size within the 22q11.2DS group. There was no difference between left and right amygdala volumes within the TD group. Elevated anxiety predicted smaller amygdala volumes within the 22q11.2DS group but not the TD group. Hippocampal volumes did not differ between groups and hippocampal volume was not clearly

related to measures of mood or anxiety in either group. Preliminary analyses suggest that children with 22q11.2DS demonstrate a flatter diurnal rhythm of salivary CORT across days versus TD children.
Conclusions: Smaller left amygdala volumes are reported in other pediatric populations with anxiety disorders (Milham et al., 2005) and may reflect atypical brain development or stress-mediated increases in function (Schumann et al., 2004). Group differences in CORT may reflect a stress response to greater social and cognitive challenges at school experienced by children with 22q11.2DS versus TD children. The observed association between anxiety, mood, and limbic structure development is likely highly complex but may serve as a developmental risk marker in conjunction with other physiological markers of stress for later psychopathology.

Title: Methylphenidate alters auditory and visual information processing in healthy volunteers

Authors: *M. KOROSTENSKAJA[1], D. KICIC[2], A. SCHAAL[1], S. KAHKONEN[2];
[1]Functional Brain Mapping and BCI Lab, Florida Hosp. For Children, Orlando, FL; [2]BioMag Laboratory, HUSLAB, Helsinki Univ. Central Hosp., Helsinki, Finland

Abstract: Introduction: Methylphenidate (MPH) is a commonly used psycho-stimulant for the treatment of attention deficit hyperactivity disorder (ADHD). Though many studies have been done to determine MPH's effectiveness in a clinical setting, little research has utilized high resolution Magnetoencephalography (MEG) combined with Electroencephalography (EEG) to

determine how MPH affects neural basis of sensory information, such as auditory and visual. Here we compare previously published study on the effect of MPH on auditory information processing by Korostenskaja et al. 2008 with the new data describing changes in visual information processing under the effect of MPH.
Methods: Neuronal activity was recorded with combined MEG/EEEG in 12 healthy subjects (F/M 5/7, age 27±5 years) after oral administration of 40 mg MPH or placebo in a randomised, double-blind, cross-over design. In auditory modality, monaural left-ear auditory stimuli were presented in an oddball paradigm with infrequent deviant tones differing in frequency and duration. We analysed both electric and magnetic N100, P200 and mismatch negativity (MMN) components. In visual modality, half-field achromatic checkerboard reversal stimuli were presented. Both electric and magnetic N75, P100, and N145 components were analyzed.
Results: During processing of auditory stimuli, MPH increased arousal levels in visual analogue scales. MPH had no effect on the dipole strength of MMN or MMN*m* in either frequency or duration deviations. MPH did, however, reduce P200 amplitudes in EEG. During processing of visual stimuli, MPH significantly increased self-reported levels of arousal and positive affect. In the MPH condition, there was a significant increase in N75 amplitude and a statistical trend for an increase in the P100 amplitude. There was a negative correlation between N75 amplitudes with the extent of changes in dizziness in VAS under the effect of MPH. The N145*m* amplitude was significantly increased after MPH administration.
Conclusions: MPH may change the neural bases of auditory information and visual information processing, such as early stimulus evaluation reflected in the P200 component as well as early and late processing of visual stimuli reflected in N75 and P145*m* components, respectively. Dopamine and noradrenaline neurotransmitter systems could be responsible for the modulation of these processes. Current results could have clinical application in the treatment of ADHD.

Title: Tomosyn dysregulation leads to aberrant glutamate release in the dentate gyrus of the hippocampus in a murine model of epileptogenesis

Authors: *S. R. BATTEN[1], E. A. MATVEEVA[2], J. E. QUINTERO[1], F. POMERLEAU[1], P. HUETTL[1], S. W. WHITEHEART[2], T. C. VANAMAN[2], P. E. A. GLASER[1], G. A. GERHARDT[1], J. T. SLEVIN[3];
[1]Anat. & Neurobio., [2]Mol. & Cell. Biochem., [3]Neurol., Univ. of Kentucky, Lexington, KY

Abstract: Epilepsy affects approximately 2.3 million adults and 500,000 children in the United States with 150,000 new cases being diagnosed each year. Despite the prevalence of epilepsy the aberrant molecular processes that initiate and propagate epilepsy (epileptogenesis) are unknown. Dysregulation in the release of the major excitatory neurotransmitter, glutamate, as well as in the function of several presynaptic proteins associated with neurotransmitter release have been indicated as potential causes of epileptogenesis. Tomosyn, one of the presynaptic proteins implicated, is a negative regulator of glutamate release. Here we use glutamate biosensors to measure tonic, KCl evoked, and spontaneous glutamate transients in distinct sub-regions of the hippocampus (dentate gyrus [DG], CA3, and CA1) in tomosyn wild type (Tom+/+; n = 7), tomosyn heterozygous (Tom+/-; n = 6), and tomosyn knockout (Tom-/-; n = 9) mice. We found a positive linear trend in KCl-evoked glutamate release as tomosyn levels were reduced across genotype in the DG ($t(19) = 2.81$, $p < 0.05$). A one-way ANOVA further revealed a significant difference between Tom+/+ and Tom-/- mice in KCl-evoked glutamate release in the DG (1.73±0.78 μM vs. 4.23±0.69 μM [Mean±SEM]; $F(2, 19) = 4.04$, $p < 0.05$). No differences were seen in measures of tonic or spontaneous glutamate. These results suggest that, in the DG, the dysregulation of proteins controlling glutamate synaptic transmission as well as aberrant glutamate release may contribute to epileptogenesis. Thus, the development of novel pharmacotherapies that work to modulate presynaptic proteins that regulate glutamate release may provide beneficial therapies to treat epilepsy in humans.

Title: AMPA receptor-mediated transmission is enhanced during status epilepticus associated with increased insertion of GluA1 subunits

Authors: *K. RAJASEKARAN, S. JOSHI, J. KAPUR;
Neurol., Univ. Virginia, CHARLOTTESVLE, VA

Abstract: We have previously demonstrated dynamic alterations in the AMPA-mediated neurotransmission associated with the expression of GluA2 subunit-lacking, calcium-permeable AMPA receptors (AMPARs) during SE. Here we extend these findings to determine SE-associated plasticity of GluA1 subunit of AMPARs and characterize underlying molecular mechanisms.

SE was induced by lithium-pilocarpine method in adult male rats. The animals were studied either 10 min (SE-10) or 60 min (SE-60) after the first Grade V behavioral seizure using electrophysiological and biochemical techniques.

AMPAR-mediated neurotransmission increased with increasing duration of SE. The frequency of action potential-independent AMPAR-mediated excitatory postsynaptic currents (mEPSCs) recorded from CA1 pyramidal neurons (PN) of SE-10 animals was similar to that recorded from naïve control animals (0.2 ± 0.04 Hz, n = 8 vs 0.4 ± 0.05 Hz, n=14), but increased in PNs of SE-60 animals (1.6 ± 0.4 Hz, n=12, $p < 0.05$). The amplitude of mEPSCs recorded from PNs from SE-10 (12 ± 0.8 pA) and SE-60 (12 ± 0.8 pA) groups were similar to that recorded from PNs of controls (11 ± 0.6 pA). The net charge transfer of AMPAR-mediated mEPSCs was significantly greater in the SE-60 group (40 ± 6 pC vs. 139 ± 30 pC; $p < 0.05$). Similar changes in the frequency or net charge transfer were not observed in the DGCs of SE animals.

The alterations in AMPAR-mediated neurotransmission were accompanied by changes in the surface expression of GluA1 subunit. The intracellular fraction of GluA1 subunit, determined using a BS^3 assay, was reduced in PNs of SE-60 animals (50 ± 10%, n=7, $p < 0.05$) but unchanged in the DGCs (104 ± 9%, n= 5, $p > 0.05$). A biotinylation assay also confirmed increased GluA1 subunit surface expression in the PNs in SE-60 animals (140 ± 12%, n=4, $p < 0.05$).

Phosphorylation of GluA1 subunit influences its surface expression, however phosphorylation of

neither S831 (118 ± 15%, n=8, p > 0.05) or S845 (117 ± 30%, n=8, p > 0.05) residues of GluA1 subunit was altered in PNs of SE-60 animals. Studies in the organotypic hippocampal slice culture revealed that treatment with NMDA (10 μM) and high extracellular potassium (10 mM KCl) increased the surface expression of GluA1 subunit (167 ± 12%, n=4). Further, treatment of animals with NMDAR open-channel blocker, MK-801 (2 mg/kg) after 10 min of continuous electrographic seizures prevented increase in GluA1 surface expression in the PNs (97 ± 10%, n=5, p > 0.05). Thus, activation of NMDARs during SE appears to trigger increased GluA1 surface expression.
Ongoing studies are focused on determining the mechanisms underlying increased GluA1 subunit surface expression during SE.

Title: Maturation of astrocytic glutamate reuptake is disrupted in a model of cortical malformation

Authors: *E. HANSON, M. ARMBRUSTER, L. ANDRESEN, D. CANTU, C. DULLA; Neurosci., Tufts Univ., Boston, MA

Abstract: Glutamate reuptake is critical to brain development and function. We have investigated the maturation of astrocytic glutamate reuptake in the developing rat cortex and hippocampus and in the malformed, hyperexcitable cortex. We hypothesize that developmental disruption of glutamate homeostasis may be epileptogenic and might drive the pathological formation of excitatory synapses in the neonatal cortex. Glutamate transporter currents were measured by voltage clamping cortical astrocytes andt photolysing MNI-glutamate near the cell body. We observed that the decay kinetics of the transporter currents were slower in immature cortex than in immature hippocampus. This difference persisted developmentally through P14. We next examined how neonatal brain insult affected glutamate transport by astrocytes during development. A cortical freeze lesion was performed on P0 rat pups, generating a focal cortical malformation. Freeze lesion animals begin to generate epileptiform network activity by P14 in region around the malformation (the paramicrogyral zone - PMZ). We examined glutamate

reuptake in the PMZ of freeze lesioned animals at P3, P7, P14, P21, and P28 and we found that at P7, PMZ astrocytes take up glutamate faster than astrocytes in control cortex. This corresponds to an increase in reactive astrocytosis in the PMZ at P7. Given that these alterations in astrocyte function occur before the onset of hyperexcitability, a remaining question is whether glutamate dysregulation during development may drive the pathological synaptogenesis associated with hyperexciteability in the malformed cortex. We hope to will expand these studies to determine whether changes in glutamate reuptake are associated with changes in synaptic and extrasynaptic glutamate concentrations as well as long-term changes in synapse number, dendritic spine structure, and cortical network organization.

Title: Head-to head comparison between mGlu1 and mGlu5 receptor enhancement in the chronic treatment of absence epilepsy in WAG/Rij rats

Hoffman LaRoche Ltd, Basel, Switzerland; [6]Univ. Sapienza, Dept. of Physiol. and Pharmacol., Rome, Italy

Abstract: Spike-wave discharges (SWDs), the electroclinical hallmark of clinical absence epilepsy, are generated within cortico-thalamo-cortical circuit. mGluRs located within this network are potential targets for SWD modulatory drugs. Symptomatic WAG/Rij rats endowed with spontaneous occurring absence seizures showed that the acute administration of positive allosteric modulators (PAMs) of mGlu1 and mGlu5 receptors (RO0711401 and VU0360172, respectively) reduced the incidence of SWDs dose dependently without affecting motor behaviour (Ngomba et al., 2011 & D'Amore et al 2012). As a follow up of these previous studies it was investigated whether tolerance during a 10 day chronic treatment occurred and whether the

sensitivity for the drugs changed after treatment. mGlu receptor expression by immunoblotting and brain concentrations of both compound during the treatment were additionally determined. The mGlu5 receptor PAM, VU0360172 (3 mg/kg, s.c., daily for 10 days) reduced the incidence of SWDs without signs of tolerance and without affecting motor behaviour during chronic administration. In contrast, tolerance developed after 2 days of treatment with the mGlu1 receptor PAM, RO0711401 (10 mg/kg, s.c., daily for 10 days). Western blot analysis data showed a down regulation of both mGlu1 and mGlu5 receptors in the cerebral cortex and thalamus in response to RO0711401 administration, whereas only the mGlu5 receptor was down-regulated in response to VU0360172 treatment. Brain levels of RO0711401 decreased with time during treatment, whereas VU0360172 levels remained constant. These data confirm the efficacy of mGlu1 and mGlu5 PAMs in the treatment of absence epilepsy, and suggest that tolerance may develop to chronic activation of mGlu1 receptors as a result of pharmacodynamic and pharmacokinetic mechanisms.

Title: Developmental expression profile of transmembrane AMPA receptor regulatory proteins and AMPA receptor subunits in Genetic Absence Epilepsy Rats from Strasbourg

Authors: *P. M. CASILLAS-ESPINOSA, R. BARMANRAY, T. J. O'BRIEN, K. L. POWELL;
Med., Melbourne Brain Centre. Royal Melbourne Hospital. The Univ. of Melbourne, Parkville, Australia

Abstract: Objective: Absence epilepsy is characterized by a temporary loss of awareness and spike-and-wake discharges on the EEG. Studies in the well validated Genetic Absence Epilepsy Rats from Strasbourg (GAERS) model have identified that absence seizures arise due to abnormal hypersynchronous activity within the thalamocortical circuit. The α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic receptors (AMPARs) mediate most of fast excitatory synaptic

neurotransmission. Transmembrane AMPAR regulatory proteins (TARPs), stargazin (γ2), γ3, γ4, γ5, γ7 and γ8, are a family of proteins that regulate AMPARs trafficking, expression and biophysical properties. Stargazin has been shown to be increased in the somatosensory cortex (SCx) of GAERS compared to non-epileptic control (NEC) rats. In this study we investigate the expression of TARPs and AMPARs in different developmental ages, 7 day (pre-epileptic), 7 weeks (early epileptic) and 22 weeks (epileptic) to determine if expression changes are causative or a consequence of the epilepsy. Methods: Male GAERS (n=10) and NECs (n=10), aged 5 and 20 week underwent surgery to implant EEG recording electrodes for confirmation of the epileptic phenotype. After a one week recovery, 2 x 4hr EEG recordings were acquired over a week after which time the animals were culled, the brains were rapidly extracted and the SCx, motor cortex (MCx) and thalamus were dissected, snap-frozen over liquid nitrogen and stored at −80 °C. GAERS (n=10) and NECs (n=10) 7 day old pups were obtained for brain dissections but these animals did not have EEG recordings. For molecular analysis, mRNA expression levels were assessed in the MCx, SCx and thalamus using qPCR for the TARPs, (stargazin, γ3, γ 4, γ5, γ7, γ8) and AMPARs subunits GluA1 to GluA4. Results: There was no significant difference in stargazin mRNA expression in the SCx, MCx and thalamus in 7 day old GAERS that are not having spontaneous absence seizures compared to NEC rats. However, in 7 week old GAERS as seizures begin to manifest, stargazin mRNA is significantly increased in the SCx, MCx and thalamus ($p<0.05$ for the 3 regions). In adult epileptic GAERS the changes are more pronounced. In MCx, stargazin ($p<0.05$), γ3 ($p<0.01$), γ5 ($p<0.001$), and GluA4 ($p<0.05$) are increased, in SCx stargazin ($p<0.05$), γ3 ($p<0.01$), γ5 ($p<0.01$), γ8 ($p<0.001$) and GluA4 ($p<0.01$) are increased. In thalamus γ4 ($p<0.05$) and γ5 ($p<0.0001$) are increased. Conclusion: These results indicate that changes in TARP expression occur as seizures begin to manifest given that GAERS do not begin to express seizures until around 7 weeks of age, these findings establish a temporal association between increased TARPs expression and seizures.

Title: Mechanisms underlying comorbid depression in temporal lobe epilepsy (tle)

Authors: *R. DHAHER, H. WANG, S. GRUENBAUM, C. ONG, H. ZAVERI, T. EID;
Lab. Med., Yale Univ., New Haven, CT

Abstract:
Depression represents one of the most common and serious comorbidities in patients with epilepsy. Glutamine synthetase (GS), an astrocytic enzyme, critical for metabolism of glutamine, glutamate, and GABA, is reduced in the amygdala in patients with epilepsy and also patients with depression (Kalkman, 2011). Here, we sought to develop a novel model of comorbid depression in TLE by microinfusion of the GS inhibitor methionine sulfoximine (MSO) unilaterally into the central nucleus of the amygdala (CeA) in rats. Male Sprague Dawley rats (380-420 g) were implanted with an osmotic pump injecting either MSO (n=7) or PBS (n=7) into the right CeA at a rate of 0.25 µl/hr. Intracranial EEG activity was monitored from the neocortex for a period of 21 days after the onset of MSO infusion. EEG analysis was correlated with video recordings to determine seizure severity according to the Racine scale. Sucrose preference testing to evaluate depressive-like behavior (anhedonia) occurred following EEG recording. Preference ratio was defined as (sucrose (mL))/ (H_2O (mL)). Recurrent seizures occurred over the three weeks of EEG testing. During the first three days following MSO surgery, 80% of seizures were non-convulsive, while during weeks 2 and 3, roughly 80% of seizures were convulsive (Racine stage 4-5). PBS-infused control rats showed a significantly higher preference ratio (7.93 ± 0.71) than MSO treated rats (2.40 ± 1.62) $p<0.05$ Sucrose consumption was also significantly higher in PBS treated rats (0.19 ± 0.05 g/kg) vs MSO-treated rats (0.08 ± 0.01) ($p<0.05$). H_2O consumption (mL) did not differ between PBS and MSO groups (2.47 ± 0.67 and 2.23 ± 0.87 respectively).This study suggests that perturbations in the glutamine-glutamate-GABA metabolism in the CeA are implicated in the causation of comorbid depression in TLE. We propose that the MSO CeA model can be used for mechanistic studies of comorbid depression in TLE and for testing of novel therapies of this condition.

Title: Traumatic brain injury alters cortical glutamate network function by compromising GABAergic inhibition

Authors: *D. CANTU, K. WALKER, L. ANDRESEN, A. TAYLOR, D. HAMPTON, G. TESCO, C. DULLA;
Neurosci., Tufts Univ. Sch. of Med., Boston, MA

Abstract: Traumatic brain injury (TBI) is a major risk factor for developing pharmaco-resistant epilepsy. Although disruptions in cortical and hippocampal circuitry are associated with TBI, the precise mechanisms by which brain injury leads to epileptic network activity is unknown. In this study, we investigated how controlled cortical impact (CCI), a model of TBI, affects the spatial and temporal parameters of cortical glutamate network activity. Using FRET-based glutamate biosensors, we optically mapped cortical glutamate signaling in real-time while simultaneously recording cortical field potentials. 10 week old, male C57BL/6 mice underwent sham or CCI injury, and acute cortical brain slices were obtained 2-4 weeks post-injury; a time after injury but prior to the onset of spontaneous seizures. Slices from CCI injured cortex were loaded with glutamate biosensor immediately prior to imaging and recording. Results were compared to slices from sham injured mice. Electrical stimulation evoked polyphasic, epileptiform field potentials and disrupted input-output relationships in CCI injured cortex. High-speed glutamate biosensor imaging showed that glutamate signaling evoked by electrical stimulation was significantly increased in the injured cortex. Elevated glutamate responses were consistent with epileptiform activity, were highest in the area directly adjacent to the injury, and spread via deep cortical layers. Cortical glutamate release from CCI injured cortex was sequentially activated with the same temporal parameters as disinhibited control slices. Areas of cortical glutamate signaling were consistent with loss of GABAergic interneurons as measured by parvalbumin and somatostatin immunohistochemistry. Protein expression of the astrocytic glutamate transporters GLT-1 and GLAST showed no differences between sham and CCI injured slices. Our results suggest that loss of GABAergic inhibition in specific cortical sub-networks may facilitate the spread of epileptiform activity following TBI. Overall, our studies suggest that loss of inhibition after TBI leads to cortical network hyperexcitability which can ultimately result in posttraumatic epilepsy.

Title: Characterization of brain structural changes in the methionine sulfoximine rat model of mesial temporal lobe epilepsy

Authors: *H. WANG[1], Y. HUANG[2], R. DHAHER[1], D. COMAN[2], H. ZAVERI[3], F. HYDER[2,4], T. EID[1];
[1]Lab. Med., [2]Diagnos. Radiology, [3]Neurol., [4]Biomed. Engin., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Patients with mesial temporal lobe epilepsy (MTLE) have often suffered from an insult to the brain several years before spontaneous recurrent (epileptic) seizures commence. This is thought to trigger a sequence of structural, molecular, and metabolic alterations that ultimately cause refractory epilepsy. The objective of the present study was to use brain diffusion tensor imaging (DTI) combined with neuropathological assessments to better define the structural alterations that underlie the development of MTLE.
Male Sprague Dawley rats were implanted with a 28-day osmotic pump that infused either the glutamine synthetase inhibitor methionine sulfoximine (MSO; n=7) or phosphate buffered saline (PBS; n=4) unilaterally into the deep entorhinal cortex at a flow rate of 0.25 uL/hr. This approach has been shown to result in epileptic seizures and neuropathological changes that resemble human MTLE. Video-intracranial electroencephalography (EEG) recordings performed in the third week following placement of the pump were used to monitor for seizures. Severity of seizures was characterized using a modified Racine Scale. Rats were perfusion fixed with 4% formaldehyde 6-8 weeks post-surgery and brains were scanned using a 9.4T horizontal bore magnet. Fractional anisotropy (FA) differences were subtracted from each group's average FA and then mapped onto an anatomical average of all brains. Brains were embedded in paraffin

after imaging, serially sectioned and processed for immunohistochemistry using antibodies against a variety of neuronal and glial components.
All of the MSO-infused rats and none of the PBS-infused rats developed recurrent seizures, which were predominantly of Racine stage 4-5. The MSO-infused rats showed extensive and *bilateral* changes by DTI in gray and white matter areas, as evidenced by *increased* FA in the thalamic nuclei and corpus callosum compared to PBS controls. Increases in FA were observed *unilaterally* in MSO vs. PBS treated rats. These increases were seen *ipsilateral* to the infusion site in the entorhinal cortex and CA3 field and *contralateral* to the infusion site in the amygdala. Since conventional MRI showed minimal lesions ipsilateral to the MSO infusion, most of the DTI-based changes are likely due to the effects of MSO. Correlations with immunohistochemistry are ongoing.
The MSO-model of MTLE exhibits significant bilateral alterations throughout the brain. The cellular and molecular correlates of these alterations are currently being investigated by immunohistochemistry. These findings are expected to provide new insights into the structural and molecular processes of epileptogenesis in MTLE.

Title: Corticotropin-releasing factor facilitates epileptiform activity via CRF2 receptor-mediated signaling mechanisms in the rat entorhinal cortex

Authors: *L. KURADA, N. I. CILZ, S. LEI;
Dept. of Pharmacology, Physiol. & Therapeut., Univ. of North Dakota, Grand Forks, ND

Abstract: Corticotropin-releasing factor (CRF) is a stress-released epileptogenic neuropeptide ubiquitously distributed in the brain, including the entorhinal cortex (EC). The EC is involved in the initiation, maintenance and spread of seizures. The role and relevance of CRF and its receptors in the EC is not known. We found that the EC expressed high levels of CRF and CRF2

receptors and bath application of CRF increased the frequency of picrotoxin-induced epileptiform activity recorded from layer III of the EC in slices, via CRF2 receptors and cyclic AMP, with a partial PKA involvement. Application of ZD 7288, a blocker of the hyperpolarization-activated channels (H-channels), significantly reduced the frequency of epileptiform activity but increased the numbers of the synchronizing events within single epileptiform activity and the duration of individual epileptiform activity. In the presence of ZD 7288, CRF failed to increase the frequency of epileptiform activity but still augmented the numbers of the synchronizing events in an epileptiform activity and the duration of epileptiform activity suggesting that part of the effects of CRF on epileptiform activity is mediated via H-channels. Furthermore, CRF increased H-channel currents recorded from layer II stellate neurons via activation of CRF2 receptors. Cyclic AMP not protein kinase A was responsible for CRF-mediated facilitation of H-channel currents.CRF caused membrane depolarization and increased action potential frequency of the principal neurons present in layer II and III of the EC, resulting in epileptiform activity.

Title: Assessing the presynaptic deficit in LIS1 mice

Authors: *W. B. POTTER, S. C. BARABAN;
Neurolog. Surgery, UCSF, San Francisco, CA

Abstract: Malformations of cortical development are associated with cognitive deficits and medically intractable epilepsy. Mutations in the gene encoding LIS1 cause Type 1 lissencephaly; a neuronal migration disorder that produces malformed cortical and subcortical structures resulting in hyperexcitable and epileptic activity. LIS1 heterozygous mutant mice recapitulate many structural and cellular hallmarks of human lissencephaly, namely: electrographic seizures, a disordered hippocampus, abnormal neurogenesis and migration, and enhanced excitatory drive to principal hippocampal neurons. Interestingly, our lab recently found that conditional, postnatal knockout of LIS1 (LIS1-cko) also produces over-excitation in the hippocampus, suggesting that LIS1 deficiency is pro-epileptic in the absence of structural malformation. This project addresses

the causal role of presynaptic dysfunction in the development of hyperexcitability due to LIS1 deficiency. To this end we applied pharmacological modulators of presynaptic function and vesicle formation, and assessed the impact on excitatory transmission at CA3-CA1 hippocampal synapses. This was accompanied by biochemical analysis of presynaptic protein expression and signaling cascades. With the ultimate goal of finding new approaches towards treating malformation-associated epilepsy, this project seeks to determine whether the manipulation of presynaptic function can correct for key pathological phenotypes in a mouse model of malformation.

Title: Early life seizures impaired homeostatic synaptic scaling in cortical neurons

Authors: *H. SUN[1,2], B. KOSARAS[2], F. E. JENSEN[1,2];
[1]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA; [2]Boston Children's Hosp. and Harvard Med. school, Boston, MA

Abstract: Both Hebbian and homeostatic synaptic plasticity are most robust during neonatal period, in which the incidence of seizures is one of the highest across the lifespan. Neonatal seizures are often refractory to conventional antiepileptic drugs, and can result in later life epilepsy, cognitive deficits and autism. We have previously shown that early-life seizures (HS) result in acute and long-term enhancement of AMPAR function and impairment in LTP. In addition to Hebbian synaptic plasticity, homeostatic synaptic scaling calibrates neuronal excitability by adjusting synaptic strengths during prolonged changes in synaptic activity. We have recently shown that HS itself can evoke PLK2-mediated homeostatic modulation of seizure-induced enhancement of AMPAR function. Here we hypothesize that neonatal seizures

may alter homeostatic synaptic scaling in epileptic neurons in response to further chronic activity changes. Neonatal Hypoxic seizures were induced by graded global hypoxia at postnatal day 10. Ex vivo slices were maintained in vitro for 48-72h using an acute culture procedure. Whole-cell patch clamp recordings of AMPAR mEPSCs were made in cortical neurons from post-HS 48h rats and their littermate controls. Compared to acute slices, acute cultured slices did not show significant changes in intrinsic membrane properties and amplitude and frequency of AMPAR mEPSCs ($p>0.05$, n=8-9). We found that chronic activity blockade by 1μM TTX for 24-48h induced significant increases in amplitude and frequency of AMPAR mEPSCs in neurons from both HS rats and normoxic controls ($p<0.05$, n=6-8). However, the decrease in synaptic strength in response to elevated synaptic activity by application of 100μM Picrotoxin 24-48h as identified in controls ($p<0.05$, n=6-8) was occluded in neurons from HS rats ($p>0.05$, n=7-8). Overall, our data reveal an impaired homeostatic synaptic scaling down in neurons following early-life seizures, which may, at least in part, contribute to neonatal seizure-induced long-term neuronal hyperexcitability and epileptogenesis.

Title: The anticonvulsant phytocannabinoid cannabidivarin (CBDV) has a disease-dependent effect on synaptic transmission

Authors: *C. L. HILL[1], B. J. WHALLEY[1], C. M. WILLIAMS[2], G. J. STEPHENS[1];
[1]Reading Sch. of Pharm., [2]Sch. of Psychology and Clin. Language Sci., Univ. of Reading, Reading, United Kingdom

Abstract: Cannabidivarin (CBDV) is a non-psychoactive phytocannabinoid and propyl analogue of cannabidiol (CBD). We previously demonstrated that CBDV reduces epileptiform activity in vitro and shows significant anticonvulsant actions in vivo (Hill et al., 2012 Br. J. Pharmacol. 167:1629-42). However, little is currently known about CBDV's anticonvulsant mechanism of action. Here, we investigate CBDV effects on synaptic transmission in hippocampal tissue from both control and epileptic rats.
Acute transverse, hippocampal slices (300 μm) were taken from 3 groups of male Wistar rats:

young controls (P24-28), rats with spontaneous recurrent seizures (induced by pilocarpine treatment and behaviourally confirmed to have epilepsy) and age-matched controls (~P50-60). Pairs of evoked local field potentials (LFPs; inter-stimulus interval 50 ms) were recorded from the stratum radiatum of the CA1 region using multi-electrode arrays (MEAs) and the ratio of paired LFP amplitudes (paired pulse ratio; PPR) was obtained. Independently, whole cell patch clamp of CA1 pyramidal cells was used to record miniature inhibitory postsynaptic currents (mIPSCs).

PPR in epileptic tissue was significantly greater than PPR in age-matched controls (1.65 ± 0.1 vs 1.36 ± 0.05; $p \leq 0.01$). CBDV (1-50 μM) significantly reduced PPR in both P24-28 and ~P50-60 control tissues (10-22%; $p < 0.05$), but had no effect on PPR in epileptic tissue. Miniature IPSC amplitude in P24-28 control slices was not significantly different when compared to epileptic slices (18.9 ± 5.1 pA vs 20.2 ± 6.7 pA). However, mIPSC frequency in epileptic tissue was significantly reduced when compared to P24-28 control tissue (0.4 ± 0.1 Hz vs 1.0 ± 0.2 Hz; $p \leq 0.05$). CBDV (10 μM) had no significant effect on mIPSC amplitude and frequency in both P24-28 control and epileptic slices.

These data demonstrate that epileptic and non-epileptic tissues have differences in synaptic transmission and that the effect of CBDV could be disease-dependent. In non-epileptic tissue, results were consistent with CBDV increasing the probability of presynaptic neurotransmitter release in hippocampus CA1. However, CBDV does not alter release probability in epileptic tissue or change action potential-independent GABAergic transmission. The interaction between disease-dependent changes in both intracellular calcium handling and responses to CBDV remain the focus of our future work.

Abstract: The therapeutic strategies on the refractory epilepsy, points to the coadministration of multidrug resistant proteins (MDR1 and MRP) inhibitors -like probenecid-, with antiepileptic drugs. There is no data that correlates MDR1 and MRP, with the activity of NMDA receptor; the main excitatory receptor involved in the epileptic activity, and in the development of *kindling.* The kindling model involves the activation of NMDA receptor for the development of 5 class of seizures, ending up in general seizures (1-5 in Racine's scale). In this study, male Wistar rats were electrically stimulated for the development of kindling. Then different doses of probenecid were administrated (75, 100 y 300 mg/kg) for 5 days. After the treatment, the rats were sacrificed by decapitation and the piriform cortex and hippocampus were dissected, for the analysis of the expression of MRP1, MDR1 and NR2B subunit of NMDA receptor; as well as the activity of nitric oxide synthase (NOS), as an indirect marker of NMDA receptor activity. The results shows a decrease in the after discharge time, and a 75% reversion of the seizure class (5-3). The cDNA levels indicate a decrease in the ARNm of MDR1 gene, but not in MRP1. The Western Blot analysis shows a decrease in the MDR1, MRP1 and NR2B expression levels. The NOS activity was reduced. The differential effect of the different doses of probenecid might be explained by the reduction of the expression of MRP1, MDR1.

Title: Hippocampal synaptic plasticity after development in a rat model of cryptogenic infantile spasms

Authors: M. TSUJI, Y. TAKAHASHI, A. M. WATABE, *F. KATO;
Lab. Neurophysiol, Dept Neurosci, Jikei Univ., Tokyo, Japan

Abstract: Infantile spasms (IS), a specific type of seizure in a catastrophic epilepsy syndrome of infancy and childhood, is strongly associated with cognitive impairment and psychosocial morbidity in adolescence and adulthood despite seizure remission. The etiology as well as the mechanism underlying such remote influence of cryptogenic IS to the higher brain function remains unidentified. To address this issue, we made an animal model of cryptogenic IS according to a method recently developed by Velisek et al (2010) and analyzed the short- and long-term synaptic plasticity in the hippocampus of young adult rats. Pregnant Sprague-Dawley rats were treated with betamethasone (0.4 mg/kg, i.p.) or saline (saline group) and the offsprings were injected with NMDA (15 mg/kg, i.p.) three times on postnatal days 12 to 15 (NMDA group). In accordance with previous reports, these injections resulted in typical flexion spasms with irregular EEG spike bursts lasting 30-60 minutes. A subset of animals was treated with ACTH before NMDA injections (2-3 times for 3 days; ACTH group). After weaning, the rats were raised with normal chow and water until postnatal week 6-8, at which hippocampal slices were prepared from these groups of animals. The paired-pulse ratio, as estimated from the slope of field EPSP in CA1 evoked by paired stimulation of the Schaffer collateral (interval, 50 ms), was significantly smaller in NMDA group than in ACTH group in female rats. Post-tetanus potentiation observed after 100-Hz stimulation for 1 s delivered twice separated by 10 s was weakest in NMDA groups. The differences in release properties between groups were not confirmed in the male rats. The NMDA group also showed the smallest long-term potentiation as measured at 35-45 min after the tetanus. These results indicate that IS-like aberrant activity in the early stage of life would result in remote effects including altered short-term plasticity in the hippocampus, appearing later in life.

Title: Alterations of TLR4 expression following brain injuries

Authors: *Z. C. XU[1], Y. LIANG[2], H. ZHANG[2], Z. LEI[1], Z. XU[2], Q. CUI[2];
[1]Indiana Univ. Med. Ctr., INDIANAPOLIS, IN; [2]The 3rd Affiliated Hosp. of Guangzhou Med. Univ., Guangzhou, China

Abstract: Brain injury is the major cause of acquired epilepsy and diabetic patients have higher incidence of seizures. Accumulating evidence suggests that toll-like receptor 4 (TLR4) plays an important role in pathogenesis of epilepsy following brain injury. We investigated the TLR4 expression after ischemia under hyperglycemia and following traumatic brain injury.
Traumatic brain injury (TBI) was induced in Sprague Daelet rats (~300g) by controlled cortical impact (CCI) method with a pneumatic piston containing a 3.0 mm diameter tip at a rate of 2.7 m/s and 1.0 mm of compression. Global ischemia was produced in adult Wistar rats using four-vessel occlusion method for 15 min. Hyperglycemia (> 200 mg/dL) was induced by intraperitoneal injection of glucose (3.0 g/kg) 15 min before ischemia. The animals were sacrificed at different time points after TBI or ischemia. The neuronal death in the hippocampus was determined by hematoxylin-eosin staining. The expression levels of TLR4 and HMGB1 were analyzed by Western blotting and immunohistochemistry. Inflammation induced by Lipopolysaccharide (LPS, i.p.) was used as positive controls.
In naïve animals, TLR4 was weakly expressed in hippocampus and HMGB1 was localized in the nucleus of neurons throughout the hippocampus. In ischemia studies, the intensity of TLR4 immunostaining was significantly increased in hippocampal interneurons in hyperglycemic group after ischemia as compared with normoglycemic and control group. Meanwhile, a dramatic decrease of HMGB1 expression was observed in the hippocampus after hyperglycemic ischemia. No difference in the expression of TLR4 and HMGB1 was observed between

hyperglycemic group and LPS group. The immunoreactivity of c-fos was also increased in hippocampal neurons in hyperglycemic animals after ischemia, suggesting the increase of neuronal activity. Most rats in the hyperglycemic group developed tonic-clonic seizures after ischemia. The animals with seizures died of status epilepticus within 2 h after the onset of seizure. In TBI studies, the cortical impacts produced a lesion in the ipsilateral cortex. However, no obvious neuronal death was found in the ipsilateral hippocampus up to 3 days after TBI. Immunohistochemical staining and Western blotting indicated a significant increase of TLR4 expression in the ipsilateral hippocampus, but not in the contralateral hippocampus. The increase of TLR4 expression reached the peak at 6 hrs after TBI.
These results suggested that up-regulation of TLR4 might contribute to the pathogenesis of seizures/epilepsy following brain injuries.

Title: Seizure-induced severe ischemic/hypoxic episodes (SISIHE) explains Todd's paresis

Authors: *J. S. FARRELL[1,2], J. F. DUNN[2], G. C. TESKEY[2];
[1]Neurosci., Univ. of Calgary, Calgary, AB, Canada; [2]Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Brief seizures cause severe local brain tissue hypoxia (pO2 <10mmHg) immediately after seizures that is linearly related to the duration of the seizure and that often lasts for over an hour in the hippocampus and neocortex. We also have observed that the resulting hypoxia is accompanied by reduced blood perfusion and, therefore, termed this novel phenomenon Seizure-Induced Severe Ischemic/Hypoxic Episode (SISIHE). In some people with epilepsy the postictal period is often marked by specific behavioural impairments. Todd's Paresis, for example, is

defined by motor weakness or paralysis after a seizure and has previously been attributed to neuronal exhaustion or motor neuron inactivation. Given that SISIHE and postictal deficits occur on similar time-scales, we hypothesized that the resulting hypoxia after seizures is responsible for the ensuing behavioural deficits. We tested this hypothesis by preventing vascular smooth muscle contraction with nifedipine and thus, dissociated the severe hypoxia from a neocortical-kindled seizure. We assessed grip strength on the hanging bar test before the seizure, during the post seizure hypoxic period (20 and 40 minutes) and following recovery of local tissue oxygen (80 minutes). Vehicle injected rats held onto the bar for a significantly shorter time during the hypoxic period at 40 minutes but recovered after return to normoxia (80 minutes). Nifedipine pretreatment was able to prevent both the hypoxia and grip-strength deficit without affecting seizure duration. This experiment provides evidence that postictal behavioural deficits are a result of prolonged insufficient oxygen and can be prevented with pharmacological agents that prevent reduced blood perfusion. Clinicians should consider treating Todd's paresis and other postictal behavioural impairments to prevent the consequences of hypoxic episodes.

Title: Role of RNA-Polymerase-1 in epileptogenesis

Authors: *M. HETMAN[1], A. VASHISHTA[1], R. PARLATO[2];
[1]Neurolog. Surgery, Univ. of Louisville, LOUISVILLE, KY; [2]DKFZ, Heidelberg, Germany

Abstract: Hyperactivation of the mTOR pathway and the following deregulation of brain cell growth including neuronal hypertrophy have been implicated in epileptogenesis. RNA-Polymerase-1 (Pol1)-mediated transcription of the nucleolar rRNA genes is the critical regulatory step of ribosomal biogenesis. The Pol1/ribosomal biogenesis pathway is stimulated by the ERK1/2 MAP kinase and the mTOR to promote proliferative cell growth. To investigate the role of ribosomal biogenesis in development of epilepsy, effects of increased neuronal activity on nucleolar transcription were determined in primary cultures of rat forebrain neurons and in the

hippocampus of mice that were subjected to seizures. In cultured cortical or hippocampal neurons gabazine stimulated Pol1-mediated transcription in an NMDA receptor-dependent manner. In whole mice, a transient seizure episode induced by the pro-convulsant pentylenetetrazole (PTZ) or status epilepticus in response to kaininc acid stimulated Pol1 and increased expression of the Pol1 co-activator Ubf. Moreover, mice that had a tamoxifen-induced knockout of the essential Pol1 co-activator Tif1a that was limited to excitatory forebrain neurons were resistant to PTZ kindling. These findings suggest that nucleolar transcription is regulated by seizures to promote development of epilepsy. Hence, ribosomal biogenesis may be a novel target for anti-epileptogenic interventions.

Title: Dysregulated NRSF expression after epilepsy-inducing insults is caused by a loss of microRNA-124

Authors: *G. P. BRENNAN[1], S. MCCLELLAND[1], S. IYER[1], T. Z. BARAM[1,2];
[1]Pediatrics, [2]Anat. & Neurobio., Univ. of California Irvine, Irvine, CA

Abstract: Rationale: Neuron restrictive Silencing factor (NRSF/REST) is a transcriptional repressor of neuronal genes in non-neuronal tissue, found at very low levels in neuronal tissue. Our previous studies found upregulation of NRSF within hippocampus during epileptogenesis that follows kainic-acid (KA)-induced status epilepticus (SE), resulting in the repression of a number of key neuronal genes. Interference with NRSF function using an oligodeoxynucleotide decoy strategy resulted in rescue of the repressed genes and, importantly, in attenuating epileptogenesis (McClelland et al, 2011). These data provided strong support for a role of NRSF upregulation in epileptogenesis, raising the question: How do epilepsy-provoking insults upregulate NRSF expression and function?
Methods: Status epilepticus was induced in P10 rats by systemic KA administration. Because NRSF might be regulated by microRNAs (Packer et al., 2008), and because reduced miR124 was

found in epileptic brain (Kan et al., 2012), we examined levels of NRSF, REST4 and miR124 levels at specific time points using qRT-PCR. To study directly whether altered levels of miR-124 regulate NRSF expression, organotypic hippocampal slice cultures were treated with KA to produce long (3h) seizure-like events. Hippocampi were then exposed to either miR-124 mimics or scrambled mimic controls for 48h and expression levels of NRSF, REST4 and a target gene of NRSF, HCN1, were determined using qRT-PCR.
Results: NRSF mRNA levels increased enduringly following SE, confirming our previous reports. Levels of miR-124 decreased as early as 60 min following KA administration, prior to reduction of NRSF levels,and corelated inversely with those of NRSF throughout the experiment. Whereas total NRSF levels increased, the REST4/NRSF ratio was reduced, suggesting lower production of alternatively spliced isoforms of NRSF. Repression of HCN1, a target gene of NRSF, was augmented after the KA-seizures, suggesting augmented NRSF function resulting from increased repressor levels. A mimic of miR-124, given after the long seizure, attenuated increases in NRSF levels and prevented repression of the NRSF target gene HCN1.
Conclusions: Together, these data support the scenario that seizures repress miR-124 levels, resulting in enhanced NRSF levels and function. Because augmented NRSF repression of key neuronal genes promotes epilepsy, miR-124 based therapeutics may provide a selective strategy option in the prevention of epileptogenesis.

Title: Aspirin prevents the development of hippocampal mossy fiber sprouting through the attenuation of mTOR signaling in a mouse model of temporal lobe epilepsy

Authors: *K. JEONG[1,2], J. KIM[1,2], M.-Y. LEE[3,2], S. KIM*[1,2];
[1]Departments of Pharmacol., Col. of Medicine, The Catholic Univ. of Korea, Seoul, Korea, Republic of; [2]Catholic Neurosci. Inst., [3]Departments of Anat., The Catholic Univ. of Korea, Seoul, Korea, Republic of

Abstract: Aspirin, a widely used non-steroidal anti-inflammatory drug (NSAID), reportedly suppresses reorganization of mossy fibers after epileptic insults. In addition, a recent study suggested that mammalian target of rapamycin (mTOR) signaling might be involved in the mossy fiber sprouting related to status epilepticus (SE). Thus, the present study was performed to investigate whether aspirin affects the mTOR signaling pathway to attenuate mossy fiber sprouting after pilocarpine-induced SE. Aspirin was daily administrated (15 mg/kg or 150 mg/kg, i.p.) for 10 days starting from 3 days before SE, continuing until 6 days after SE. In order to induce SE, C57BL/6 mice (aged 8 weeks) were administrated with pilocarpine hydrochloride (280 mg/kg, i.p.) at 30 min after pretreatment with atropine methyl nitrate (2 mg/kg, i.p.) and terbutaline hemisulfate (2 mg/kg, i.p.). Mossy fiber sprouting was measured in the hippocampus using Timm staining. Phosphorylated S6 ribosomal protein (pS6) was used as a biomarker of mTOR activity. Seven days after SE, mossy fiber sprouting was significantly decreased in the high dose (150 mg/kg) aspirin-treated group as compared to the vehicle-treated control group. In addition, treatment with high dose aspirin significantly reduced the number of pS6-positive cells which was increased in the dentate granule cell layer of the hippocampus of vehicle-treated mice at 7 days after SE. These findings suggest that aspirin could attenuate mossy fiber sprouting, probably through inhibition of mTOR signaling, after pilocarpine-induced epilspy.

Title: Chromatin remodeling in neurons in the caudate-putamen after excessive neuronal excitation

Authors: T. MORI, *T. WAKABAYASHI, Y. HIRAHARA, Y. TAKAMORI, T. KOIKE, H. YAMADA;
Dept. of Anat. and Cell Sci., Kansai Med. Sch., Hirakata, Osaka, Japan

Abstract:

Status epilepticus (SE) induces pathological and morphological changes in the brain. Recently, it has become clear that excessive neuronal excitation, stress and drug abuse induce chromatin remodeling in neurons, thereby altering gene expression. Chromatin remodeling is a key mechanism of epigenetic gene regulation. Histone H3 phosphorylation is frequently used as a marker of chromatin remodeling and is closely related to the upregulation of mRNA transcription. In the present study, we analyzed H3 phosphorylation levels *in vivo* using immunohistochemistry in the brains of mice with pilocarpine-induced SE. A substantial increase in H3 phosphorylation was detected in neurons in specific brain structures. Increased H3 phosphorylation was dependent on neuronal excitation. In particular, a robust upregulation of H3 phosphorylation was detected in the caudate putamen, and there was a gradient of phosphorylated $H3^+$ ($PH3^+$)
neurons along the medio-lateral axis. After unilateral ablation of dopaminergic neurons in the substantia nigra by injection of 6-hydroxydopamine, the distribution of $PH3^+$ neurons changed in the caudate putamen. Moreover, our histological analysis suggested that, in addition to the well-known MSK1 (mitogen and stress-activated kinase)/H3 phosphorylation/c-fos pathway, other signaling pathways were also activated. Together, our findings suggest that a number of genes involved in the pathology of epilepsy are upregulated in $PH3^+$ brain regions, and that H3 phosphorylation is a suitable indicator of strong neuronal excitation.

Title: Transcriptome profiling of hippocampal CA3 reveals spatially distinct patterns of gene expression after early-life seizure-induced preconditioning

Authors: *S. HU, A. M. SLOMKO, Z. NASEER, S. S. ALI, Y. GLICKSMAN, L. K. FRIEDMAN;
Cell Biol. and Anat., New York Med. Col., Valhalla, NY

Abstract: The immature brain is relatively resistant to seizure-induced injury. Moreover, multiple early-life seizures result in spatial preconditioning. For example, injury to the CA1 but not CA3 hippocampal subregion of juvenile animals (P20) is attenuated following a single injection of kainic acid (KA) ($1\times KA_{p20}$) if animals have a history of two sustained neonatal seizures on P6 and P9 ($3\times KA_{p20}$). The underlying mechanisms of age-dependent, spatially distinct neuroprotection and the responsible major signaling cascades remain unknown. In order to identify gene candidates involved in the age-dependent and spatially protective effects, we previously profiled transcriptomes of the isolated CA1 subregion after $1\times KA_{p20}$ and $3\times KA_{p20}$. The present study isolated transcriptomes of the CA3 subregion under three conditions [after $1\times KA_{p20}$, $3\times KA_{p20}$, and 3×KA on P6, P9 and P13 ($3\times KA_{p13}$)]. Under all three conditions, 11346 genes (Agilent platform) were regulated: $1\times KA_{p20}$ (22.1%) vs. $3\times KA_{p20}$ (50.2%), vs. $3\times KA_{p13}$ (28.7%). A large number of genes were uniquely regulated, of which only 830 were commonly upregulated and 290 commonly downregulated when comparing the P20 group. More genes were upregulated in the CA3 subregion after $3\times KA_{p20}$ compared to $1\times KA_{p20}$ and $3\times KA_{p13}$. Moreover, many more genes were downregulated in the CA3 compared to the CA1 after $3\times KA_{p20}$ (Duke Platform) (1393 vs. 41). Although many autophagy genes were triggered by single or multiple seizures within the CA3, many protective genes were also differentially upregulated, particularly after 3×KA in both age groups, but with different expression profiles. These included, but were not limited to, calcium modulated proteins (e.g. annexins, calmodulin), apoptosis inhibitors (e.g. anti-apoptotic Bcl2 members), adaptor-related protein complexes, ADAM metalloproteinases, adaptor ATG autophagy genes, caspase cascade activators, ATP-mediated gliotransmitters, GTP binding proteins, cyclins, F-box proteins, growth factors, interleukins, heat shock proteins, and certain ionotropic and metabotropic glutamatergic and GABAergic neurotransmitter receptors and synthesizing enzymes. Examples of genes that were differentially downregulated between the groups include ankyrin-repeat proteins, adenosine receptors, ATP synthases, caspase recruitment domains, calcium channels, certain heat shock proteins, NFKB activating proteins, synaptosomal associated proteins, potassium voltage gated channels, and zinc finger domains. Age and regional differences in gene expression are likely responsible for early-life resistance to injury as well as the early-life seizure-induced neuroprotective effects.

Title: May neonatal seizures plant the roots for epileptogenesis?

Authors: *E. Y. SONODA[1], M. J. G. MARQUES[1], E. A. CAVALHEIRO[1], R. M. CYSNEIROS[2], F. A. SCORZA[1];
[1]Federal Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Mackenzie Univ., Sao Paulo, Brazil

Abstract: Seizures in newborns (NBs) remain the most frequent neurological problem in the nursery. Although seizures per se do not cause irreversible damage in the immature (developing) brain, NB seizures may immediately alter some electrical parameters and behavioral patterns. However, it remains unclear whether or not NB who had seizures will be more prone to develop epilepsy later in life. The effects caused by seizures in this population can be either transient or persistent, and the long-term effects may occur even with no histological evidence of neuronal injury. In order to address the unresolved question of whether seizures in NBs can plant the roots for epileptogenesis, the objective of this research was to analyze whether a status epilepticus (SE) in the NB facilitates the amygdala kindling process in the adult period of life. Firstly, nine days postnatal Wistar rats were divided into two groups: one was injected with pilocarpine solution (380mg/kg) and the other was injected with saline solution (control group). The animals injected with pilocarpine had a single SE and did not present spontaneous recurrent seizures thereafter, while control animals presented no SE and no spontaneous seizures. At the sixtieth day postnatal, all animals were submitted to the electrical amygdala kindling process. The number of stimulus required to complete the kindling model of epilepsy (3 consecutive seizures at stage 5, as described by Racine 1972), the time of afterdischarges (AD) and afterdischarge threshold (ADT) necessary for seizure initiation were analyzed. The results showed that the animals which presented SE needed a smaller number of stimuli to complete the kindling process than the control animals. Although the number of stimuli was different, the AD and ADT did not differ between groups. Additionally, animals submitted to the SE in the neonatal period firstly presented seizures classified as stage 2 of the kindling model, thereby bypassing stage 1 seizures. In conclusion, unlike in the adult brain, SE in the NB may lead to neuroplastic effects that protect the brain from recurrent seizures, as the animals injected with pilocarpine solution did not present spontaneous recurrent seizures and the AD and ADT was not different between experimental and control animals. On the other hand, the kindling process was faster in the experimental group than in the control animals, which suggests that the SE in the NB may lead to some alterations in the brain, probably as a consequence of disrupted cortical synapses, myelin formation in the cerebral hemispheres, and formation of the long tracts.

Title: Exposure to caffeine during pregnancy and lactation increases network excitability and seizure susceptibility in rodent offspring

Authors: *A. W. FAZELI[1], A. GHESTEM[2], S. MARGUET[1], R. CUNHA[3], M. ESCLAPEZ[2], D. ISBRANDT[1], C. BERNARD[2];
[1]Ctr. For Mol. Neurobiology, Exptl. Neuropediatrics, Hamburg, Germany; [2]INSERM UMR1106, Inst. de Neurosciences des Systèmes, Marseille, France; [3]Ctr. for Neurosci. and Cell Biology, Univ. of Coimbra, Coimbra, Portugal

Abstract: Purpose: Consumption of psychoactive drugs during pregnancy interferes with brain development leading to deleterious long-term psychiatric, neurological and cognitive impairments in offspring. Caffeine, the most widely consumed psychoactive substance, is a naturally-occurring antagonist of adenosine receptors, which regulate numerous intracellular processes. Its effect on brain development is controversial. We tested whether maternal caffeine exposure in mice dams affected the physiology of their offspring.
Method: Dams were exposed to 0.3 g/L caffeine in their drinking water during pregnancy and lactation. In vivo recordings were performed with silicon probes in caffeine-exposed and control pups during the first postnatal week in the hippocampus and visual cortex V1. Seizure susceptibility was assessed with PTZ.
Results: Caffeine exposed pups displayed network hyperexcitability in vivo and reduced threshold to PTZ-induced seizures.
Conclusion: Caffeine exposure during pregnancy and lactation leaves a mark in neuronal circuits rendering them hyperexcitable. Maternal ingestion of caffeine during pregnancy and lactation may constitute a risk factor for the development of seizures in human neonates.

Title: Post-traumatic epileptogenesis in APP/PS1 mouse model of Alzheimer`s disease

Authors: *D. MISZCZUK[1,2], H. TANILA[2,3], K. LUKASIUK[1], A. PITKANEN[2,3];
[1]Neurobio., Nencki Inst. of Exptl. Biol., Warsaw, Poland; [2]A. I. Virtanen Institute, Univ. of Eastern Finland, Kuopio, Finland; [3]Dept. of Neurol., Kuopio Univ. Hosp., Kuopio, Finland

Abstract: Amyloidogenesis is a common pathology in traumatic brain injury (TBI) and Alzheimer`s disease (AD), both of which associate with an elevated risk of epilepsy. Moreover, TBI is a risk factor for AD, facilitating amyloidogenesis. To elaborate the role of increased amyloid-β load on post-TBI epileptogenesis we investigated whether traumatic brain injury (TBI) facilitates epileptogenesis in an AD mouse model, and whether that associates with acquired channelopathy.
TBI was triggered using control cortical impact (CCI) in 13-15 wk old male APP/PS1 mice (n=14) and their wild type (Wt) littermates (n=17). Mice were assessed with composite Neuroscore for motor recovery at 2 d, 7 d, and 14 d post-TBI. Spatial memory was evaluated using Morris water-maze (MWM) at 14 d post-TBI. Then, mice were followed-up for 2 wk (24h/7d) with continuous video-EEG monitoring starting at 6 wk and 14 wk post-TBI to assess occurrence of spontaneous seizures and epileptiform discharges (EDs). At the end, mice were sacrificed and gene expression profiling of perilesional cortex, ipsilateral thalamus and ipsilateral hippocampus was performed using Affymetrix microarray system (Affymetrix Mouse Gene 2.1 ST Array).
APP/PS1 injured mice showed motor deficits at 2 d, 7 d and 14 d post-TBI as compared to

APP/PS1 controls ($p<0.01$). APP/PS1 injured mice were more impaired than Wt injured mice at 14 d post-TBI ($p<0.01$). Latency to find the platform in MWM was longer in APP/PS1 injured mice than in the Wt injured group ($p<0.05$). In the probe trial, APP/PS1 injured mice spent less time in the target quadrant than APP/PS1 controls ($p<0.05$). Video-EEG monitoring performed at 6 wk post-TBI revealed spontaneous seizures in 86% of APP/PS1 injured animals and 36% of APP/PS1 controls ($p<0.05$). In Wt groups, 7% of Wt injured mice and none of Wt controls displayed spontaneous seizures (p0.05). Neither Wt injured mice nor Wt controls had spontaneous seizures. The number of EDs did not differ between the groups. Preliminary microarray data analysis revealed changes in transcriptome between the groups.
Enhanced amyloidogenesis results in more pronounced epileptogenesis and more severe motor and cognitive co-morbidities following TBI.

Title: Long-term effects of the initial pattern of activity-dependent synaptic depression on seizure probability in a hippocampal network model

Authors: *W. B. SWIERCZ[1,2], K. J. STALEY[1,2];
[1]Massachusetts Gen. Hosp., CHARLESTOWN, MA; [2]Neurol., Harvard Med. Sch., Boston, MA

Abstract: Using a large scale computational model of hippocampal area we modeled changes in network activity following trauma and during epileptogenesis. The model was comprised of a 105 x 105 array of integrate-and-fire neurons synaptically connected via glutamatergic connections, and a 18 x 18 array of interneurons with GABAA outputs. For each modeling session, inputs and outputs were stochastically generated using the same connectivity probabilities, so that each session was comprised of a different instantiation of the core network. Fractional cell loss due to trauma was equally and randomly distributed in both glutamatergic and GABAergic networks. After cell loss followed by recurrent axon sprouting networks developed bursts of synchronous activity. Axon sprouting continued until surviving cells to

reconstituted original number of synapses. As a result bursts increased in frequency and in fraction of participating neurons, sometimes generating sustained (tonic) ictal-like activity that slowly transitioned into intermittent (clonic) activity.
We then used this model to address two questions: 1) What factors other than the pattern of sprouting contribute to the transformation from periodic synchronous bursting to ictal-like activity? 2) What factors contribute to the transformation of ictal-like activity from the tonic to clonic phase? We analyzed spatial and temporal patterns of synchronous activity propagation, synaptic depression and recovery, and local and global imbalances between inhibition and excitation. Our findings include 1) recurrent sprouting is necessary but not sufficient for ictal-like activity. 2) In networks with identical connectivity, transition from bursting to ictal activity depended on the initial conditions, specifically the distribution of activity-dependent synaptic depression. 3) Transition from tonic to clonic activity and eventually back to periodic synchronous bursting was not caused by global activity-dependent synaptic depression, but depended instead on the anatomical distribution of synaptic depression and recovery. 4) Differences governing these transitions were relatively small and it was surprisingly difficult to correlate them with obvious changes in network activity.
These simulations provide insight into our difficulties understanding and controlling ictogenesis. Understanding ictogenesis requires not only knowledge of connectivity but also subtle, activity-dependent inhomogeneities permissive for seizure onset. Similarly, control of seizure onset would require precise knowledge of extensive areas of network with high temporal resolution that is currently not technically feasible.

Title: Homeostatic synaptic scaling mediates distinct types of paroxysmal activity following brain trauma

Authors: *O. GONZALEZ[1], G. KRISHNAN[1], T. SEJNOWSKI[2], I. TIMOFEEV[3], M. BAZHENOV[1];

[1]Univ. of California, Riverside, Riverside, CA; [2]Salk Inst. for Biol. Studies, La Jolla, CA; [3]Laval Univ., Quebec, QC, Canada

Abstract: Epilepsy is commonly observed following brain trauma, however mechanisms that cause epileptic seizures are still not fully understood. Experimental and modeling studies suggested that homeostatic scaling of synaptic efficacy due to deafferentation resulting from head trauma could lead to epilepsy. Epileptic seizures involve large changes in ion concentrations, however, it remains unknown how homeostatic changes interact with ion concentration dynamics during interictal and ictal periods. In this study, we examined the effect of homeostatic synaptic scaling in a biophysically realistic cortical network model that included the dynamics of extra- and intracellular ion (Na+, K+ and Cl-) concentrations. In the model, trauma was induced by partial deafferentation of neurons and excitatory connections between neurons were then scaled by homeostatic processes to maintain a firing rate of about 5 Hz. We observed two distinct types of abnormal activity following deafferentation and synaptic scaling. Increases in synaptic strength led to intermittent periods of high frequency activity accompanied by a small increase in extracellular K+ concentration (from 3 to 4.5 mM) and followed by periods of low activity; this network state did not transition to full-scale seizures. However, application of a brief (1 sec) high frequency external stimulus transformed the network, inducing seizure-like events with extracellular K+ increasing up to 8-10 mM and repetitive transitions occurring between tonic and clonic states. This observation was in contrast to results obtained from the intact (without deafferentation) network where the same external stimulation caused only a transient increase in firing rate followed by a return to the baseline after the stimulus was removed. Our study suggests the existence of bistability in the deafferented network, and that the threshold for the spike-wave type of epileptiform activity triggered by external input is reduced following deafferentation and homeostatic scaling. Overall, we show that a model considering interactions between ion dynamics and homeostatic processes can differentiate between interictal paroxysmal activity involving high frequency activity and full-fledged seizure as seen in experimental and clinical settings.

Title: The development of an epileptic network following brain injury

Authors: *K. P. LILLIS[1], W. B. SWIERCZ[1], M. A. KRAMER[2], B. J. BACSKAI[1], K. J. STALEY[1];
[1]Neurol., Harvard Med. Sch., Charlestown, MA; [2]Dept. of Math and Statistics, Boston Univ., Boston, MA

Abstract: Following traumatic brain injury, new neurites and synapses form to replace lost connections and restore lost function. If this homeostatic sprouting creates predominantly local connections, a likely result is a recurrently connected neuronal network, prone to generating seizures. In this study, we used the organotypic slice culture model of post-traumatic epileptogenesis (Berdichevsky et al. J Neurosci 2013) to determine the most basic principles by which neurons re-wire following injury. Using genetically encoded calcium indicators and high-frequency two-photon targeted path scan imaging, we recorded calcium signals daily in populations of ≥30 cells to track the spontaneous emergence of synchronous activity in the days leading up to the first seizure. Interestingly, in this severe model of injury, bursts of synchronous activity begin within hours of slice trauma. Using correlation-based network analysis of calcium signals to quantify functional connectivity, we find that statistically significant correlations are initially weak and only exist between nearby cells. As interictal bursting continues, these correlations become progressively stronger and more far-reaching, with correlation strength between pairs of neurons being nearly independent of the distance between them and seizures develop. To more closely examine network changes associated with the initial emergence of synchrony after injury, slices were cultured in a stage mounted miniature incubator and the same 40 cells were imaged hourly for the first 24 hours in vitro. During this time, a similar pattern of initially local and progressively more distal correlations was observed. These results describe the spatial evolution of correlated activity during post-traumatic epileptogenesis. The data support a model in which neurons replace synapses lost to injury by connecting first to neighboring cells, and indicate that the emergence of seizure activity is coincident with the development of longer-range connectivity.

Title: Potential underlying mechanisms of epileptogenesis after traumatic brain injury

Authors: *Z. WANG, K. STALEY;
Dept. of Neurol., Massachusetts Gen. Hosp. & Harvard Med. Sch., Charlestown, MA

Abstract: Posttraumatic epilepsy is a common long-term consequence of traumatic brain injury (TBI). The underlying mechanisms of the epileptogenesis after TBI are poorly understood.
To investigate the underlying mechanisms of epileptogenesis after TBI, we used the hippocampal organotypic slice culture model of post-traumatic epileptogenesis (Berdichevsky et al. J Neurosci 2013. We combined dual whole-cell patch clamp recording with two photo imaging to study the neuronal activities and networks changes in hippocampal CA1 area during the days in culture after severe slicing trauma. Electrophysiological data were analyzed by custom software (DClamp: available at www.ieeg.org/?q=node/34) to record,identify, separate, and correlate ictal, interictal and postsynaptic activities. Using whole cell patch clamp recording, we found that hippocampal organotypic slices became epileptic after several days of slicing-induced traumatic injury. Interictal spikes occurred earlier than ictal activities, consistent with the chronic EEG telemetry in vivo (White et al Epilepsia 2010) and in vitro field recordings (Berdichevsky et al. Neurobio Dis 2012). After analyzing the ictal activity, interictal activity, and spontaneous postsynaptic currents, we measured the cross-correlation of events between the pair of neurons that we recorded. We found that the cross-correlation of all three activities were greatest locally shortly after slicing, but the correlations of activities in distant pyramidal cell pairs (> 200 um interelectrode distance) increased in the first and second weeks in culture. Two photon imaging of pyramidcal cells in CA1 area after Alexa Fluor 594 Hydrazides was injected through the recording pipette, showed that the dendritic arborization of expanded continuously with days in culture.
Based on above results, we hypothesize that, after severe slicing trauma, neuronal synaptic activities and circuitry undergo continuous modification and rewiring. Increased long-distance correlations in synaptic activities are coincident with the appearance of seizure activity in this preparation, suggesting either that synaptic connections of these distances are necessary for epilepsy, or that ongoing seizure activity favors the survival of these synaptic connections vs. the more local connectivity established earlier.

Title: Involvement of D3 dopamine receptor and dopamine transporter in epileptogenesis in Genetic Absence Epilepsy Rats from Strasbourg

Authors: F. CAVAREC[1], P. KRAUSS[1], C. BEAUMONT[1], A. BROIZAT[2], J. TOCZEK[2], C. GHEZZI[2], *A. DEPAULIS[1], C. DERANSART[1];
[1]Inserm U836 - Team #9, Grenoble Inst. Neurosci, Grenoble, France; [2]Radiopharmaceutiques Biocliniques Inserm U1039-UJF-CHU, Grenoble, Grenoble, France

Abstract: Genetic-Absence-Epilepsy-Rats-from-Strasbourg (GAERS) and Non-Epileptic-Control rats (NEC) derive from an original Wistar-Hannover rat strain (WH). The onset age of spike-and-waves discharges in GAERS is about 25 days post-natal. In adult GAERS with fully developed epilepsy, dopamine plays a modulatory role in seizure expression. Adult GAERS display an over-expression of dopaminergic D3-receptors (D3R) as compared to NEC. Expression and function of D3R and dopamine transporter (DAT) are closely related. The aim of this work was to investigate the putative involvement of D3R and DAT during epileptogenesis by measuring their expression and functionality in GAERS before the onset of epilepsy (P25). D3R expression and functionality was investigated by [125I]-PIPAT autoradiography and quinpirole-induced yawning, respectively, in the three strains at P14 and P21. DAT expression was investigated in GAERS and NEC by [123I]-Ioflupane SPECT imaging in adults and [3H]-GBR12935 autoradiography in adults, P14 and P21 rats. Furthermore, DAT activity was assessed by 3H-dopamine reuptake in synaptosomal living fractions of striatum, cortex and hippocampus of adult rats in the three strains.
Finally, the involvement of D3R was investigated by video-EEG recordings following systemic or intra-accumbens injections of either the D3R agonist (PD128907) or antagonist (SB277011). Autoradiography showed an over-expression of D3R in GAERS in structures known to be involved in seizure initiation (somato-sensory cortex), seizure control (nucleus accumbens,) as well as in other structures (anterior thalamus, olfactory tubercles and islands of Calleja) at P14 and P21, as compared to age-matched NEC and WH. As in adults, this over-expression was associated with a higher number of quinpirole-induced yawns in GAERS at P14 and P21. Neither SPECT imaging nor autoradiographic data revealed any modification in DAT expression between the three strains at any ages. However, we found a consistent increase in 3H-dopamine

reuptake in adult GAERS as compared to NEC and WH in the functional assay.
Both systemic and intra-accumbens administrations of PD128907 increased spike-and-wave discharges, whereas SB277011 had no effect.
Our results suggest that an over-expression of functional D3R already exists before the onset of seizures in GAERS and that, despite a lack of changes in DAT expression, functional changes in this transporter occur in adults. They further support that a profound modification in basal ganglia function together with changes in D3R could be a conditional factor for epileptogenesis.

Title: The role of adult-generated granule neurons in epileptogenesis and cognitive impairment

Authors: *K. CHO[1,2], N. ITO[3], Z. LYBRAND[2], L. GOOD[4], S. BIRNBAUM[3], S. G. KERNIE[5], H. E. SCHARFMAN[6], A. J. EISCH[3], J. HSIEH[2];

Ctr., Dallas, TX; [5]Dept. of Pediatrics and Pathology & Cell Biol., Columbia Univ., New York, NY; [6]The Nathan Kline Inst. for Psychiatric Res. and NYU Langone Med. Ctr., New York, NY

Abstract: Clinical evidence showing hippocampal pathology and cognitive deficits in patients with temporal lobe epilepsy suggests that neurogenesis may be associated with epileptogenesis and seizure-related memory impairment. Moreover, experimental epilepsy models demonstrate a dramatic increase of hippocampal neural stem cell proliferation and ectopic migration of newborn neurons with hilar basal dendrites and mossy fiber sprouting, which may contribute to spontaneous recurrent seizures (SRS). While previous attempts have been made to examine the role of seizure-generated granule neurons, it is not known if there is a strict cause-and-effect relationship due to the possibility of non-specific side effects of the treatments used to manipulate neural progenitors. Therefore, to investigate the specific role of seizure-induced new neurons in epileptogenesis and cognitive decline, we took advantage of a genetic approach and used a conditional transgenic mouse (Nestin-thymidine kinase) to selectively delete dividing neural stem/progenitors and neuroblasts by ganciclovir (GCV) treatment. Four weeks of GCV administration led to >90% reduction of doublecortin (DCX)-positive cells in the dentate gyrus. Ten-week-old mice were injected with pilocarpine (i.p.) to induce status epilepticus (SE) after GCV treatment. SE was monitored using the Racine scale. Six weeks after SE, the number of DCX-positive cells in the dentate gyrus and the hilus were reduced in GCV-treated mice. Moreover, the frequency of SRS in the GCV group was significantly lower than vehicle-treated mice when examined by 24 hr/day video-EEG from 5 to 7 weeks after SE. Using the novel object location test, which is a well-known paradigm to test hippocampal dependent memory, GCV-treated mice showed recognition of the novel object location whereas vehicle-treated mice did not. Our results suggest that dividing neural progenitors and neuroblasts are a target population for preventing or treating epilepsy in addition to its cognitive comorbidities. The results support the hypothesis that aberrant neurogenesis after seizures contributes to epileptogenesis and cognitive impairment in temporal lobe epilepsy.

Title: Targeting isoketals to attenuate learning and memory deficits associated with epileptogenesis

Authors: *J. PEARSON[1], L.-P. LIANG[1], L. ROBERTS, II[2], M. PATEL[1];
[1]Univ. of Colorado, Aurora, CO; [2]Vanderbilt Univ., Nashville, TN

Abstract: Oxidative stress has been identified as a contributing factor to the cognitive decline associated with aging and Alzheimer's disease. Most recently, oxidative stress has been implicated in temporal lobe epilepsy (TLE), however to what degree oxidative stress products contribute to cognitive decline in TLE is unknown. Isoketals (IsoKs) and neuroketals (NeuroKs) are highly reactive gamma-ketoaldehydes formed via the isoprostane and neuroprostane pathways of non-enzymatic, free radical catalyzed oxidation of arachidonic acid and docosahexaenoic acid, respectively. To determine the role of gamma-ketoaldehydes in TLE-associated cognitive dysfunction, we determined 1)hippocampal IsoK and NeuroK adducts by mass spectrometry and 2) the ability of a gamma-ketoaldehyde scavenger to attenuate cognitive dysfunction in a rat model of TLE. Adult male Sprague-Dawley rats were treated with a single, high dose of kainic acid (KA) and monitored for behavioral seizures during status epilepticus and the progression to chronic epilepsy. IsoK, but not NeuroK adducts were increased in hippocampal subregions (dentate gyrus>CA3>CA1) 24 hours following KA. Additionally, IsoK, but not NeuroK adducts were increased in all subregions of the hippocampus 6 weeks after KA. Salicylamine (SA) is an orally active scavenger of IsoKs. A separate cohort of animals was treated with KA as described above, followed by an acute injection of SA, 30 minutes after KA. Seizure intensity and duration was not altered by SA. Animals were allowed to recover and given ad lib access to water supplemented with SA (1g/L) for 7 days (acute) or 6 weeks (chronic). After the 7 day medication period, animals were tested for indices of learning and memory in a novel object recognition task (NOR). The NOR task is uniquely suited for testing KA treated animals at this time point as it is minimally stressful and requires little training of the animal. KA treated animals that received SA performed significantly better than animals not treated with SA (KA vs KA+SA $p= 0.01$), at a level equivalent to control animals (KA+SA vs Control $p=0.15$). Animals in the 6 week treatment group were tested in the standard Morris Water Maze to assess spatial learning and memory. KA animals that received SA performed significantly better than animals that received KA alone on days 4 and 5 of learning (treatment effect $p<0.0001$). Additionally, animals treated with SA had a significantly reduced latency to reach the target quadrant on the probe test for spatial memory (KA vs KA+SA $p < 0.05$) indicative of improved spatial memory. These data suggest that IsoKs are potential mediators of learning and memory deficits associated with experimental TLE.

Title: Pathaphysiology and treatment of epileptic seizures in immature mice following hypoxic/ischemic brain injury

Authors: *J. PENG, C. WU, L. ZHANG;
Divisions of Genet. & Development, Toronto Western Res. Inst., Toronto, ON, Canada

Abstract: Hypoxia-ischemia (HI) encephalopathy is a major cause of brain injury and seizure/epilepsy in children. The underlying pathological process is currently not well understood. Effective treatments that lessen brain injury and prevent or reduce subsequent development of epileptic seizures remain to be established. Thus far, one study has described post-HI epileptic seizures in a rat model (Kadam et al, J Neurosci 2010, 30: 404). Our attempt was to replicate the rat model as per the previous study and then to effective treatment strategies. However, we failed to replicate the rat model of HIE under experimental conditions nearly identical to the previous study. We thus used a different approach based on our study of brain ischemia in adult/aging mice. We conducted a reversible model of middle cerebral artery occlusion (rMCAO) in C57 black of 22- 23 day-old. Severe convulsions were observed within 12 hrs post rMCAO but not after sham operation. After treatments with lorazepam and phenytoin, ~70% of seized animals were allowed to survive. These animals ereceived implantation of intracranial recordings at 2 months post rMCAO and then underwent video and EEG monitoring for seizure detection. Of 8 post-rMCAO animals examined intermittently thus far, 6 exhibited interictal- like EEG spikes and 2 exhibited spontaneous seizures during overnight monitoring. Thus, rain ischemia, produced by via the rMCAO model in immature mice or HI episodes in neonatal mice, may induce late-onset epileptic seizures and allow further examination of treatment strategies. We will address these in further experiments. We will first conduct the HI model in neonatal mice. Mouse pups at postnatal day 10 will receive a unilateral occlusion of the common carotid artery and then undergo a hypoxic episode (8% O2 for 90 min). Control animals will receive sham operation without the hypoxic challenge. Post HI animals will receive daily ip injection of memantine (20mg/kg) or saline for 2-3 weeks. If needed, ip injections of diazepam and phenytoin will be applied within 24 hours post HI to control early-onset seizures. All animals will undergo continuous video monitoring (24 hours daily for several weeks, starting from postnatal day 21) to detect spontaneous seizures. After video monitoring,

the animals will undergo magnetic resonance imaging to detect brain injury in vivo. Data from the video monitoring and MRI will reveal animals with spontaneous behavioral seizures and gross brain injury. The animals will then receive implantation of intracranial electrodes and telemetric transmitter and under continuous 24-hour video and EEG.

Title: Epileptogenesis in urokinase-type plasminogen activator receptor deficient mice after traumatic brain injury

Authors: *T. BOLKVADZE[1], A. PITKÄNEN[2,3];
[1]Dept. of Neurobio., A.I.Virtanen Inst. For Mol. Sciences, Univ. of Eastern Finland, Kuopio, Finland; [2]Dept. of Neurobio., A.I.Virtanen Inst. for Mol. Sciences, Univ. of Eastern Finland, Kuopio, Finland; [3]Dept. of Neurol., Kuopio Univ. Hosp., Kuopio, Finland

Abstract: Objectives. A growing body of evidence has suggested that urokinase-type plasminogen activator receptor (uPAR) contributes to tissue remodeling and plasticity after various epileptogenic insults like traumatic brain injury and status epilepticus. In the present study we investigated consequence of *uPAR* gene deficiency on post-TBI epileptogenesis and co-morbidity.
Methods. The 4 month follow-up study was done on 12 wk old male uPAR (n=26) and Wt (n=20) mice. Traumatic brain injury was induced by controlled cortical impact injury (CCI, velocity 5m/s, depth 0.5 mm) to parietal cortex over the left hippocampus. Motor performance was tested with neuroscore, spatial learning with Morris water-maze, and emotional learning with fear-conditioning to tone and context. At 3 month post-CCI epilepsy phenotype was assessed with a 3-wk continuous video-EEG monitoring and pentyleneterazol (PTZ) seizure-susceptibility test. At 4 month post-CCI mice were pefused for histology.
Results. At 1 wk post-CCI, uPAR-CCI mice performed more poorly in neuroscore than Wt-CCI mice (p=0.05). At 6 wk uPAR-CCI group were also impaired in fear-conditioning to tone and

context as compared to the Wt-CCI group ($p<0.05$). However, spatial memory did not differ between the uPAR-CCI and Wt-CCI groups. At 3 months post-injury, none of mice in the uPAR-CCI and 11% in the Wt-CCI group had spontaneous seizures ($p>0.05$). Spontaneous spiking was detected in 100% of mice in the uPAR-CCI group and in 78 % in the Wt-CCI group ($p>0.05$). In both the uPAR-CCI and Wt-CCI groups the total number of spikes in a 24-h epochs/wk was higher than that in corresponding controls ($p < 0.01$, $p < 0.05$) but there was no difference between the injured groups. Spontaneous epileptiform discharges (EDs) were observed in 43 % of mice in the uPAR-CCI and 11% in the Wt-CCI group ($p>0.05$). In the PTZ test both the uPAR-CCI and Wt-CCI groups had a reduced latency to the first spike ($p<0.01$) and increased total number of spikes ($p<0.01$) as compared to corresponding controls but there was no difference between the injured groups. At 4 months post-CCI, the volume of the cortical contusion was similar in the uPAR-CCI and Wt-CCI mice.
Conclusion. The present study suggests that uPAR deficiency does not alter epileptogenesis after TBI but has an unfavorable co-morbidity modifying effect.

Title: Abnormal integration of adult-generated granule cells two weeks old at the time of an epilepsy-inducing insult disrupts local dentate microcircuit during epileptogenesis

Authors: *R. T. JONES[1], L. ORMISTON[2], I. MODY[3];
[1]Dept. of Neurobio., UCLA, LOS ANGELES, CA; [2]Neurol., [3]Neurol. and Physiol., UCLA, Los Angeles, CA

Abstract: The dentate gyrus (DG) of the hippocampal formation exhibits significant anatomical reorganization during the epileptogenic process following a precipitating insult (i.e. status epilepticus, SE). Alterations in DG microcircuits include a loss of distinct classes of local interneurons, excitatory mossy cells and the formation of aberrant excitatory connections between DG granule cells (GCs). The DG is one of the few brain regions where neurogenesis

occurs throughout adult life. Progenitor cells in the sub-granular zone of the DG give rise to newborn GCs (NGCs) that develop and integrate into the local DG microcircuit over 6-7 weeks. Previous anatomical studies have demonstrated that precipitating insults, such as SE, disrupt GC integration into the local network. We used retroviral vectors (RV) expressing either G/RFP or channelrhodopsin-2-EYFP (ChR2) to test the hypothesis that abnormally integrated GCs result in functional disruption of the DG microcircuit during epileptogenesis. NGCs were fluorescently labeled with retrovirus in adult C57BL6/J mice two weeks prior to a unilateral cortical kainic acid injection (70 nl, 20 mM) induced SE. Control animals received a saline injection. Following a two-week recovery period (4 wks post-RV), whole-cell recordings were obtained from labeled GCs in coronal brain slices. We find that at two weeks into epileptogenesis, NGCs receive dramatically altered synaptic connectivity despite exhibiting intrinsic excitability comparable to controls. When ChR2 was expressed in NGCs, voltage-clamp recordings from nearby ChR2-negative GCs revealed that a brief (50 ms) photoactivation results in a significant increase in EPSC frequency and amplitude that persists for up to 30 seconds post-ChR2 activation. Our data demonstrate an enhanced synaptic connectivity of NGCs during epileptogenesis and provide evidence that their disrupted integration is sufficient to generate abnormal activity within the epileptic DG microcircuit.

Title: Refined kainate C57BL/6J mouse model of epileptogenesis

Authors: S. PUTTACHARY[1], E. BEAMER[2], K. TSE[2], G. SILLS[3], *T. THIPPESWAMY[1]; [1]Dept. of Biomed. Sci., Iowa State Univ., Ames, IA; [2]Inst. of Ageing and Chronic Dis., [3]Univ. of Liverpool, Liverpool, United Kingdom

Abstract:
The development of a refined kainate (KA) C57BL/6J mouse model of status epilepticus (SE) and epileptogenesis by a repeated low-dosing (RLD) of KA (5 mg/kg, i.p; at 30min interval) is compared with an established single-high dose (SHD) of KA (20 mg/kg, i.p) model. In RLD group, a greater inter-animal uniformity, increase in the duration of convulsive motor seizure (CMV, Racine scale ≥3) with a great advantage of a significant reduction in the mortality rate were achieved when compared to the SHD. EEG analysis of 2h duration from the point of first observed CMS to diazepam treatment and up to 7days post-KA showed consistently higher spike frequency, except between 38 and 58h, in RLD group. Neuronal activation marker, c-Fos expression in the hippocampus was widespread with 3-3.5 fold increase in CA3 and CA1 region in RLD mice, when compared with SHD group, at 2h after the onset of first CMS. Both groups had gliosis at 7d post-KA. In RLD group the reactive
astrocytes and microglia dominated amongst the dispersed CA3 pyramidal cells and the hilus of the dentate gyrus, and NeuN immunoreactivity demonstrated marginally decreased number of hilar cells when compared to SHD group. Cresyl violet did not reveal morphological changes in either group. However, fluorojade-B staining showed greater number of positive cells in CA3 and, surprisingly, in dentate granule cells and the hilus. Timm staining at 7d post-KA revealed distinct staining in the supragranular layer of the dentate gyrus in RLD group, while it was mild in SHD mice and absent in control. Overall these results from integrated behavioral, electrographic, histological and immunohistochemical analyses confirm that RLD of KA is a reliable and better mouse model of SE and epileptogenesis than a SHD model of KA.

Title: Dynamic changes in kainate receptor mediated responses in hippocampal area CA3 during epileptogenesis in the rat

Authors: *T. MODEBADZE, G. WOODHALL;
Sch. of Life and Hlth. Sci., Aston Univ., Birmingham, United Kingdom

Abstract: Adaptations in neuronal network function in response to destabilizing influences are the subject of much current research, however, changes underlying the establishment of epilepsy in temporal lobe networks remain poorly characterised. We investigated spontaneous and kainate-induced oscillatory neuronal network activity in a model of chronic epileptogenesis in the juvenile rat. Epileptogenesis was induced using a low-dose lithium-pilocarpine-xylazine (LPX) model, and 450 μm thick slices were made at 3 time points: 24h post-induction, at 4-6 weeks during the latent period and at 3 months following the development of spontaneous recurrent seizures. Local field potential (LFP) recordings were made in slices containing hippocampal area CA3 in epileptic and age-matched control (AMC) animals. In almost all slices, spontaneous oscillatory activity could be recorded in the gamma (30-80 Hz) and/or very fast oscillation (VFO; >150 Hz) bands. At 24 hours post induction, spontaneous gamma activity and VFO were prominent features in area CA3 of lesioned rats, while much less VFO activity was seen in controls. When we applied 100 nM kainic acid to slices at 24 hours post-induction, mean peak gamma power increased by 3198.4 ± 1333 μV^2 and this was similar in AMC data. During the latent period, however, whilst spontaneous activity remained present, the response to kainate was depressed, such that challenge with 200 nM kainate elicited only a 267.4 ± 259.3 μV^2 increase in peak gamma power compared to 840.4 ± 371 μV^2 in controls. Interestingly, at this time point seizure-like activity was extremely difficult to evoke, even using higher concentrations of kainate. Following the expression of behavioural seizures, spontaneous activity in area CA3 was characterised by florid VFO (150-800 Hz) and challenge with 100 nM kainic acid resulted in a significant increase in mean peak gamma power similar to controls (1140 ± 184.8 μV^2) and often elicited ictal-like events. These data suggest that during the latent period, the destabilizing influence of seizure activity is mitigated through altered network excitation, perhaps mediated by a reduction in kainate receptor expression.

Title: Low-dose lithium-pilocarpine-xylazine epileptogenesis - a refined model of chronic epilepsy in the rat

Authors: *G. WOODHALL, N. MORGAN;
Aston Univ., Birmingham, United Kingdom

Abstract: Epileptogenesis in the rat has provided a wealth of data concerning alterations in intrinsic and synaptic function underlying the establishment of epileptogenic neuronal circuits, however, many models of epilepsy show high rates of mortality. In addition, Sloviter (2005) has raised the potentially confounding issue of global cortical damage related to long-duration *status epilepticus* and questioned whether such procedures encompass vascular, as well as neuronal pathology. The refined lithium-pilocarpine-xylazine (LPX) model make use of an animal-specific titration of pilocarpine dose, coupled with early intervention (Racine stage 4) by intramuscular injection with xylazine to produce seizures that do not progress uncontrollably, and which are terminated fully after 60 minutes using a multi-drug cocktail acting at NMDA, GABA-A and mGluRs. This method provides tractable and repeatable seizure generation and reduces risk of uncontrolled generalization. Following initial recovery, mortality rates are 0-4% within groups, and epileptogenicity at 67-84% is comparable to other models. Animals typically undergo a quiescent period of 7-10 weeks prior to the onset of spontaneous recurrent seizures (SRS), which vary in frequency from several per day to low numbers per week, a feature that mimics variability in human disease. Initial investigations using the *in vitro* brain slice preparation in animals at various time points following epileptogenic insult with the LPX model show spontaneous neuronal network activity, including VFO (200-600 Hz), beta (15-29 Hz) and gamma (30-80 Hz) oscillations in area CA3 of hippocampus and slow-wave-burst complexes in layer II of the medial entorhinal cortex (mEC). These data suggest strongly that neuronal networks are hyperexcitable, but essentially intact, and few ictal-like events are seen. The patterns of activity recorded *in vitro* using the LPX model closely mimic events recorded in this laboratory using slices of human brain tissue resected from paediatric patients undergoing treatment for intractable epilepsy at Birmingham Children's Hospital, suggesting that the model shares at least some features with human disease. Further experiments have shown that even moderate increases in the duration of the initial insult show a much different pattern of activity to that described above, with little spontaneous rhythmicity and a prevalence of complex, long duration epileptiform discharges in CA3 and mEC. These data suggest the existence of a clear window, within which epileptogenicity can be maintained in intact networks and beyond which activity is indicative of more widespread neuronal damage.

Title: Impact of the endocannabinoid and endovanilloid system on the generation of a hyper-excitable neuronal network

Authors: *E.-L. VON RÜDEN[1,2], M. JAFARI[2,3], R. M. BOGDANOVIC[2,4], L. VILELA[5], C. T. WOTJAK[6], H. POTSCHKA[1];
[1]Inst. of Pharmacology, Toxicology, and Pharm., Munich, Germany; [2]Grad. Sch. of Systemic Neurosciences, Munich, Germany; [3]Inst. of Clin. Neuroimmunology, Munich, Germany; [4]Inst. of Pharmacology, Toxicology and Pharm., Munich, Germany; [5]Inst. of Biol. Sci., Minas Gerais, Brazil; [6]Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: The endocannabinoid (EC) system serves a key function in regulating neuronal activity throughout the central nervous system.
The EC anandamide not only activates cannabinoid type 1 (CB1) receptors on presynaptic terminals of several neuronal populations, but also transient receptor potential vanilloid (TRPV1, formerly vanilloid receptor) channels which are nonselective cation channels. Whereas activation of CB1 leads to a decrease in neurotransmitter release, TRPV1 channels enhance glutamate release.
Given their role in balancing excitatory and inhibitory transmission, both the EC and the endovanilloid (EV) systems can be considered as putative targets in central nervous system diseases with unrestricted neurotransmission, including epilepsies. In this study, we modulated the EC/EV system both pharmacologically and genetically and analyzed the impact on kindling progression in mice.
The following mouse strains were used for pharmacological and genetic modulation of the EC/EV system: NMRI mice, conditional CB1-receptor knockout (KO)- mice, with selective deletion of CB1 from principal neurons (CamK-CB1-KO) or GABAergic neurons of the forebrain (GABA-KO) and conventional TRPV1-KO mice. All strains were backcrossed to the C57BL/6N strain. Experiments were performed with corresponding wildtype controls. Male mice were implanted with a stimulus and recording electrode into the right basolateral amygdala. The mice were electrically stimulated once daily. NMRI mice received i.p. injections of either the selective CB1 receptor-antagonist rimonabant (5 mg/kg i.p.), the selective TRPV1 antagonist SB366791 (1 mg/kg i.p.) or vehicle 30 minutes prior to each kindling stimulation. Six to twelve animals were used per group.
Pharmacological antagonism of CB1 and the absence of CB1 from principal neurons of the forebrain failed to affect the development of generalized seizures. The mean number of stimulations needed to reach a generalized stage five seizure did not differ between the groups. However, both pharmacological and genetic interventions caused longer seizure duration. The

opposite was achieved when CB1 was deleted from GABAergic neurons, which resulted in shorter seizure duration. Initial seizure thresholds proved to be lower in naïve CamK-CB1-KO mice as compared to controls. No effects were seen upon pharmacological and genetic modulation of the EV system.
The study indicates that EC but not EV signaling affects seizure susceptibility as well as endogenous termination of seizure activity, without influencing seizure severity over time. This is dependent on the neuronal subpopulation being modulated.

Title: LIM-domain-binding proteins interaction in neuronal development and epileptogenesis

Authors: *B. K. IWANIUK[1], A. GROTE[2], K. VAN LOO[1], S. SCHOCH[1], A. J. BECKER[1]; [1]Neuropathology, [2]Neurosurg., Univ. Bonn Med. Ctr., Bonn, Germany

Abstract: Recent data suggested LIM-domain-binding 2 (LDB2) expression to be strongly reduced in the most frequent epilepsy-associated glioneuronal brain tumors, i.e. gangliogliomas (Fassunke et al., Brain 2008). LDB proteins are multi adapter proteins that interact with different transcription factors and kinases like the STE-20 like kinase (SLK). LDBs and SLK are strongly expressed during developing brain.
Here, we examined in detail the functional interplay of LDB1 and -2 with SLK in brain development and potentially aberrant patterns in the emergence of cortical malformations. shRNA-mediated silencing of mouse LDB1, LDB2 or mouse SLK in primary neurons resulted in

aberrant morphology affecting axons and dendrites *in vitro*. Overexpression of the human LDB2 isoform or of human SLK rescued the phenotype of altered neuronal arborization. Furthermore double knock down of LDB1 and LDB2 could not be rescued by SLK overexpression indicating the necessity of LDB-SLK complexes for regular neurite growth *in vitro*. Currently, mice embryos (E14) are subjected to intraventricular *in utero* electroporation (IUE) with shRNAs targeting mouse LDB1 and 2 isoforms. Our first results indicate adult mice with IUE of LDB2 shRNAs to have neurons with aberrant morphology, i.e. potentially reflecting the irregular neuronal component of gangliogliomas.
LDBs and SLK represent key factors of neuronal development, for which our current data suggest fine tuned interactions and a potential functional impact in epilepsy-associated tumor pathogenesis, i.e. an aspect we currently analyze in IUE models more in detail.

Title: Benefits of early exposure to enriched environment on motor behavior and on the spinal cord plasticity in a cerebral palsy rat model

Authors: *S. MARCUZZO[1,2], M. R. MARQUES[3], F. STIGGER[3], O. A. AUGUSTIN[3], E. SEGABINAZI[3], S. BARBOSA[3], F. V. PIAZZA[3], M. ACHAVAL[3];
[1]Univ. Federal Do Rio Grande Do Sul, Porto Alegre, Brazil; [2]Programa de Pós Graduação em Neurociências - UFRGS, Porto Alegre, Brazil; [3]Univ. Federal do Rio Grande do Sul, Porto Alegre, Brazil

Abstract: Cerebral Palsy (CP) results from nonprogressive lesions in the immature brain. The secondary impairment associated with CP normally is accompanied by morphologic,

biochemical and physiological changes in the neuromuscular system. Rehabilitation in CP is recommended throughout early childhood while the normal neuromotor development can be facilitated. In experimental studies, the environmental enrichment (EE) may be considered a rodent correlate of therapeutic interventions in humans. It provides physical activity, learning experiences, increased somatosensorial inputs and social interaction.
The aim of this study was to verify the effects of the early EE on balance and gait in a CP rat model and investigate possible biological substrate involved in it.
All procedures were approved by the Ethical Committee at the Universidade Federal do Rio Grande do Sul, Brasil (23594). The CP model was induced with the association of maternal exposure to low doses of bacterial endotoxin (lipopolysaccharide), perinatal anoxia and sensorimotor restriction of the pups. The pups were divided in control group (CT group), animals exposure to EE (EE group), CP model (CP group) and CP exposure to EE (CP-EE group).
At 29 days of life, the motor balance was assessed using a Rotarod and the walking pattern consisted in measure the hind paw stride length. After motor testing, the rats were euthanized by transcardiac perfusion and the spinal cord segments were removed. To motoneuronal analysis, the cross-sectional area (CSA) of the motoneurons in ventral horn of the spinal cord was estimated by the point-couting technique. To immunoistochemical procedure, the intensity of the synaptophysin immunoreaction was measured in the ventral horn of the spinal cord. The data were analyzed by Two-way analysis of variance, followed by post hoc Tukey.
The CP-EE group showed better performance on motor balance when compared to CP ($p = 0.04$). The CP group had a shorter stride length compared to CT ($p = 0.0005$) and EE ($p = 0.0004$); however, CP-EE improved the stride length when compared to CP ($p = 0.004$). The mean size of motoneuronal somata showed an increase in CP-EE group in relation to CP ($p = 0.04$) and CP-EE group had more synaptophysin immunoreactivity in ventral horn of the spinal cord when compared to CP ($p = 0.02$).
The increase of the stimulus provided for EE prevented motor deficits in a cerebral palsy rat model. The increase in CSA of the motoneurons and the synaptophysin immunoreaction in ventral horn of the spinal cord could be possible biological substrate involved in these effects. These results emphasize the importance of the early therapeutic intervention in CP to prevent secondary impairment.

Title: A loud acoustic stimulus evoked- response during movement planning facilitates voluntary reach in patients with chronic stroke

Authors: C.-L. YANG, *S. MCCOMBE WALLER, A. HOWE, M. W. ROGERS;
Dept. of Physical Therapy and Rehabil. Sci., Univ. of Maryland, Sch. of Med., BALTIMORE, MD

Abstract: Objective: Delivering a loud acoustic stimulus (LAS) during the preparation phase of an intended action can trigger preplanned movement with earlier movement onset and comparable movement characteristics as the voluntary movement. Our previous work found a marked reduction in the incidence of LAS-evoked responses in stroke subjects compared to controls during the planning period for both anticipatory postural adjustments and the goal intended reach in standing. However the impact of an altered LAS-evoked response on cued voluntary movement after stroke has not been examined. We investigated the influence of LAS presented at 200 ms prior to a go cue on timing of a voluntary reach in standing for individuals with stroke. **Subjects:** Eight participants with chronic ischemic stroke. **Methods:** Using a simple reaction time paradigm, subjects were standing on separate force platforms and received a warning light cue to "get ready to reach" followed 2000 ms later by a go light cue to "reach as quickly as you can" with the paretic arm to touch a target ball. In 1/3 of the trials we applied LAS of 124 dB at 200ms prior to the "go" cue. We selected this time as it represents the point at which a movement is normally almost fully prepared. For the voluntary cued movement, we compared the timing of reach onset and reach onset to peak displacement in LAS trials that did and did not result in an LAS- evoked response. We further compared this to the reach onset and onset to peak timing during cued reaching with no LAS (control reach). **Results:** Of the eight participants three subjects presented with LAS trials that did and did not result in an LAS-evoked response. In this subset of three subjects, trials in which an LAS-evoked movement at 200ms prior to the go cue was elicited, the voluntary reach demonstrated earlier movement onset and faster onset to peak compared to the trials in which there was no LAS-evoked movement and our control trials where no LAS was introduced. **Conclusion:** There is a marked reduction in LAS-evoked responses in subjects with stroke that may indicate suppression of ascending brainstem pathways potentially by corticoreticular inputs. When LAS-evoked responses are present, the ascending pathways may be activated, which in turn may result in increased inputs to motor cortex and therefore facilitation of a faster voluntary reach. The altered ability to achieve LAS-evoked responses may represent variability in the state of preparation as a result of stroke.

Title: Promoting recovery after stroke using botulinum toxin for limb immobilization

Authors: *A. ORR, D. BINGHAM, M. KAWABORI, J. KIM, Z. ZHENG, T. LAM, S. MASSA, J. LIU, M. YENARI, R. SWANSON;
Neurol., Univ. of California San Francisco, San Francisco, CA

Abstract: Motor rehabilitation strategies after stroke aim to improve function of the paretic limb. Evidence suggests that immobilization of the healthy limb can promote functional recovery of the paretic limb following stroke involving motor cortex. In rodents this has be modeled using casts, harnesses, and other means of restricting use of the non-paretic forelimb after middle cerebral artery stroke. Here we evaluated an alternative approach, using botulinum toxin injections to limit function of the non-paretic forelimb. Adult male rats were subjected to permanent ligation of the left distal middle cerebral artery, resulting in a paretic R forelimb, or sham surgery alone. The rats were then randomized to one of 3 treatment groups: 1) no treatment; 2) botulinum toxin injections on day 1; or 3) cast placement on day 2. All rats were subsequently given “physical therapy” consisting of 60 minutes / day of assisted exercise on climbing nets, roller balls, and rope climbing. Botulinum toxin injections were made into the left (non-paretic) forelimb. The forelimb was injected with 10 units of botulinum toxin A, distributed over 8 sites in both the ventral and dorsal compartments of the distal and proximal limb. Weakness in the injected limb became apparent after 24 hours. Casting was accomplished by wrapping ipsilateral limb in felt and positioning against sternum with elastic wrap and plaster, and was left in place for 3 weeks. Rats with bilateral forelimb impairment due to either stroke plus casting or stroke plus botulinum injections were able to feed and groom normally. However, ambulation was impaired, and the rats were less able to participate in physical therapy than rats treated with either botulinum alone or stroke alone. Nevertheless, both groups showed modest improvement over the stroke only group with respect to function on the cylinder test and foot-fall tests when assessed 3 months after stroke. The botulinum toxin approach to limb paresis had both advantages and disadvantages over traditional physical limb immobilization. The major advantage was that it was far less stress-inducing to the subject animals. A disadvantage was that

the paresis took roughly 10 weeks to resolve, and any degree of residual paresis confound interpretation of the behavioral assessments.

Title: Protection by LOXBlock-1 in novel mouse models of permanent and transient focal ischemia: Inhibiting 12/15-lipoxygenase to treat stroke

Authors: *H. KARATAS-KURSUN[1,2], Y. LIU[2], E. LO[2], K. VAN LEYEN[2];
[1]Hacettepe University, Inst. of Neurolog. Sci. and Psychiatry, Ankara, Turkey; [2]Massachusetts Gen. Hospital, Harvard Med. Sch., Neuroprotection Res. Laboratory, Dept. of Radiology, Charlestown, MA

Abstract: Stroke damages the neurovascular unit and causes massive cell death during the acute phase. 12/15-LOX contributes to brain damage after middle cerebral artery occlusion (MCAO), and is increased in humans following a stroke. The aim of this study was to investigate the effects of the 12/15-LOX inhibitor LOXBlock-1 (LB1) in a mouse permanent distal MCAO model induced by FeCl3, and in conjunction with subsequent thrombolysis with tPA, the only drug with current FDA approval for acute stroke treatment.
We topically applied 30% FeCl3 to induce permanent distal MCAO in C57Bl6 mice. LB1 (50 mg/kg) or vehicle (DMSO) treatments were given intraperitoneally (ip) 2 hours after MCAO. Regional cerebral blood flow was monitored by laser-Doppler flowmetry. A neurological severity score (NSS) test was performed before ischemia and 24 h after MCAO. Outcomes were NSS result, weight loss and infarct volume.
To study tPA-induced reperfusion, we initiated thrombosis with 10% FeCl3 in CD1 mice. 4 hours after onset of ischemia either LB1 (50 mg/kg) or vehicle was injected ip and at the same time, iv tPA (10 mg/kg, the dosage commonly used in rodents) administered for reperfusion. NSS was performed before ischemia and 24 h after MCAO. Outcomes were NSS result, weight loss, infarct and hemorrhage volume, and reperfusion rate.
FeCl3 induced distal MCAO caused increased LOX immunoreactivity in the ischemic cortex,

along with an increase in apoptosis-inducing factor AIF. LB1 treatment, applied 2 hours after ischemia, significantly decreased infarct volume at 24 h of permanent distal MCAO (n=6/group). Weight loss was also significantly better in LB1 treated group. NSS results were in favor of LB1 group but it was not significant.
Distal MCAO induced by 10 % FeCl3 and treatment with 10 mg/kg tPA plus LB1 or vehicle 4 hours after onset of ischemia showed that tPA plus LB1 treatment significantly decreased infarct and hemorrhage volume, compared to tPA alone. Successful reperfusion was achieved more frequently in the LB1 treated group (5/8) than in the vehicle group (2/9). NSS results and weight loss were improved in LB1 treated group, but differences were not significant.
LB1 treatment, applied 2 hours after ischemia, significantly decreases infarct volume and NSS values in permanent distal MCAO. LB1 treatment applied 4 hours after ischemia and reperfused with tPA, significantly decreases infarct volume and hemorrhage volume. Distal MCAO with FeCl3 model may be useful to screen drugs in short-term recovery phase. LB1 provides significant treatment effects over several models of stroke and represents a promising new approach to stroke therapy, either alone or in conjunction with tPA treatment.

Title: Frontal-subcortical function and use of assistive speech devices for aphasia

Authors: *A. CHAUDHARI[1,3], J. S. MANISCALCO[3,4,5,6], J. ZHANG[3], D. S. WILLIAMSON[7], U. ADLER[8], A. M. BARRETT[2,3,8,9];
[1]Dept. of Med., [2]Dept. of Neurol. and Neurosciences, New Jersey Med. School, UMDNJ, Newark, NJ; [3]Kessler Fndn., West Orange, NJ; [4]Dept. of Psychology, CUNY Grad. Ctr., New York, NY; [5]Dept. of Psychology, CUNY Queens Col., Flushing, NY; [6]Dept. of Neurol. and Neurosciences, Weill Cornell Med. Col., New York, NY; [7]The Stroke Comeback Ctr., Vienna, VA; [8]Kessler Inst. of Rehabil., Saddlebrook, NJ; [9]Kessler Inst. of Rehabil., West Orange, NJ

Abstract: Objective: To identify neuropsychological predictors of successful assistive device use in aphasia. **Background:** Assistive speech devices (ASDs) may augment communication efficacy in aphasia.However, patients may have difficulty using a mobile device, which requires

diverse mental abilities including cognitive motor planning, concentration, visuospatial orientation and sequencing. We wished to evaluate whether performance on specific neuropsychological tests could predict device use success, thereby assisting clinicians in identifying ASD candidates. **Methods:** 20 people with aphasia (60.6 ± 14.3 years) completed 9 neuropsychological tasks, including Finger Tapping Test (FTT), aphasia-adapted Frontal Assessment Battery (FAB), Test of Oral and Limb Apraxia (TOLA), Western Aphasia Battery (WAB), Behavioral Inattention Test (BIT), Communicative Effectiveness Index (CETI), Catherine Bergego Scale (CBS), Naturalistic Action Test (NAT), and Neuropsychological Assessment Battery (NAB). All patients were trained to use an ASD (O'Brien Technologies Survivor Speech Companion System) followed by 7 days' unrestricted home use. Then, each participant completed 3 device-based communication tasks (use the device to tell your marital status, give directions to Kessler Foundation, and ask for a glass of water). We performed a Stepwise Discriminant Function Analysis to evaluate how pre-trial tests performed in grouping High (>80%) vs. Low (<80%) scorers at device-based communication. We also conducted a factor analysis to explore the underlying structure of the groups' neuropsychological test scores. **Results:** The Frontal Assessment Battery (FAB) was the only significant predictor of device use success (Wilk's Lambda=0.713, F=6.856, p=0.018, 28.7% variance), correctly classifying 80% of High/Low scores. A Factor Analysis indicated that a factor including the FAB, WAB, BIT, NAB and TOLA explained 45% of variance in overall neuropsychological performance (eigenvalues>1). **Conclusions:** Identifying people with aphasia who can benefit from an assistive speech device is vital to prescribing an ASD. Here, aphasia severity was *not* predictive, but an aphasia-adapted version of the Frontal Assessment Battery predicted device success. These results show that frontal cognitive assessment may be needed in standard ASD assessment. Further research to identify which skills assessed by the FAB best predict device use success, and their relation to other neuropsychological deficits in aphasia, are indicated.

Title: Evaluating the relationships between hand function with measures of brain structure and function in chronic stroke

Authors: *M. R. BORICH[1], E. DAO[1], J. D. EDWARDS[2], S. K. MEEHAN[3], L. A. BOYD[1]; [1]Physical Therapy, [2]Sch. of Population and Publ. Hlth., Univ. of British Columbia, Vancouver, BC, Canada; [3]Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Stroke is the leading cause of adult disability and less than half of individuals regain full arm function. Transcranial magnetic stimulation (TMS) techniques can be used to gain insights into brain neurophysiology. Neuroimaging can provide information about brain anatomy that may be used in conjunction with TMS to identify new biomarkers of recovery after stroke. Here, we aimed to characterize the relationship between TMS measures of transcallosal interhemispheric cortical excitability, brain structure, and manual dexterity in chronic stroke. Thirty-four individuals with chronic (>6 months) stroke (mean age: 65.6±7.4 years, 8F) underwent a TMS assessment, magnetic resonance imaging scanning session, and manual dexterity testing (Box and Blocks Test or BBT). The magnitude of transcallosal inhibition (TCI) elicited by TMS applied over primary motor cortex during active ipsilateral hand contraction was used to index interhemispheric cortical excitability. Precentral gyral thickness and corpus callosum volume were used as metrics of brain structure and extracted using the Freesurfer image analysis suite. Performance on the BBT was defined as the number of blocks transferred in one minute. One-way analyses of variance were performed to evaluate hemispheric differences in TCI magnitude and cortical thickness and differences between paretic and non-paretic hand dexterity. Correlational analyses were conducted to characterize relationships between interhemispheric excitability, precentral gyral thickness, callosal volume, and hand dexterity.

Results demonstrate significant differences in TCI ($p=0.01$) and precentral gyral thickness ($p=0.001$) between lesioned and non-lesioned hemispheres and in BBT performance between hands ($p<0.001$). BBT performance was positively correlated with precentral gyral thickness ($r=.55$, $p<0.001$). Magnitude of TCI was linked to central callosum volume ($r=-.45$, $p=0.006$). No other significant correlations were observed.

Differences in interhemispheric cortical excitability were observed in individuals with chronic stroke, as reflected by greater TCI during stimulation of the ipsilesional primary motor cortex. Reduced dexterity was demonstrated in the paretic hand. Increasing TCI magnitude was correlated with larger central callosum volume. Higher levels of hand dexterity were correlated with greater precentral gyrus thickness. These results suggest changes in brain neurophysiology

and anatomy may be correlated and related to hand function in individuals with chronic stroke. These findings may be used in future work to evaluate and predict response to rehabilitation.

Title: Probabilistic tractography of transcallosal motor tracts in the chronic phase after stroke

Authors: *D. B. ARCHER, G. MISRA, C. PATTEN, S. COOMBES;
Univ. of Florida, Gainesville, FL

Abstract: Following stroke, the integrity of white matter tracts can be affected both locally and distally to the primary lesion location. Diffusion magnetic resonance imaging (MRI) can provide unique and detailed information about white matter integrity. Although previous observations have demonstrated that inter-hemispheric interactions are altered after stroke, potential deficits in the structural integrity associated with these interactions remains poorly understood. Of particular interest are the motor fibers that link the corpus callosum to the primary motor cortex (M1). A reduction in the integrity of M1-callosal motor fibers was recently demonstrated, but the authors interpreted their findings with caution because they used a low-resolution scan with non-isotropic voxels and 25 diffusion directions. The goal in the current study was to examine the integrity of the M1-callosal tracts in the chronic phase of stroke using 2x2x2 resolution 64-direction diffusion MRI. Left and right M1 regions were isolated from the human motor area template and were transformed from standardized space to native subject space to create M1 seed regions. Probabilistic tractography was used to identify the tracts that link M1to the corpus callosum in each hemisphere. Analyses were performed in native subject space. Directional diffusivity values of the callosal tract in each hemisphere were obtained. A contralesional/ipsilesional ratio was then calculated between hemispheres, with a value of one reflecting similar integrity between hemispheres, and a value greater than one reflecting an ipsilesional deficit. Fugl-Myer assessments were collected. Maximum voluntary contractions (MVC) of each hand were also recorded and a corresponding ratio was calculated. We report four findings. 1) MVC of the impaired hand and MVC ratios between hands revealed force

deficits in the stroke as compared to control group. 2) Tract volume ratios were higher in stroke patients compared to controls. 3) Structural integrity in the ipsilesional M1-callosal motor tract was reduced after stroke as indexed by increases in the mean and variability of perpendicular diffusivity and parallel diffusivity. 4) Mean diffusivities and ratios of diffusivities correlated with Fugl-Myer and MVC scores, demonstrating that deficits in the structural integrity of M1-callosal tracts relate to deficits in motor function. Our findings replicate and extend previous studies which have linked the integrity of callosal motor fibers to function in the chronic phase after stroke.

Title: Influence of BDNF genotype to the response of rTMS modes in chronic stroke patients

Authors: *W. CHANG, K. UHM, J. HWANG, H. SHON, Y.-H. KIM;
Physical Med. and Rehabil., Samsung Med. Ctr., Seoul, Korea, Republic of

Abstract: Objective: Brain-derived Neurotrophic Factor (BDNF) polymorphism was known to influence on the response of repetitive transcranial magnetic stimulation (rTMS). In Asian population, especially Korean, a higher incidence of the BDNF polymorphism was reported than the western. This study aims to investigate the different response to rTMS modes according to the BDNF genotype in stroke patients. **Methods:**
Nineteen patients (9 males, mean age 57.1) with chronic stroke. All participants received randomly arranged 3 rTMS modes over the non-dominant M1 with more than 24 hrs of washout period; 1st condition; 10 Hz rTMS with sub-threshold intensity (90% of rMT), 2nd condition; 10 Hz rTMS with supra-threshold intensity (110% of rMT), and 3rd condition; sham rTMS. Cortical excitability was assessed using amplitude of the motor-evoked potentials (MEPs) before and after rTMS. Hand function was also assessed using the Box and Block test. Data were grouped and analyzed according to the BDNF polymorphism; Val/Val group vs. Met allele group.

Results: Five (26.3%) and 14 (73.7%) patients were classified into Val/Val and Met allele groups, respectively. Before rTMS, there was no significant difference in age, type and duration of stroke, MEP amplitude, and hand function between two groups. In each Val/Val and Met allele group, MEP amplitudes were significantly increased after applying sub- and supra-threshold rTMS (the 1^{st} and the 2^{nd} conditions, $p<0.05$), but not in the sham condition. However, there was no statistically significant difference in MEP amplitude changes between the 1^{st} and 2^{nd} conditions. The hand motor function showed significant improvement in only 1^{st} condition ($p<0.05$) in both Val/Val and Met allele groups without significant difference between two groups. **Conclusion:** This study revealed that high-frequency rTMS with both sub- and supra-threshold resulted in enhanced cortical excitability and improvement of hand function in patients with chronic stroke irrespective of BDNF polymorphism. In contrast with healthy subjects, high-frequency rTMS with the supra-threshold intensity over M1 did not demonstrate enhancement effect on the cortical excitability changes compared to the sub-threshold rTMS in stroke patients in both groups. Therefore, rTMS with sub-threshold intensity can be used as an intervention of enhancing cortical excitability in stroke patients irrespective of BDNF polymorphism (Supported by

Title: Resting-state functional connectivity in a somatomotor network and its association with the continuum of upper extremity behavioral recovery in chronic stroke

Authors: *M. URBIN[1], X. HONG[2], C. LANG[2], A. CARTER[2];
[1]Washington Univ. Sch. of Med., MO; [2]Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Stroke disrupts the connectivity between functionally related brain regions that are both adjacent to and remote from the lesion site. One neuroimaging technique used to investigate connectivity between motor-related brain regions involves measuring the temporal synchrony of low-frequency (<0.1 Hz) fluctuations in the fMRI BOLD signal during resting wakefulness. Recent findings indicate that the coherence of this intrinsically generated brain activity (i.e., resting-state functional connectivity, rsFC) is associated with upper extremity control in persons approximately one month poststroke. This study examined rsFC within a somatomotor network in persons greater than six months poststroke (n=19). The respective associations between rsFC and multiple parameters representing the continuum of upper extremity behavioral recovery were evaluated. The variance in connectivity explained by these parameters also was determined. Three patterns of somatomotor network connectivity were quantified using fMRI. Volitional activation, control, and real-world use of the affected upper extremity were measured with the Motricity Index, Action Research Arm Test, and accelerometer activity counts, respectively. Results indicated that rsFC between interhemispheric, homotopic regions was stronger than intrahemispheric rsFC in the contralesional and ipsilesional hemispheres. Homotopic connectivity was significantly associated with both upper extremity control (r = .53, p = .02) and real-world use (r = .54, p = .02); however, there was no association with volitional activation of upper extremity muscle groups (r = .23, p =.34). A regression model indicated that the combination of these behavioral parameters accounted for 40% of the variance in rsFC (p = .05). The results reported here are consistent with previous findings, indicating that interhemispheric rsFC strength and its association with upper extremity control are similar in persons with acute and chronic stroke. The association between rsFC and real-world use of the affected upper extremity indicates that connectivity in the resting state provides insight into the activation history of the somatomotor network. Though the continuum of upper extremity behavioral recovery explained 40% of the variance in rsFC, there appear to be other sources influencing somatomotor network connectivity in post-stroke hemiparesis.

Title: Focal cerebral ischemia induced motor cortex ascorbate increase is attenuated by pre-ischemia treadmill running

Authors: *K. LIU, Y. WANG, H. WANG, J. LI;
Capital Univ. of Physical Educ. and Sports, Beijing, China

Abstract: Ascorbate plays a key role in brain as an important antioxidant and neuromodulator. Previous studies have demonstrated that ascorbate, as a significant biomarker in cerebral ischemia pathological processes, is influenced by pre-ischemia physical activity. However, the dynamic change of ascorbate in motor cortex in focal cerebral ischemia and its modification with pre-ischemia treadmill running has not been explored. This study aims to investigate the motor cortex ascorbate change in the process of focal cerebral ischemia modified by pre-ischemia running. Adult male Sprague-Dawley rats were randomly assigned into 4 groups. (1) Running and ischemia (RI) group was treated with treadmill running for 2 weeks before undertake a focal middle cerebral artery occlusion (FMCAO). (2) Running and sham operation (RS) group was treated with the same treadmill running for 2 weeks before sham operation. (3) No-running and ischemia (NI) group was treated with FMCAO without pre-ischemia running. (4) No-running and sham operation (NS) group was treated with sham operation without the running. Motor cortex ascorbate level was monitored continuously in 30 min before and in 60 min after the ischemia or sham operation with in vivo microdialysis coupled with on-line electrochemical detection. A passive avoidance test was used to evaluate learning performance 24 hours after ischemia and the next day. The results demonstrate that the motor cortex ascorbate level was increased by FMCAO in 60 min after ischemia. This increased motor cortex ascorbate level was attenuated by 2 weeks pre-ischemia treadmill running. The behavioral results showed a better cognitive function in RI group compared with NI group. These results suggested that pre-ischemia running can modulate ascorbate change induced by FMCAO and is possibly benefit to neural protection.

Title: Gait training with full weight bearing Gait-Assistance Robot for subacute stroke patients with severe gait disturbance: A prospective, randomized, open, blinded-endpoint trial

Authors: OCHI, F. WADA, S. SAEKI, K. HACHISUKA;
Dept. of Rehabil. Med., Univ. of Envrn. and Occup. Hlth., Fukuoka, Japan

Abstract: Objective: To examine whether gait training with a full weight-bearing Gait-Assistance Robot (GAR) improves the gait disturbance in subacute stroke patients more than overground conventional gait training.
Design: Prospective, randomized, open, blinded-endpoint trial
Subjects: Based on the inclusion criteria, 26 non-ambulatory subacute hemiplegic patients were selected from 274 stroke inpatients, and were randomly assigned to the robot-assisted gait training with a GAR (RGT) group and an overground conventional gait training by a physical therapist (OGT) group.
Intervention: The RGT and OGT groups underwent 40 minutes of standard physical therapy and 60 minutes of standard occupational therapy five days a week for four weeks, and 20 minutes of RGT and OGT were added to the two groups, respectively.
Main outcome measures: The severity of hemiplegia was evaluated by determining the Brunnstrom stage, the activities of daily living, the motor score of the Functional Independence Measure (FIM®), gait disturbance, the Functional Ambulation Classification (FAC), the extensor muscle strength of the lower extremities, the StrenthErgo240®; gait speed and by performing the 10 meter Walking Test (10MWT). These outcomes were measured before and four weeks after treatment.
Results: The FAC and extensor muscle strength of the unaffected lower extremities in the RGT group had significantly improved four weeks after treatment (P=0.030 and P=0.007). The gait speed in the RGT group measured with the 10MWT tended to be faster than that in the OGT group after four weeks of treatment (P=0.051).
Conclusions: RGT plus physiotherapy for subacute stroke patients led to a significant improvement in the gait and extensor muscle strength of the unaffected lower extremities in comparison to physiotherapy alone.

Title: Evidence for ipsilateral corticospinal control in hemiparetic upper limb after cortical lesions as demonstrated by transcranial direct current stimulation

Authors: *W. KLOMJAI[1,2], A. LACKMY-VALLÉE[1], N. ROCHE[3,4], B. BUSSEL[4], P. PRADAT-DIEHL[1,5], R. KATZ[1,5];
[1]MPR, ER6 UPMC, Paris, France; [2]Fac. of Physical Therapy, Mahidol Univ., Bangkok, Thailand; [3]EA 4497, Univ. Versailles-Saint-Quentin, Garches, France; [4]Mpr, Hôpital Raymond Poincaré, Garches, France; [5]Mpr, Hôpital Pitie Salpetriere, Paris, France

Abstract: Transcranial direct current stimulation (tDCS) has emerged as a method for exploring cortex excitability, and has also begun to be used as a tool to enhance recovery from hemiplegia. Previous studies in healthy subjects have shown that anodal tDCS over the hand motor cortex induces a net increase of reciprocal inhibition between wrist muscles in the contralateral limb while a slight increase of reciprocal inhibition is observed in the ipsilateral limb. It is unknown whether ipsilateral motor activity from the unaffected cerebral hemisphere could be employed after semi-brain damage in patients with paraplegia. To investigate this possibility, reciprocal inhibition of the H-reflex in the forearm flexor muscles was examined in hemiplegic patients at rest. Our results from a small number of patients with unilateral motor deficit showed an increase of reciprocal inhibition in the affected hand during a single application of 20 mins 1.75 mA anodal tDCS over the non-lesioned hemisphere. This increase was greater, and appeared earlier after tDCS onset than in healthy subjects. If the results are confirmed in a subsequent larger study currently underway, this would suggest that ipsilateral motor activity from the unaffected hemisphere provides prominent descending control acting on spinal interneurons, mediating reciprocal inhibition in the hemiparetic limb. As we also found that the level of reciprocal inhibition between wrist muscles at rest was decreased in patients with paraplegia, anodal tDCS could be further developed as a tool for rehabilitation, enhancing reciprocal inhibition between wrist muscles in these patients.

Title: Effects of GHB and baclofen on sleep and motor function in healthy rats and rats with focal cerebral ischemia

Authors: *A. HODOR, S. PALCHYKOVA, B. GAO, C. L. BASSETTI;
Dept. of Neurol., Univ. Hospital, Inselspital, Bern, Bern, Switzerland

Abstract: Objectives: Ischemic stroke remains one of the leading causes of death worldwide, but no effective treatment is available for the patients. Promotion of neuroplasticity during stroke recovery may represent an alternative therapeutic strategy. Several studies have suggested that neuronal plasticity can be facilitated by sleep. We investigated 1) changes in sleep induced by gamma-hydroxybutyrate (GHB) and baclofen (Bac) in healthy rats, 2) stroke outcome following delayed repeated treatment with Bac in ischemic (isch) rats.
Methods: 1) Rats were implanted with EEG/EMG electrodes. Two doses of GHB and Bac were administered 1h after light onset/offset. 2) Rats were treated with Bac or saline 24h after middle cerebral artery occlusion (MCAo) and then twice daily for 10 consecutive days. Isch/Bac, isch/saline and sham/Bac groups were designed. EEG was recorded during 24-h baseline preceding MCAo and on days 2, 6 and 11 following surgery. Functional recovery was evaluated by single pellet reaching (SPR).
Results: 1) GHB and Bac induced atypical behavior and altered EEG pattern. Vigilance states were evaluated after the end of the drug effect. Bac enhanced NREM sleep in the light and dark phase and REM sleep in the dark phase ($p<0.05$). Moreover, in the light phase Bac increased the duration of NREM sleep episodes, but reduced their frequency, while during the dark only episode frequency was increased ($p<0.05$). Sleep fragmentation was reduced after Bac administration in the dark phase ($p<0.001$). GHB had no major effect on vigilance states. 2) Repeated Bac treatment after MCAo induced changes in vigilance states and motor function. NREM sleep amount was increased significantly during the dark phase in isch/Bac compared to the isch/saline group ($p<0.05$; days 2, 6 and 11). SPR performance dropped to 0 immediately after MCAo in both ischemic groups and recovered slowly thereafter. No significant difference in reaching was found between isch/Bac and sham/Bac groups 33 days after MCAo. In contrast, isch/saline rats never attained the level of sham group and performed significantly worse than isch/Bac rats ($p=0.01$, Tukey-Kramer). Bac had no effect on the size of the brain damage.
Conclusion: Our data showed that 1) GHB and Bac induced sub-anesthetic state distinct from physiological sleep. In contrast to GHB, Bac increased sleep after the end of the drug effect. Time of day determined magnitude of the Bac effect. 2) Delayed repeated Bac treatment might benefit motor function recovery after stroke. This beneficial effect of Bac might be mediated by sleep.

Title: Diffusion Tensor Imaging exhibits more proximate and reliable Transcranial Magnetic Stimulation measures compared to fMRI in stroke

Authors: *D. A. CUNNINGHAM[1], A. MACHADO[2], V. RAJAGOPALAN[4], M. LOWE[3], S. JONES[3], E. BEALL[3], K. SAKAIE[3], E. PLOW[1];
[1]Biomed. Engin., [2]Ctr. for Neurolog. Restoration, [3]Diagnos. Radiology, Cleveland Clin., Cleveland, OH; [4]Human Performance and Engin., Kessler Fndn., West Orange, OH

Abstract: In stroke, functional MRI (fMRI) serves as a poor guide to direct Transcranial Magnetic Stimulation (TMS). Localization with fMRI is variable since its hemodynamic contrast is contorted in and around infarcted tissue. Further, fMRI reflects activity in the grey matter, whereas TMS examines conduction via white matter, such as corticospinal tracts (CST). To develop a better guide for TMS in stroke, we examined whether imaging CST terminations in cortices using diffusion tensor imagining (DTI) is more reliable and proximate to sites of TMS than fMRI. Four patients with stroke and four aged-matched healthy controls underwent fMRI during hand movement, and DTI. Stereotactic TMS was delivered to motor cortical sites in a 7 X 5 grid in patients' affected hemispheres while we recorded 5 motor evoked potentials (MEPs) in the paretic first dorsal interosseous (FDI) muscle. We compared the distances between and reliability of MEPs at the following sites: site of highest fMRI activation, cortical sites with best myelin (transverse diffusion) and overall (fractional anisotropy) integrity of CST terminations, and optimal site of TMS (weighted center of gravity of MEPs). Overall, MEPs were reliable when TMS was applied to sites with best integrity of CST terminations; however, when TMS was applied to site of maximum fMRI activation, MEPs were absent in 50% patients and 25% controls. At sites of best myelin integrity of CST, trial-to-trial reliability of MEPs (measured with coefficient of variation) trended towards being better than that at site of maximum fMRI activation (55.58 ± 44.74% vs. 70.32 ± 13.63%) ($p = .07$). In the affected hemisphere, cortical site with best myelin integrity and overall integrity of CST terminations were closer to the optimal TMS site than site of maximum fMRI activation (4.1mm±5.0mm and 5.7mm±6.7mm vs.

14.9mm±3.9mm, respectively) ($p < .05$). Preliminary results of this ongoing work suggest that imaging corticospinal tracts may be reliable and accurate in localizing TMS in stroke. Future studies can explore whether DTI-guidance maximizes outcomes of therapeutic TMS in stroke rehabilitation. Exploring reliable navigation for TMS will allow us to customize therapy to the patient's own neural substrates.

Title: Improving hand and arm therapy outcomes with rTMS is related to paretic limb motor evoked potentials

Authors: *L. M. ROGERS[1,2], H. R. ROTH[1], R. S. TAPPAN[1], M. B. HARVEY[1], J. W. STINEAR[3], R. L. HARVEY[1,2];
[1]Neuralplasticity Lab., Rehabil. Inst. of Chicago, CHICAGO, IL; [2]Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [3]Univ. of Auckland, Auckland, New Zealand

Abstract: Background: Following stroke, the injured hemisphere has reduced ability to drive movement on the opposite side of the body, impeding function. In addition, the non-lesioned hemisphere (NLH) sends inhibitory signals to the lesioned hemisphere, further reducing its drive to the weak arm and hand. Recent research suggests that the extent of damage to functional and structural integrity of corticospinal pathways originating from the lesioned hemisphere can predict rehabilitation potential. However it is not known whether rehabilitation potential can be improved with enhanced therapy. One enhancement strategy is to reduce the inhibitory signals

from the NLH with low frequency repeated transcranial magnetic stimulation (1hz rTMS) prior to task-oriented occupational therapy (OT). The present study examines whether the functional and structural integrity of corticospinal projections from the lesioned hemisphere are related to therapeutic gains from neuro-navigated 1hz rTMS targeted to the NLH combined with task-oriented OT.
Subjects and Methods: N=30, 3-9 months post-stroke, with incomplete recovery (Chedoke score ≤ 6), randomly assigned to sham, or active 1hz rTMS. At baseline, patients completed TMS assessments of functional integrity (MEP+ or MEP-), anatomical MRI and DTI, and assessments of behavior. Patients then completed 3 therapy visits per week for 6 weeks that included: 20min of pre-functional OT, neuro-navigated 1hz rTMS therapy, and 60min upper-limb task-oriented OT. Once per week TMS recruitment curves were taken from a non-paretic wrist extensor (EDC) both before and after rTMS. Subjects returned for 1 week, 1 month, and 6 month follow-up visits.
Results and Conclusions: Patients receiving active rTMS achieved greater behavioral improvements on the Upper Extremity Fugl Meyer by 6 months post therapy than those receiving therapy alone. Patients with compromised ipsilesional corticospinal tract integrity (MEP-) who received active rTMS achieved significantly greater behavioral gains at all time points following therapy compared to MEP- patients who received therapy alone (sham). For MEP- patients who received rTMS, the degree of behavioral improvement following therapy was significantly correlated with the degree of rTMS induced downregulation in the NLH. These findings suggest that 1hz rTMS targeted to the NLH can be particularly effective in improving the post-stroke rehabilitation potential for individuals with compromised functional integrity of ipsilesional corticospinal projections to the hand and arm.

Title: Differential effects of rtms on genes concerning neural plasticity in young and old rats

Authors: *J. KIM[1,2], B.-M. OH[2], T. HAN[2];
[1]Dept. of Neurorehabilitation, Korea Natl. Rehabil. Ctr., Seoul, Korea, Republic of; [2]Rehabil. Med., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Background: Repetitive transcranial magnetic stimulation (rTMS) has been widely used for neuromodulation, however, few mechanisms were well-established on its cumulative effects on neural plasticity. Furthermore, young rats have been used in animal experiments, while rTMS is more commonly applied to the elderly people clinically.
Objectives: To evaluate the differential cumulative effects of rTMS on mRNAs and proteins correlated with the neural plasticity in brain, and to compare these changes between young and old rats.
Methods:
(Experiment 1: selection of the optimal timing of sacrifice after rTMS) To know when is the appropriate time to obtain tissues following rTMS, 8-week-old SD rats were divided into 4 groups (N=20); sacrificed immediate after, 15, 30, and 60 minutes after cessations of rTMS (150% of the motor threshold (MT)) with either high- or low-frequencies. The mRNA of immediate early genes (IEGs) including c-fos, zif268, egr-2 were investigated. (Experiment 2) Unilateral rTMS with low- (1Hz, n=15), high- (20Hz, n=15) frequency, or sham (n=15) stimulations were applied to 8-week (N=45) and 43-week (N=45) old SD rats. Each were divided into 3 subgroups as the number of stimulation sessions; 1-, 5-, and 10-day (n=5 for each subgroup). The mRNAs concerning IEGs (c-fos, zif268), angiogenesis (vegf), neurotrophin (bdnf), long term potentiation and depression (mglur1 and gabar) were performed. Western blots were performed for Akt, PKC, and their phosphorypated forms which are protein kinases related to neurogenesis.
Results: (Experiment 1) In the stimulated hemisphere, zif268 was increased 30 and 60 minutes after high frequency rTMS, while c-fos level was depressed in the contralateral side. Thirty minutes, in which maximal level of IEGs was shown, were selected as a timing of sacrifice in the following experiment. (Experiment 2) Both low- and high-frequency rTMS exerted cumulative effects only in old rats on bdnf ($p=0.024$ and 0.005 respectively), and mglur1 ($p=0.004$ and 0.007 respectively). Low-frequency stimulation had cumulative effects on vegf ($p=0.004$). PKC expression was higher in a 5-day than in 10-day stimulation, with low- and high-frequency rTMS in old rats ($p=0.026$ and $p<0.001$ respectively).
Conclusions: Evidence on cumulative effects of rTMS was shown only in old rats, which correspond to elderly persons, who may be more clinically relevant subjects of rTMS. Furthermore, 5 days of stimulation consistently increased mRNA and protein expression concerning neural plasticity. Five days of duration, rather than 10 days, might be appropriate to the experimental models for rTMS using rats.

Title: Contracture of finger and hand after cerebral stroke was improved in a short duration by grasping a high repulsion grip

Authors: *H. NISHINO[1], M. SHIRAKI[1], M. YAMAUCHI[1], S. URAKAWA[2], K. SAKAKIBARA[4], H. NISIJO[3];
[1]NPO Corp. Healthy Brain, Nagoya, Japan; [2]Dept of Integ Physiol., [3]Dept of Integ Physiol, Toyama Univ., Toyama, Japan; [4]Sun Barden, Nagoya, Japan

Abstract: In aging society, many persons are attacked by cerebral stroke and suffering from its aftereffects. Rehabilitation is a useful treatment but generally it doesn't work so well. During hand contracture, flexion dominant afferents are sent to the spinal cord and brain, and these would disturb the normal activity. A bouncing cushion made from tangled polyethylene fibers has a high repulsion power and is used in training of football players. We found the blood flow (oxy-Hb) in prefrontal cortex was increased during standing and stepping on the cushion. So we hypothesized if this high repulsion power is delivered to contracted hands, sensory afferents to spinal cord and brain are activated and would offer an appropriate environment for motor output. Under these ideas we designed a high repulsion cushion grip to offer a proper stimulus to contracted hands. We introduced the grip to over 150 patients of brain stroke, Parkinson disease, Alzheimer disease etc. Data were got from 100 patients and in all of them the symptoms were improved in some extent within a week or month: opening of hand and fingers, decrease in muscle tonus, enlargement of joint movement, and disappearance of rash. In some patients who had lost verbal communication recovered mild outlooks and finally spoke a few words. EMG activities recorded from forearm and upper arm muscles increased strongly, and those from jaw and perioral muscles increased moderately during grasping the grip. The oxy-Hb measured by NIRS in the frontal pole area, prefrontal cortex and motor area was increased during intermittent grasping the grip. The stronger patients grasp the grip, the stronger repulsion power is produced and flexor muscles are relaxed. Increase in activity of Ib afferent and decease in activity of Ia afferent, α-,γ-motor neurons of flexor muscles would be the base of the relax. Balance in flexor and extensor activity offers an appropriate environment to promote recovery from contracture. Data indicate that proper afferents from finger and hand offer a natural environment for

sensorimotor coordination in the spinal cord and brain and lead to the improvement of contracture.

Title: Mapping abnormal functional connectivity in brain injury

Authors: *J. S. SIEGEL[1], N. V. METCALF[2], R. P. FUCETOLA[2], L. RAMSEY[2], C. HACKER[2], A. CALLEJAS[2], A. BALDASSARRE[2], A. Z. SNYDER[2], J. S. SHIMONY[3], G. L. SHULMAN[2], M. CORBETTA[2,3,4];

Abstract: Evidence from stroke and brain injury literature suggests that cognitive deficit can result from dysfunction distal to areas of tissue damage. Structural brain imaging tools fail to detect pathological changes to brain function in the absence of observable structural damage. Here we present a novel methodology for using resting state functional connectivity MRI (fcMRI) to identify dysfunctional cortex. We apply this method to a patient who has suffered a stroke to the anterior thalamus and a subsequent stable diagnosis of Abulia (loss of will to initiate goal-oriented behavior). This patient's brain shows minimal structural damage that does not adequately explain the profound functional deficit observed. The method presented here compares functional connectivity throughout the patient's gray matter to that of 23 healthy age-matched controls and produces a map of areas in the patient's brain from which connectivity is abnormal. Results identify areas or abnormality proximal to the lesion, as well as small number of regions distal to the lesion. One such region is the dorsal anterior cingulate cortex, a region classically associated with Abulia in lesion studies. Additional experimental evidence presented to validate these results includes 1) a high spatial correlation with a second set of data obtained from the same patient three years later, and 2) data from ten putamen stroke subjects and ten healthy controls that establishes positive and negative controls for this method. Results suggest

that clinically significant functional connectivity changes can occur distal to areas of structural damage and that fcMRI may provide a tool for identifying and localizing brain dysfunction at the level of individual subjects.

Title: Imaging brain activation after motor task in the rat using small animal micro PET

Authors: *S.-Y. TSAI[1,2], S.-H. CHENG[3], H.-M. TSAI[3], H. KIM[3], H. ZHANG[3], L. LEONI[3], G. L. KARTJE[1,2], C.-T. CHEN[3], C.-M. KAO[3];

Abstract: The use of in vivo imaging has become a powerful tool for studying brain function in either healthy or brain damaged rodents. Although small animal positron emission tomography (μPET) and functional MRI imaging studies have provided help in studying the change of sensory function in a spatiotemporal manner, there is no small animal imaging model available to study corresponding motor activation in the brain.
In this study, we examined whether high-sensitivity small animal mPET imaging can detect and quantify regional differences in brain metabolism/activity corresponding to the performance of a specific motor task.
Male Sprague-Dawly rats were first trained in the skilled forelimb reaching task until successfully obtaining sixteen out of twenty pellets. Animals were then anesthetized and an intravenous catheter inserted into the tail vein. Animals were placed in the forelimb testing box until recovery from anesthesia. 18F-deoxyglucose (FDG, 0.6 mCi) was injected during the following conditions: 1) freely obtain testing sugar pellets placed on the box floor for fifteen minutes, or 2) reaching for sugar pellets placed on the platform as trained for fifteen minutes.

Animals were anesthetized again and scanned with micro CT (mCT) and mPET. mPET images were co-registered with mCT images, and area of interest was outlined and analyzed. Image analysis results showed that there was higher FDG uptake in the corresponding sensorimotor cortex and striatum when the rat performed the skilled forelimb reaching task with the preferred limb. On the other hand, there was no noticable difference in FDG uptake in both sensorimotor cortexes and striata when animals obtained sugar pellets from the floor with their mouths or with symmetric limb movements. These results indicate that high sensitivity small animal mPET can be used for the detection of motor activation and may be very useful in longitudinal studies of the change in brain activation during functional improvement after brain lesions.

Title: Nanoparticle-mediated therapeutic delivery in a rabbit model of cerebral palsy: Mechanism of nanoparticle uptake

Authors: *E. NANCE[1], B. BALAKRISHNAN[1], F. ZHANG[2], M. MISHRA[3], R. KANNAN[3], S. KANNAN[4];
[1]Anesthesiol. & Critical Care Med., [2]Materials Sci., [3]Nanomedicine, [4]Anesthesiology-Pediatric Critical Care, Johns Hopkins Univ., Baltimore, MD

Abstract: Cerebral palsy is a chronic childhood disorder that currently has no effective cure. Injury to the developing brain that occurs either in utero or soon after birth can result in motor, sensory and cognitive deficits as seen in cerebral palsy, with neuroinflammation playing a key role in the pathophysiology. Nanoparticles such as dendrimers provide opportunities for the targeted delivery of multiple drugs that can mitigate pathways involved in injury and can be delivered selectively to cells that are responsible for neuroinflammation and injury. We have previously demonstrated that a systemic, postnatal therapy with dendrimer-drug nanodevices in rabbit kits with CP, can cross the disrupted BBB and localize in activated microglia and

astrocytes, resulting in an improvement in motor deficits.
Understanding factors affecting uptake will allow for better design and more efficient delivery of dendrimer platforms to diseased cells, further increasing therapeutic efficacy. In this work, we used a combination of in vivo and ex vivo methods to study the effect of dendrimer size (generation 4 (G4), ~4nm in size) and surface charge (-OH terminated neutral vs -NH2 terminated cationic dendrimers) on the ability to cross an impaired BBB, diffuse within the brain parenchyma, and selectively uptake in microglia cells in rabbit kits exposed to endotoxin in utero. In brain slices from endotoxin kits, the neutral G4-OH-Cy5 dendrimer could diffuse through the brain parenchyma, preferentially accumulating in microglia, whereas the cationic G4-NH2-FITC dendrimers did not diffuse in slices. Following intracranial administration into an endotoxin day 1 kit, G4-OH dendrimer was found distributed in the parenchyma at 4 hrs and 24 hrs, and localized in microglial cells at 24 hrs. In age-matched healthy controls, minimal uptake in microglia was seen in either white matter or cortical regions; however, dendrimer was spread throughout the parenchyma at 24 hours confirming the diffusive nature of these particles. Following intravenous (IV) administration, G4-OH-Cy5 dendrimer penetrate a disrupted BBB in endotoxin kits and were found within the parenchyma at 4 hours, and within microglial cells at 24 hours. Polystyrene nanoparticles (20nm) did not cross the BBB or selectively uptake into microglia cells. Dendrimer was not found in the brain in age-matched healthy controls following systemic administration. These results suggest that appropriate tailoring of the physicochemical properties of the dendrimer nanodevice to optimize targeting and localization can lead to improvement in drug delivery to the brain.

Title: Cortical connectivity predicts motor impairment and improvement with Telerehabilitation therapy in chronic stroke

Authors: *J. WU, R. SRINIVASAN, N. KATHURIA, L. DODAKIAN, J. SEE, S. C. CRAMER;
Univ. of California, Irvine, Irvine, CA

Abstract: A number of predictors of response to rehabilitation therapy after stroke have been identified. Some of these rely on MRI scanning, however, expense and acquisition demands can limit access to such data. Dense-array electroencephalography (dEEG) may be a useful tool for improving prediction, as this technique is safe, inexpensive, easy to use, and can be employed at the bedside to characterize brain function. In this study, dEEG was used to predict motor impairment and response to therapy in patients with chronic stroke enrolled in a Telerehabilitation study. METHODS. Ten adults (mean age = 53.8±16.9 years) with chronic stroke and mild to moderate hemiparesis (mean Fugl-Meyer (FM) score = 41.4±11.6, normal = 66) underwent 3 minutes of resting-state dEEG recording prior to 4 weeks of Telerehabilitation therapy. Analyses were performed with custom MATLAB code. Continuous raw dEEG were filtered, segmented, and cleaned of artifacts with visual inspection and Infomax-Independent Component Analyses. Mean coherence with an ipsilesional M1 (iM1) seed region was derived for the high beta (20-30 Hz) frequency band, which is known to capture motor network interactions. Partial least squares (PLS) regression was used to predict baseline FM score and change in FM score using resting-state mean beta coherence with iM1. A leave one out and validate procedure was used to determine predictive strength of the model. RESULTS. With therapy, the group demonstrated significant improvement on the FM scale (mean FM change = 4.7±2.8, p=0.0005, 2 tailed paired t-test). The PLS model using beta coherence with iM1 to predict baseline FM score revealed ipsilesional parietal (iPr) and premotor (iPM) regions, with r^2=0.92. The PLS model using beta coherence with iM1 to predict improvement in FM score revealed iPM, iPr, midline supplementary motor area, and contralateral M1 regions, with r^2=0.61. CONCLUSIONS. Resting-state measures of cortical connectivity were able to predict both baseline impairment and response to 4 weeks of therapy in individuals with chronic stroke with a very strong degree of accuracy.

Title: Changes in collateral blood flow and neuroprotective efficacy of transient aortic occlusion during acute ischemic stroke

Authors: *G. RAMAKRISHNAN[1,2], B. DONG[3], G. ARMITAGE[4], K. TODD[4,2], A. SHUAIB[5,6], I. R. WINSHIP[4,2];
[1]department of psychiatry, [2]Ctr. for Neurosci., [3]Dept. of psychiatry, [4]Dept. of Psychiatry, [5]Div. of Neurol., [6]Dept. of medicine, Fac. of Med. and Dent., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Stroke is the rapid loss of brain function, due to blockage or haemorrhage of a cerebral blood vessel. The occlusion of a cerebral blood vessel results in oxygen and nutrient deprivation in the tissue leading to an ischemic stroke. The region immediately downstream of the occlusion is the ischemic core, which suffers fast and irreversible tissue damage due to blood flow reduction to below 20% of baseline flow. The region surrounding the ischemic core has partially preserved perfusion of 30-40% baseline blood flow and is called an ischemic penumbra. This partial blood flow to the ischemic territories is maintained via collaterals that provide an alternate passage for blood flow to reach the ischemic tissue when the principal conduits fail. Augmenting blood flow through the cerebral collaterals might further protect the tissue and reduce the damage caused by an ischemic insult. Here, we evaluate the efficacy of a novel form of collateral therapy, transient aortic occlusion (TAO), to increase collateral blood flow during stroke in two models of middle cerebral artery occlusion (MCAo) in rodents. The blood flow changes were monitored by laser speckle contrast imaging (LSCI), which provides a high resolution maps of cortical blood flow from which relative changes in blood flow velocity and diameter determined. Analysis of LSCI maps acquired after thromboembolic MCAo (using a clot volume designed to selectively occlude the MCA) identified significant increases in blood flow velocity and vessel diameter in MCA segments downstream of anastomoses between the middle and anterior cerebral arteries (MCA, ACA) during TAO treatment. Notably, enhanced collateral blood flow persisted even after the TAO treatment in thromboembolic MCAo rats. To evaluate blood flow augmentation in a model of stroke highly resistant to recanalization therapies, we next used a filament occlusion model to induce a stable, proximal occlusion of the MCA/internal carotid (mimicking a tandem ACA/MCA occlusion). In this model, LSCI did not identify

persistent increases in blood flow velocity or vessel diameter in MCA segments downstream of MCA-ACA anastomoses after TAO treatment. These data support preliminary clinical findings suggesting that TAO is most effective in strokes of moderate size, and highlights the importance of patient selection in evaluation of acute stroke therapies.

Title: Modulatory effects of three different non-invasive brain stimulation techniques

Authors: *H.-T. GOH[1], L. ABDUL LATIF[2], H.-Y. CHAN[2];
[1]Rehabil. Med., [2]Univ. of Malaya, Kuala Lumpur, Malaysia

Abstract: High frequency repetitive transcranial magnetic stimulation (HF-rTMS) has been found to be an effective tool to up-regulate corticospinal excitability of primary motor cortex (M1). The technique is expensive and maybe unsafe because of its potential of triggering seizure. Compared to HF-rTMS, anodal transcranial direct current stimulation (A-tDCS) is cheaper and safer to up-regulate corticospinal excitability; however, it is less focal and powerful. Previous study has shown that inhibitory low frequency rTMS (LF-rTMS) applied to dorsal lateral prefrontal cortex (DLPFC) increased premotor activity (Gangitano et al. 2008). LF-rTMS is safer than HF-rTMS while providing the same level of preciseness. To date, there is no study directly comparing these three different non-invasive brain stimulation techniques on their effectiveness on up-regulating M1 excitability. The purpose of this study was to compare the effectiveness of HF-rTMS, LF-rTMS and A-tDCS on corticospinal excitability of M1.
Eight healthy participants (mean age = 28 years; 4 males) participated in the study. Each participant went through 3 different stimulation sessions, namely HF-rTMS, LF-rTMS and A-tDCS. Each session was at least 1 week apart from the other and the order was counterbalanced among participants. For HF-rTMS, 5Hz rTMS at 90% of RMT was structured into 24 10s trains with an inter-train interval of 30s (total pulse = 1200) and applied to the M1 of the non-dominant hemisphere. For LF-rTMS, 1Hz rTMS (90% RMT) was continuously applied to the DLPFC for 20 minutes (total pulse = 1200). We applied 20 minute 1mA tDCS to M1 via anodal electrode

during A-tDCS session. M1 corticospinal excitability was determined by motor evoked potential (MEP) using single pulse TMS. MEP was measured before stimulation, immediately after, 15 minutes, 30 minutes and 60 minutes after stimulation. Behavioral changes were assessed. Significant increase in MEP measured at M1 was found after stimulation ($p = .00$). The increase lasted up to 60 minutes post-stimulation. There was no significant effect of stimulation type ($p = .31$) or interaction between stimulation type and time of measurement ($p = .16$). Participants' performance on Trail Making Test improved significantly after stimulation ($p = .00$). Both A-tDCS and LF-rTMS led to significant improvement on Trail Making Test while HF-rTMS did not.
These findings suggest that all three stimulation techniques may be equally effective in up-regulating M1 excitability while the rTMS seemed to have a longer lasting effect than tDCS. LF-rTMS applied to DLPFC could be used as an alternative way to increase M1 excitability other than HF-rTMS.

Title: Transfusion of carbon monoxide-bound pegylated hemoglobin during reperfusion from transient focal cerebral ischemia reduces infarct volume

Authors: *X. LIU, H. KWANSA, E. KULIKOWICZ, J. ARMSTRONG, D. SPICER, R. C. KOEHLER;
Dept. of Anesthesiology/Critical Care Med., The Johns Hopkins Univ., Baltimore, MD

Abstract: Early transfusion of carbon monoxide-bound pegylated hemoglobin (PEG-COHb) helps to maintain pial arteries in a dilated state and reduces infarct volume when transfused at 20 min of a 2-h period of middle cerebral artery occlusion (MCAO) (Zhang et al. J Appl Physiol 2012; 113:1709). The CO is quickly released from the Hb, which is converted into an oxygen carrier. Because PEG-COHb was superior to PEG-Hb without CO, the small amount of released CO provides additional protection. Here, we determined if delaying transfusion until after reperfusion also is protective. Male rats weighing 300±10 g were subjected to 2 h of MCAO by the filament technique and 2 days of reperfusion for triphenyltetrazolium chloride-determination

of infarct volume. Three groups of rats (n = 10-12) were transfused with 10 ml/kg of a 4% solution of PEG-COHb over 6 min starting at 20 min, 2 h, or 4 h after onset of MCAO. Infarct volume in cerebral cortex (% of ipsilateral structure) was significantly decreased from 36.1 ± 5.1% (SE) in a normal saline-treated control group to 19.2 ± 7.0% in the group transfused at 20 min, to 14.9 ± 4.6% in the group transfused at 2 h of MCAO (onset of reperfusion), and to 17.4 ± 4.9% in the group transfused at 4 h of MCAO (2 h of reperfusion). Infarct volume in striatum also was significantly decreased from 48.8 ± 5.4% in the control group to 21.3 ± 6.7% in the group transfused at 20 min and to19.1 ± 6.3% in the group transfused at 2 h. However, infarct volume in striatum was no longer significantly different (33.4 ± 7.8%) when PEG-COHb was transfused at 4 h after MCAO, consistent with the rapidly evolving cell death in striatum. These data indicate a significant therapeutic time window for transfusion of small amounts of PEG-COHb after ischemic stroke and that protection may be additive to that associated with early reperfusion.

Title: Measuring vascular reactivity with breath-holds after stroke: Implications for fMRI study interpretations

Authors: *F. GERANMAYEH[1], R. J. S. WISE[1], K. MURPHY[2];
[1]Imperial Col. London, London, United Kingdom; [2]Cardiff Univ. Brain Res. Imaging Ctr., Cardiff, United Kingdom

Abstract: Introduction:
Blood oxygenation level dependent (BOLD) contrast fMRI is a widely used technique to map brain function after stroke. Changes over time after stroke in the coupling between blood flow and neural activity may result in problems with interpretation, particularly in the acute phase when neurovascular decoupling may be maximal. This study measured within- and between-subject differences in vascular reactivity in stroke patients and normal participants.
Methods:

38 patients (mean age 61 years, range 26-79, 26 male) with left hemisphere infarct underwent a breath-holding (BH) paradigm similar to that published previously1. Of these, 18 subjects were scanned in the subacute phase post stroke (SPPS) (mean 15 days), 11 of whom had a second scan in the chronic phase post stroke (CPPS). A further 14 patients were scanned in the CPSS. The 25 scans in the CPPS were obtained at a mean of 113 days post stroke. 26 healthy older controls (mean age 57 years, range 37-78, 9 male) were also scanned.
End tidal CO2 (ETCO2) traces were measured during the breath-holds and a vascular reactivity measure was derived as a percentage BOLD signal increase per mmHg rise in ETCO2. Vascular reactivity maps were registered to standard space. The mean reactivity was calculated in the lesion, lesion penumbra, lesion homologue in right hemisphere, and the entire left (LH) and the right hemispheres (RH).
Results:
In both APPS and CPPS, the penumbra displayed higher vascular reactivity measures than the lesion ($P<0.004$). In both APPS and CPPS, the penumbra also had reduced vascular reactivity compared to the lesion homologue ($P=0.008$ APPS, 0.011 CPPS) and the RH ($P=0.01$ APPS, 1x10-6 CPSP). The RH vascular reactivity in APPS and CPPS was no different from the whole brain reactivity in controls.
Of the 11 patients who had data in both the APPS and CPPS, 1 subject was excluded as reactivity in APPS was >2SD away from the mean of all 18 APPS scans. Of the remaining 10, there was a significant increase in vascular reactivity over time in both hemispheres ($P= 0.02$ LH, 0.04 RH).
Conclusion:
Since vascular reactivity is reduced, lack of fMRI activity in the stroke penumbra should be treated with caution early after stroke. The fMRI activity in the unaffected hemisphere is less likely to be contaminated by vascular reactivity alterations at these time points. Inclusion of vascular reactivity response as a voxel-dependent covariate in fMRI studies of lesioned brain may be necessary to account for regional and between subject variability in BOLD response after stroke.

Title: Optogenetic stimulation of the striatum promotes functional recovery after focal ischemic stroke in mice

Authors: *M. SONG, O. MOHAMAD, X. GU, S. WEI, L. WEI, S. YU;
Dept. of Anesthesiol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Optogenetics has emerged as an innovative and promising technology in mapping neuronal infrastructure and functional activities at a highly accurate and specific level. It also provides an opportunity to develop new therapies for nervous system disorders. The present investigation tested whether optogenetic technique can be translated into stroke treatment by photo-stimulation of the striatum based on the notion that the striatum region of the brain may support self-repair process after cerebral ischemia. Focal ischemic stroke was induced in male adult Channelrhodopsin-2 (ChR2) transgenic mice, taking the advantage of high expression of the light sensitive cation channel ChR2 in the striatum. Electrophysiological recording on brain slices from these mice showed channel activation upon flashing blue laser light (473 nm). Before stroke, mice were trained 5 times per day for 3 days with a modified adhesive removal test. Mice were then subjected to the ligations of middle cerebral artery branches, targeting the right sensorimotor (barrel) cortex. Four days after stroke, optical fibers were implanted into the striatum and fixed with a cannula on the skull. In control group, stoke mice received optical fiber implantation but without photo-stimulation. In treatment group, daily photo-stimulation pulses were applied at 5 days after stroke and repeated for 8 days. Intensity of the blue laser light was set below the threshold to induce excessive body movement. The adhesive removal test on forepaws was performed 3, 10, 17, 24, and 31 days after stroke. The impaired forepaw sensorimotor function in these two groups progressively recovered over the timeline. Stroke mice treated with photo-stimulation, however, showed significantly better recovery detected 31 days after stroke compared to stroke control. Current experiments are exploring the underlying mechanism of the optogenetic treatment in the post-ischemic brain.

Title: Voluntary forced use of the impaired forelimb facilitates neurological recovery after focal cerebral ischemia in the rat

Authors: *J. LIVINGSTON-THOMAS, T. A. DOUCETTE, R. A. TASKER;
Univ. of Prince Edward Island, Charlottetown, PE, Canada

Abstract: Constraint induced movement therapy (CIMT), which forces use of the impaired arm following unilateral stroke, promotes functional recovery in the clinic. Modeling CIMT in animals has proven challenging, and has yielded mixed results. Our aim was to develop a refined endothelin-1 (ET-1) model of focal ischemic injury in rats that results in reproducible, well-defined lesions and reliable upper extremity impairments, and to determine if an appetitively motivated form of forced use rehabilitation (REHAB) would accelerate post-ischemic motor recovery. Male Sprague Dawley rats (N = 23) were subjected to focal unilateral stroke via intracerebral microinjections of endothelin-1 (ET-1) to forelimb motor regions, or sham surgery. Three days later, ET-1 animals were then assigned to either daily REHAB or CTRL therapy. REHAB consisted of 30 minutes of voluntary generalized movement (exercise ball) sessions, followed by 30 minutes of voluntary task-specific movement (pellet reaching). A number of behavioural tests of forelimb function were used to determine the effect of REHAB on functional recovery, and histological and immunohistochemical examinations were performed to assess lesion volume and expression of markers of neuroplasticity. We found that voluntary forced use of the impaired forelimb results in accelerated functional recovery in forelimb placing and staircase reaching, without significantly affecting infarct volume. Animals that received REHAB had significantly more migrating neuroblasts in the ipsilesional subventricular zone and perilesional tissue than sham controls. Furthermore, REHAB altered the cellular origin of expressed BDNF, resulting in more expression from non-neuronal, non-astrocytic cells. Our results suggest that improved appetitively-motivated forced use rehabilitation protocols may prove useful in developing new strategies to improve rehabilitation and for mechanistic studies

of functional neuroplasticity.

Med., Samsung Med. Center, Sungkyunkwan Univ. Sch. of Med., Seoul, Korea, Republic of

Abstract: Effective rehabilitation therapies in the acute stage can improve functional recovery and minimize impairments. Robot-assisted rehabilitation therapies have been developed to overcome the problem of labor-intensive work in the traditional physical therapy. Recently, an approach to combine brain-computer interfaces (BCIs) with the robot-assisted technology has emerged, enabling volitional and asynchronous control of robots by detecting movement intentions via BCIs. A prerequisite to this approach includes understanding how brain activity in stroke patients is modulated during the rehabilitation training with robotic devices. Hence, the present study investigates how brain activity patterns change when the patients volitionally control devices in rehabilitation training. Specifically, we aim to find differences in electroencephalography (EEG) patterns during active and passive control of a haptic device. Eleven chronic stroke patients participated in the study and were asked to grasp or supinate the

handle of a haptic device with active or passive control modes. The haptic device operated regardless of the patient's intention in the passive mode whereas it was completely moved by the patients in the active mode. Each trial was composed of three successive periods, including the task period (2s), the hold period (1s) and the return period (2s). We recorded 64-channel EEG in the patients during the experiment. After processing EEG signals to extract event-related synchronization/desynchronization (ERS/ERD) of the sensorimotor rhythms, we extracted features of temporal ERS/ERD patterns, including a minimum peak, a slope of ERD and the area under curve (AUC), and analyzed the effects of different tasks (active and passive) on these features. In the task period, paired sample t-tests revealed significantly greater minimum peak values and stiffer slopes of ERD during the active mode than during the passive modes ($p < 0.05$). In the hold period, tests revealed significantly greater minimum peak values and larger AUC during the active mode than during the passive mode ($p < 0.05$). These results demonstrated that volitional hand movement in stroke patients' elicited different EEG patterns from those by passive hand movement. Our results may provide a basis for further development of an index of how actively stroke patients are engaged in rehabilitation training.

Title: Protein kinase C epsilon regulates mitochondrial NAD+/NADH following resveratrol and ischemic preconditioning in cortical cultures

Authors: *K. MORRIS, J. T. NEUMANN, C. H. COHAN, S. V. NARAYANAN, M. A. PEREZ-PINZON;
Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Following cerebral ischemia, severe reductions in NAD^+/NADH cause energy depletion and neurodegeneration [1]. Preserving mitochondrial pools of nicotinamide phosphoribosyltransferase (Nampt), the major biosynthetic pathway for NAD^+/NADH production, confers cytoprotection when cytoplasmic NAD^+/NADH is depleted[2]. However, the signaling pathways involved in regulating mitochondrial Nampt are currently unknown. Nampt overexpression has been shown to protect the brain against ischemic injury in via and AMP-activated protein kinase (AMPK) pathway[3]. Since both AMPK and protein kinase C epsilon (PKCε) enhance mitochondrial function and ischemic neuroprotection, we hypothesized that these enzymes work together to regulate mitochondrial-localized Nampt and NAD^+/NADH during resveratrol (RPC) or ischemic preconditioning (IPC), a paradigm where a brief ischemic insult protects the brain against a subsequent lethal ischemic insult. Preconditioning was induced by exposing mixed cortical cultures to 1h exposure of oxygen-glucose deprivation (IPC), resveratrol (RPC), ψεRACK (PKCε agonist; εPC), AICAR (AMPK activator; APC), εV1-2 (PKCε antagonist) or Compound C (AMPK inhibitor; CC) and the mitochondria were assessed 48h later. Nampt protein levels were increased in purified mitochondrial fractions following εPC and APC which were blocked with exposure to CC and εV1-2, respectively. IPC and RPC required PKCε, but not AMPK, to mediate increased mitochondria-localized Nampt ($p < .01$, $n = 6$) indicating PKCε was essential for regulating mitochondrial Nampt levels. Assessment of NADH autofluorescence using 2-photon microscopy revealed larger delta changes in NADH fluorescence following cyanide treatment in εPC-treated groups in comparison to controls ($p<.001$, $n=6$), indicating PKCε activity increased the NAD^+/NADH ratio. Biochemical analysis of NAD^+/NADH revealed that εPC increased mitochondrial concentrations of NAD^+, NADH, and the NAD^+/NADH ratio ($p < .01$, $n = 5$) in an AMPK and Nampt-dependent manner. During IPC and RPC, PKCε activity was required for increases NAD^+ concentrations and the NAD^+/NADH ratio. Collectively these results showed that PKCε is a major regulator of mitochondrial pools of Nampt and NAD^+/NADH during IPC and RPC. Furthermore, these findings suggest a novel mechanism by which the PKCε-AMPK pathway provides protection to brain mitochondria against ischemic stress.

Title: AMP-activated protein kinase (AMPK)-induced preconditioning in primary neurons requires MCL-1

Authors: *U. ANIL KUMAR[1], P. WEISOVÁ[1,2], H. DÜSSMANN[1], C. G. CONCANNON[1], H. G. KÖNIG[1], J. H. M. PREHN[1];
[1]Dept. of Physiol. and Med. Physics and RCSI Neurosci. Res. Cen, Royal Col. of Surgeons In Ireland, Dublin, Ireland; [2]Max F. Perutz Laboratories, Univ. of Vienna, Vienna, Austria

Abstract: Neuronal preconditioning is a phenomenon where a stressful but not damaging stimulus activates an endogenous adaptive response to reduce the impact of subsequent, more severe stimuli. Activation of the energy stress sensor, AMP-activated protein kinase (AMPK) has been shown to contribute to the protective effects of ischemic, excitotoxic and mitochondrial uncoupling-induced preconditioning in neurons, however the molecular factors contributing to AMPK-induced preconditioning have been less well characterised. Here we investigated the role of AMPK signaling pathways during 5-aminoimidazole-4-carboxamide riboside (AICAR) preconditioning against NMDA-mediated excitotoxicity in primary mouse cortical neurons. Activation of AMPK with low concentrations of AICAR (0.1 mM for 2 h) induced a sustainable increase in the phosphorylation state of AMPK, and protected neurons against NMDA-induced excitotoxicity. Conversely, AMPK gene silencing abolished protection against NMDA-induced excitotoxicity. By characterizing potential bioenergetic, transcriptional and post-translational effects of transient AMPK activation, we observed a marked increase in mRNA expression and protein levels of both MCL-1^{OM} (40 and 38 kDa) and MCL-1^{Matrix} (36 kDa) form of the anti-apoptotic BCL-2 family protein MCL-1 in AICAR-preconditioned neurons. Interestingly, overexpression of MCL-1 protected neurons against NMDA-induced excitotoxicity but did not show any further significant protection in AICAR-preconditioned neurons. Conversely, MCL-1 gene silencing was sufficient to induce cell death, and abolished the effect of AICAR preconditioning. Gene silencing or inhibition of AMPK attenuated the increase in mRNA expression and protein levels of MCL-1. To identify the mechanism through which MCL-1 confers neuroprotection during excitotoxicity, we monitored intracellular Ca^{2+} levels during NMDA excitation, and noted that MCL-1 overexpressing neurons exhibited markedly reduced

Ca^{2+} elevations. Furthermore, MCL-1 gene silencing increased the NMDA-mediated Ca^{2+} elevations in AICAR preconditioned neurons. Therefore this study identifies MCL-1 as a key effector of AMPK-induced preconditioning in neurons.

Title: Effects of ischemic postconditioning on the progression of focal cerebral ischemia

Authors: *E. ESPOSITO[1,2], K. HAYAKAWA[2], K. VAN LEYEN[2], S. POLI[1], U. ZIEMANN[1], E. LO[2];
[1]Hertie Inst. For Clin. Brain Res., Tübingen, Germany; [2]Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Ischemic postconditioning is an endogenous neuroprotective mechanism that has recently been shown to be broadly effective after ischemic stroke. Postconditioning is thought to recruit natural adaptive responses that the brain and other organs utilize to protect themselves from various insults (Pignataro et al., 2008, Pignataro et al., 2009, Zhao, 2007, Zhao, 2009, Zhao et al., 2006 and Zhao et al., 2012, Pignataro, et al., 2013). To be clinically relevant, long-term safety and efficacy must be further explored. Here, we assessed the effects of postconditioning after 100 min of focal cerebral ischemia induced by intraluminal middle cerebral artery occlusion (MCAO) in adult male Sprague-Dawley rats. Reperfusion was established for 10 minutes after which postconditioning was performed by re-occluding the MCA for another 10 minutes (Pignataro, et al., 2008).
The rats were randomized into a control vs. postconditioning group and analyzed 3 days or 2 weeks post reperfusion. Infarct volumes and behavioral outcomes were blindly quantified (Fujiwara, et al., 2011, Singhal AB, et al., 2002). Immunohistochemistry was used to examine the effects of postconditioning on glial activation; GFAP, a marker of activated astrocytes and BDNF, a neurotrophic factor, were analyzed (Hayakawa, et al., 2010).
After 3 days and 2 weeks of reperfusion the infarct volume was markedly reduced in animals subjected to postconditioning. They also had better outcomes in forelimb placement test and in

body-swing test. Reactive astrocytes co-expressing GFAP and BDNF increased in peri-infarct cortex at 3 days after postconditioning compared to controls while there was no longer a difference after 2 weeks.
These results suggest that neuroprotective effects of postconditioning may persist for up to 2 weeks post-stroke in a model of transient focal ischemia and that astrocytes may be involved in this neuroprotection at different stages after ischemia.

Abstract: Stroke is one of the leading causes of long-term motor disabilities. There is therefore a pressing need for a more complete understanding of the mechanisms of post-infarct brain plasticity that mediate both spontaneous and rehabilitation-induced motor recovery. Such knowledge can be gained in appropriate animal models, and in this context, the mouse allows carrying out detailed mechanistic investigations.
Here, we have assessed behavioral and neuroanatomical changes following focal photothrombotic stroke in the caudal forelimb area of the mouse. In particular, we have evaluated the time course of the consequent motor deficits using classical behavioral tests such as the Gridwalk Test, the Schallert Cylinder Test and the Swim Test. We have also performed anatomical investigations using immunostaining for neuroplasticity markers at different time-points after the ischemic lesion (7, 21 and 30 days).
Behavioral outcomes indicated a reliable motor deficit that was selective for the contralesional forelimb and persisted for at least 30 days after phototrombotic stroke. Neuroanatomical analysis in the peri-infarct cortex showed a decrease in the density of perineuronal nets and parvalbumin-positive interneurons. We are currently examining other neuroplasticity markers such as the ratio of excitatory and inhibitory terminals, and the expression of the neurotrophin BDNF. We are also using intracortical microstimulation to map rearrangements in the motor cortex following stroke. These experiments provide information on the spontaneous evolution of behavioral, electrophysiological and neuroanatomical measures following focal cortical infarction in the mouse. The data will be important for understanding the correlates of rehabilitation-induced motor recovery. In particular, the same measures will be extracted from mice subjected to post-stroke rehabilitation with a robotic device that we have recently described (Spalletti and Lai et al., Neurorehabil Neural Repair, 2013).

Title: Establishment of pterygopalatine artery (PPA) ligation murine model of retinal ischemia to test efficacy of stem cells

Authors: *G. MINHAS, S. PRABHAKAR, A. ANAND;
Dept. of Neurology, Post Grad. Inst. of Med. Educ. & Res., Chandigarh, India

Abstract: Current treatments available for retinal ischemia are not sufficient to restore the visual functions. The replenishment of neurons and retinal cells by transplanted stem cells has been given increasing attention to treat retinal diseases (Singh et al., Stem Cells & Dev 2011; Tomita et al., Stem Cells 2002). Retinal ischemia is a major cause of blindness and is associated with a wide range of clinical disorders like ischemic optic neuropathies, obstructive retinopathies, carotid occlusive disorders, diabetic retinopathy, glaucoma and stroke (Osborne et al., Prog Retin Eye Res 2004). Different animal models of retinal ischemia have been generated to study its pathophysiology and to test potential therapeutics. The models that have been established to study retinal ischemia are high intraocular pressure, optic nerve ligation and vascular models. Each of these models has its own disadvantages. The recent development is the pterygopalatine artery (PPA) ligation model to study transient retinal ischemia (Lelong et al., Stroke 2007; Ogishima et al., IOVS 2011) which has an advantage over the middle cerebral artery occlusion (MCAO) model (Block et al., Neuroscience Lett 1997; Steele et al., Stroke 2008), has a problem of poor reproducibility and high mortality rate leading to problem in evaluating retinal ischemia. The intraluminal suture MCAO model in C57BL/6J mice with 1 hour of occlusion and 23 hours of reperfusion showed an approximate 42% mortality within 24 hours of occlusion. In this study the PPA ligation model was established and characterised. Age-matched and sex-matched C57BL/6J mice were subjected to PPA ligation. The external carotid artery and the pterygopalatine artery were ligated for 3.5 hours which reduces the ocular blood flow. After 5 days of reperfusion, the mice were sacrificed and the eyes were enucleated. The retinal damage was assessed against controls using histological, molecular and immunohistochemical techniques. The glial fibrillary acidic protein (GFAP) expression was evaluated in retina and the expression was found to be up-regulated at both the protein and mRNA level. The immunohistochemical analysis demonstrated an increase in GFAP expression in retinal cryosections as compared to the control sections. Similarly an increase in GFAP mRNA levels was manifested in real-time PCR from the cDNA synthesised from whole retina homogenate. Thus, this murine model of transient retinal ischemia will be used to check the migration and differentiation efficacy of lineage negative population of stem cells derived from mouse bone-marrow after transplantation. All the experiments conducted were approved by the Institutional ethical committee.

Title: Functional connectivity between the cerebellum and the cerebral cortex related to higher brain function

Authors: *S. JUNG[1], Y. KIM[2], N.-J. PAIK[3];
[1]Rehabil. Med., [2]Nuclear Med., Seoul Natl. Univ. Boramae Med. Ctr., Seoul, Korea, Republic of; [3]Rehabil. Med., Seoul Natl. Univ. Bundang Hosp., Seongnam-Si, Gyeonggi-Do, Korea, Republic of

Abstract: Background
This study is to investigate whether there is functional connectivity between the cerebellum and the cerebral cortex and whether this connectivity can be used as a therapeutic application for cognitive improvement.
Methods
The intracerebellar Endothelin-1 (Et-1) injection was used to elicit focal cerebellar ischemia in male Sprague-Dawley rats. Et-1 was injected stereotaxically in the left posterior cerebellar hemisphere and in the left vermis. Repetitive transcranial magnetic stimulation (rTMS) was applied to the right cerebral cortex at post-ischemia day 7 over a 2-week period. Rats were randomly assigned to 20Hz frequency rTMS (a total of 1,600 impulses), 1Hz frequency rTMS (a total of 1,200 impulses), and sham rTMS group. Functional outcome regarding motor and cognitive function was measured before and after rTMS. Furthermore, protein expression was determined using Western blot. We performed [18F]FDG PET scans 1, 7, 14, 30 days after after the administration of Et-1.
Results
The intracerebellar Et-1 injection caused neurological deficit. Although there was no significant difference in the improvement of motor function among rTMS groups, both 1Hz and 20Hz rTMS group after left vermis infarction showed stastistically significant improvement in the attention and the memory. Phospho-pkc and mGluR1α decreased in the left cerebellar hemisphere of 1Hz and 20Hz rTMS group after the left cerebellar posterior hemisphere infarction. Synaptophysin increased in the right cerebral cortex of 20Hz rTMS group after the left cerebellar posterior hemisphere infarction. Phospho-pkc increased in the right cerebral cortex of 20Hz rTMS group after the left vermis infarction. pkc increased in the right cerebellar hemisphere of 20Hz rTMS group and decreased in the right cerebellar hemisphere of 1Hz rTMS group after the left vermis infarction. mGluR2 decreased in the right cerebral cortex of 1Hz and 20Hz rTMS group after the

left vermis infarction.

Conclusions

Therapeutic effects of rTMS applied to contralateral cerebral cortex after the vermis infarction suggests that there may be functional cerebro-cerebellar connectivity.

Title: Transient MCAO prevents habit formation in C57Bl/6J mice

Authors: J. LINDEN[1], A. FERRARA[3], M. BASTIN[3], *J.-C. L. PLUMIER[2];
[1]Psychologie: cognition et comportement, [2]Univ. De Liège, Liège, Belgium; [3]Univ. de Liège, Liège, Belgium

Abstract: Pathologies affecting the striatum (e.g., Parkinson's and Huntington's disease) can result in impaired habit learning abilities. Likewise, such impairments have also been observed after stroke affecting the middle cerebral artery territory (encompassing the striatum). However, habit learning has never been investigated in animal stroke models, for which it could be a reliable measure of cognitive deficits. We thus assessed the ability to learn a habitual sequence of lever-presses using operant conditioning in mice after MCAO, one of the most common stroke models.

C57Bl/6J mice underwent MCAO or sham surgery. Sensorimotor functioning was assessed using the vertical pole test, rotarod and amphetamine-induced rotation test. Habit learning was evaluated using the operant serial order learning (SOL) task: mice had to perform a series of two consecutive lever-presses (i.e., left then right) to obtain a food reward. Lesion extents were finally determined using anti-NeuN immunohistochemistry.

MCAO mice were significantly impaired in both the rotarod and vertical pole test, and displayed a significantly greater number of ipsilateral rotations after amphetamine administration. In the operant SOL task, MCAO committed more errors than sham; moreover, they did not show any significant increase in performance along the sessions. Histological analysis showed consistent striatal and cortical infarctions.

The lack of habit learning ability in MCAO mice is congruent with both the literature

investigating the effect of striatal lesion in animals and the symptomatology observed in human stroke patients. Habit learning could thus be regarded as a reliable measure of functional outcome after MCAO, in combination with test assessing sensory and motor aspects.

Title: The spread of sensory-evoked cortical activity along long-range horizontal projections is critical to complete protection from ischemic stroke following permanent MCA occlusion

Authors: R. FROSTIG, *C. C. LAY, N. JACOBS, P. VU, M. DAVIS;
Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Using a rodent model of ischemic stroke (permanent middle cerebral artery occlusion; pMCAO), previous research has shown that tactile or auditory stimulation, delivered within 2 hours of ischemic onset can confer complete protection from impending stroke by re-directing blood flow through collateral vessels. How can sensory stimuli, such as whisker stimulation or white noise, protect such a large area of cortical MCA territory (including motor, somatosensory, auditory cortices)? Blood flow redirection is clearly necessary for protection, but it may not be sufficient. Prior research in our lab has demonstrated that sensory stimulation results in a large spread of evoked intracortical subthreshold activity supported by long-range intracortical horizontal projections directly connecting unimodal primary cortices, and we hypothesized that such spread within the ischemic cortex is fundamental to protection from stroke. Using functional imaging, neuronal recording, blood flow imaging, and histological analysis, we tested the role of neuronal activity, by blocking the spread of auditory-evoked cortical activity via surgical transection of the gray matter between primary auditory, and primary somatosensory cortices. Experimental animals (n=10) received protective auditory stimulation immediately following pMCAO and transection, while sham-pMCAO controls received auditory treatment

following transection and sham-occlusion of MCA (n=10). Within control animals, the transection with sham-pMCAO did not disrupt function, blood flow, or tissue health in either the auditory or somatosensory cortex. Experimental animals also maintained baseline or greater levels of cortical function (evoked and spontaneous neuronal activity) and did not sustain infarct within the auditory cortex. Beyond the transection location, however, experimental animals demonstrated highly reduced somatosensory function and cortical infarct (38.2±6.9mm3). Interestingly, blood flow in both cortices returned to baseline levels. Thus, protection occurs specifically within the spread of evoked cortical activity which is supported by an underlying system of long-range horizontal projections, and regions outside the bounds of this spread remain vulnerable to ischemic stroke damage. Therefore, while sensory-evoked blood flow redistribution is a necessary prerequisite, the spread of evoked activity is also critical for complete protection following pMCAO. If applicable to humans, a greater emphasis upon the role of cortical activity during ischemia may lead to innovative treatment strategies that help protect the human brain from stroke.

Title: Time course of behavioral and hippocampal neurogenesis after transient global cerebral ischemia in swiss mice

Authors: *L. M. SOARES, A. P. SCHIAVON, H. MILANI, R. M. M. W. DE OLIVEIRA; Farmacologia e Terapêutica, Univ. Estadual De Maringá, Maringá, Brazil

Abstract: Introduction: Hippocampal neurogenesis has been demonstrated to occur in response to transient global cerebral ischemia (TGCI), as a compensatory mechanism. However, the role

of hippocampal neurogenesis induced by TGCI in ischemic mice is not clear. The objective of this study was to characterize the time course of behavioral and hippocampal neurogenesis in Swiss mice subjected to TGCI. **Methods**: The procedures were approved by the Ethical Committee on Animal Research (004/2011). Male Swiss mice (30-40g) were subjected to TCGI by the two-vessel occlusion method. Seven, 14 or 28 days after reperfusion the animals were submitted to the Morris water maze (MWM), for evaluation of spatial memory, or to the open field (OF) and elevated plus maze (EPM), to access general locomotor activity and anxiety levels, respectively. Hippocampal neurodegeneration and neurogenesis were evaluated using Fluoro-Jade C (FJC) histochemistry and doublecortin (DCX) immunohistochemistry, respectively. Data, expressed as mean ± SEM, were analyzed by two-way ANOVA or Kruskall Wallis ANOVA (KW), followed by post hoc Duncan's or Dunn´s tests. **Results**: Ischemic animals presented an increase in the latency to find the platform as compared to controls (KW = 12.9, P = 0.005), 7 days after reperfusion (ischemic 466.8±36.1, control 337.1±22.0). ANOVA showed that ischemic animals presented a significant decrease in the 'number of entries in the center' (K-W=9.6, P=0.02) and 'time spent in the center' in the OF (K-W=10.9, P=0.01) 28 days after reperfusion (ischemic 13.5±4.1, control 26.7±2.5). In the EPM, ischemic animals presented a significant decrease in the '% of open arm entries' ($F_{3,39}$=4.5, P=0.009) and in the '% of time in the open arms' ($F_{3,39}$=9.2, P=0.0001) 7 and 14 days after reperfusion (7 days=7.9±2.70; 14 days=7.4±1.97; control=20.2±1.81). An increase of FJ-C positive cells (KW =13.3, P = 0.04) was detected at 7 (100.0±24.3) and 14 (16.8±10.2) days after ischemia. A decrease in the number of DCX-positive neurons was detected at 14 (209.1±30.2) and 28 days (188.8±20.2) following TGCI ($F_{3,24}$=19.7, P<0.0001). **Conclusions:** TGCI induced memory impairments at 7 days after reperfusion. Anxiety-related behaviors were observed at 7 days and sustained up to 28 days after reperfusion. Hippocampal neurodegeneration was detected at 7 and 14 days after reperfusion and decreased hippocampal neurogenesis was observed at 14 and 28 days after TGCI. Knowledge of the time course of hippocampal neurogenesis following TGCI has important implication on the assessment of neuroprotective drugs within a period when the intervention could change the ongoing ischemic processes and functional outcome.

Title: Amelioration of motor dysfunction in the rat spinal air embolism model by human spinal stem cell implantation

Authors: *O. KAKINOHANA[1], M. HRUSKA-PLOCHAN[1], S. MARSALA[1], K. JOHE[2], J. DUMPIT[1], A. MIYANOHARA[1], M. MARSALA[1];
[1]Anesthesiology, Neuroregeneration Lab., UCSD, La Jolla, CA; [2]Neuralstem, Inc., Rockville, MD

Abstract: Background: In our previous study, we have developed a rat spinal air embolism model which displays comparable neurological dysfunction and spinal pathology as seen in human patients with decompression
sickness. Using this animal model, we now explored the treatment effect of spinal grafting of human fetal spinal stem cells (hSSCs) (Neuralstem, Inc., MD) in rats with fully developed spinal air embolism-induced spinal injury. Methods: To induce spinal air embolism, male SD rats (n=18) were anesthetized with isoflurane and a 2F Fogarty catheter was placed into the descending aorta from the left femoral artery with the balloon tip of the catheter resting just above the truncus coeliacus. The PE-10 catheter was placed from the left carotid artery to the descending thoracic aorta to reach the Th7-8 level. After heparinization (200 IU), the balloon was inflated (50 µl) and air (200 µl/kg BW) was injected through the PE-10 catheter at a rate of 50 µl/min. After air injection, the balloon was deflated, catheters were removed and animals were allowed to recover. Two weeks after surgery, rats received spinal lumbar (L2-L6) injections (20 bilateral injections, 30,000 cells/µl/inj) of GFP-labeled human spinal stem cells (RSC566, Neuralstem) and survived for 3 months. All animals were continuously immunosuppressed with Tacrolimus (3 mg/kg/day). Recovery of neurological function was assessed using BBB score and Hoffman-reflex. Before sacrifice, descending motor tracts (corticospinal, rubrospinal) and primary afferents (L2-L6) were labeled with AAV9-syn-dsRED and cholera toxin B subunit, respectively. At 3 months, animals were perfused with 4% PFA. The presence of grafted human cells was validated by GFP+ fluorescence and combined with staining with human-specific (hNUMA, HO14, hNSE, hSYN) and non-specific (DCX, MAP2, Chat) antibodies and analyzed with confocal microscopy. Results: Animals receiving spinal grafts of hSSCs that showed grafted cell survival had progressive improvement in BBB score (6.8±0.6 ◊ 14.8±6.8), which was significantly higher than seen in media-injected animals or in animals with no graft survival (4.7±0.5 ◊ 5.5±1.0; $p<0.05$). No significant differences in H-reflex were seen. Grafted human stem cells showed extensive axo-dendritic sprouting and expression of neuronal (DCX, NSE, NeuN) and non-neuronal (GFAP, Olig2) markers. Terminals of descending motor tracts were found in the vicinity of grafted human neurons. Conclusion: These data indicate that spinal grafting of human spinal stem cells can represent an effective treatment modality to ameliorate neurological dysfunction associated with the spinal form of decompression sickness.

Title: SIRT1 plays a potent protective role against chronic cerebral hypoperfusion

Authors: Y. HATTORI[1,2], *M. IHARA[3], N. OISHI[4], Y. OKAMOTO[5], K. NAGATSUKA[6], R. TAKAHASHI[1], H. FUKUYAMA[4], M. KINOSHITA[7];

Ctr., Suita, Japan; [7]Div. of Biol. Science, Nagoya Univ. Grad. Sch. of Sci., Nagoya, Japan

Abstract: **Background—**SIRT1 is the mammalian homologue of yeast silent information regulator-2, a member of the sirtuin family of protein deacetylases which have gained increasing attention as mediators of lifespan extension in several model organisms. Previous reports have suggested a protective role of SIRT1 in neurodegenerative diseases and cardiac ischemic/reperfusion injury. We here examined whether SIRT1 is protective against chronic cerebral hypoperfusion in rodents.
Methods and Results—Mice overexpressing SIRT1 under the control of mouse prion promoter and their wild-type littermates were subjected to bilateral common carotid artery stenosis (BCAS) using external microcoils. Laser speckle flowmetry and ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) showed significant preservation of cerebral blood flow (CBF) and metabolism in the SIRT1-overexpressing mice compared to the wild-type littermates following BCAS. Prior administration of
eNOS-inhibitor, caveollin-1 scaffolding domain peptide, abolished the above CBF-preserving effect of SIRT1-overexpressing mice, suggesting that eNOS had a direct role in the CBF preservation by SIRT1. The level of reactive oxygen species labeled for 8-hydroxy-2'-deoxyguanosine in the cerebral vessels was dramatically reduced while cerebral expression of MnSOD was significantly upregulated in SIRT1-overexpressing mice at 2 hours after BCAS. As

a result, SIRT1-overexpressing mice at one month after BCAS showed significantly less impairement in the brain metabolism (as assessed with FDG-PET), the white matter integrity (Klüver-Barrera
staining), and the spatial working memory (8-arm radial maze test) compared to the wild-type littermates. Intraperitoneal administration of resveratrol (SIRT1 activator: 100mg/kg body weight x 7 days prior to BCAS) significantly preserved CBF after BCAS compared to the vehicle administration.
Conclusion—These results suggest that SIRT1 is a promising therapeutic strategy against cerebral hypoperfusion due to the antioxidative activity, the eNOS-associated vasodilation, and the resultant CBF preservation.

Title: Non-invasive biomarkers estimate the time of onset of cerebral ischemia

Authors: C. BERTHET[1], L. XIN[2], C. BENAKIS[1], *R. GRUETTER[2,3,4], L. HIRT[1,4], H. LEI[2,3]; [1]Dept. of Clin. Neurosciences, Ctr. Hospitalier Universitaire Vaudois, Lausanne, Switzerland; [2]EPFL, Lausanne, Switzerland; [3]Univ. of Geneva, Geneva, Switzerland; [4]Univ. of Lausanne, Lausanne, Switzerland

Abstract: Thrombolysis, the only currently available treatment for ischemic stroke can be administered only in a narrow time window of 4.5 hours. A significant number of patients have an unknown time of onset as the stroke occurred during their sleep, which disqualifies them for thrombolysis. The objective of this study was to determine whether magnetic resonance spectra

of the ischemic striatum could provide useful information for the estimation of the onset time of cerebral ischemia.
We modeled ischemic stroke in male ICR CD1mice using a permanent middle cerebral artery filament occlusion model with laser Doppler control of the regional cerebral blood flow (<20% during ischemia). Mice were then measured by repeated magnetic resonance spectroscopy of the ipsilateral striatum in a 14.1T system. The acquired MR spectra were processed and quantified referencing to striatal water contents, as previously described for transient cerebral ischemia (Lei H et al. 2009, Berthet C et al. 2011) yielding metabolite concentrations.
We observed different spectral patterns after permanent ischemia than after transient ischemia, with an initial striking increase in gamma-aminobutyric acid (GABA) and no increase in glutamine. We observed a mono-exponential decline (coefficient of determination, R2>0.90) of e.g. taurine (Tau), N-acetylaspartate (NAA) and the sum of Tau, NAA and glutamate (Glu, as in figure). Using these characteristic reductions, in a set of blinded measurements we were able to estimate the time of onset of permanent ischemia with an accuracy of approximately +/- 30 min (SDs).
This is a novel approach, in mice, addressing the clinically highly relevant problem of determining the time of onset of ischemic stroke in stroke patients.

Title: Chronic cerebral hypoperfusion results in distinct behavioral and pathological outcomes in normotensive and hypertensive rats

Authors: *J. CHOI[1], Y. CUI[2], B. KIM[3];
[1]Brain Dis. Res. Ctr., Inst. For Med. Sciences, Ajou Univ. Sch. of Med., Woncheon-Dong, Yongtong-Gu, Suwon, Korea, Republic of; [2]Brain Dis. Res. Center, Inst. for Med. Sci., [3]Brain Dis. Res. Center, Inst. for Med. Sci. and Dept. of Neurol., Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Vascular dementia (VaD) is the second most common form of dementia. VaD is often caused by chronic subcortical ischemia accompanied by white matter stroke where ischemic demyelination and axonal damages are observed. A lack of adequate animal model for VaD prevents systematic studies into pathomechanism of chronic subcortical ischemia and resultant white matter injury. Chronic cerebral hypoperfusion by steno-occlusion of one or both carotid arteries has been frequently employed in rodents to induce white matter stroke. However, reported pathological findings varied and the extent of white matter injury has been often modest at best. This study was undertaken to test a hypothesis that chronic cerebral hypoperfusion to rats with underlying hypertension may result in more pronounced white matter injury. We compared neurobehavioral and neuropathological features between normotensive (NR) and spontaneously hypertensive rats (SHR) in Wistar background after chronic cerebral hypoperfusion induced by bilateral common carotid artery occlusion (BCCAO). There was no difference in neurobehavioral measures between NR and SHR before BCCAO. SHR exhibited obvious spatial memory deficit after BCCAO, while spatial memory was intact in NR. While performance in delayed alternation task was worsened to a similar extent after BCCAO in both groups,,only SHR showed dimished ability in novel object recognition test after BCCAO but not NR. Neuropathological evaluation in white matter and hippocampus showed increased blood-brain barrier disruption in white matter and increased inflammation in hippocampus in SHR than WR. Differences in oligodendrocytes damage and myelination are being examined. The results of our study will provide important information on whether rodents with underlying hypertension would be more susceptible to chronic cerebral ischemia in developing white matter ischemic damages as is often observed in human patients.

Title: Post-ischemic mitochondrial dysfunction in brains of diabetic rats exposed to recurrent hypoglycemia

Authors: P. FUCHS, F. DIAZ, *K. DAVE;
Neurol., Univ. Miami Sch. Med., MIAMI, FL

Abstract: Stroke and heart disease are the most serious complications of diabetes. The major side effect of intensive therapy to control blood glucose levels in both type 1 and type 2 diabetics is recurrent hypoglycemic (RH) episodes. Prior exposure to RH exacerbates cerebral ischemic damage in insulin-treated streptozotocin-diabetic rats. The present study investigates the nature of post-ischemic mitochondrial dysfunction in RH-exposed diabetic rats, as mitochondrial dysfunction plays an important role in cerebral ischemic damage. Streptozotocin-induced diabetic rats were used as an animal model. Four experimental groups were examined: 1) naïve (non-diabetics), 2) insulin-treated diabetics (ITD), 3) ITD + RH (diabetics on insulin therapy experiencing RH), and 4) ITD + RH + Glucose (control for additional insulin injected to induce hypoglycemia). RH was induced once a day for five days. Global cerebral ischemia (8 min, 2VO + hypotension) was induced the day after the last hypoglycemia treatment. Hippocampal mitochondrial function was assessed overnight after induction of global cerebral ischemia. Earlier, presented in abstract forms, we observed that the rate of oxygen consumption in the presence of pyruvate and malate was lower in the ITD + RH group compared to naïve (25%, $P<0.05$), ITD (46%, $P<0.001$), and ITD + RH + Glucose (33%, $P<0.001$) groups. Complex I activity was lower in the ITD+RH group compared to naïve (36%, $P<0.001$), ITD (38%, $P<0.001$), and ITD + RH + Glucose (33%, $P<0.01$) groups. The decrease in Complex I activity could be due to a decrease in the steady-state levels of the fully assembled complex, deficits in the assembly or stability of the complex, or posttranslational modifications such as phosphorylation. Currently, we are investigating the molecular mechanisms responsible for the decrease in Complex I activity using blue native gel electrophoresis and western blotting to assess the assembly status of this respiratory complex. Our results suggest that enhanced post-ischemic mitochondrial dysfunction at the level of Complex I may be responsible for exacerbated cerebral ischemic damage in in RH-exposed diabetic rats. Understanding the mechanism by which RH exposure increases cerebral ischemic damage may help lower the severity of ischemic damage in diabetic patients.

Title: Increased hemorrhage and mortality rate after transient focal ischemia in a genetic mouse model of type 1 diabetes

Authors: *A. K. LAI, A. C. LO;
Ophthalmology, The Univ. of Hong Kong, Hong Kong SAR, China

Abstract: PURPOSE: Epidemiological studies showed that type 1 diabetic patients have a higher risk of cerebrovascular mortality from stroke. Amongst those who survived after stroke, the median survival is only half as compared with those in the general population. It has been suggested that type 1 diabetes is a risk factor for stroke; however, the underlying mechanisms are still not clear. In the current study, we aim to elucidate the potential mechanisms contributing to the exacerbation.
METHOD: $Ins2^{Akita/+}$ mice, a type 1 diabetic murine model, and their wildtype ($Ins2^{+/+}$) littermates at 12 weeks of age were challenged with experimental stroke induced by middle cerebral artery occlusion (MCAO) (2h ischemia and 22h reperfusion). Mortality rate was calculated at 1, 2, 4, and 22h of reperfusion and neurological deficits were accessed by the end of the 22h-reperfusion. Brain slices were prepared and stained with 2, 3, 5-triphenyltetrazolium chloride for estimating the infarct area, infarct volume, hemispheric swelling, and hemorrhagic area. Immunohistochemical experiments using antibodies against immunoglobulin G, aquaporin 4 and occludin were performed on brain sections to compare blood vessel integrity.
RESULTS: A higher mortality rate and a shorter survival period were observed in $Ins2^{Akita/+}$ mice after the MCAO challenge when compared with $Ins2^{+/+}$ mice. In the survived $Ins2^{Akita/+}$ mice, hemorrhage was observed in almost every individual (90%). The hemorrhagic areas were remarkably increased in $Ins2^{Akita/+}$ mice, with the majority localizing in the infarct core while a small proportion residing in the penumbra. However, no significant difference was found in neurological deficits, infarct area, infarct volume or hemispheric swelling when compared with $Ins2^{+/+}$ mice. Immunohistochemistry results showed similar staining pattern and intensity of proteins associated with blood vessel integrity, including immunoglobulin G, aquaporin 4 and occludin, in both $Ins2^{Akita/+}$ and $Ins2^{+/+}$ mice.
CONCLUSION: We showed that induction of MCAO in $Ins2^{Akita/+}$ mice could mimic the clinical observations of high mortality and shortened survival in type 1 diabetic patients upon stroke. The

presence of hemorrhage, which was associated with blood vessel leakage and extravasation, may be a potential cause of the exacerbation in the injured brains. The similarities in infarct size, hemispheric swelling as well as blood vessel integrity may possibly be due to a selection of surviving animals that were relatively more resistant to ischemic insult.

Title: Measures of long-term neurological recovery differentially affected by stroke severity in an intraluminal filament MCAO model in adult rats

Authors: *C. MCEWEN, S. J. E. WONG-GOODRICH, Z. HUANG, E. L. TROY, A. GANGULY, R. W. COLBURN, A. O. CAGGIANO, T. J. PARRY;
Res. and Develop., Acorda Therapeut., Ardsley, NY

Abstract: Ischemic stroke induced by occlusion of cerebral vasculature in humans leads to long-term disability and mortality. Depending on the neuroanatomical location of the stroke, many individuals experience devastating loss of motor function, sensory function, aphasia, visual disorders, and/or memory loss. Middle cerebral artery occlusion (MCAO) in rats is the most commonly used method to study and assess potential therapies for cerebral ischemic stroke. Although some reports have described chronic neurological deficits following intraluminal filament MCAO in rats with modest infarct size (Lindner et al., 2003), the goal of this study was to evaluate long-term neurobehavioral recovery at higher temporal resolution using a filament modified to produce a greater degree of infarct severity. Baseline assessment of neurological function was conducted on adult male Wistar rats, using the forelimb/hindlimb placing, body swing, ledged beam, and cylinder tests. Rats were then subjected to MCAO for 1 or 2 h via the intraluminal filament method. Sham animals were also included. To assess functional recovery, all rats were retested on 1, 3, and 7 days and then weekly following sham or MCAO surgery. At 9 weeks post-surgery, rats were then perfused and brains harvested for histological analyses. In a subset of animals, infarct size was also examined as a function of occlusion time. Coronal brain sections were collected throughout the extent of the brain, stained with hematoxylin and eosin, and percent infarct size was recorded for each rat at each section interval. Analyses of behavioral

scores on each test revealed significantly different recovery profiles between 1 h and 2 h MCAO groups. Notably, 2 h MCAO rats exhibited a more protracted recovery in forelimb placing, body swing, and cylinder tests through 9 weeks post-injury. Through 14 days post-MCAO, the rate of recovery of forelimb placing for 2 h MCAO rats was significantly slower than 1 h MCAO rats (slopes = 0.26 ± 0.06 and 0.62 ± 0.89 for 2 h and 1 h, respectively). In contrast, both groups had similar recovery profiles on the hindlimb placing and ledged beam tests. Analysis of infarction (% of contralateral hemisphere) revealed that rats subjected to 2 h MCAO had almost twofold larger infarct areas (41.80 ± 4.58%) compared to 1 h MCAO rats (22.1% ± 3.81, $p < 0.05$). Analysis of specific neuroanatomical correlates differentially affected by stroke severity as well as immunolabeling of neuroplasticity markers is ongoing.

Title: Introduction of an alternative focal cerebral ischemia model in adult zebrafish by photothrombosis

Authors: *X. YU[1], Y. LI[2];
[1]Biol. Sci., [2]Biomed. Sci., Ohio Univ., Athens, OH

Abstract: As the more commonly used models (suture model and distal middle cerebral artery occlusion) for focal cerebral ischemia are often technically challenging, using simpler models to induce a predictable focal ischemic lesion have been developed as an alternative. One of these methods consists of the photothrombosis, which is induced by the illumination of the brain after the systemic delivery of a photosensitive dye, Rose Bengal. Rose Bengal releases singlet oxygen, which breaks the endothelial cells of the blood vessel under light exposure, and triggers the coagulation pathway in the location of the irradiated tissue. In the past decades, the zebrafish (Danio rerio) is widely used to model human diseases, including neurological disorders and in stress research. In the present study, we used the adult zebrafish as a model of focal cerebral ischemia. Zebrafish with the body weight ranging from 0.3 g to 0.5 g were used in the experiment. After anesthesia, Rose Bengal was systemically delivered to zebrafish by intraperitoneal injection according to the body weight (50 μg/g, 100 μg/g and 200 μg/g). The zebrafish was then placed into a self-designed chamber in the upright posture with continuous water and O2 perfusion. Cold light probe was placed right above the optic tectum region of the zebrafish brain. The zebrafish was covered with only the optic tectum exposed for different periods of time (5 minutes, 10 minutes, 20 minutes and 30 minutes). Rose Bengal treated zebrafish without light exposure behaved normally. However, the zebrafish after light exposure exhibited abnormal swimming patterns or movement behaviors. The recovery and behavioral changes after photothrombosis were recorded daily for 3 days. The mortality rate of each group was also measured. The results showed the photothrombosis effect is dose-dependent with Rose Bengal and light exposure. The optimal dose of Rose Bengal (100 μg/g) and light exposure (intensity of 800 μW/cm2 for 30 minutes) yielded significant brain damage. After treatment, 41% of the treated zebrafish exhibited abnormal swimming patterns such as circling and rotating swim, which were related to the damage of the optic tectum. Among those abnormal swimming zebrafish, 78% of them died subsequently. In addition, 27% of the zebrafish died after treatment without showing circling or rotating swim pattern. Quantified TTC (2,3,5-triphenyltetrazolium chloride) staining showed the significant damage of the optic tectum on photothrombotic treated zebrafish. Data suggest that Rose Bengal, with light exposure induces reproducible photothrombotic brain damage on zebrafish, and that zebrafish can be used as a model of focal cerebral ischemia.

Title: Diffusional kurtosis imaging (DKI): A potential novel MRI biomarker of acute stroke and rehabilitation-induced neural plasticity

Authors: *R. WEBER[1], E. S. HUI[2,3], J. H. JENSEN[2,3], X. NIE[2,3], M. F. FALANGOLA[1,2,3], J. A. HELPERN[1,2,3], D. L. ADKINS[1];

Abstract: Currently, there are only limited prognostic tools or biomarkers to determine who will recover motor functions and who will respond best to rehabilitation treatments following stroke. Magnetic Resonance Imaging (MRI) does reveal some common characteristics in brain activation patterns that indicate level of motor recovery following stroke and has been shown, to a limited degree, to reveal training-induced changes in cortical thickness. Advanced diffusional MRI (dMRI) techniques, such as diffusional kurtosis imaging (DKI), are highly sensitive to microstructural changes in brain and provide unique information about white matter connectivity and integrity and thus may be of great prognostic value However, the application of these techniques to stroke has only recently been investigated and a clearer understanding of the relationships between novel dMRI metrics, tissue biophysics and morphology, and behavioral outcomes following acute stroke and post-injury rehabilitative training is needed. In this study, we investigated the relationship between DKI metrics and peri-lesional alterations in glia, neurons and axons; we related these findings to stroke- and rehabilitation-induced sensory and motor recovery. Following unilateral endothelin-1 ischemic lesion of the sensorimotor cortex, adult Long-Evans male rats (3 - 4 mo) underwent sensitive behavioral assessments and were imaged pre-injury and at 2, 24, or 72 h post-surgery, using a 7T Bruker Biospec MRI scanner. Diffusion-weighted images were acquired with 3 b-values (650, 1300, 2000 s/mm^2) along 30 directions using TR/TE=4750/32.5ms, matrix=128x128, resolution=0.23x0.23x1mm^3, and NEX=2. Diffusion and kurtosis tensors were calculated with Diffusional Kurtosis Estimator (DKE) and Cerebral Microenviroment Modeling (CMM) parameters, a new analysis technique,

were computed using in house C and MATLAB programs. Multi-slice regions-of-interest (ROIs) were manually drawn in the infarct (ipsilateral) and contralateral hemisphere. The mean diffusivity (MD), mean kurtosis (MK), and fractional anisotropy (FA) revealed longitudinal changes following stroke. Consistent with a previous study, MK of the infarcted tissue remains higher than normal during the first 72hr post-ischemia, although MD pseudonormalized. It is possible that the sustained increase in MK is due to axon beading, reactive gliosis or cellular oedema. Ongoing analysis will provide further insight into the pathophysiological events underlying the change in DKI metrics during acute and early subacute phases. These data will be further related to chronic alterations induced by motor rehabilitative training.

Title: Visualizing ganglioside expression using MALDI imaging mass spectrometry in a rat model of beta amyloid toxicity and stroke

Authors: *S. CAUGHLIN, J. D. HEPBURN, D. H. PARK, D. F. CECHETTO, S. N. WHITEHEAD;
Anat. and Cell Biol., The Univ. of Western Ontario, London, ON, Canada

Abstract: Stroke and Alzheimer's disease (AD) are often co-morbid conditions that show synergistic damaging effects within the brain. Previous experimental work has demonstrated that in the presence of beta amyloid (Aβ) stroke infarct size grows over time, however clear mechanisms mediating this observation are unknown. Gangliosides, a member of the glycosphingolipid family which are enriched in the central nervous system, may play a role in mediating this synergism as their expression is altered in both AD and stroke. Gangliosides have a heterogeneous expression profile within the brain. Complex gangliosides that contain longer oligosaccharide chains and more sialic acid residues such as GD1 and GM1 can be degraded to smaller, simpler ganglioside species such as GM2 and GM3. The degradation of complex

gangliosides in AD and stroke may lead to neurodegeneration. Here we examine the expression of various ganglioside species in the striatum of rats using Matrix-Assisted Laser Desorption/Ionization (MALDI) Imaging Mass Spectrometry (IMS). MALDI IMS enables the visualization of molecule distribution within intact tissue sections and also produces corresponding mass spectra. Each species of ganglioside can distinguished based on their mass-to-charge ratio and can be imaged simultaneously in a single scan. 3 month old male Wistar rats were either given a unilateral striatal injection of endothelin-1 (stroke condition), an endothelin-1 injection and bilateral intracerebroventricular (ICV) injections of Aβ (25-35) (combination Aβ and stroke condition), injection with endothelin-1 and the non-toxic reverse Aβ fragment (35-25), or underwent sham surgery. Ganglioside expression was examined via MALDI IMS at both 3 and 21 days after treatment. With or without Aβ, GM1 was decreased within the striatum at 3 and 21 days following stroke compared to control. Conversely, with or without Aβ, GM2 and GM3 expression were increased within the striatum 3 days post stroke. Interestingly, by 21 days following stroke, only GM3 remained elevated within the striatum of combined Aβ/stroke rats and not stroke alone rats. Overall, increases in simple ganglioside species were observed immediately after stroke indicating that these potentially toxic gangliosides play an important role in stroke pathology. Over time, the accumulation of GM3 in the periphery of the stroke region observed only in the Aβ/stroke condition may be indicative of a mechanism of pathological synergism between AD and stroke.

Title: TRPM2-mediated NO production in microglia/macrophage contribute to the progression of cerebral ischemic injury in mice

Authors: S. SAKIMOTO, H. SHIRAKAWA, K. ASAKURA, M. MUNAKATA, T. NAKAGAWA, *S. KANEKO;
Kyoto Univ., Kyoto, Japan

Abstract: Ischemic stroke is the third leading cause of death worldwide. Emerging evidence indicates that the activation of inflammatory cells in ischemic brain tissue can extend the brain infarction, but the activation mechanisms of the inflammatory cells remain to be elucidated. Transient Receptor Potential melastatin 2 (TRPM2), a Ca2+ permeable nonselective cation channel, is functionally expressed in the brain and immune cells, implying that TRPM2 could be involved in neuroinflammation during cerebral ischemia. Because of a lack of selective pharmacological blockers, the pathophysiological role of TRPM2 in ischemic brain damage has not been well-defined. In this study, we investigated the involvement of TRPM2 in transient focal cerebral ischemia using wildtype (WT) and TRPM2-knockout (KO) mice. Cerebral infarction and neurological deficits in WT mice were gradually aggravated after reperfusion whereas those in KO mice were not. Immunohistochemical analysis revealed that the migration of microglia/ macrophage in ischemic boundary zone was reduced in KO mice. In addition, the minocycline, an inhibitor of microglia/ macrophage activation, treatment prevented ischemic neuronal injuries in WT mice, but not KO mice. To explore the underlying mechanisms in TRPM2-KO mice. We generated bone marrow chimeric mice by transplanting bone marrow from GFP-wild-type or GFP-TRPM2-KO mice into irradiated recipients of both genotypes. Analysis of chimeric mice revealed that both central and peripheral deficiency of TRPM2 improved neurological deficits, suggesting that both microglia and macrophages play important roles in cerebral ischemia. Next, we focused on inducible nitric oxide synthase (iNOS) and found that administration of a selective iNOS inhibitor 1400W prevented ischemic neuronal injuries in WT mice, but not TRPM2-KO mice. Moreover, in vitro experiments demonstrated that the production of nitric oxide induced by toll-like receptor agonist, lipopolysaccharide and lipoteichoic acid, was markedly reduced in microglia as well as macrophages derived from TRPM2-KO mice. These results indicate that TRPM2 could mediate the cerebral ischemic injury through NO release from both microglia and macrophage.

Title: Microglial TREM2 promotes neuronal phagocytosis after oxygen-glucose deprivation

Authors: R. KACIMI[1], T. M. KAUPPINEN[1,3], C. CALOSING[1], Z. ZHENG[1], C. L. HSIEH[2], M. NAKAMURA[2], *M. A. YENARI[4];
[1]Neurol., [2]Med., Univ. of California, San Francisco & the San Francisco VAMC, San Francisco, CA; [3]Pharmacol. & Therapeut., Univ. of Manitoba, Winnipeg, MB, Canada; [4]Neurol, Univ. California, San Francisco and San Francisco Veterans Affairs Med. Ctr., San Francisco, CA

Abstract: Triggering receptor expressed by myeloid cells-2 (TREM2) is a surface receptor present on microglia and macrophages. It was first described as a receptor of the innate immune system which bound pathogens and led to their phagocytosis. However, TREM2 was also found to bind an as yet undefined receptor in brain cells, particularly injured neurons. TREM2 deficiency leads to dementia. Thus, TREM2 may be an important molecule in the clearance of injured cells paving the way towards recovery and repair. We tested the hypothesis that TREM2 facilitates post-ischemic phagocytosis of ischemic brain cells, and limits the extent of injury caused by excessive inflammation. Using in vitro models of ischemia-like injury, we explored the potential contribution of TREM2 in neuron death and phagocytosis, and attempted to identify its ligand. We first studied Neuro2a cell cultures in combination with BV2 microglial. We confirmed the presence of TREM2 expression in microglial cells. When fluorescently labeled Neuro2a cells were co-cultured with BV2 cells and exposed to oxygen glucose deprivation (OGD), BV2 cells were found to robustly phagocytose Neuro2a cells because they took up the dye used to label neurons. When TREM2 was silenced using siRNA, neuronal phagocytosis was decreased. Microglial treatment with IL-4 induced a M2 phenotype as determined by arginase 1 induction, but had little effect on TREM2 expression. LPS exposure decreased TREM2 expression, whereas PMA, by inducing a phagocytic phenotype, had a modest effect. Since HSP60 has previously been described as a ligand of TREM2, we applied recombinant HSP60 to BV2 cells, but failed to observe transformation to a phagocytic phenotype. To determine potential TREM2 ligands in our models, we used a fusion protein consisting of TREM2 linked to a human Fc receptor and through a modified ChIP assay, found that it bound DNA. Since nucleic acids may be released from ischemic cells, we then determined that supernatants from OGD exposed Neuro2a cells led to TREM2 signaling using a reporter cell line. Finally, we studied TREM2 in primary cell cultures consisting of microglia co-cultured with neuron-astrocyte cultures exposed to OGD. Ablation of microglial TREM2 expression reduced microglial transformation into amoeboid morphology and their tendency to cluster around neurons. TREM2 ablation in microglia did not affect overall acute neuron cell death, but neurons appeared more damaged when TREM2 was deficient, and there was accumulation of cell debris. These results

indicate that TREM2 plays a role in the phagocytosis of ischemic brain cells, and suggests that TREM2 signaling may occur through the binding of extracellular nucleic acids.

Abstract: Assays of global cerebral ischaemia by bilateral clamping of the carotid arteries for 15 minutes were carried out in 3- and 18-month-old male Sprague Dawley rats. Blood pressure was maintained in the range of 40-50 mm Hg during the clamping. After 48 hours of reperfusion (48I/R), brains were quickly removed and transferred to a stainless steel rat brain matrix to obtain one parasagital section (3 mm) of each hemisphere (1.0 to 4.0 mm from the medial line) at 4ºC. In each section, CA3 and CA1 hippocampal areas, as well as the cerebral cortex just dorsal to the hippocampus, were dissected, frozen and stored at -80ºC until used. Protein and RNA were isolated and used for antibody assays and real time PCR quantification. Main adhesion molecules related with the inflammatory response, I-CAM1, V-CAM1, P-selectin and E-selectin were studied. Both cerebral cortex and hippocampus presented similar response in the transcripts of all the molecules studied. I-CAM1 transcripts increased in both young and old injured animals with respect to those of the sham operated animals. In contrast, V-CAM1 transcripts increased in young injured animals but decreased in old injured animals. E-selectin transcripts increased in the old injured animals and decreased in young animals, however E-selectin protein presented different behavior between cerebral cortex and hippocampus in both young and old injured

animals. We only found significant increases in P selectin levels between young injured and young sham animals.
Our results show that 48I/R induces significant age-dependent changes in the mRNA levels of these molecules. The response observed supports the existence of age-dependent differences in the mechanisms of rolling and adhesion induced by 48I/R, and correlates with differences in the apoptosis at this time.

Title: T helper cell subsets and regulatory T cells in long-term survived experimental stroke mice

Authors: *H. HU, X. REN, J. W. SIMPKINS;
Physiolgoy & Pharmacol., West Virginia University, Ctr. For Basic and Translational Stroke Res., Morgantown, WV

Abstract: Ischemic stroke is a devastating Central Nervous System (CNS) condition marked by ischemic brain cell death and breakdown of Blood Brain Barrier (BBB). BBB dysfunction promotes leakage of brain signals to the periphery, which initiates the activation of the peripheral immune system. During the acute stroke phase, the activation- and stroke damage-induced immune cell apoptosis could compromise the immune system resulting in the immunosuppression, systemic infection and septicemia. The immune system has to experience a long-term to recovery following acute stroke. However, it is unknown when and how the immune system is revived normal. We employed the murine experimental stroke model, middle cerebral artery occlusion (MCAO) in the combination with immunological technology to determine the periphery immune system repair following stroke. The T helper cell (Th) subsets response reflects the function of the immune system and we here analyzed Th1, Th2, and Th17

cytokine level in the peripheral blood and spleen T cells of mice 3-month after MCAO. The MCAO mice express lower Th1 cytokine IFN-γ (5.683 ± 0.9243 vs. 8.450 ± 0.5169, n=6, P=0.03) and Th2 cytokine IL-10 (0.35 ± 0.05 vs. 1.133 ± 0.236, n=6, P=0.01) in the blood compared to control mice. However, in the spleen, both IFN-γ and IL-10 have recovered to normal. Interestingly, IL-17 secreting T cells (marker of Th17) were lower in the spleen of MCAO mice but regained relative normal in the blood. Foxp3+ regulatory T cells remained unchanged in both blood and spleen of long-term survived MCAO mice compared to age-matched control mice. These novel observations suggest that the recovery of the immune system after stroke requires an extended period of time. These findings provide evidence supporting the need for recovery therapy of the immune system after stroke.

Title: Restoration by hesperetin of tryptophan metabolic enzyme systems protects against ischemic brain injury in mice

Authors: *W. LEE, S. KIM, S. KIM, Y. FANG, S. BAE, C. KIM;
Dept of Pharmacol, and MRCITR, Pusan Natl. Univ. Sch. of Med., Yangsan, Gyeongsangnam-Do, Korea, Republic of

Abstract:
The tryptophan metabolic enzyme systems of indoleamine 2,3-dioxygenase (IDO) and tryptophanyl-tRNA synthetase (TrpRS), which are involved in L-tryptophan catabolism and its use in protein synthesis, respectively, are associated with the neuroinflammation and immune response to acute cerebral ischemia. Hesperetin, a citrus flavanone, is known to help prevent tissue damage from oxidative stress in the brain. In this study we investigated the mechanisms

involved in cerebroprotective action of heseperetin in connection with the tryptophan metabolic enzyme systems. Male C57BL/6 mice were anesthetized and subjected to photothrombotic cortical ischemia. Hesperetin was administered i.p. 1 h after ischemic insult. Posttreatment with hesperetin significantly reduced the infarct size including infarct area and volume. Ischemic insult markedly altered the tryptophan metabolic enzyme systems, i.e. an increase in the expression of IDO, CD11b, and CD11c, and a simultaneous decrease in that of TrpRS. Hesperetin significantly decreased the expressions of IDO, CD11b, CD11c, p-JAK2 and p-STAT1 via increasing the expression of TrpRS. Hesperetin significantly restored the tryptophan metabolic enzyme system, inhibiting JAK/STAT signaling activation. These results suggest that the cerebroprotective effects of hesperetin might be associated with the increase in the TrpRS expression as well as the suppression of the IDO expression.

Title: Triggering receptor expressed on myeloid cells 2 (trem2) deficiency attenuates phagocytic activities of microglia and exacerbates ischemic damage in experimental stroke

Authors: *M. KAWABORI[1], Z. ZHENG[1], C. CALOSING, Ph.D.[1], C. HSIEH[2], M. NAKAMURA[2], M. YENARI[1];
[1]Neurol., [2]Med., VA Med. Center/UCSF, San Francisco, CA

Abstract: Clearing cellular debris after brain injury represents an important mechanism to re-attain tissue homeostasis and promote functional recovery. Triggering receptor expressed by myeloid cells-2 (TREM2) is involved in the innate immune system, and carries out surveillance functions by binding and phagocytosing pathogens. TREM2 is expressed on macrophages and microglia, and promotes the phagocytosis of apoptotic brain cells. TREM2 also has anti-inflammatory properties and may promote tissue repair without the damaging effects of inflammation. Deficiency of functional TREM2 leads to accelerated dementia, and mutations in the TREM2 gene have been linked to Alzheimer's. Here we explore the significance of TREM2

in a stroke model. TREM2-knockout (KO) and wildtype (WT) mice were subjected to permanent distal middle cerebral artery occlusion ischemic model to elucidate the precise mechanisms of the TREM2 in the ischemic stroke model. While phagocytosis and infarcted brain tissue resorption was observed in wild-type mice by 28d, no phagocytosis and little infarcted brain resorption was seen in TREM2 KO ($p < 0.01$). TREM2 KO mice also had worsened neurological recovery ($p < 0.05$), and decreased viable brain tissue in the ipsilateral hemisphere. Numbers of activated microglia and macrophages in KO mice was decreased compared to WT. These findings establish the relevance of TREM2 in phagocytosis of the infarcted brain and emphasize the importance of phagocytosis in neurological outcome following experimental stroke.

Title: Postischemic exercise increases cell survival and modulates differently astrocyte and microglia functions in hippocampal dentate gyrus following global cerebral ischemia in Wistar rats

Authors: *G. A. LOVATEL, K. BERTOLDI, V. R. ELSNER, F. V. PIAZZA, C. BASSO, F. D. MOYSÉS, P. V. WORM, C. A. NETTO, S. MARCUZZO, I. R. SIQUEIRA;
Univ. Federal Do Rio Grande Do Sul, Porto Alegre, Brazil

Abstract: The effect of exercise on glial cells activation and cell survival after global cerebral ischemia yet remains poorly understood. Here, we investigated the effect of both pre and postischemic treadmill exercise protocols (20 min/day during 2 weeks) on glial cells immunostaining and survival of BrdU+ cells in the hippocampus of Wistar rats submitted to global ischemia. It was observed an increase of area occupied by astrocytes in both dentate gyrus and stratum radiatum induced by global ischemia. Moreover, a synergistic effect between ischemia and exercise on area occupied by astrocytes was showed. Postischemic exercise partially reversed the ischemia-induced increase on area occupied by microglia. It was showed an increase of the survival of BrdU-positive cells in the in dentate gyrus induced by cerebral ischemia and the postischemic exercise potentiated this phenomenon. In conclusion,

postischemic exercise increases cell survival and modulates differently astrocyte and microglia immunostaining in hippocampal dentate gyrus following global cerebral ischemia in Wistar rats.

Title: Interleukin-33 induces a peripheral Th2-type shift that is protective in a mouse model of cerebral stroke

Authors: *P. K. KORHONEN, K. M. KANNINEN, S. LEHTONEN, S. WOJCIECHOWSKI, S. LEMARCHANT, I. KIDIN, E. POLLARI, E. SAVCHENKO, J. KOISTINAHO, T. MALM; A.I. Virtanen Inst. For Mol. Sci., Kuopio, Finland

Abstract: Cerebral stroke is one of the leading causes of death and disability. Ischemia induces a massive Th1-shifted inflammatory response both in the brain and the periphery, contributing to the outcome of stroke. Th1-type responses are usually neurotoxic due to increased pro-inflammatory cytokines whereas Th2-type responses and anti-inflammatory cytokines, including interleukin-4 (IL-4), are generally beneficial. Interleukin-33 (IL-33) is a recently discovered cytokine that acts as a transcription factor, a secreted traditional cytokine and danger signal. IL-33 induces cells of the immune system to produce anti-inflammatory cytokines including IL-4, IL-5, IL-10 and IL-13, and guides undifferentiated T cells to become Th2-type cells.
The aim of this study was to test whether peripherally administered IL-33 could induce a shift in the inflammatory response towards the Th2 direction and whether this response would be protective in a mouse model of ischemic stroke. IL-33 was injected intraperitoneally to young Balb/c male mice either one week prior to permanent middle cerebral artery occlusion (pMCAo) or immediately after the injury. One group of mice also received an anti-IL-4 antibody. Neuronal

damage was imaged by magnetic resonance imaging (MRI) and the mice were sacrificed either 1 or 3 days post ischemia. Tissues and plasma were analyzed by immunohistochemistry, flow cytometry and RT-PCR.
Peripheral IL-33 treatment significantly reduced the lesion size both 1 and 3 days after ischemia regardless of whether the treatment was started prior to or after induction of the injury. The treated mice exhibited significantly higher IL-4 expression in plasma and spleen, and administration of the anti-IL-4 antibody partly prevented the IL-33 mediated protection. IL-33 treatment also reduced astrocytic activation in the peri-ischemic area of the brain.
Our results show that peripheral modulation of immune response by IL-33 to the beneficial Th2-type direction is protective against ischemic insult and may represent a novel therapy for cerebral stroke.

Title: Increased ephrin expression by neutrophil and microglia in a rat model of small-vessel stroke

Authors: *F. S. CAYABYAB[1], K. GOWRIBAI[2], W. WALZ[2];
[1]Dept. of Physiol., [2]Dept. of Psychiatry, Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: In a modified pial vessel disruption (PVD) protocol used as a rat model of small-vessel stroke, increased expression of matrix metalloproteinases-2 and -9 (MMPs) contributes to the formation of lacuna-like cavity. Minocycline injections prevented the cavitation by inhibiting major expressions of MMPs from microglia/macrophages. However, we also observed MMPs in cells that did not label with microglial markers. Here we further characterized the cellular sources of MMPs that could regulate cavity formation. Inside the PVD-induced lesion sites, we found MMP-expressing cells with multi-lobulated nuclei that did not label with the microglia

markers ED1or OX-42. We hypothesized that these are neutrophils that invade the brain parenchyma after breach of blood brain barrier with PVD. Since the ephrin receptors are major substrates of MMPs and EphrinB1 ligands are known to be expressed by neutrophils, we therefore determined whether neutrophils expressed ephrins. In Western blots, we confirmed that EphB1 receptors were upregulated in cortical extracts from PVD-injured rat brains. In contrast, EphB1 expression was lower in minocycline-treated rats and was undetectable in sham animals. Using confocal imaging, we found that neutrophils, but not microglia (ED1), expressed EphB1 in the PVD lesion sites. In contrast, both neutrophils and microglia expressed EphB2 receptors and EphrinB2 ligands in the lesion areas. Moreover, EphA4 was also found in neutrophils and microglia after PVD. Surprisingly, we did not observe ephrins and MMPs in astrocytes both inside and outside the lesion sites. Finally, we confirmed that circulating neutrophils expressed ephrins in non-injured rats. Together these results suggest that expression of ephrins and MMPs by neutrophils contributes to lacuna-like cavity formation in ischemic brains.

Title: Neuroprotection of ethyl pyruvate in the postischemic brain by inhibiting HMGB1 release

Authors: *H. LEE[1], J.-H. SHIN[2], I.-D. KIM[1], L. LUO[1], H.-B. LEE[1], J.-K. LEE[1];
[1]anatomy, Inha Univ., Incheon, Korea, Republic of; [2]Seoul Univ., Seoul, Korea, Republic of

Abstract: Ethyl pyruvate (EP), a simple aliphatic ester of pyruvic acid, has been shown to have anti-inflammatory effects and to confer protective effects in various pathological conditions. For example, EP inhibits secretion of high mobility group box 1 (HMGB1), which is known to be released from dying cells and to aggravate inflammatory pathways. In the present study, we investigated whether EP reduces HMGB1 release in ischemic brain of Sprague-Dawley rats and in cultured microglia. In the postischemic brains (60 min MCAO (middle cerebral artery occlusion)), HMGB1 was released extracellularly, generating dual peaks in cerebrospinal fluid (CSF) at around 1 and 7 days after ischemic insult, which were probably generated from damaged neurons and from activated inflammatory cells, respectively. Here, we showed that treatment with EP 30 min post-MCAO (5 mg/kg, i.v.) reduced both peaks. Moreover, delayed EP treatment from 4 days post-MCAO (5 mg/kg, i.v.) reduced accumulation of HMGB1 in CSF at 7

day post-MCAO without significantly ameliorating ischemic brain damage, indicating that EP-mediated suppression of HMGB1 release is a direct effect. EP markedly suppressed the LPS-induced nuclear translocations of protein kinase C alpha and calcium/calmodulin-dependent protein kinase IV, HMGB1 phosphorylation, and subsequent secretion of HMGB1 induced by LPS in BV2 cells, primary microglia, and RAW264.7 cells. Moreover, EP-mediated above-mentioned effects were also independent of cell death or survival. These results indicate that the inhibition of HMGB1 release by EP contributes, at least in part, to its protective effects.

Title: Meninges modulate post-stroke brain pathology via resident mast cells

Authors: *A. ARAC[1], M. A. GRIMBALDESTON[3], A. R. B. NEPOMUCENO[2], O. OLAYIWOLA[2], M. P. PEREIRA[2], Y. NISHIYAMA[2], H. VOGEL[2], M. TSAI[2], S. J. GALLI[2], T. M. BLISS[2], G. K. STEINBERG[2];
[1]Neurosurg., Stanford Univ., STANFORD, CA; [2]Stanford Univ., Stanford, CA; [3]SA Pathology, Div. of Human Immunology, Ctr. for Cancer Biol., Adelaide, Australia

Abstract: Mast cells (MCs), perivascular cells best known as effector cells involved in the development of inflammatory processes, do not circulate but are resident in virtually all anatomical sites including brain parenchyma and meninges. Brain parenchymal MCs have been reported to exacerbate stroke pathology, however the role of meningeal MCs, if any, in stroke pathology is not known. To address this, we used ‘mast cell knock-in’ mouse models whereby

genetically MC-deficient mice were selectively repaired of their MC deficiency by engraftment of in vitro grown mast cells, either systemically or locally in the meninges.
The WBB6F1-KitW/W-v MC-deficient mouse model was used. 3 groups were tested: wild-type, MC-deficient, and MC-engrafted (after systemic or meningeal engraftment). Mice were subjected to 30 min occlusion of the middle cerebral artery. Brain swelling and infarct size were assessed by T2-weighted MRI and histology. The immune response was quantified by flow cytometry.
MC-deficient mice had less brain swelling at 3d post-stroke, smaller lesions at 3d and 2wk post-stroke, and fewer brain granulocytes at 3d post-stroke than their corresponding wild-type or systemically MC-engrafted groups, implying that MCs exacerbate ischemic injury. Analysis of the central nervous system MC distribution in wild-type and MC-engrafted mice revealed equivalent numbers of MCs in meninges in both groups but almost no MCs in brain parenchyma of MC-engrafted groups. This suggests that meningeal MCs, rather than parenchymal MCs, are key effectors of stroke pathology. To test this, MCs were engrafted locally into the meninges. These meningeal MC-engrafted mice had significantly more brain swelling, larger infarcts, and more brain granulocytes after stroke than MC-deficient mice.
Our results support the conclusion that meningeal MCs can exacerbate stroke pathology. Hence, targeting these cells may be a novel therapeutic strategy for stroke.

Title: Inducible nitric oxide synthase in blood borne neutrophils mediates brain damage after transient focal cerebral ischemia

Authors: *L. GARCIA-BONILLA, J. MOORE, G. RACCHUMI, J. ANRATHER, C. IADECOLA;
Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Nitric oxide (NO) produced by inducible nitric oxide synthase (iNOS) contributes to brain damage after cerebral ischemia (J Neurosci, 17:9157, 1997), but the cell types expressing iNOS and mediating tissue damage have not been elucidated. We hypothesized that iNOS present in neutrophil infiltrating the ischemic brain is responsible for tissue injury. To test this hypothesis, $iNOS^{-/-}$ male mice (7 weeks old) were lethally irradiated and transplanted with wild type bone marrow ($BM^{+/+}$) to produce chimeric mice expressing iNOS in peripheral leukocytes (n=10-15 per group). Five to six weeks after transplant, mice were subjected to transient (30 min) MCAO and injury volume was assessed 3 days later in cresyl violet-stained brain sections. Infarcts in $iNOS^{-/-}BM^{+/+}$ mice, in which iNOS is present in peripheral leukocytes but not in brain cells, were larger (43 mm^3, Mean±SE) than those of controls ($iNOS^{-/-}BM^{-/-}$) (24±3 mm^3, $p<0.05$) and not different from those of $iNOS^{+/+}BM^{+/+}$ mice (35±3 mm^3; $p>0.05$). Thus, the data suggest that iNOS positive peripheral leukocytes aggravate ischemic damage in iNOS null mice. Then, we sought to investigate which cell types express iNOS after ischemia in the BM chimeras. To this end, we performed flow cytometry followed by cell sorting. Infiltrating neutrophils and monocytes, as well as microglia and endothelial cells (EC) were purified from brains of $iNOS^{-/-}BM^{+/+}$ and $iNOS^{+/+}BM^{-/-}$ mice 3 days after MCAO. iNOS gene expression was assessed using qRT-PCR. $iNOS^{-/-}BM^{+/+}$ mice showed iNOS mRNA induction in neutrophils ($14x10^{-3}$ copies/cell number) and, to a lesser extent, monocytes ($2x10^{-3}$). As anticipated, iNOS was not detected in EC or microglia. In $iNOS^{+/+}BM^{-/-}$ mice, iNOS was detected in EC ($16x10^{-3}$), but not microglia or infiltrating leukocytes. To provide independent evidence that neutrophils expressing iNOS contribute to tissue damage, adoptive-transfer experiments were performed. Granulocytic cells (Ly6G+) from $iNOS^{+/+}$ or $iNOS^{-/-}$ mice were isolated by negative selection and $5x10^5$ cells were given retro-orbitally to $iNOS^{+/+}$ or $iNOS^{-/-}$ 24 hours after MCAO (n=7 per group). Consistent with the result in chimeric mice, transfer of $iNOS^{+/+}/Ly6G^+$ cells into $iNOS^{-/-}$ mice increased the infarct at 3 days after MCAO (vehicle: 30±4 mm^3; $iNOS^{+/+}/Ly6G^+$ cells: 46±5 mm^3; $p<0.05$) but not when $iNOS^{-/-}/Ly6G^+$ cells were transferred (27±6 mm^3; $p>0.05$ from vehicle). The findings identify iNOS in blood borne leukocytes, particularly neutrophils, as a mediator of tissue damage in the post-ischemic brain and establish iNOS in circulating cells as a therapeutic target for ischemic brain injury.

Title: microRNA associated with the inflammatory and immune response to stroke in humans may regulate many important targets including MMP9, TLR4, IL1 and IL6

Authors: *G. JICKLING, B. P. ANDER, X. ZHAN, B. STAMOVA, P. VERRO, D. LIU; Neurol., Univ. of California Davis, Sacramento, CA

Abstract: Background: microRNA (miRNA) are important regulators of messenger RNA translation to protein. We have previously shown that miRNA is differentially expressed in the brain and blood of rodents with ischemic stroke compared to controls. In this study we sought to determine whether miRNA is differentially expressed in patients with ischemic stroke, and potentially regulate aspects of the immune response to ischemic brain injury.
Methods: miRNA from 22 patients with ischemic stroke were compared to 22 controls matched for age, sex, race and vascular risk factors. miRNA was isolated from blood, and processed on Affymetrix miRNA 3.0 microarrays. In silico analysis was performed to identify miRNA targets of importance to stroke.
Results: We identified 31 miRNA that were differentially expressed in patients with ischemic stroke compared to controls (corrected p-value <0.05, fold change>|1.2|). These miRNA are predicted to regulate the translation of several molecules important in ischemic stroke, including matrix metalloproteinase 9, toll like receptor 4, interleukin 1 beta, tumor necrosis factor alpha and interleukin 6.
Conclusions: Several miRNA were identified as differentially expressed in the blood of ischemic stroke patients compared to controls. These may have potential importance as markers of brain ischemia, and as regulators of biological functions and pathways involved in the inflammatory and coagulation response in ischemic stroke.

Title: Peri-infarct responses of microglia and astrocytes in a photothrombotic model of stroke in rats

Authors: *N. R. SIMS, W. YEW, N. D. DJUKIC, J. S. P. JAYASEELAN, H. MUYDERMAN; Discipline of Med. Biochem. Flinders Univ., Adelaide, Australia

Abstract: Infarcts produced by a stroke trigger changes in neighbouring microglia and astrocytes that ultimately lead to formation of a glial scar. Indirect evidence suggests that responses of these glial cells can limit the plastic changes in neurons that are an important contributor to restoration of function following a stroke. Thus, the glial cell responses provide a potential target for treatments that can enhance recovery even when initiated many hours to days after stroke onset. The development of peri-infarct glial cell responses have not been analysed in detail, particularly in the photothrombotic model of stroke that has been widely used to study neuronal plasticity. In the present investigation, photothrombosis was induced in the forelimb motor cortex of male Sprague-Dawley rats. Brains were analysed between 3 h and 7 days later using cresyl violet staining, immunoblots and immunohistochemistry for cell specific markers. Rats showed severe deficits in a forepaw placing test by 3 h that persisted at 3 days and then partially recovered by 7 days. Infarcts identified from cresyl violet staining were readily detectable at 3 h and attained a maximum volume by 24 h. Morphological changes in peri-infarct microglia were seen as early as 3 h. At 24 h, these cells exhibited marked activation as revealed by gross changes in cell morphology and the expression of the marker protein, cyclooxygenase-2. Furthermore, such changes extended well beyond the peri-infarct region. In contrast, astrocytic changes detected from expression of vimentin and glial fibrillary acidic protein, were essentially absent at 24 h. By 7 days, the infarct volume was greatly reduced due to a combination of lesion contraction and invasion of the lesion by microglia and by astrocytic processes. Between 1 and 7 days, the area fraction of immunolabelling for markers of both microglia and astrocytes increased several fold in the peri-infarct tissue, at least in part explained by large increases in cell numbers. These studies provide evidence of earlier and more extensive activation of microglia than has been reported previously following stroke. The microglial changes apparently precede responses in astrocytes by many hours. The studies have also established markers of glial cell changes that will facilitate future investigations into mechanisms underlying treatments that enhance neurological recovery.

Title: Early responses of microglia to tissue infarction in a photothrombotic model of stroke in rats

Authors: *W. YEW, J. S. P. JAYASEELAN, N. D. DJUKIC, H. MUYDERMAN, N. R. SIMS; Flinders Univ., Adelaide, Australia

Abstract: Neuronal plasticity in tissue immediately surrounding an infarct is likely to contribute to functional recovery following a stroke. Changes in peri-infarct glial cells influence the extent of neuronal plasticity and therefore are a possible therapeutic target to enhance recovery. Microglia in this tissue are thought to play a critical role in initiating these glial cell responses. However, there have been few attempts to characterise the early responses of these cells or to assess approaches for manipulating the changes. We have addressed these issues in a model of stroke that has been widely used to study neuronal plasticity. Rats were subjected to photothrombotic stroke targeting the forelimb region of the primary motor cortex. At 3 and 24 h after the stroke, forelimb function was assessed (paw-placing test) and the brains perfusion fixed and sectioned for cresyl violet staining and immunohistochemistry for neurons (NeuN) and microglia (Iba1). A measure of circularity of Iba1-positive cells was developed that provided a sensitive indicator of morphological changes indicative of activation. Area fraction of the Iba1 immunoreactivity (percentage of Iba1-positive pixels in thresholded images) was used to detect changes associated with cell activation, migration or cell death. At 3 h after stroke induction, function of the contralateral forelimb was markedly impaired and a lesion readily detectable by cresyl violet staining and NeuN immunolabelling. Microglial circularity was significantly increased in peri-lesional tissue suggesting activation of these cells had been initiated at this time. At 24 h, the impairment of forelimb function persisted and lesion volume (from cresyl violet staining) had increased. Morphological changes in peri-infact microglia were much larger than at 3 h and were also detectable in cortical tissue distant from the lesion. The area fraction of Iba1 in peri-infarct tissue was decreased relative to that in other parts of the ipsilateral cortex. Treatment at 1 h after stroke with minocycline (50 mg / kg i.p.), a widely-used inhibitor of microglial activation, did not significantly alter either the microglial response or forelimb function at 24 h. These results provide evidence for rapid microglial activation that spreads well beyond the peri-infarct tissue. Changes in Iba1 area fraction suggest a subsequent depletion of microglia from the peri-infarct tissue, perhaps due to migration into the lesion or selective cell death that extends beyond the infarct.

Title: Lipocalin 2 is a detrimental factor induced after stroke-reperfusion injury

Authors: G. WANG[1], Y.-C. WENG[2], X. HAN[2], *W.-H. CHOU[2,1];
[1]Biomed. Sci., [2]Biol. Sci., Kent State Univ., Kent, OH

Abstract: Stroke is a leading cause of morbidity and mortality worldwide, yet limited therapeutic options exist. The plasma concentration of lipocalin-2 (LCN2) is elevated in human patients with acute ischemic stroke, but its role in stroke is unknown. Recent studies revealed the ability of LCN2 to induce apoptosis. The LCN2 internalized by its cell surface receptor, brain type organic cation transporter (BOCT), chelates intracellular iron and induces apoptosis. Here we show that LCN2 proteins were induced in mouse plasma and ipsilateral hemisphere after transient middle cerebral artery occlusion (tMCAO). The induction of LCN2 proteins in the ischemic hemisphere was detected in the infiltrated neutrophils and a subset of reactive astrocytes. The BOCT displayed a punctate staining pattern in the microtubule-associated protein-2 (MAP-2) positive cultured neurons and brain tissues. To determine the role of LCN2 in vivo, we induced tMCAo in wild-type and LCN2 null mice, and found that the LCN2 null mice showed reduced infarct size and improved neurological outcomes after tMCAo. The recombinant LCN2 proteins when added to the primary cultured neurons caused cell death in a dose-dependent manner. These results indicate that LCN2 is a detrimental factor induced after ischemic stroke, and suggest that reduction of LCN2 could prove useful in the treatment of stroke.

Title: Influences of diet and stroke on expression of genes that modulate inflammation and neuronal remodeling in the adult and aged male rat cerebral cortex

Authors: *E. D. GRISLEY[1], T. REHNBERG[1], J. A. MACLEAN, II[1], W. J. BANZ[3], D. A. BUTTEIGER[4], J. L. CHEATWOOD[1,2];
[1]Physiol., [2]Anat., SIU Sch. of Med., Carbondale, IL; [3]Animal Science, Food, and Nutr., SIUC, Carbondale, IL; [4]Solae, LLC, St. Louis, MO

Abstract: Stroke is a leading cause of lasting neurological deficit in humans, and few options are available for improving outcomes. We have previously shown that rats fed a diet containing soy protein isolate exhibited significantly lower behavioral deficits for 4 weeks following stroke when compared to rats fed a diet containing sodium caseinate. However, the mechanism mediating these observed benefits was not clear. Herein, we describe the effects of diet on several key anti-inflammatory proteins and markers of neuroanatomical remodeling in uninjured rats and at 3 and 7 days after middle cerebral artery occlusion. As before, rats were fed semi-purified diets containing either soy protein isolate or sodium caseinate as the protein source. A third diet group was used in which the soy isoflavones genistein and daidzein were added to the sodium caseinate diet, in an effort to determine the role of these compounds in the previously observed neuroprotection. Rats were pre-fed the appropriate study diet for two weeks prior to stroke. All rats in the Day +3 and Day +7 time points underwent a permanent unilateral middle cerebral artery occlusion, as described previously, and were euthanized on either Day +3 or Day +7, respectively. Brains were removed and tissue from each cerebral hemisphere was isolated and placed in Trizol for mRNA extraction. Relative gene expression was determined for each sample via quantitative real time PCR. Genes of interest in the current study included *Pparg*, *Ywhae* (*14-3-3e*), *Arg1*, *Sod1*, *Gap43*, and *Syp*. At the time of abstract preparation, no significant difference was detected in expression of *Pparg* in any groups of adult male rats. Analyses of additional genes and aged rats are ongoing.

Title: Blood-derived Ly6C^{low} macrophages contribute to spontaneous recovery after stroke

Authors: A. ARAC, Y. NISHIYAMA, T. HIU, T. M. BLISS, *G. K. STEINBERG; Stanford Univ., STANFORD, CA

Abstract: Understanding the mechanisms of post-stroke inflammation is essential to develop therapeutics that would promote recovery. Macrophages are known to promote both injury and repair in various pathologies, and these divergent properties may be due to different macrophage subtypes. Here, we investigated whether the brain macrophage subtypes alter the post-stroke outcome.

C57BL/6 mice (11-14 weeks old) were subjected to transient middle cerebral artery occlusion (tMCAo). Flow cytometry was used to analyze the immune cells in brain, blood. To deplete blood monocytes, clodronate filled liposomes (CL) were used. Phosphate-buffered saline (PBS)-filled liposomes (PL) served as controls. Lesion size was assessed by TTC at 2d post-stroke and silver staining at 7d post-stroke. A time-course analysis of immune cells after stroke identified two macrophage subpopulations in the brain with different temporal profiles: Ly6C^{high} macrophages were the dominant cell population early after stroke, reaching a peak by 3d, and then decreasing in number by 5d. Conversely, the number of Ly6C^{low} macrophages were initially low and peaked by 5d. To investigate the effects of these cells, we used clodronate depletion of monocytes with different injection paradigms. Injecting clodronate 10 min plus 2d after stroke had no significant effect on infarct size at 2d and 7d post-stroke, or on functional deficit, compared to the PL group. However, when the injections were given every other day after stroke, from day 0 to day 6, CL-treated mice had significantly larger infarct sizes at 7d post-stroke (48.9±4.3 vs 35.6±5.8, % of contralateral hemisphere, n=10; $p<0.01$), and worse neurological scores (11.1±1.1 vs 6.2±1.1, n=10; $p<0.01$) than PL-treated mice. Furthermore, this injection paradigm resulted in significantly fewer Ly6C^{low} macrophages in the CL-treated group, suggesting a protective role for these cells.

Macrophage subtypes may have distinct roles in promoting brain damage and recovery after stroke.

Title: TLR2-induced MMP9 activation compromise blood brain barrier and enhances brain damage in collagenase-induced Intracerebral Hemorrhage

Authors: *S. LEE[1], H. MIN[1], J. HONG[1], Y. JANG[1], K. KWAK[1], S. LEE[2];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Microbiology, Sch. of Systems Biol., Chungnam Natl. Univ., Daejeon, Korea, Republic of

Abstract: Innate immune response plays an important role in the pathogenesis of cerebral ischemia/reperfusion injuries. Recent studies have shown that Toll-like receptor 4 (TLR4) is involved in the innate immune responses after cerebral ischemia/reperfusion injuries, yet, the role of TLR2 in stroke or the mechanisms of its function have not been resolved. In this study, we tested it in a collagenase-induced mouse intracerebral hemorrhage (ICH) model using TLR2 knock-out (KO) mice. To induce ICH, collagenase or blood was injected into the right caudate putamen in 8-10 week old male mice. TLR2 expression was upregulated in the ipsilateral hemorrhagic tissues of the collagenase-injected mice. Brain injury volume and neurological deficits following ICH were reduced in the TLR2 KO mice as compared to the wild type (WT) mice. Heterologous blood-transfer experiments show that TLR2 signaling in the brain-resident cells, but not leukocytes, contributes to the injury. In our study to elucidate underlying mechanisms, we found that damage in the blood-brain barrier (BBB) integrity following the ICH was attenuated in the TLR2 KO mice compared to the WT mice, which may be due to reduced MMP-9 activation in brain astrocyte. The reduced BBB damages accompanies with reduced neutrophil infiltration and proinflammatory gene expression the injured brain parenchyma, which may account for the attenuated brain damage in the TLR2 KO mice after ICH. Conclusively, these data demonstrate that TLR2 contributes to brain injury following ICH by compromising BBB through activating MMP-9 in brain.

Title: Fingolimod causes antidepressant-like effects and corrects the reduction in hippocampal BDNF levels in mice exposed to chronic unpredictable stress

Authors: *L. DI NUZZO[1], R. ORLANDO[1], J. MIELE[1], P. DI PIETRO[3], M. MOTOLESE[3], A. CARUSO[1], S. SCACCIANOCE[1], G. BATTAGLIA[3], V. BRUNO[1,3], C. POZZILLI[2], F. NICOLETTI[1,3];
[1]Physiol. and Pharmacol., [2]Neurol., Univ. Sapienza, Rome, Italy; [3]Neurosci., I.R.C.C.S. Neuromed, Pozzilli, Italy

Abstract: Recent evidence suggests that fingolimod, the first oral drug approved for the treatment of relapsing-remitting multiple sclerosis, exerts a direct effect on the CNS independently of its peripheral action on the immune system. We and others have found that nanomolar concentrations of fingolimod protect cultured neurons against excitotoxic death through the activation of type-1 sphingosine-1-phosphate (S1P1) receptor (Di Menna et al., Pharmacol Res. 67, 2013; Deogracias et al., Proc Natl Acad Sci USA 109, 2012). Deogracias and collegues also showed that systemic treatment with fingolimod enhances hippocampal levels of brain-derived neurotrophic factor (BDNF). Hippocampal BDNF levels have been associated to the pathophysiology of major depression and to responses to antidepressant medication. Hence, we decided to examine whether fingolimod could cause antidepressant-like effects in the chronic unpredictable stress (CUS) model of "reactive" depression. C57BL/6J adult male mice were exposed to a 4-week CUS protocol, which was sufficient to induce depressive-like behaviour at the forced swimming test (FST). CUS mice showing an increased immobility time at the FST also displayed a substantial reduction in hippocampal BDNF levels. Fingolimod (3 mg/Kg i.p.) was administered daily in the last week of CUS and the treatment was prolonged for 3 weeks after the discontinuation of the stress protocol. Fingolimod reduced the time spent immobile at the FST in about 30% of treated animals, which are considered 'responders' to the drug. In these responder mice, Western blot analysis showed an increase of hippocampal BDNF protein levels, which were restored to values similar to control animals. Fingolimod did not show any effect on BDNF concentrations in mice that did not respond to the drug at the FST. These data show for

the first time an antidepressant-like activity of fingolimod. This raises the interesting possibility that fingolimod may relieve depressive symptoms associated with multiple sclerosis.

Title: Dietary walnut alters neurochemical and behavioral functions in young and old rats

Authors: *D. F. BIELINSKI, S. POULOSE, D. FISHER, M. MILLER, F. RAMIREZ, B. SHUKITT-HALE;
Neurosci. & Aging Lab., USDA Human Nutr. Res. Ctr, Tufts Univ., BOSTON, MA

Abstract: Diets rich in either polyunsaturated fatty acids or polyphenols have been shown to promote indices of brain functions, primarily with effects on the lipid microenvironment or neuronal signaling. Walnuts are known to contain high amounts of omega fatty acids such as alpha linoleic acid (ALA) and linolenic (LA), as well as neuroactive polyphenols and minerals. Previous studies from our laboratory have shown that feeding diets rich in walnuts protected against age-associated behavioral declines in rats, primarily via enhancing protective signaling, reducing inflammation and preventing accumulation of ubiquitinated inclusion bodies in key regions of the brain. In order to assess whether walnut diets affect age-associated changes in the epigenetic phenomenon, young (3 month) and old (18 month) rats were fed with walnut diets at concentrations of 0%, 6% or 9% w/w for 12 weeks, and subjected to a battery of motor and cognitive tests. Blood serum was collected to test for its exogenous protective effects at the beginning (baseline) and end of the feeding period. Brains were collected to examine global DNA methylation as well as gene-specific DNA methylation patterns in key areas of the brain affecting behavior. The behavioral tests showed significant effects of age. Positive effects of the diet were seen for the wire suspension test, with both 6% and 9% walnut groups performing significantly better than controls. The walnut-fed rats also made fewer errors in the radial arm

water maze. BV2 microglial cells treated with serum from walnut-fed animals and then exposed to the endotoxin lipopolysaccharide (LPS) showed reduced stress-induced inflammatory signals compared to serum from control-fed rats. A correlation of serum effects from respective animals to their behavior is being done along with differential epigenetic patterns. Overall results indicate long-term benefits of a walnut diet rich in both polyphenols and omega fatty acids.

Title: Tart cherries improve working memory in aged rats

Authors: *B. SHUKITT-HALE, M. G. MILLER, D. F. BIELINSKI, S. M. POULOSE; USDA, ARS, Human Nutrit Res. Ctr. On Aging, BOSTON, MA

Abstract: Aged rats show impaired performance on cognitive tasks that require the use of spatial learning and memory. In previous studies, we have shown the beneficial effects of various dark-colored berry fruits (blueberries, strawberries, and blackberries) in reversing age-related deficits in behavioral and neuronal function when fed to rats from 19-21 months of age. These effects may be due to the phytochemicals in the fruits, which increase antioxidant and anti-inflammatory levels, and directly affect signaling and autophagy in the brain. Tart cherries, like other berry fruits, are rich in polyphenolics, particularly anthocyanins. Thus, the present studies were carried out to determine if tart cherries, added to the diet of 19 mo Fischer 344 rats at 2% for 8 weeks, would be efficacious in reversing the deleterious effects of aging on cognitive behavior as measured with the working memory version of the Morris water maze. Results showed that the cherry diet improved working memory in the Morris water maze, but not in the control group. However, reference memory was better in the control group, possibly because they were not using spatial strategies to solve the maze. Currently, westerns are being done on brain tissue homogenates to measure the levels of four markers involved in the aggregation of polyubiquitinated proteins and activation of autophagy: phospho-mTOR, beclin-1, p62, and

LC3-I/II. We will then be able to assess whether alterations in these autophagy markers may be involved in the mechanisms of action through which the tart cherry polyphenols produce their effects.

Title: Dietary acai fruit improves cognition in aged rats

Authors: *M. G. MILLER[1], D. FISHER[2], A. N. CAREY[3], S. M. POULOSE[2], B. SHUKITT-HALE[2];
[1]Psychology, Tufts Univ., Medford, MA; [2]Neurosci. and Aging, USDA HNRC on Aging at Tufts Univ., Boston, MA; [3]Psychology, Simmons Col., Boston, MA

Abstract: Acai is a black-purple fruit (genus Euterpe) cultivated in the Amazon delta and in Brazil (Euterpe oleracea Mart.; EO), as well as Bolivia (Euterpe precatoria Mart.; EP). The fruit's pulp is known to be rich in polyphenolics that may affect cell-to-cell signaling, receptor sensitivity, inflammatory enzyme activity, oxidant/antioxidant balance, and gene regulation. In previous studies, we have shown the beneficial effects of various berry fruits (blueberries, strawberries, and blackberries) in reversing age-related deficits in behavioral and neuronal function when fed to aged rats. Thus, the present study was carried out to determine if EO or EP, fed in the rat diet at 2% for 8 weeks, would be efficacious in reversing the deleterious effects of aging on cognitive behavior in 19-21 mo old Fischer 344 rats. Both the EO and EP diet improved working memory, relative to controls; however, only the EO diet improved reference memory. When BV2 cells were pretreated with serum collected from the rats and then treated with LPS, serum from EO fed rats reduced nitrite release and serum from both acai-fed groups reduced TNF-alpha release. Reductions in nitrite and TNF-alpha release in the cell model were associated with improved water maze performance. Western blots were conducted on BV-2 lysates to measure the levels of two inflammatory markers: inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2). Treatment of BV-2 cells with serum from acai-supplemented rats

resulted in significant decreases in iNOS and COX-2 expression. Protection of memory during aging by dietary acai may result from its anti-oxidant and anti-inflammatory properties.

Title: Elucidate the neuroprotective mechanisms of Scutellaria lateriflora

Authors: M. LOHANI[1], M. AHUJA[2], M. BUABEID[2], D. BHATTACHARYA[2], A. ROMANDO[3], V. SUPPIRAMANIAM[2], D. SHANNON[4,3], R. AMIN[2], *E. S. COLEMAN[1], D. SCHWARTZ[1], B. KEMPPAINEN[1], M. DHANASEKARAN[2];
[1]Auburn Univ, Coll of Vet Med., Auburn, AL; [2]Harrison school of Pharmacy, Auburn Univ., Auburn, AL; [3]USDA,, Oxford, MS; [4]Col. of Agriculture, Auburn Univ., Auburn, AL

Abstract: Introduction: Scutellaria lateriflora (American skullcap), a native plant of North America, has been used by Americans and Europeans as a nerve tonic and an anxiolytic agents. GABA and glutamate are the major neurotransmitters associated with hyperarousal and excitotoxicity. Bioactive compounds (phytochemicals) present in the medicinal plants affect the neurotransmission and also can have neuroprotective properties. The neuroprotective effects of Scutellaria lateriflora (alcoholic extract) are not fully elucidated. Therefore, the objective of the current study is to investigate the neuroprotective mechanisms of Scutellaria lateriflora.
Methods: Neuroprotective effects were evaluated against hydrogen peroxide induced cytotoxicity using cell viability assay. The antioxidant and anti-apoptotic potential of Scutellaria lateriflora was determined in differentiated hippocampal (H19-7) and pheochromocytoma (PC-12) cells. Furthermore, the effect on glutamatergic receptor expression was also studied. One way ANOVA and appropriate post hoc test was used for finding statistically significant differences between each mean value at $P \leq 0.05$.
Results and Conclusion: Scutellaria lateriflora dose-dependently suppressed caspase-3 expression and scavenged the reactive oxygen species significantly. Decreased reactive oxygen species and caspase activity strongly correlated with the increased cell viability. Additionally, Scutellaria lateriflora increased N-methyl-D-aspartate(NR2A and NR2B) receptors, phosphorylated cAMP response element-binding protein (pCREB) and brain-derived

neurotrophic factor(BDNF) expressions in H19-7 cells. Therefore, the findings of the current research indicate that Scutellaria lateriflora exhibit neuroprotection by affecting the glutamatergic neurotransmission and exhibiting antioxidant and anti-apoptotic action. Thus, Scutellaria lateriflora can be an effective botanical therapy against various neurodegenerative diseases.

Title: Chemical analysis and effect of blueberry and lingonberry fruits and leaves against glutamate-mediated excitotoxicity

Authors: *S. KALIDINDI[1], P. VYAS[2], L. CHIBRIKOVA[1], A. U. IGAMBERDIEV[2], J. T. WEBER[1,3];
[1]Sch. of Pharm., [2]Dept. of Biol., [3]Fac. of Med., Mem. Univ. of Newfoundland, St.John's, NL, Canada

Abstract: Production of reactive oxygen species (ROS) and reactive nitrogen species (RNS) are natural processes occurring in the brain. However, overproduction of ROS and RNS may occur during aging and contribute to neurodegenerative diseases and disorders such as stroke. Phenolic compounds are a large class of phytochemicals that are widespread in the plant kingdom and are known to have antioxidant capacities. This study aimed to determine the radical scavenging capacity and reducing power, as well as the polyphenolic content in fruits and leaves of blueberries and lingonberries growing in Newfoundland. We also determined the potential neuroprotective effect of extracts against glutamate-mediated excitotoxicity, which is believed to contribute to disorders such as stroke and neurodegenerative diseases. We found that extracts of fruits and leaves of blueberry and lingonberry plants had high levels of total soluble phenolics, anthocyanins, tannins, and flavonoids. Overall, the levels of these compounds were significantly

higher in the leaves of these plants versus the fruits. Total antioxidant capacity, in terms of radical scavenging activity and reducing power, were much higher in the leaves of both plants as compared to their fruits. We next tested the effects of the extracts against glutamate-mediated excitotoxicity, a pathological process partially involving overproduction of ROS and RNS. Brain-derived cortical cell cultures from neonatal rat pups were prepared and grown for 9-16 days in vitro. Cells were exposed to glutamate (100 μM) for 24 hours. Glutamate-exposed cells displayed morphological alterations such as disrupted cell bodies, and increased dark punctae, which is often indicative of condensed nuclei. Glutamate also caused a ~23% cell loss after 24 hours as determined by the amount of DAPI-positive nuclei. While lingonberry fruit extract did not provide protection from glutamate toxicity, blueberry fruit extracts were extremely protective. Cultures treated with leaf extracts of lingonberry and blueberry showed no cell loss in the presence of glutamate, indicating a strong protective effect of both the leaf extracts. The overall greater protective effect of leaf extracts was in correlation with the levels of phenolics and antioxidant capacity. These findings suggest that berries or their components may provide protection to the brain from various pathologies. This protective effect of berry extracts may be due to a decrease in oxidative stress, nitrosative stress, or other damaging mechanisms caused by exposure to glutamate.

Title: Vitamin D and/or calcium deficient diets preferentially affect type II muscle fiber neuromuscular junction genomic expression and innervation

Authors: *D. J. GIFONDORWA[1], Y. WANG[1], B. L. ADAMS[2], B. C. YADEN[1], J. G. MACKRELL[1], P. K. SHETLER[1], T. D. THOMPSON[3], K. TYLER[1], K. L. KNOPP[2], Y. L. MA[1], V. KRISHNAN[1], H. U. BRYANT[1];
[1]Muskuloskeletal Res., [2]Neurosci. Res., [3]Cardiovasc. Res., Eli Lilly and Co., Indianapolis, IN

Abstract: Low serum vitamin D levels have been associated with reduced physical ability in older adults, resulting in abnormal balance and coordination with an increased incidence of falls. Type II muscles are initially recruited to prevent falls and maintain balance in humans. The exact

mechanism of how vitamin D deficiency produces these deficits remains to be elucidated. The purpose of the current study is to provide insight into how reduced vitamin D levels preferentially affect the neuromuscular junction (NMJ) integrity of type II muscle fibers. Studies with genetically manipulated mice and those with a vitamin D modified diet have provided valuable insights which have translated into humans. Previous work has demonstrated that mice fed a vitamin D deficient diet at the time of weaning and continuing for six weeks is sufficient to increase the total body muscle/fat mass ratio, while decreasing performance on locomotor behavioral tasks and NMJ innervation of type II skeletal muscles. The heat stress response was also determined to be more highly activated in type I compared to type II skeletal muscle, as determined by increases in mRNA and protein expression of heat shock proteins 70, 90 and the DnaJ homologue cysteine string protein.
The current study was designed to investigate the role of dietary vitamin D and/or calcium in regulating muscle function in a heterogeneously fiber comprised skeletal muscle. Three week old mice were fed diets with varied combinations of vitamin D and calcium. Serum levels of calcium and parathyroid hormone (PTH) along with behavioral testing were performed to confirm previous results. As expected, body composition and behavioral data from animals fed with a vitamin D deficient diet correlated with previous studies. Gastrocnemius force generation was performed and as expected the VD^-/Ca^- group had decreased measures including but not limited to maximum tetanic
force and twitch tension as compared to the other three dietary groups that contained vitamin D and/or calcium. Preliminary findings from gait analysis suggest decreased stride length in both the forelimbs and hindlimbs of mice fed a vitamin D deficient diet. Genomic and single fiber analysis, along with histology will be done to assess multiple aspects of neuromuscular junction integrity and fiber type composition in the gastrocnemius. The results of the study will provide insight into how a vitamin D and/or calcium deficient diet detrimentally affects mobility in the context of alterations in specific muscle fiber types, within a mixed fiber type skeletal muscle, resulting in changes that regulate structure and function of the NMJ.

Title: Walk-training increases expression of glial cell line-derived neurotrophic factor in pectoralis muscle but not diaphragm from mouse

Authors: *E. K. DONOVAN[1], M. J. MCCULLOUGH[2], J. M. SPITSBERGEN[2];
[2]Biol. Sci., [1]Western Michigan Univ., Kalamazoo, MI

Abstract: Neurotrophic factors are proteins that play an important role in the development and maintenance of neurons. Recent studies have shown that neurotrophic factors may hold promise for treating damage to the nervous system caused by trauma or diseases, such as amyotrophic lateral sclerosis or Parkinson's disease. Glial cell line-derived neurotrophic factor (GDNF) is expressed in skeletal muscles and affects peripheral motor neurons. Results of previous studies have demonstrated that exercise can increase GDNF content in skeletal muscle of rat. The goal of the current study was to examine whether expression of GDNF in skeletal muscle of mouse is also regulated by physical activity. Our hypothesis states that muscles undergoing higher levels of contractile activity will express GDNF at higher levels than muscle exhibiting lower levels of contractile activity. For these studies we examined GDNF protein content in tissues from sedentary control mice and in mice following exercise. Muscles examined included the diaphragm (DIA), an involuntary slow twitch muscle and pectoralis major (PEC), a voluntary slow twitch muscle. Treatment groups included 7 control mice and 6 mice that underwent walk training. The treatment group had a one-week training period, and then exercised for 30 minutes a day, at 8 meters/minute, five days a week. Following completion of the exercise regimen muscles were removed and processed for determination of GDNF protein content using enzyme-linked immunosorbant assay, GDNF protein localization and end plate morphology. The results show that DIA from control animals contains more GDNF than PEC, while exercise increased GDNF protein content in PEC but not DIA. These findings suggest that GDNF production is altered by exercise in voluntary slow-twitch muscles, but not involuntary slow-twitch muscles. These results contribute to understanding the mechanisms underlying the normal control of GDNF expression in skeletal muscles. It is important to develop a more complete understanding of normal expression of GDNF in skeletal muscle before we can determine whether GDNF-based therapies may be used in the treatment of traumatized or diseased neural tissues.

Title: Deletion of selenoprotein m leads to obesity without cognitive deficits

Authors: *M. W. PITTS, M. A. REEVES, A. H. HASHIMOTO, A. OGAWA, P. KREMER, L. A. SEALE, M. J. BERRY;
Dept. of Cell and Mol. Biol., Univ. Hawaii, HONOLULU, HI

Abstract: Selenium is an essential trace element that is co-translationally incorporated into selenoproteins in the form of the 21st amino acid, selenocysteine. This class of proteins largely functions in oxidation-reduction reactions and is critically involved in maintaining proper redox balance essential to health. Selenoprotein M (SelM) is a thioredoxin-like ER-resident protein that is highly expressed in the brain and possesses neuroprotective properties. In this study, we first assessed the regional pattern of SelM expression in the mouse brain to provide insights into the potential functional implications of this protein in physiology and behavior. Next, we generated transgenic mice with a targeted deletion of the SelM gene and subjected them to a battery of neurobehavioral tests to evaluate motor coordination, locomotion, and cognitive function in comparison to wild-type controls. Finally, these mice were tested for several measures of metabolic function and body composition. Our results show that SelM knockout mice display no deficits in measures of motor coordination and cognitive function, but exhibit elevated weight gain and increased white adipose tissue deposition. These findings suggest that SelM plays an important role in the regulation of body weight and energy metabolism.

Title: The effects of proton radiation on neurogenesis in adult mice that have consumed pomegranate juice

Authors: *M. S. DULCICH[1], V. POP[3], N. MISTRY[1], J. BADAUT[2], R. E. HARTMAN[1]; [1]Psychology, [2]Basic Sci., Loma Linda Univ., LOMA LINDA, CA; [3]Univ. of California, Irvine, Irvine, CA

Abstract: Exposure to ionizing radiation may have deleterious effects on physical and mental health, with an increased risk of proton radiation for astronauts traveling outside Earth's atmosphere into lower earth orbit. In animal models, radiation has been shown to suppress neurogenesis in the subgranular zone of the hippocampus, a key area for learning and memory (Rola et al., 2004). In animal and human studies, several antioxidant polyphenols were shown to be neuroprotective (reviewed by Pandey & Rizvi, 2009). Few studies have looked at the effects of proton radiation on the central nervous system, although proton radiation is the most prevalent ionizing radiation in space. This study determined whether the suppression of neurogenesis using proton irradiation in mice could be reversed by ingestion of pomegranate juice, which has high levels of antioxidant and anti-inflammatory polyphenols. Adult C57BL/6 mice received dilute pomegranate juice (n=48) or a control sugar water (n=48) in their drinking bottles for 1 week before irradiation with protons (2 Gy at 150 MeV/n at 1-2 Gy/min) or sham treatment. Sham animals were placed in the same chambers as irradiated mice for the same amount of time, but did not receive radiation beam. Animals were maintained on the pomegranate or control juice for a total of 10 weeks. Subsequent behavioral testing revealed that proton irradiation induced depression-like behaviors, but this effect was ameliorated by the pomegranate diet (Dulcich & Hartman 2013). One day after BrDU injections (50mg/kg body weight, 2x/day for 3 days) were completed, brain tissue was prepared (at 11 weeks post-radiation) for quantification of BrdU+ and DCX+ cells in the dentate gyrus of the hippocampus. Radiation suppressed overall cell proliferation and neurogenesis. Pomegranate juice increased cell proliferation and neurogenesis, but only in non-irradiated animals. Our results demonstrate that proton radiation can suppress neurogenesis in the hippocampus, and that pomegranate juice may be beneficial in promoting neurogenesis.

Abstract: Aluminum is the most plentiful metal in earth crust and its usage in cooking utensils, cosmetics, drinking containers, pharmaceutical products, building materials makes many chances of aluminum consumption. However, its toxicity is low and higher amount of deposition is required for the development of its harmful effects. In this study we investigated the effects of aluminum treatment (40 mg/kg/day) on cell proliferation and neuroblast differentiation in the D-galactose-induced aging mice. Additionally, we compared the complex effects of aluminum, D-galactose, and high fat diet on adult hippocampal neurogenesis via immunohistochemistry using the marker protein, Ki67 (a marker for cell proliferation) and doublecortin (DCX, a marker for differentiating neuroblasts). Solely D-galactose, aluminum or high fat diet treatment decreased the level of adult neurogenesis, but the dual treatment exacerbated the reduction of Ki67 and DCX expression. Additionally, aluminum treatment exacerbated the degree of reduction in D-galactose or/and high fat diet treated mice. These results suggest that aluminum decreases the cell proliferation and neuroblast differentiation in the augmentative way.

Title: Brain activation informs risk in genome-wide association

Authors: *B. E. SPENCER[1], R. E. STRAUB[2], Y. TONG[1], K. F. BERMAN[1], D. R. WEINBERGER[2], J. H. CALLICOTT[1];
[1]Clin. Brain Disorders Branch, DIRP, NIMH, NIH, Bethesda, MD; [2]Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: Background: It has been difficult to identify risk genes for complex psychiatric disorders such as schizophrenia, although findings have begun to replicate across very large samples. Alternatively, genetic risk can be studied using intermediate phenotypes, of which prefrontal inefficiency is one (Callicott et al., 2003), under the assumption that some of the genes underlying brain function in health (but abnormal in psychiatric illness) may confer increased risk of disease and with a smaller sample size. As opposed to data-driven GWAS, most intermediate or endophenotype studies have followed the candidate gene approach, although recent evidence suggests these phenotypes can be assayed genome-wide, though no true GWAS-positive findings have emerged (Potkin et al., 2009; Potkin et al., 2008). Here we used imaging data to query genome-wide variants in order to find single nucleotide polymorphisms (SNPs) associated with BOLD fMRI activity during working memory (WM) in healthy people.
Methods: 442 healthy volunteers and unaffected siblings of patients with schizophrenia performed the N-back working memory task on a 3T MRI scanner. Mean values of activation were extracted for each individual's 2Back vs. 0Back contrast map over 22 ROIs defined by the Automated Anatomical Labeling (AAL) atlas. The effects of age and sex were removed from these extracted values in SPSS and residuals were used in this GWAS. These values were tested over 687,947 variants for the 442 subjects using a linear regression in PLINK. Significant effects were then examined using a multiple regression in Statistical Parametric Mapping (SPM5) with age and gender as covariates.
Results: Rs6065270, a SNP upstream of the MAFB gene, was found to significantly affect activation ($p=1.02\cdot10^{-8}$) during the N-back working memory task using the GWAS approach. In parallel, a significant cluster of activation was found in the dorsolateral prefrontal cortex (Brodmann Area 9) ($p<0.01$ FWE whole-brain corrected) for this SNP with minor allele homozygotes displaying prefrontal inefficiency during the N-back task.
Conclusions: In healthy volunteers, rs6065270 predicted changes in prefrontal activation at a genome-wide level and implies imaging data can be used to inform risk SNPs associated with intermediate phenotypes in schizophrenia.

Title: Are individuals with schizophrenia who experience semantic encoding memory deficits can improve their performance following specific training?

Authors: *S. GUIMOND, M. LEPAGE;
McGill Univ., Montréal, QC, Canada

Abstract: Cognitive deficits appear to be a core characteristic of schizophrenia and there is a great need to develop efficient techniques in order to improve cognitive function in this population. Considering the significant variability of memory difficulties between individuals with schizophrenia, it could be beneficial to develop training which focuses precisely on one specific deficit. A relation between the impairment in associative episodic memory (EM) and the difficulty to self–initiate semantic encoding strategies in people with schizophrenia has been recently proposed. Prefrontal cortex (PFC) dysfunction observed in these patients might also play a role in the difficulty to self-initiate effective semantic encoding strategies in EM. The goal of this study was to design an EM task allowing us to select patients that seem to have this specific deficit and to develop a memory training that would specifically target this problem. Two specific measures of memory were taken: the CVLT (a standardized measure of the use of semantic encoding strategy) and the BVMT (a control spatial memory task). We developed an EM task, in which self-initiation of semantic encoding strategies was isolated in one condition. This memory task was used to select patients with the deficit. Our preliminary data, based on 8 individuals with enduring schizophrenia, revealed that this specific memory deficit seems to be present in approximately half of them. These individuals were selected for two sessions of semantic encoding strategy training, after which they were administered the same task but with new items to memorize, and once again performed the CVLT and the BVMT.
Our preliminary results suggest that the performance of individuals with schizophrenia involved in training improved in the self-initiation condition (Cohen's d= 3.22). Participants also considerably increased the number of semantic clusters for the trials 1-5 of the CVLT (Cohen's d= 3.36), while no clear differences were found on the BVMT.
Our results suggest that half of individuals with enduring schizophrenia seem to experience deficits in semantic encoding strategy in EM. We also developed a memory training program that successfully helped these patients improve their self-initiation of semantic encoding strategy, as demonstrated by their increased performance in the task, and also by the number of semantic clusters used after the training in the CVLT. This study is a part of a larger research project that

will investigate the role of the PFC in the self-initiation of semantic encoding strategy using functional neuroimaging. Therefore, we will further evaluate the impact of the training on prefrontal neural activity.

Title: Altered functional brain networks in schizophrenia - a resting state fMRI study

Authors: *K. C. SKATUN[1,2], L. T. WESTLYE[1,3], G. P. BIELE[3], O. A. ANDREASSEN[1,2]; [1]Div. of Mental Hlth. and Addiction, KG Jebsen Ctr. For Psychosis Res. - TOP, Oslo Univ. Hosp., Oslo, Norway; [2]Inst. of Clin. Med., [3]Dept. of Psychology, Univ. of Oslo, Oslo, Norway

Abstract: Schizophrenia (SZ) is a severe mental disorder characterized by symptoms such as hallucinations, delusions, and cognitive dysfunction. Magnetic resonance imaging (MRI) studies have documented abnormalities in brain structure and function, with the emerging notion that symptoms in schizophrenia are not only modulated by focal pathologies, but rather aberrant connections between brain regions at the network level. Resting-state functional MRI (rFMRI) targets large-scale functional connectivity patterns in the brain. Previous studies have yielded an inconclusive pattern of spatiotemporal differences in resting-state networks (RSNs) in SZ. The discrepancies may be largely due to methodological differences and relatively small sample sizes. Based on rFMRI we characterized and compared RSNs and their interactions between patients with SZ (n=45) and healthy controls (n=95). Independent component analysis was used to identify brain networks, including the default mode network and fronto-parietal networks. Individual spatial maps and corresponding time series were estimated using dual regression (1, 2). The spatial maps, representing the nodes in the network structure, were compared between groups using permutation testing, and associated time series were submitted to hierarchical clustering based on the temporal correlations. Next, each element in the correlation matrices, representing edges in the network, was submitted to between group comparisons. The results revealed altered functional connectivity between specific brain nodes in SZ, supporting that large-scale brain network configuration during rest show promise as a candidate imaging intermediate phenotype in psychiatry. A detailed characterization of the brain functional

abnormalities in SZ may advance and refine diagnostics, clinical care, and treatment strategies.

Title: Emotional distractors result in aberrant activation within fronto-polar cortex in schizophrenia

Authors: *D. RAMANATHAN[1], J. M. FORD[1,2], V. D. CALHOUN[3], J. TURNER[3], J. T. VOYDOVIC[4], A. BELGER[5], T. G. M. VAN ERP[6], J. G. VAIDYA[7], D. H. MATHALON[1,2]; [1]Univ. California, Irvine, Irvine, CA; [7]Psychiatry, Univ. of Iowa, Iowa City, CA

Abstract: Subjects with schizophrenia demonstrate differences in the neural processing of emotional stimuli. It has not been entirely clear how these differences in neural processing relate to the disease process or to other aspects of cognition. Prior studies on emotional interference of cognition in schizophrenia have not consistently demonstrated either greater behavioral deficits or greater interference within executive control/prefrontal circuits compared to healthy control individuals. However, prior studies have generally utilized smaller sample sizes with limited variation in task difficulty, both issues that might have confounded results. In this study, through

a large, multi-site collaboration (the Functional Bio-Informatics Research Network, or FBIRN), we were able to recruit a significantly greater sample size than has been previously been utilized in emotion-cognition studies of schizophrenia (a total of 165 schizophrenic subjects and 176 healthy controls). These subjects underwent functional neuroimaging while participating on a Sternberg delayed match to sample working memory paradigm, with either emotional or neutral distracting images displayed during the delay period of the task. Task difficulty was systematically normed for all subjects prior to neuroimaging by individually varying working memory load until accuracy was close to 80%. During the neuroimaging task, each subject was then tested at 3 task-loads (their behaviorally normed load; and loads both lower and higher than that). Using this paradigm, we found that while both patients and healthy control subjects demonstrated emotional interference at high working memory loads ($p<0.0001$ for Emotion; $p<0.001$ Load x Emotion effects) no group differences in the degree of emotional interference were identified. However, emotional distractors during the WM paradigm did result in significantly greater activation within dorsal posterior cingulate and left fronto-polar cortex during low WM loads ($p<0.025$, cluster-corrected for multiple comparisons). Interestingly, the aberrant activation of left fronto-polar cortex following emotional vs. neutral distractors strongly correlated with PANSS scores in the positive ($R = 0.25$, $p <.0001$); negative ($R = 0.15$;$p <0.05$) and general ($R = 0.3$; $p <0.0001$) psychopathology domains. Fronto-polar cortex is often thought of as the apex of executive control and decision-making, particularly suited for long-range planning and goals. These findings suggest that deficits in long-range planning and goals, a feature of schizophrenia, may be related to aberrant function or perturbation of this system by emotional stimuli.

Title: Network dysfunction during associative learning in schizophrenia: Direct evidence of disordered cortico-striatal-hippocampal interactions using fMRI and Dynamic Causal Modeling

Authors: *S. WADEHRA[1], P. PRUITT[2], V. DIWADKAR[1];
[1]Wayne State Univ., Detroit, MI; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Introduction: Dynamic Causal Modeling (DCM; Stephan et al., 2010) provides a substantive new approach for investigating disordered network interactions in the schizophrenia brain. Using information priors, DCM permits evaluation of competing models of network architecture distinguished at the second-level using Bayesian selection. Coupling estimates between regions evidence effective connectivity (Friston, 2005) related to endogenous connections and modulatory effects of task on these connections. Here, we applied DCM to assess fronto-hippocampal-striatal interactions in SCZ and controls during paired-associate learning (Diwadkar et al., 2008).
Methods: fMRI (4.0T) was collected in 19 subjects (SCZ=9, controls=10; 18≤age≤35yrs). Because DCM relies on Bayesian model selection (BMS) to identify the most appropriate generative model for the data relative to neurobiologically-plausible competitors, 144 models were constructed by permuting connections between 6 brain regions. In addition to the three primary regions, the supra-network included visual, inferior-temporal, and superior-parietal cortices. These 2,736 models (144 modelsx19 subjects) were submitted to second-level RFX analyses for BMS. Inter-group inferences were based on Bayesian averages of estimated coupling (Penny et al., 2010).
Results: BMS identified one winning model (exceedance probability: 60% greater than its closest competitor). Model architecture revealed reduced fronto-hippocampal coupling, but increased striatal-hippocampal coupling in SCZ.
Conclusion: These preliminary data demonstrate that DCM is sensitive to identifying reduced fronto-hippocampal coupling and compensatory increases in fronto-striatal coupling during associative-learning in schizophrenia. Application of DCM to in vivo fMRI data constitutes a substantive advance in the ability of fMRI to identify mechanisms (rather than mere correlates) of schizophrenia-related pathophysiology (Diwadkar, Wadehra et al., 2012, Arch Gen Psychiatry).

Title: Trans-synaptic retrograde tracing of an auditory cortical circuit from posterior caudatoputamen in the rat

Authors: *A. PARGA[1,3], V. LAVARNWAY[3], E. M. NIKULINA[2], R. P. HAMMER, Jr.[2];
[2]Col. of Medicine-Phoenix, [1]Univ. of Arizona, Phoenix, AZ; [3]Arizona State Univ., Tempe, AZ

Abstract: Auditory hallucinations constitute a hallmark in the diagnosis of schizophrenia. Functional studies have reported activation of the auditory cortex (AudCx) during hallucinations, as well as increased dopamine (DA) transmission in the caudate nucleus. In addition, current treatments with classical antipsychotic drugs diminish hallucinations by DA antagonism.
We have shown that DA infusion into the posterior caudatoputamen (CPu) of the rat dose-dependently activates AudCx, as does a sound stimulus, and that co-infusion of selective D_1- and D_2-like antagonists attenuate this effect. The present study sought to describe the neuronal circuit by which manipulation of striatal DA transmission alters functional activity of AudCx. We hypothesized that the posterior CPu affects the primary AudCx through a multi-synaptic striato-pallido-thalamo-cortical (SPTC) circuit. The circuit was traced using recombinant pseudorabies virus (PRV-152), a retrograde transsynaptic tracer that express enhanced green fluorescent protein (eGFP) as an indicator of viral passage between connecting neurons. We infused PRV-152 (100 nl of 7×10^4 pfu/ml) in the primary auditory cortex (coordinates: AP -4.3 mm, ML 6.69 mm, DV -4.45 mm) of adult Sprague Dawley rats. Maps of eGFP-expressing neurons were produced using Neurolucida software (MBF Bioscience; Williston, VT) by tracing the spread of PRV-152 at 24-72 h post-inoculation. Image analysis revealed the spread of PRV-152 across layers within the ipsilateral AudCx at 24 h; subsequently at 72 h, labeling was observed in the ipsilateral ventrolateral nucleus of the thalamus and the posterior CPu bilaterally. Analysis of intermediate post-inoculation times is ongoing. These neuroanatomical data delineate the circuitry which may underlie striatal DA-induced functional activation of AudCx. Further analyses will examine the involvement of both direct and indirect striatal projection neurons, as well as auditory sensory pathways. We propose that this auditory SPTC circuit may represent the biological substrate for intrinsic activation of the AudCx, and the pathophysiology of auditory hallucinations.

Title: Reward processing in unaffected siblings of schizophrenia patients: An fMRI study

Authors: *M. DE LEEUW, R. S. KAHN, M. VINK;
Psychiatry, Rudolf Magnus Inst. of Neuroscience, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: Schizophrenia is characterized by impaired functioning of the frontal-striatal network: hyperdopaminergic activation in the striatum and hypodopaminergic activation in the frontal cortex. These network dysfunctions result in cognitive deficits such as impaired reward processing. Reward processing can be dived into two sub-processes: anticipation and the outcome of reward. Functional MRI studies in patients have shown hypo-activation of the ventral striatum during reward anticipation. Whether this impaired reward processing is related to the genetic risk of schizophrenia is not known. To answer this question, we investigated reward processing using fMRI in siblings of schizophrenia patients who share on average 50% of their ill siblings' genes. Twenty-eight unaffected siblings and 29 matched controls performed a monetary delayed incentive task during fMRI scanning. All subjects were rewarded in 50% of the reward trials. Despite this equal performance, during reward anticipation siblings showed hypoactivation in the ventral striatum compared with controls. During the outcome of reward, hyperactivation in the ventral striatum and in the orbital frontal cortex was found in siblings compared to controls. These findings are consistent with the notion of impaired dopaminergic functioning in the fronto-striatal network typically associated with schizophrenia. Impaired reward processing may constitute a vulnerability factor for schizophrenia. Twin studies should clarify whether these phenotypic abnormalities are a full genetic risk factor of schizophrenia.

Title: Early antipsychotics response in first-episode male schizophrenia patients coincides with rapid modulation of cognitive behaviors and neuronal plasticity in adult male rats

Authors: *M. M. KHAN[1,3], N. T. HWISA[2], A. R. ELTUMI[4], A. E. MEHEMED[1], S. P. MAHADIK[5];

Abdur Rahman Univ., Chennai, India; [4]Psychiatric care, Al-Razi Mental Hostpital, Tripoli, Libyan Arab Jamahiriya; [5]Psychiatry and Hlth. Behaviour, Georgia Reagents Univ., Augusta, GA

Abstract: Early response to antipsychotic drugs has been shown to predict subsequent long-term improvement in the first-episode schizophrenia patients. However whether early antipsychotics response in first-episode schizophrenia patients coincides with early antipsychotics effects in animals has not been investigated. In this study we have made a retrospective analysis of the early response of haloperidol, risperidone and clozapine therapy in first-episode male schizophrenia patients (N=108) admitted during the year 2003-2010 to the Al-Razi Mental Hospital, Hay Al Andalous, Tripoli, Libya. Parallel studies were performed to see the early effects of the above antipsychotic drugs on the cognitive behaviour, neurogenesis and synaptic plasticity in normal and pre-trained latent adult male rats. In first-episode schizophrenia patients, early response to haloperidol and risperidone was observed in 68% patients with 51% reduction in the PANSS (Positive and Negative Symptoms Scale) total score at week 1-2. In clozapine treated patients similar early response was found in 48% patients at weeks 2-3. In animal studies, we analysed early effects of antipsychotic drugs in the normal rats as well as rats pre-trained for 10 days on various behaviour paradigms followed by a 2 months latent period, as well as in pre-trained latent rats treated with MK-801. Both haloperidol and risperidone treated animals performed better on various behaviour paradigms after 3-4 days treatment compared to control group. This early-improved performance was associated with a rapid enhancement in the neurogenesis in SVZ, and spine density in the prefrontal cortex. Clozapine treated animals were slow in responding to improvement on various behaviour parameters, as well as induction of neurogenesis and spine density. These results suggest that antipsychotics-induced early response in first-episode male schizophrenia patients coincides with rapid enhancement in the cognitive parameters, neurogenesis and synaptic plasticity in both the normal and pre-trained MK-801 treated animals, however; variations may exist with respect to antipsychotic drugs and their early response both in schizophrenia patients and animals.

Title: Common and distinct neural effects of risperidone and olanzapine on procedural learning in schizophrenia

Authors: *V. KUMARI[1], U. ETTINGER[2], S. LEE[3], C. DEUSCHL[3], A. P. P. ANILKUMAR[4], S. C. WILLIAMS[3];
[1]Psychol, Inst. of Psychiatry, London, United Kingdom; [2]Univ. of Bonn, Bonn, Germany; [3]Inst. of Psychiatry, King's Col. London, London, United Kingdom; [4]South London and Maudsley NHS Fndn. Trust, London, United Kingdom

Abstract: Available antipsychotic treatments do not improve all symptoms of schizophrenia. Most cognitive domains show only minimal improvement following typical or atypical antipsychotic treatments, and some may even worsen following typical antipsychotic treatment. One such domain is procedural learning (PL), or sequence learning, a function relying on the integrity of the fronto-striatal system. In this study we ascertained, using functional magnetic resonance imaging (fMRI), whether switching to atypical antipsychotics would normalise PL and task-related activation in patients previously on stable doses of typical antipsychotics. Furthermore, we explored differential effects of the atypical antipsychotics risperidone and olanzapine. The study involved 30 patients with schizophrenia who underwent fMRI on two occasions, at baseline and six weeks later, during a 5-min PL task on which performance is known to improve within a session as a function of practice without the need for conscious awareness. Ten of these 30 patients remained on typical antipsychotics throughout the study while 20 patients were switched randomly in equal numbers to receive either olanzapine or risperidone for 6 weeks. We found that, at baseline, patients (all on typical antipsychotics) showed no PL. At follow-up, those who remained on treatment with typical antipsychotics continued to show lack of PL whereas patients who were switched to atypical antipsychotics displayed significant PL (i.e. improvement) and increased activation in the superior frontal gyrus extending to the inferior frontal gyrus, and the anterior cingulate extending to the striatum. These neural effects were strongly present as a linear increase over five successive 30-s blocks of sequenced trials. A switch to either risperidone or olanzapine resulted in comparable improvement in PL but with partially overlapping and distinct task-related activation. We conclude that atypical antipsychotics are effective in restoring PL deficits and associated neural activity in schizophrenia. Furthermore, different atypical antipsychotics produce idiosyncratic

task-related neural activations and this specificity may contribute to their differential clinical profiles in the longer term.

Title: Multivariate analysis reveals sex differences in distributed neural networks of attention, language and emotion regulation in typically developing youth and pediatric mania

Authors: *L. IORDANESCU[1], M. C. STEVENS[2], J. FITZGERALD[1], M. N. PAVULURI[1]; [1]Psychiatry, Pediatric Brain Res. And Intervention Center, Univ. of Illinois At Chic, Chicago, IL; [2]Psychiatry, Yale Univ. Sch. of Medicine, Olin Neuropsychiatry Res. Center, The Inst. of Living/Hartford Hosp., Hartford, CT

Abstract: An emerging area of interest in mood disorder neuroimaging research is the characterization of abnormalities in large-scale, distributed neural networks involved in the interface of cognitive and emotional processing. In this study, we examined brain function in 63 adolescent boys and girls with pediatric bipolar disorder (PBD) matched on mean IQ and demographics to 82 healthy controls elicited by an Affective Synonym functional magnetic resonance imaging (fMRI) task designed to probe neural networks engaged in identifying synonyms of target words. This task required attention to semantic meaning instead of distracting emotional content. Group differences in regional functional connectivity, network timecourse spectral power, and functional network connectivity (FNC) among circuits were examined using a multivariate strategy (MANCOVAN) on brain networks identified using group independent component analysis (ICA). Analyses tested whether network properties differed between diagnostic groups, gender, and their interaction, while statistically controlling for any developmental changes. Significant multivariate effects were further characterized post hoc to identify which specific brain regions, spectral frequencies, or inter-network connections had the strongest effects across specific networks. Significant diagnostic group differences in regional connectivity were found in networks found previously to be engaged for attention, language and emotion regulation - mostly PBD under-connectivity, e.g., in right middle frontal gyrus, but

some hyper-connectivity as well. Some PBD abnormalities interacted with gender, e.g., more abnormal left superior medial frontal cortex in PBD females. Greater spectral power in PBD at very low frequencies (<.05 Hz) was found only in the network ascribed to emotion regulation and also in females. Causal interactions among networks (FNC) as measured by lagged correlation found a complex array of diagnostic group differences in the degree to which the engagement of one distributed network preceded activation in others. The most pronounced gender effect is shown within the language network which exhibits increased correlations with the Valence Evaluation network. Overall, these findings show robust support for emotion-cognition network disconnection in PBD using several different but complementary analyses that assess different aspects of brain connectivity. Many of these findings depended strongly on the gender of the participant, raising important questions about specific biological contributions to abnormalities in brain network function.

Title: D-cell hypothesis for etiology of schizophrenia

Authors: *K. IKEMOTO;
Iwaki Kyoritsu Gen. Hosp., Iwaki, Fukushima, Japan

Abstract: Recent pharmacological discovery on trace amine-associated receptor, type 1(TAAR1) has emphasized importance of trace amines in pathogenesis of psychoses, such as schizophrenia. TAAR1 has many ligands, including tyramine, *β*-phenylethylamine (PEA), tryptamine, amphetamines, and 3'-iodothyronamine. So-called D-neuron is putative producer of trace amines, endogenous ligands of TAAR1. The D-neuron is defined "the aromatic L-amino acid decarboxylase (AADC)-containing neuron, but neither dopaminergic nor serotonergic", *i.e.* containing neither tyrosine hydroxylase nor tryptophan hydroxylase. AADC is an enzyme, also called dopa decarboxylase (DDC). The localization of D-neurons in the central nervous system has been specified into 15 groups, from the spinal cord (D1) to striatum (D15).
The author showed the decrease of D-neurons in D15 in postmortem brains of schizophrenia,

where midbrain dopamine (DA) neurons are heavily innervated. As the localization of neural stem cells of the human subventricular zone was coincide with that of striatal D-neurons (D15), the decrease of striatal D-neurons was supposed to be closely linked with neural stem cell dysfunction in schizophrenia. The reduction of striatal D-neurons may cause trace amine reduction in the striatum, and decrease stimulation of TAAR1 on striatal terminals of ventral tegmental area (VTA) DA neurons. This would increase firing frequency of VTA DA neurons, and causes mesolimbic DA hyperactivity. The author introduces a novel theory, "D-cell hypothesis", for mesolimbic DA hyperactivity of schizophrenia.
Some clinical and/or experimental evidences that support this hypothesis would be shown.

Title: Perinatal choline as an alpha7-nicotinic receptor agonist during human fetal development

Authors: *R. FREEDMAN, R. G. ROSS;
Dept. of Psychiatry, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Cerebral inhibition, measured as the decrement in P50 auditory evoked response amplitude to the second of paired stimuli, is already partially developed to adult levels at the birth of most human infants. Deficits in this inhibitory sensory gating mechanism in adults are associated with schizophrenia and linked to CHRNA7, the gene for the alpha7-nicotinic receptor subunit. Parental mental illness and maternal cigarette smoking are among the factors that delay prenatal development of this function. Delayed development is associated with future problems in attention in childhood. Alpha 7-nicotinic receptor expression is one factor identified as necessary for timely development of GABA-mediated inhibition. Alpha 7-nicotinic receptors are expressed at nearly an order of magnitude higher levels in human fetal brain than in newborns or adults, but cholinergic synapses do not reach the hippocampal site of P50 generation and inhibition until shortly before birth. The endogenous ligand may be choline, present in the requisite mM concentrations in amniotic fluid. Based on positive results in a mouse model, we conducted a double-blind, randomized, placebo-controlled trial of choline supplementation at twice normal dietary levels in 100 women. Women received supplementation during the second

and third trimester, and their offspring received supplementary drops for the first 6 weeks post birth. There were no significant adverse effects. Newborns who received choline were more likely to have developed cerebral inhibition, measured as suppression of the amplitude of the second response by at least 50%, by one month, compared to infant who received placebo (76% versus 43%, Chi-square = 6.90, P = 0.009). Infants were genotyped with a SNP in the 5' promoter of CHRNA7. The minor allele previously found to be associated with schizophrenia was associated with diminished sensory inhibition in the placebo-treated newborns, but this genetic effect was not seen in choline-treated newborns. The results suggest that perinatal choline, acting as an alpha 7-nicotinic receptor agonist, may help prevent a developmental abnormality in inhibitory sensory gating associated with a portion of the genetic transmission of schizophrenia.

Title: SCN2A (rs10174400) differentially modulates prefrontal activation during a fMRI processing speed task in healthy adults

Authors: *G. BAUM[1], D. DICKINSON[1], K. F. BERMAN[1], D. R. WEINBERGER[2,3], J. H. CALLICOTT[1];
[1]Clin. Brain Disorders Br., Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Lieber Inst. for Brain Develop., Baltimore, MD; [3]Depts. of Psychiatry, Neurology, Neuroscience, and The Inst. of Genet. Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Processing speed is a well-documented impairment in schizophrenia; argued by some to be the single strongest indicator of abnormal cognition in patients and their unaffected siblings (Knowles et al., 2012). Neuroimaging studies with healthy individuals have suggested a prominent role for the dorsolateral prefrontal cortex (DLFPFC) in mediating processing speed via functional interactions with hippocampus and motor, visual, and parietal cortices (Rypma et al., 2006). We used an event-related digit symbol substitution task (DSST), the Digit Symbol Verification Task (DSVT), using blood-oxygen-level-dependent (BOLD) functional magnetic resonance imaging (fMRI) with 101 healthy individuals.
Recent findings have suggested that SCN2A, a brain-specific gene that encodes the α2 subunit of

neuronal sodium channels, is strongly associated with variation in general cognitive ability (g) in schizophrenia patients (Dickinson et al., In Review). Physiologically, g has been related to the integrity and recruitment of the prefrontal cortex (PFC) (Duncan & Owen, 2000; Duncan et al., 2000). In a sample of 338 patients, SCN2A (rs10174400) was associated with DSST performance (p =.013; Dickinson, Personal Communication). Recent findings suggest that prefrontal activation during an fMRI version of the DSST is a potentially heritable phenotype in schizophrenia, such that patients and unaffected siblings of patients show reduced activation in the DLPFC relative to healthy individuals (Lau et al., In Process). In this study sample, healthy individuals' mean reaction time, the crucial variable in DSVT, varied by SCN2A genotype at a trend level (p = .077). Subjects did not differ by genotype in handedness, estimated IQ, or age. In this study we investigated the role of SCN2A in modulating prefrontal activation in healthy individuals during a processing speed task. Our findings suggest that SCN2A modulates reaction time and DLPFC activation in healthy individuals during a processing speed task, with minor allele (T) homozygotes showing significant increases in bilateral DLPFC activation relative to major (C) homozygotes and heterozygotes (R-DLPFC: pFWE = .01 SVC; L-DLPFC: -54 9 39, pFDR = .048 SVC).

Title: Delayed Interplay between frontal activity and neurocardiac regulation in subjects with bipolar II disorder

Authors: *J. CHANG, K. HA, T. HA, J. HER;
Dept. of Psychiatry, Seoul Natl. Univ. Bundang Hosp., Seongnam, Korea, Republic of

Abstract: Subjects with bipolar disorders exhibit altered pattern of central autonomic function. In the frame of central autonomic network, frontal-amygdalar complex is involved in both emotion regulation and cerebral control of cardiac autonomic function. This study aimed to investigate the changes in the synchronization between frontal activity and neurocardiac dynamics in patients with bipolar II disorder during acute mental stress. Time-series data from

high-density electroencephalograms and electrocardiograms were simultaneously obtained from 40 euthymic patients with bipolar II disorder and 40 healthy controls. All the participants performed mental arithmetic task after 7 min of resting control followed by 7 min of recovery. The relationship between cardiac vagal activity (high frequency component of heart rate variability) and resting frontal alpha activity was investigated using a coherence analysis, which provides a coherence function, a gain function, and a phase shift between two time series data. Coherencies between high frequency component of heart rate variability and frontal alpha power did not differ between the bipolar II disorder and the control groups between the rest and the recovery phase. No significant difference was observed in the gain between the two groups. In contrast, values of phase shift revealed a significant phase advance of left frontal alpha activity in the bipolar II disorder group compared to the control group during the rest phase. In contrast, a significant phase delay of left frontal activity was observed in the bipolar II disorder group while performing mental arithmetic task. During recovery phase from mental stress, a greater phase delay was observed in the bipolar II disorder group compared to the control group. The results of our study suggest that the neuronal networks linking frontal activity to cardiac autonomic regulation are intact but their interaction is less efficient than that of healthy controls, implicating that patients with bipolar II disorder may exhibit maladaptive pattern of the central autonomic regulation in response to stress.

Title: Synaptic connectivity in olfactory bulb of schizophrenia

Authors: *C. N. EGBUJO[1], K. BORGMANN-WINTER[1], S. ARNOLD[1], K. TALBOT[1], B. TURETSKY[2], C.-G. HAHN[1];
[1]TRL, Dept. of Psychiatry., [2]Dept. of Psychiatry., Univ. of Pennsylvania., Philadelphia, PA

Abstract: Multiple lines of evidence suggest altered synaptic plasticity/connectivity as a pathophysiologic mechanism for various symptom domains of schizophrenia. This notion is supported by the findings that patients with schizophrenia exhibit abnormalities in neurocognitive function and changes in EEG and brain imaging parameters that may be associated with synaptic connectivity. Moreover, postmortem studies offer further support by demonstrating ultra-structural changes in synapses, i.e., decreased dendritic spine densities, as well as altered expression levels of synaptic proteins. Among endophenotypes of schizophrenia is olfactory dysfunction, which is manifested by decreases in olfactory sensitivity, discrimination and memory. Electrophysiological underpinnings of these abnormalities have also been demonstrated by decreased odorant induced evoked potentials (EP) in the patient group. The olfactory circuit is based on a mono-synaptic connection in the glomeruli of the olfactory bulb, which conveys signals from olfactory receptor neurons to the olfactory cortex. We hypothesized that olfactory dysfunction and decreased olfactory EP in schizophrenia is associated with dysregulations in synaptic in the glomeruli of the olfactory bulb. To test this, we have examined the olfactory bulbs of 11 patients with schizophrenia and their age- and sex-matched pairs for the expression of 5 pre- and post-synaptic molecules in the glomeruli. Olfactory bulbs, paraformaldehyde fixed, were examined by quantitative histologic assessment of the immunoreactivity detected by DAB. The intensity of signals was corrected for the background and measured as optical density using Image-Pro 7.0 software. We found significant decreases in PSD-95, a scaffolding protein in the PSD, in the glomeruli of schizophrenia cases compared to their matched controls (-34.06%, p=0.015, two tailed t test paired). Spinophilin and Synaptopodin play critical roles in modulating the morphology and activity of dendritic spines. The SCZ group showed significant decreases in Spinophilin (-18.07%, p=0.043, two tailed t test paired). In addition, we found decreases in Synaptophysin (-23.94%, p=0.003, two tailed t test paired), which targets the vesicles to the plasma membrane was also decreased in the SCZ group. Together, our results present preliminary evidence for altered synaptic connectivity in schizophrenia and demonstrate that the glomeruli of the olfactory bulb is a structure that may reveal disease related alterations in synaptic connectivity.

Title: Potential influence of miR-137-associated rs1625579 genotype on structural brain variation in schizophrenia

Authors: V. PATEL[1], N. COTA[1], C. WRIGHT[2], N. I. PERRONE-BIZZOZERO[2], M. MORGAN[1], V. D. CALHOUN[1], T. WASSINK[3], B. HO[3], S. EHRLICH[4], J. HASS[4], K. ALPERT[5], L. WANG[5], *J. A. TURNER[1];

Abstract: Objective. The single nucleotide polymorphism (SNP) rs1625579 in the miR-137 host gene has recently been shown to be associated with risk of developing schizophrenia (SZ). In vivo animal studies suggest that miR-137 and select targeted genes may also regulate neuronal development. A previous study into the role of rs1625579 on structural brain volumes observed larger lateral ventricles and smaller hippocampal volumes in SZ patients who were homozygous for the risk allele. We examined potential effects of the miR-137-associated SNP genotype on subcortical brain volume in SZ patients versus controls.
Methods. Our sample was combined across two legacy datasets, comprising in total 370 individuals (185 SZ patients, 244 males), genotyped for rs1625579 and with subcortical volumes from T1-weighted MRI scans (segmented using Freesurfer 4.5 and 5.x). We performed a MANCOVA analysis to examine the relationship between SNP genotype and diagnosis on 35 volumes. We used genotype as a factor with two levels, and assigned data collection site, age, gender, and intracranial volume as covariates. Due to the low incidence of homozygous non-risk allele carriers, these and heterozygous individuals were combined in the genotype factor.
Results. Our analysis yielded a significant main effect of SNP genotype only on the volume of the right inferior lateral ventricle. The number of risk alleles corresponded to higher ventricle volume in both patients and controls. We also observed significant genotype by diagnosis interactions in the bilateral putamen, right thalamus, and right caudate. In all three regions, there was a positive relationship between number of risk alleles and volume in SZ patients, and a negative relationship in controls.
In a 228 subject subset of the data (110 SZ patients, 154 males) that included corpus callosum

and striatal volume measures, an additional MANCOVA revealed significant genotype by diagnosis interactions on the volume of the anterior corpus callosum and right dorsal striatum, with a near-significant effect on the left dorsal striatum. In the anterior corpus callosum, the number of risk alleles was positively related to volume in patients and negatively related in controls. This relationship was maintained in both the left and right dorsal striatum. Conclusions. Our results suggest a potential role of the rs1625579 genotype in subcortical volumes of SZ. While many of these subcortical areas show volume loss in SZ, the effects of the SNP genotype could impact certain regions differently across diagnostic groups. This may bear relation to the role of miR-137 in the regulation of neuronal development in the brain.

Title: Difference of reward system activation in patients with schizophrenia treated with olanzapine, blonanserine and aripiprazole-2nd report

Authors: *N. HASHIMOTO, A. TOYOMAKI, T. MIYAMOTO, I. KUSUMI;
Grad. Sch. of Medicine, Hokkaido Univ., Sapporo, Japan

Abstract: In schizophrenia, unmedicated patients or patients medicated with typical antipsychotics, confronted with reward-indicating stimuli displayed a reduced activation of the ventral striatum. On the other hand, patients treated with atypical antipsychotics showed ventral striatal activation in response to reward-indicating cues. However, to our knowledge, an effect on ventral striatal activation in reward-indicating stimuli of the atypical antipsychotics other than olanzapine (OLZ), risperidone and amisulpiride have never been studied. Therefore, we examined schizophrenia patients treated with OLZ, blonanserin (BLN) and aripiprazole (ARP), and healthy controls by measuring ventral striatal activation during a monetary incentive delay (MID) task. Methods: The local ethics committee of Hokkaido University approved the study,

and written informed consent was obtained from all participants. Twenty six schizophrenics and fourteen healthy volunteers participated in a fMRI study performing a MID task. In this task incentive cues predicting monetary gain (200, 50), no gain (0) or uncertain gain (???), target stimuli, and feedback stimuli were presented. Participants were requested to response as quick as possible against target stimuli and would be notified the result of their responses by feedback stimuli. Results: In a behavioral level, reaction time was significantly longer in schizophrenia group than that in control group, but no difference was observed in the hit rate. The region of interest analysis using a two-way ANOVA [two contrast factors("200 vs 0", "50 vs 0") x two diagnosis factors or two contrast factors x three main antipsychotic factors (OLZ, BNS, ARP)] revealed a significant main effect of contrast for the activation in the bilateral ventral striatum["200 vs 0" showed significantly higher activation than "50 vs 0" in the both ventral striatum]. There was no main effect of diagnosis and interaction of contrast x diagnosis. However, we found a significant interaction of contrast x antipsychotics in the bilateral ventral striatum. Conclusion: OLZ, BNS and ARP would improve disturbance in ventral striatum reward system in schizophrenia patients. OLZ and BNS might be better to improve the ventral striatum reward system disturbance than ARP.

Ctr., VA San Diego Healthcare Syst., La Jolla, CA

Abstract: Background
Research on schizophrenia has failed to find physical biomarkers of the disease. An alternative

approach is to consider dynamics of brain activity within large-scale cortical circuits. Here we report first results of a source-resolved, high-density EEG study of cortical network information flow in schizophrenia patients and control subjects during rest.

Materials and Methods

47 subjects (27 schizophrenia, 20 control) participated in the study. EEG data were recorded from 68 scalp sites while the seated subjects sat relaxed with eyes open for 5 minutes. Data were processed using software tools from EEGLAB (sccn.ucsd.edu/eeglab). After cleaning the data using methods from the BCILAB toobox (sccn.ucsd.edu/wiki/BCILAB), the data were decomposed into maximally independent component sources using adaptive mixture ICA (AMICA). Brain-based sources were localized by equivalent dipole, and information flow between them was measured using SIFT toolbox (sccn.ucsd.edu/wiki/SIFT) methods based on multivariate vector autoregression. Total renormalized partial directed coherence (rPDC) values, summing spectral information inflow to and outflow from each localized source process, were submitted to Measure Projection (sccn.ucsd.edu/wiki/MPT) for group-level imaging.

Results

Measure projection found a spatial domain in or near mid-cingulate cortex within which schizophrenia patient sources showed significantly more low-frequency information outflow (1-7 Hz), and a spatial domain in or near anterior cingulate cortex in which patients showed significantly less high-frequency information inflow (above 90 Hz).

Conclusion

Cortical network analysis during rest revealed that schizophrenia patients and control subjects at rest have distinguishable patterns of functional EEG connectivity in mid-cingulate and anterior cingulate cortex. These findings are in harmony with previous research and demonstrate the utility of EEG information flow analysis in psychiatric studies.

Title: Small saccades and image complexity during free viewing of natural images in schizophrenia

Authors: *R. MAYOL[1,2], J. EGAÑA[3,2], C. DEVIA[1,2], J. PARRINI[1], A. RUIZ[1], P. MALDONADO[3,2];
[1]Univ. De Chile, Santiago, Chile; [2]Biomed. Neurosci. Inst. & CENEM, Santiago, Chile; [3]Hosp. Clínico Univ. de Chile, Santiago, Chile

Abstract: Abnormalities in persons affected with schizophrenia encompass a variety of brain cognitive processes, including eye movement's control, which require extensive resources from the brain. Patients display dysfunctions during the execution of simple visual tasks such as anti-saccade or smooth pursuit. In more ecological scenarios, such as free viewing of natural images, patients appear to make fewer and longer visual fixations and display shorter scanpaths. It is not clear whether these measurements reflect alterations in their proficiency to perform basic eye movements such as saccades and fixations or are related to higher-order brain mechanisms, such as visual exploration or attention. We utilized free
exploration of natural images of different complexity as a model of an
ecological context where normally operative mechanisms of visual control can be accurately measured. We quantified visual exploration, scanpaths, saccades and visual fixation, using the standard SR-Research eye tracker algorithm (SR) and compared this result with a computation that include saccades and microsaccades (EM). We evaluate 8 schizophrenia patients and corresponding healthy controls and tested whether the decrement in the number of saccades and fixations, as well as their increment in duration reported previously in schizophrenia patients, resulted from the increasing occurrence of undetected small saccades. We found that when utilizing the standard SR algorithm, patients display shorter scanpaths as well as fewer and shorter saccades and fixations, showing significant difference with the control group. When we employed the EM algorithm, difference in these parameters between patients and healthy controls were no longer significant. On the other hand, we found that content of images plays an important role in exploratory behaviors.
These results contribute to elucidate the mechanisms of visual motor control that are affected in schizophrenia and contribute to the finding of adequate markers for diagnosis and treatment for this condition.

Group, Ctr. of Brain and Cognition, Univ. Pompeu Fabra, Barcelona, Spain; [4]Warneford Hosp., Oxford, United Kingdom; [5]Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain

Abstract: Pediatric bipolar disorder (PBD) with psychosis (delusions and/or hallucinations) is currently not well understood in terms of its underlying neurobiology. The diagnosis of PBD is based primarily on taking clinical history, which is considerably more difficult to obtain from children and adolescents than from adults. The clinical diagnosis could potentially benefit from a better understanding of the underlying neurobiology of PBD, and in particular of the early structural changes in connectivity.
In the current study, we examined the changes in cognitive scores and structural connectivity in a group of 15 adolescents with PBD and psychosis compared to a 25 euthymic matched healthy controls, having constructed the connectomes using probabilistic tractography and diffusion tensor imaging.
We found significant differences in the structural connectivity of anterior regions within the so-called ‘default mode’ network including regions of the medial orbitofrontal cortices and precuneus. These results show that PBD is associated with changes in structural connectivity in regions involved in brain networks associated with emotional processing and regulation.

Title: Disrupted slow wave modulation of spindle oscillations during Non-REM sleep correlates with procedural memory deficits in patients with schizophrenia

Authors: *U. BARTSCH[1], E. J. WAMSLEY[2], M. A. TUCKER[2], R. STICKGOLD[2], M. W. JONES[1], D. S. MANOACH[3];
[1]Sch. of Physiol. & Pharmacol., Univ. of Bristol, Bristol, United Kingdom; [2]Dept. of Psychiatry, Harvard Med. Sch., Boston, MA; [3]Dept. of Psychiatry, Massachusetts Gen. Hosp., Boston, MA

Abstract: Abnormalities in sleep EEG have been linked to the severity of cognitive deficits in schizophrenia. A recent study identified a decoupling of characteristic EEG/LFP oscillations during NREM sleep in an animal model of schizophrenia (Phillips, Bartsch et al. Neuron 76 (3): 526-533, 2012).
Motivated by the results from the animal model we re-analysed a patient dataset in which reduction of spindle amplitude and coherence was linked to procedural memory deficits (see Wamsley et al., Biol Psychiatry 71 (2): 154-161, 2012). We particularly focused on the interaction of slow (0.5-1.5Hz) and spindle oscillations (10-15 Hz) during NREM sleep, since these have been implicated in memory consolidation in both humans and rodents.
Our new analysis revealed a slight reduction in overall slow wave amplitude evident in wave triggered averages of detected slow waves. To assess coordination of spindle oscillations relative to slow waves, we computed moving window multi-taper spectrograms and compared local slow wave triggered spindle power at all recording sites. We found that spindle power is strongly modulated by slow waves in control subjects, but this modulation is markedly reduced in schizophrenia patients.
We next computed slow wave triggered coherograms to quantify remote coupling of frontal to parietal and central to occipital regions during slow wave events. We found strong spindle coherence after slow waves in the control group, and this coherence increased significantly after learning but was significantly attenuated in patients. In contrast, coherence between spindles not associated with slow waves (at least 3 seconds outside any slow wave activity) was less severely reduced and showed no learning-dependent increase in patients. A regression analysis confirms that slow wave modulated spindle coherence is significantly correlated with overnight motor task improvement; whereas non-slow wave modulated spindle coherence shows no such correlation.

In summary we confirm findings from an animal model of schizophrenia in a patient dataset, showing reduced frontal to occipital coupling during NREM sleep. We propose slow wave-spindle interactions as a new EEG based translational biomarker that implicates thalamocortical circuit dysfunction in cognitive symptoms of the disease.

Title: Temporal stability of default mode network in euthymic bipolar patients

Authors: *S. KOVACEVIC[1], G. N. SAVLA[2], V. OLAFSSON[3,5], C. WONG[3,5], A. SUTHERLAND[1], K. LU[3,5], E. GHOBRIAL[3,5], T. T. LIU[3,5], L. T. EYLER[4,2];
[1]Veterans Med. Res. Fndn., San Diego, CA; [2]VA San Diego Healthcare Syst., San Diego, CA; [3]Radiology, [4]Psychiatry, UCSD, San Diego, CA; [5]UCSD Ctr. for Functional MRI, La Jolla, CA

Abstract: Disturbances in functional connectivity have been suggested to contribute to cognitive and emotion processing deficits observed in bipolar disorder. Functional connectivity between medial prefrontal cortex (MPFC) and other brain regions may be particularly abnormal. The goal of the present study was to characterize temporal dynamics of the default mode network during rest in bipolar disorder using high resolution sequences adapted from the Human Connectome Project.
Bipolar participants (N=13, age 50.7±12.1) were medicated and euthymic at the time of participation (HAM-D = 4.0±2.7, YMRS = 1.0±1.7, PANSS Total =37.0±5.9). Healthy comparison participants (N=14, age 53.3±10.8) were comparable in age, gender, and education. Participants were given a cognitive battery focused on executive function including DKEFS Trail Making and Color Word Interference and rated their sleepiness and anxiety prior to the fMRI scan. Ten minutes of 2x2x2 mm multi-band gradient echo data were collected at a repetition time of 720 ms while participants rested quietly in a 3T GE MR750 scanner. We used a seed-based approach to measure default mode network correlations in each participant with seeds placed in

the MPFC, posterior cingulate, and lateral parietal cortex (Fox et al, 2005). We then divided the continuous scan into eight epochs and calculated average connectivity between MPFC and other default mode nodes for each epoch.
The bipolar group performed worse on Trails Number Sequencing and Letter Number Switching and Color Word Interference/Switching tasks suggesting slight impairment in visual attention and executive function. In addition, bipolar patients' self-rated anxiety level was higher at the time of the scan. Functional connectivity between MPFC and other cortical regions was slightly decreased in the bipolar group. Importantly, within-subject temporal variability in connectivity between MPFC and other default network regions was reduced in bipolar group.
The preliminary results suggest that default mode network connectivity in euthymic bipolar patients appears to be more stable across a ten minute period. Further explorations will be needed to assess the relationship between temporal stability of default mode network connectivity and other factors such as psychotropic medication.

Title: Distinguishing 1H-MRS metabolites in schizophrenia and methamphetamine-induced psychotic disorder

Authors: J. HSIEH, H. TEMMINGH, D. J. STEIN, *F. HOWELLS;
Dept. of Psychiatry, Univ. of Cape Town, Cape Town, South Africa

Abstract: The neurobiological mechanisms that result in the development and persistence of psychotic disorders are currently unknown. Methamphetamine-induced psychosis (MAP) may provide useful insights into the neurobiology of psychotic processes. Magnetic resonance spectroscopy (MRS) provides an in vivo assessment of brain metabolites, and has not previously been used to compare similarities and differences in schizophrenia and MAP in regions putatively involved in these disorders.1H-MRS was used to measure absolute metabolites in individuals with schizophrenia, MAP, and healthy socio-demographic controls. Metabolites were measured in left dorso-lateral prefrontal cortex, anterior cingulate cortex, and left thalamus. Our results revealed both similarities and differences in MRS metabolites in schizophrenia and MAP.

In particular NAA was decreased in anterior cingulate in both schizophrenia and MAP compared to controls, while schizophrenia was characterized by increased glutamate and glutamine (glx) in thalamus compared to healthy controls. Both schizophrenia and MAP involve alterations in neuroplasticity with evidence of decreased neuronal integrity and viability, as indicated by decreased NAA in anterior cingulate cortex. However, schizophrenia may be characterized by more severe disruptions in cortico-thalamic structures, as indicated by increased glutamate and glutamine in the thalamus.

Title: Localized changes in white matter connectivity in early-onset schizophrenia and its functional consequences

Authors: *J. CABRAL[1,2], H. M. FERNANDES[2,3], T. J. VAN HARTEVELT[2,3], A. C. JAMES[4]; [1]Ctr. of Brain and Cognition, Barcelona, Spain; [2]Dept of Psychiatry, Univ. of Oxford, Oxford, United Kingdom; [3]Ctr. of Functionally Integrative Neurosci., Aarhus Univ., Aahrus, Denmark; [4]Warneford Hosp., Oxford, United Kingdom

Abstract: Early-onset schizophrenia is a severely disabling illness which is currently not well understood in terms of its underlying neurobiology. However, emerging evidence suggests that schizophrenia is strongly linked to problems with cortical connectivity.

In the current study, we compared the structural connectivity between 90 brain areas of a group of 20 adolescent patients with early-onset schizophrenia with a group of 20 age-matched healthy controls. The structural connectomes were constructed from diffusion tensor imaging data using probabilistic tractography and analyzed using statistical tests and measures from graph theory. Subsequently, we used a computational model to gain insight on the functional impact of the observed structural alterations on the large-scale brain dynamics of patients and healthy controls. In the model, each brain area was represented by a dynamic mean field model, receiving excitatory input from connected areas in proportion to the number of white matter fibers detected between them.

We found significant changes in structural connectivity between patients and controls. Significant decreases were observed in primarily left lateralized anterior networks centered around the left orbitofrontal and anterior insular cortices. In addition, the connectivity between the superior orbito-frontal cortex and the caudate gyrus, exhibited a significant decrease in both the left and right hemispheres in schizophrenia. We also found significant increases in connectivity between the left cingulate cortex and right thalamus, right caudate and right superior frontal cortex.

Our computational model indicates that the brain in schizophrenia operates with lower global coupling strength, which shifts the dynamics from the optimal healthy regime to a point where functional networks appear subtly randomized and less small-world when compared to healthy participants.

Results show that schizophrenia is associated with lateralized changes in structural connectivity in regions involved in brain networks associated with emotional processing and regulation.

Title: Anterior but not posterior hippocampal volume is reduced in schizophrenia

Abstract: MRI studies have consistently reported smaller bilateral hippocampal volume in schizophrenia. However, it is unclear whether the volume loss is diffuse or localized to one region of the hippocampus. Manual segmentation of the hippocampus in 83 patients with schizophrenia and 78 controls matched for age, gender and race, revealed a significant region by diagnosis interaction, with significantly smaller anterior, but normal posterior, hippocampal volume bilaterally in schizophrenia. From a candidate list of six genes known to affect hippocampal volume, we investigated whether single nucleotide polymorphisms (SNPs) can account for the lower anterior hippocampal volume in schizophrenia. Our results indicate that the BDNF Val/Val (rs6265), MIR137HG AC/CC (rs1625579), and the TNF GG (rs1800629) alleles each account for the hippocampal volume differences in our sample. We then investigated functional consequences of smaller anterior hippocampal volume. Specifically, we studied whether the normal anterior right > left hippocampal volume asymmetry was maintained in schizophrenia. We found the normal anterior hippocampal asymmetry in schizophrenia, which correlated with verbal fluency and processing speed when controlling for age, gender, and group. Future studies should explore further how smaller anterior but normal posterior hippocampal volume can explain the clinical features of schizophrenia.

Title: Synchronization and schizophrenia: What about cross frequency coupling disturbances?

Authors: *N. POLIZZOTTO[1], C. WALKER[2], T. WOZNY[2], R. Y. CHO[2];

Abstract: Study: Brain rhythm disturbances are often observed in schizophrenia and are typically reported as independent or merely co-occurring alterations of both high and low frequency activity. However functional integration of activities occurring across different frequencies is an important feature in the healthy brain. In particular phase-amplitude coupling (PAC), i.e. the modulation of high frequency amplitude by the phase of low frequencies, has been suggested to be functionally relevant to perception and cognition and possibly providing an integrative account of wide spectral alterations in schizophrenia (Lisman, 2008). Only 2 studies have empirically addressed this hypothesis to date (Spencer, 2009; Kirihara, 2012). Critical methodological differences (e.g. different frequencies of interest), and analytical problems intrinsic to PAC estimations (e.g. dependence on amplitude) do not allow reconciling of their disparate results. We aimed to provide a more rigorous and comprehensive account of PAC in schizophrenia patients, investigating PAC across a broad range of EEG bands, together with its relation to amplitude differences.
Methods: Cross-frequency coupling analysis was applied to previously published eeg data (Kömek, et al 2012), where 12 schizophrenia vs. 12 healthy controls (age 30.3 ±9.5 vs. 31.4 ±9.1, gender and parental education matched) performed an auditory entrainment paradigm. Modulating phase and modulated amplitude were analytically extracted as angle and magnitude of the wavelet transformed time series. Phase-amplitude interaction was assessed by mutual information between their distributions.
Results: Schizophrenia subjects had impaired alpha-gamma coupling compared to healthy controls. This decreased coupling was found in the context of increased alpha power and decreased gamma power in patients compared to controls, indicating that coupling strength cannot be predicted simply by activity patterns at the respective frequencies. Other PAC alterations were observed possibly related to amplitude differences between populations, for instance, increased gamma power higher in controls and theta power in patients.
