Title: Extracellular and secreted microRNAs are novel pain mediators: Involvement of TLR7 and TRPA1

Authors: *T. BERTA[1], Z.-Z. XU[1], C.-K. PARK[1], Q. HAN[1], X.-J. LIU[1], R.-R. JI[1,2]

Abstract: MicroRNAs (miRNAs) are small non-coding RNAs and play critical roles in regulating gene expression. Although miRNAs are typically considered intracellular entities, miRNAs can also been detected in various body fluids including CSF as biomarkers for diseases. However, the functional role of extracellular miRNAs is still elusive. The miRNA let-7b is one of the most abundant miRNAs and contains immune stimulatory GUUGUGU motif. It is highly

enriched in dorsal root ganglion (DRG). Using quantitative RT-PCR we detected let-7b in the culture medium of DRG neurons and let-7b secretion is increased following neuronal depolarization (KCl) and nociceptor activation (capsaicin), indicating an activity-dependent release of let-7b. Interestingly, intraplantar injection of let-7b inhibitor reduced formalin (0.5%) induced spontaneous pain, suggesting a possible role of secreted let-7b in mediating inflammatory pain. Intraplantar injection of let-7b, but not the mutated oligonucleotides also elicited dose-dependent spontaneous pain. In particular, let-7b-induced spontaneous pain is abolished in mice lacking toll-like receptor 7 (TLR7), which is known to be activated by single-strand RNAs and expressed in nociceptor neurons of DRG. let-7b-induced spontaneous pain is also reduced in TRPA1 knockout mice and suppressed by TRPA1 antagonist. Intraplantar let-7b also induced persistent mechanical allodynia, which is abrogated in mice lacking TLR7, TRPA1, and MyD88. Patch clamp recordings revealed that let-7b induced rapid (within a minute) inward currents and action potentials in small-sized DRG neurons that co-express TLR7 and TRPA1, and these actions of let-7b are all abolished in TLR7 and TRPA1 knockout mice. Finally, low concentration formalin (0.01%)-induced TRPA1 currents is reduced by extracellular application let-7b inhibitor. Collectively, our findings support a functional role of extracellular and secreted miRNA for rapid nociceptor excitation and pain induction via TLR7 and TRPA1. Extracellular miRNAs represent a new class of pain mediators/neuromodulators and potential targets for developing novel pain treatments.

Title: Anti-nociceptive actions of Botulinum toxin B on spinal sensory processing and AMPA receptor trafficking

Authors: *S. SIKANDAR[1], M. MAARDH[2], A. H. DICKENSON[1], L. SORKIN[2], T. L. YAKSH[2]
[1]Univ. Col. London, London, United Kingdom; [2]Anesthesiol., UCSD, San Diego, CA

Abstract: Aim We explored the effects of intraplantar (i.pl.) Botulinum toxin B (BoNTB), which blocks neurotransmitter release from primary afferent terminals, on spinal nociceptive processing and AMPA receptor trafficking in an inflammatory model of pain. We also investigated transsynaptic effects of i.pl. BoNTB by activating the system post-synaptically using i.pl. BoNTB pretreatment in conjunction with i.t. NMDA. Methods Adult male mice (C57Bl6; 20-30g) were used for all experiments. Drugs were administered i.pl. (30 μL BoNTB, 30 μL saline or 20μL 2% carrageenan) and i.t. (5 μL NMDA or saline). Mechanical withdrawal thresholds were assessed with von Frey filaments. For c-Fos staining, carageenan mice were perfused and spinal cord tissue cut at 30 μm. For Western blots, following i.pl. carrageenan (2 h) or i.t. NMDA (5 min), spinal cords were hydroextruded and lumbar quadrants and L3-L6 DRGs were snapfrozen. Western membranes were probed for relevant antibodies and incubated with horseradish peroxidase-linked secondary antibodies. All data was normalized to a loading control. Results We found that i.pl. carrageenan induces mechanical allodynia, as well as phosphorylation of spinal dorsal horn AMPA receptor subunit, GluA1, at the PKA site and phosphorylation of protein kinase B (AKT). Our data shows that a 48-hour pretreatment with i.pl. BoNTB blocked evoked allodynia, the increase in p-GluA1ser845 and p-AKTser473 and the increase in carrageenan-induced Fos expression. BoNTB also elicited a decrease in vesicle-associated membrane protein products (VAMP) in DRGs. All of these data can be explained by BoNTB inhibition of primary afferent release. Administration of i.t. NMDA increased dorsal horn levels of p-GluA1ser845 and p-AKTser473. Surprisingly, these postsynaptic effects were also blocked by ipsilateral i.pl. BoNT. Effects of i.pl. BoNTB on NMDA-evoked GluA1 trafficking to the plasma membrane are currently being investigated. Conclusions We report novel findings of BoNTB actions on spinal nociceptive processing. Pretreatment with i.pl. BoNTB reduces pain behavior in a carrageenan model of acute inflammation. Furthermore, BoNTB pretreatment in carrageenan mice reduces neural activation and phosphorylation of Akt and GluA1. By using spinal administration of NMDA, we bypass the primary afferent and show that i.pl. BoNTB has postsynaptic actions on pAkt and pGluA1. Given these results it is likely that we will observe modulation of GluA1 trafficking into the plasma membrane. These results provide crucial insight into the mechanisms of BoNT in modulating central nociceptive processing, and importantly its potential to exert transynaptic actions.

Title: Signaling transduction events involved in agonist-induced PGE2 EP4 receptor externalization in cultured dorsal root ganglion neurons

Authors: B. ST-JACQUES[1], *W. MA[2]
[1]Douglas Mental Hlth. Univ. Inst., [2]Psychiatry, McGill Univ., Montreal, QC, Canada

Abstract: Prostaglandin E2 (PGE2), a well-known pain mediator enriched in inflamed tissues, plays an essential role in the development of chronic pain conditions such as inflammatory and neuropathic pain. PGE2 EP4 receptor, which couples to Gs and activates cAMP/protein kinase A signaling, is known to play a major role in those chronic pain conditions. Both peripheral and central sensitizations underlie the genesis of chronic pain state. Although PGE2 is known to sensitize nociceptive dorsal root ganglion (DRG) neurons (nociceptors), the underlying mechanisms remain incompletely understood. We recently reported that PGE2 and EP4 agonists stimulated cell surface trafficking of EP4 in cultured DRG neurons and that dual stimulations of EP4 agonist induced greater levels of intracellular cAMP in cultured DRG explants than a single stimulation (St-Jacques & Ma, Pain, 154:313-323, 2013), suggesting that facilitating EP4 cell surface trafficking likely underlies PGE2-induced nociceptor sensitization. However, the signaling transduction pathways mediating PGE2-facilitated EP4 externalization remains largely unknown. In the present study, using antibody feeding based EP4 externalization assay, we attempted to dissect out those signaling transduction events invovled in EP4 agonist-induced EP4 externalization in cultured DRG neurons. We found that EP4 agonist, and EP3 agonist to a lesser extent, but not EP1 and EP2, induced EP4 externalization. The CaMKII inhibitor, extracellular and intracellular calcium chelators blocked EP4 agonist 1-OH-PGE1-induced EP4 externalization. The inhibitors of cAMP, PKA, PKC, PKCε, MAPK, PI3K and Akt, but not PLC, suppressed 1-OH-PGE1-induced EP4 externalization. The activators of adenylate cyclase, two PKA specific cAMP analogs and an Epac specific cAMP analog induced EP4 externalization. We also observed that capsaicin and potassium chloride enabled to induce EP4 externalization to a lesser degree than EP4 agonist. A neutralizing IL-6 antiserum or a NGF sequester partially suppressed agonist-induced EP4 externalization. Taken together, these data suggest that by activating cAMP/PKA, cAMP/Epac, PKC/PKCε, MAPK and PI3K-Akt signaling transduction

pathways, EP4 agonist induced EP4 externalization. Agonist-induced EP4 externalization requires extracellular and intracellular calcium and CaMKII. IL-6 and NGF are partially involved in agonist-induced EP4 externalization while capsaicin and KCL enable to stimulate EP4 externalization, suggesting that cross-stimulation of cell surface trafficking of pain-facilitating receptors likely underlies cross-sensitization of nociceptors among pain mediators.

Title: Akap150 mediates transition to chronic pain

Authors: *N. A. JESKE[1], M. P. ROWAN[1], R. GOMEZ[1], J. DU[2], S. M. CARLTON[2]
[1]UTHSCSA, San Antonio, TX; [2]UTMB, Galveston, TX

Abstract: Chronic pain affects over 100 million Americans every year, and remains one of the most under-treated conditions in the world. Despite this, little is know about the mechanisms that control the transition from acute to chronic pain. Although many central, synaptic, and peripheral mechanisms contribute to this transition, we have discovered a unique signaling pathway that engenders chronic sensitivity to peripheral sensory neurons. In animals challenged with an acute prostaglandin E2 (PGE2) injection, we waited 5 days and determined sensitivities to thermal and mechanical stimuli. Rodent behavioral models indicate that AKAP150 is required for the transition from acute to chronic pain. Our hypothesis was that a feed-forward mechanism is created by acute injury (PGE2) that stimulates glutamate receptor-mediated AKAP150 association with and sensitization of TRPV1 in sensory neurons. Indeed, depolarization of peptidergic sensory neurons elicits the release of neuromodulators, including calcitonin gene-related peptide (CGRP) and glutamate, which can act on either adjacent terminals or the same terminal. We found that sensory neuron depolarization increases extracellular glutamate, and that activation of mGluR1 increased AKAP150 association with TRPV1, and sensitized naïve

responses to an agonist stimulus. Further, recording from nociceptors using an *in vitro* skin-nerve preparation confirms that AKAP150-dependent TRPV1 sensitization is occurring at the level of terminal innervation. Together, our findings identify AKAP150 scaffolding as an important event in the transition from acute to chronic pain.

Title: The activation of neuronal cannabinoid CB1 receptor inhibits inflammatory hyperalgesia via inactivation of P2X3 receptor in rats

Authors: *C. A. PARADA, M. G. OLIVEIRA-FUSARO, D. ARALDI, I. J. M. BONET, C. H. TAMBELI
Structural and Functional Biol., State Univ. of Campinas - Unicamp, Campinas, Brazil

Abstract: Aim of investigation: The present study was addressed to investigate the mechanism by which activation of cannabinoid CB1 receptor in the primary afferent neuron reduces the inflammatory hyperalgesia. Methods: Experiments were conducted in accordance to the Committee on Animal Research of the State University of Campinas- Unicamp, São Paulo - Brazil. Drugs or vehicle were subcutaneously injected in the rat's hind paw. The functional blockade of CB1 receptors expression on peripheral sensory neurons was performed by the intrathecal injection of ODN antisense: 5'- TGA ATC ATG CGG ACC GCG T -3' or ODN mismatch: 5'- TTA CTC AGG CTG GCC GAG T -3', one time a day (30 μg/10 μL per day) for 4 days. Intrathecal injection was performed in anesthetized rats with halothane. A 26-gauge needle was inserted in the subarachnoid space on the midline between L4 and L5 vertebrae. ODN was injected at 1μl/s. Western Blot was performed using specific primary antibodies to CB1. Data was performed with G-BOX, and normalized to the ponceau control. The mechanical nociceptive threshold was measured using electronic von Frey. The hyperalgesia was presented as Δ withdraw threshold. ELISA was used to determine the concentration of TNF-α, IL-1β and

CINC-1 in subcutaneous tissue. The neutrophil migration was evaluated by myeloperoxidase kinetic-colorimetric assay. One-way ANOVA followed by Tukey test was used for statistical analysis as appropriated ($P<0.05$). Rats per group = 6 to 8. Results: We confirmed that anandamide or ACEA, the non-selective or the selective cannabinoid CB1 receptor agonist, respectively, administrated in the peripheral tissue of rat hind paw reduces the carrageenan-induced mechanical hyperalgesia in a dose-response manner. This response is not reversed by naloxone, but was reversed by the selective cannabinoid CB1 receptor antagonist AM251 locally administrated in the subcutaneous tissue, as well as by the intrathecal treatment with oligodeoxynucleotide (ODN) antisense against CB1 receptor. ACEA also reduced the hyperalgesia induced by bradykinin or by the selective P2X3 and P2X2/3 receptors agonist αβmeATP, but not by TNF-α, IL-1β, CINC-1 or PGE2. Although local peripheral administration of ACEA prevented carrageenan-induced hyperalgesia, it did not affect neither the release of TNF-α, IL-1β, CINC-1 or the neutrophil migration induced by carrageenan. Conclusion: Take together the data of this study suggest that the mechanism underlying the anti-hyperalgesic effect mediated by CB1 receptor activation in peripheral afferent nociceptor involves inactivation of neuronal P2X3 receptor. Title: Effects of morphine on formalin-evoked somatic and affective components of nociception in male and female rats

Authors: L. HARTON[1], J. RICHARDSON[1], *A. NAZARIAN[2]
[1]Pharmaceut. Sci., Western Univ. of Hlth. Sci., Pomona, CA; [2]Western Univ. Hlth. Sci., Pomona, CA

Abstract: There is increasing evidence for the presence of sex differences to pain and nociception in humans and animals. Occurrence of certain chronic pain conditions is more prevalent in women than in men. Similar to the findings in humans, female rats have a greater nociceptive sensitivity in behavioral models of mononeuropathy, inflammatory, and tonic pain

conditions as compared to male rats. Sex differences in models of tonic nociception is of particular interest to us, because i) tonic nociceptive transmission is a critical component in development of wind-up and the early stages of central sensitization; and ii) animal models of tonic nociception (notably the formalin model) are easily reproducible and well characterized. Therefore, we sought to determine the somatic and affective components of formalin-evoked nociception in male and female rats. Moreover, the effects of morphine in the two components were also examined. The somatic component of formalin-evoked nociception was measured by assessing paw flinches across a 60min testing session using an automated formalin nociceptive analyzer. The affective component of formalin-evoked nociception was measured using a conditioned place aversion (CPA) paradigm. In this model, formalin was paired with the preferred compartment of a CPA apparatus in a 2-day CPA conditioning procedure. Our preliminary findings suggest that male and female rats exhibited similar levels of formalin-evoked flinching behavior across phases 1 and 2. Likewise, male and female rats exhibited similar levels of aversion to a formalin paired environment. Morphine treatment during conditioning in the CPA study resulted in diminished place aversion in male and female rats. Although, morphine exhibited a trend for a stronger blockade of formalin-evoked CPA in males as compared to females. If these results persist, they will suggest that morphine produces a sexually dimorphic response in somatic and affective responses to tonic spontaneous pain.

Title: Role of microglia and P2X7 receptors in arthritis pain

Authors: *M. J. MOUSSEAU[1,2,3], A. PILAPIL[3], J. MATYAS[2], T. TRANG[2,3]
[1]Neurosci., [2]Vet. Med., Univ. of Calgary, Calgary, AB, Canada; [3]Univ. of Calgary, Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Arthritis pain is one of the most common and debilitating chronic pain conditions, and its negative impact will continue to grow in scope as the population ages and arthritis becomes more prevalent. The sequelae of arthritis pain are commonly attributed to peripheral joint pathology. Although joint pathology is an underlying factor, some patients with severe joint degeneration report little to no pain, while others with minor joint pathology experience debilitating and unremitting pain. The discordance between joint pathology and pain severity suggests joint damage is not necessarily a direct predictor of ensuing chronic pain. Rather, new lines of evidence implicate pathological changes within the central nervous system as being an important component of arthritis pain. In the present study, we examined the importance of microglia and ATP-gated P2X7 receptors (P2X7R) within the spinal cord in arthritis pain. The principal goal was to evaluate the cellular changes in spinal microglia and the concomitant progression of joint pathology in a monosodium iodoacetate (MIA) rat model of osteoarthritis (OA). Adult male Sprague Dawley rats were given an intra-articular injection of MIA. Changes in mechanical and thermal nociceptive threshold following MIA-injection were assessed using the Von Frey and thermal Hargreaves tests, respectively. We found that the onset of mechanical allodynia and thermal hyperalgesia occurred as early as day 3 post-MIA injection. On day 7 post-MIA injection, we detected a significant increase in iba-1 expression, a microglia marker, on the ipsilateral spinal dorsal horn. Given that ATP-gated P2X7Rs are critically involved in the pathophysiology of osteoarthritis, and the emergent role of these receptors in microglia mediated chronic pain signaling, we next asked whether spinal P2X7Rs are causally involved in MIA-induced arthritic pain behaviours. We found that repeated intrathecal injection of the P2X7R antagonist, Brilliant Blue G (BBG), over 7 days markedly attenuated the development of mechanical allodynia and thermal hyperalgesia in MIA-injected rats. In addition, we discovered that a single acute injection of BBG in animals with established MIA-induced arthritic pain transiently reversed both the mechanical and thermal pain hypersensitivity. Collectively our results suggest that spinal P2X7Rs are causally involved in the development and tonic ongoing expression of arthritis pain.

Title: Sex differences in the antihyperalgesic and anti-inflammatory effect of P2X7 receptor blockade on carrageenan-induced arthritis in the rats knee joint model

Authors: *C. H. TAMBELI, J. M. TEIXEIRA, C. A. PARADA, E. V. DIAS
FUNCTIONAL AND STRUCTURAL BIOLOGY, UNIVERSITY OF CAMPINAS, CAMPINAS, Brazil

Abstract: Aim: The aim of this study was to investigate whether the anti-hyperalgesic and anti-inflammatory effects induced by the blockade of P2X7 receptors in the knee joint differs between male and female rats. Methods: Male and females Wistar rats (2 months old, 200-250g) were used in this study. The experimental procedures were approved by the Ethics Committee in Animal Research at the UNICAMP (2049-1). The hyperalgesic responses (gait disturbance, seconds) were quantified using the Knee-joint Incapacitation Test (Tonussi, Pain 48; 421, 1992), the local concentrations of TNF-α, IL-1β, IL-6 and CINC-1 were measured by Enzyme-linked Immunosorbent Assay (ELISA) and neutrophil migration was quantified in the rats knee joint by the method of quantification of myeloperoxidase enzyme activity (MPO), 3 hours after the administration of carrageenan (300µg/knee). One-way ANOVA followed by Tukey test was used for statistical analysis as appropriated ($P<0.05$). Rats per group = 6 to 8. Results: Intra-articular administration of carrageenan (300µg/knee) induced articular hyperalgesia (Mean±EPM, males: 54.3±1.3s; females: 49.6±1.5s), release of TNF-α (males: 1139.17±90.47pg/mL; females: 947.1±130.47pg/mL), IL-1β (males: 12670.1±1271pg/mL; females: 12251.4±1089.5pg/mL), IL-6 (males: 8720.94±335.2pg/mL; females: 8044.3±1013.5pg/mL), CINC-1 (males: 3967.7±521. 2pg/mL; females: 3887.2±162.3pg/mL) and neutrophil migration (males: 23645.6±2145.13 neutrophils/joint; females: 21858.1±1253.1 neutrophils/joint). Co-administration of the selective P2X7 receptor antagonist A-740003 (568µg/Knee in males and 142µg/knee in females) significantly reduced the articular hyperalgesia (males: 14.5±1.3s; females: 17.6±1.4s; $P<0.05$, Tukey test), the release of TNF-α (males: 305.4±43.3pg/mL; females: 304.9±59.8pg/mL; $P<0.05$, Tukey test), IL-1β (males: 6013.7±832.9pg/mL; females: 9190.7±832.9pg/mL; $P<0.05$, Tukey test), IL-6 (males: 1285.5±218.6pg/mL; females: 1127.8±336.3pg/mL; $P<0.05$, Tukey test), CINC-1 (males: 250.5±21.6pg/mL; females: 1829.3±323.9pg/mL; $P<0.05$, Tukey test) and the neutrophil migration (males: 5174.3±704.68 neutrophils/joint; females: 9795.1±1179.1 neutrophils/joint; $P<0.05$, Tukey test) induced by carrageenan. Although, the lowest dose of A-740003 (142µg/knee) significantly reduced ($P<0.05$, Tukey test) carrageenan-induced articular hyperalgesia, cytokines release and neutrophil migration in females it did not in males.

Conclusion: Females are more responsive than males to the anti-hyperalgesic and anti-inflammatory effects induced by the blockade of P2X7 receptors in the rat knee joint.

Title: A novel phenotypic marker reveals resident macrophage monitoring of neuronal activity within sensory ganglia

Authors: *D. C. MOLLIVER[1], E. S. SCHWARTZ[2]
[1]Biomed. Sci., Univ. New England, Biddeford, ME; [2]Anesthesiol., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: There is extensive evidence for interactions between peripheral sensory axons and immune cells at sites of peripheral injury. However, there has been limited investigation of resident immune cell function within peripheral sensory ganglia, and whether their actions have an impact on functional properties of nociceptors. We report the identification of a novel marker of resident macrophages whose expression is rapidly suppressed within dorsal root ganglia (DRG) in response to a noxious insult to a distant peripheral tissue. The initial project asked whether one-dimensional SDS-PAGE provided sufficient resolution to identify changes in protein levels occurring in sensory ganglia in response to peripheral inflammation. The protein banding profile from lumbar L2-5 DRG was visualized by silver stain, and compared between mice with and without inflammation of the hindpaw induced by injection of complete Freund's adjuvant (CFA) 24 hours before sample collection. A striking difference was the loss of a high molecular weight band (250 kD) in samples from inflamed mice. This band was excised and analyzed by mass spectroscopy. A high confidence target ($p<0.01$) was identified as myosin-4. Validation by Western blot revealed that the myosin-4 band matched the molecular weight of the

band identified in silver-stained gels and was almost completely lost 24 hours after hindpaw injection of CFA. Immunohistochemistry for myosin-4 in combination with F4/80, a macrophage marker, revealed a network of F4/80+ macrophages in naïve DRG and extensive colocalization with myosin-4, indicating expression of myosin-4 in resident macrophages. Staining was also seen in macrophage-like cells cultured from bone marrow, but not in neuronal cultures. Analysis of mouse and human peripheral tissues revealed labeled macrophage-like cells, suggesting that myosin-4 is a marker of resident macrophages in human as well as mouse. To confirm that this phenotypic switch was not due to a systemic inflammatory response to CFA, the TRPV1 agonist capsaicin was injected into the hindpaw to directly excite nociceptors. 24 hours later, Western blot analysis indicated a loss of myosin-4 protein in L2-5 DRG. We propose that resident immune cells within DRG monitor nociceptor activity and respond to noxious insult with a change in phenotype. The significance of ganglionic resident macrophage responsiveness to neuronal activity and the possibility of a role in the regulation of nociceptor function at the soma are under investigation.

Title: The systemically active NAAA inhibitor, ARN726, alleviate inflammation in an animal model of rheumatoid arthritis

Authors: F. BONEZZI, O. SASSO, S. PONTIS, *D. PIOMELLI
Fondazione Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: Fatty acid ethanolamides (FAEs) are a family of lipid messengers that participate in the control of multiple physiological functions including pain and inflammation. They include agonists of cannabinoid receptors, such as anandamide, and agonists of type-α peroxisome proliferator-activated receptors (PPAR-α), such as oleoylethanolamide and palmitoylethanolamide. The FAEs are degraded by two intracellular lipid amidases: N-acylethanolamine acid amidase (NAAA) and fatty acid amide hydrolase (FAAH). Although NAAA and FAAH share the ability to cleave lipid amide bonds, they differ markedly in primary structure, substrate selectivity, and cellular localization. NAAA, primarily localized to the

lysosomal compartment of macrophages, is an N-terminal nucleophile cysteine amidase that displays a strong preference for saturated FAEs such as PEA. FAAH, found on the outer face of mitochondria and endoplasmic reticulum of most mammalian cells, is a member of the amidase signature family of serine hydrolases and displays broader substrate selectivity, but preferentially hydrolyzes monounsaturated and polyunsaturated FAEs such as OEA and the endocannabinoid anandamide. These enzymes have attracted growing attention as potential targets for drug therapy. In the present study we tested the effects of the first systemically active NAAA inhibitor, ARN726, in a model of rheumatoid arthritis, and compared them to those of the peripherally restricted FAAH inhibitor URB937. Arthritis was developed in Sprague-Dawley rats by hind-paw injection of Complete Freund's Adjuvant (CFA). The disease developed within 24 h of injection and caused paw oedema and thermal hyperalgesia. Drugs were administered 7 and 14 days after induction. Immunohistochemistry for NAAA was performed on tissue sections from paw, spinal cord and brain, with focus on the areas involved in pain sensation and modulation. Spinal cord sections were stained with Iba-1 as a marker of microglia. Behavioral tests demonstrated that ARN726 reduces both paw oedema and heat hyperalgesia, while URB937 is active on hyperalgesia, but as no effect on oedema. NAAA immunoreactivity was found in paw and in the rostral ventrolateral medulla (RVM) of CFA-treated animals. Low NAAA signal was detected in paw tissue, but not in RVM of naïve rats. Robust microglial activation in spinal cord, especially at the lumbar level, was observed, but NAAA immunoreactivity was not evident in this structure. The results suggest that pharmacological blockade of intracellular NAAA activity causes significant anti-inflammatory effects in the CFA model of arthritis.

Abstract: Metabotropic P2Y receptors subfamily consists of eight functional mammalian receptors. P2Y1 and P2Y6 receptors have been described in the sensory nervous system, but their participation in behavioral pain models at peripheral levels has been scarcely studied. This study assessed the role of peripheral P2Y1 and P2Y6 receptors in formalin-induced inflammatory pain, and determined their localization and distribution in dorsal root ganglia (DRG) by western blot and immunostaining. Ipsilateral, but not contralateral, local peripheral pre-treatment with the endogenous non-selective P2Y1 (ADP, 100-1000 nmol/paw) and P2Y6 (UDP, 180-300 nmol/paw), or selective P2Y1 (MRS2365, 0.1-10 nmol/paw) and P2Y6 (PSB0474, 0.1-0.10 pmol/paw) receptor agonists increased 0.5% formalin-induced flinching behavior. Concordantly, local peripheral pre-treatment with the selective P2Y1 (MRS2500, 0.01-10 pmol/paw), and P2Y6 (MRS2578, 3-30 nmol/paw) receptor antagonists significantly decreased 1% formalin-induced flinching behavior. Furthermore, the pronociceptive effect of ADP (100 nmol/paw) or MRS2365 (10 nmol/paw) and UDP (300 nmol/paw) or PSB0474 (10 pmol/paw) was blocked by the selective P2Y1 (MRS2500, 0.01 nmol/paw) and P2Y6 (MRS2578, 3 nmol/paw) receptor antagonists, respectively. Western blot analysis confirmed the presence of P2Y1 (66 KDa) and P2Y6 (36 KDa) receptors in DRG and sciatic nerve, and double immunostaining showed that 62.2% and 81.2% of DRG neurons express P2Y1 and P2Y6 receptors, respectively. Results suggest that peripheral activation of P2Y1 and P2Y6 receptors plays a pronociceptive role in formalin-induced pain. The use of antagonists of these receptors may be a useful strategy to treat local inflammatory pain.

Title: Protein levels of the resolvin D1 receptors GPR32 (G-protein coupled receptor 32) and FPR2 (formyl peptide receptor 2) are higher in juvenile rats with arthritis compared to young adult rats with arthritis

Authors: *T. D. WILSON-GERWING, A. M. ROSENBERG
Dept. of Pediatrics, Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: The pathophysiologic networks that mediate inflammatory pain in the peripheral and central nervous systems differ depending on whether inflammation is acute or, as in arthritis, progresses to become chronic. We have shown that age influences inflammatory pain responses and that juvenile rats with experimental arthritis (collagen-induced arthritis; CIA) have different outcomes than young adults; juvenile rats exhibit more rapid resolution of inflammation while young adults have more destructive and persistent inflammatory disease. Our preliminary results suggest that age-related differences in joint inflammation and pain may be explained by an imbalance between endogenous pro- and anti-inflammatory mediators. We hypothesized that the more favourable outcomes observed in juvenile rats with arthritis were due to a greater availability of receptors for the potent anti-inflammatory resolvin D1. Juvenile (5 week old) and young adult (13 week old) rats were injected intradermally with bovine type II collagen resulting in monophasic polyarthritis in the hind paws. Naïve age-matched rats were included as controls. Two weeks after the onset of CIA, animals were euthanized and dorsal root ganglia (DRG) were sectioned and processed by immunohistochemistry to detect levels of the resolvin D1 receptors GPR32 (G-protein coupled receptor 32) and FPR2 (formyl peptide receptor 2). In the naïve state, juvenile rats have higher levels of both GPR32 and FPR2 in the DRG compared to naïve young adult rats. Two weeks following CIA, there were increased levels of both GPR32 and FPR2 that was most noticeable in the juvenile CIA rats. Young adult rats with CIA had a slight increase in levels of GRP32 and FRP2 compared to the naïve state. This suggests young adult rats are less able to resolve acute inflammatory insult at the onset of CIA, and thus predisposed to experiencing higher levels of inflammation and pain following CIA than juvenile rats. A better understanding of interrelationships involved in the balance between resolution of acute inflammation and development of chronic inflammation/inflammatory pain will guide development of new approaches for arthritis patient care.

Title: Autoantibody profiling in complex regional pain syndrome using luciferase immunoprecipitation system (lips) assay

Authors: A. BAYAT[1], *M. J. IADAROLA[1], A. BUVANENDRAN[2], A. J. MANNES[1], J. S. KROIN[3]
[1]Clin. Center, NIH, Dept. of Perioperative Med., BETHESDA, MD; [2]Dept. of Anesthesia & Critical Care, Univ. of Chicago, Chicago, IL; [3]Rush Med. Col., Chicago, IL

Abstract: Background: Complex regional pain syndrome (CRPS) represents a chronic pain condition that arises subsequent to peripheral nerve injury (CRPS-II) or in the absence of an apparent precipitating nerve injury (CRPS-I). It is usually occurs in the extremities and is characterized by severe pain, swelling, autonomic disturbances, skin changes and functional and movement impairments. The age range at presentation for CRPS is typically between 36 and 42 years, but it can occur in the extreme ages of children as well as the elderly. The presentation of CRPS occurs mainly in women who predominate over men in the range of 60 to 80%. The pathogenesis of CRPS is unclear and some evidence of immune system involvement has been elaborated. To test this possibility further we directly examined serum from CRPS and nerve injury patients for the presence of autoantibodies to a wide variety of potential autoantigens as well as antibody levels to some neurotropic viruses. **Methods:** Antibody levels against 50 different antigens were determined in serum samples of 103 patients [70 patients with CRPS (M=27,F=33); 28 patients with neuropathic pain (NP) (M=F=14); 4 patients with low back pain (LBP) (M=4) and one patient with post herpetic neuralgia (PHN) (F=1)] and 37 healthy volunteers to evaluate the role of the adaptive immune system in pathology of CRPS disease by using Renilla luciferase-antigen recombinant proteins in an immunoprecipitation (LIPS) assay. Antibody levels were measured as light units with a luminometer. Selection of target antigens was made based on previous studies in CRPS patients as well as antigens identified using a high density protein array probed with patient sera. Some known auto-antibodies in common auto-immune disorders and as well as antibodies against neurotropic viruses were measured in these patients. **Results:** Eleven patients in the CRPS group (16%) had high antibody titer against IL1-α. High titers to IL1-α were also observed in two NP patients and one healthy volunteer. Although we saw some sporadic high levels of antibodies to several other antigens; we did not

observe enrichment of specific autoantibodies in the CRPS patients for eighteen other cytokines or for antigens from known autoimmune disorders such Sjogren 's syndrome, Stiff Person Syndrome or Lupus, nor was there a clear association with antibody titers to neurotrophic viruses such as HSV. **Discussion:** These data identify a subset of patients with IL1-a autoantibodies. While a broad-spectrum sensitivity to auto-antigens does not appear to be a component of CRPS, further investigation of additional proteins and peptides may reveal a CRPS autoimmune signature.

Title: Endothelin and bradykinin signaling divergence in sensory neurons

Authors: *K. SZTEYN, R. GOMEZ, N. A. JESKE
OMS, Univ. of Texas Hlth. Sci. Ctr. San Anto, San Antonio, TX

Abstract: Endothelin (ET) and bradykinin (BK) are two endogenous peptides that signal through Gαq-protein coupled receptors (GPCRs) to cause nociceptor sensitization and pain. Both peptides activate phospholipase C to stimulate Ca^{2+} accumulation, diacylglycerol production and protein kinase C activation, and are desensitized by a G-protein receptor kinase 2-dependent mechanism. However, ET produces a greater and longer-lasting nocifensive response than BK in multiple models, indicating a divergent signaling mechanism in primary afferent neurons. Using sensory neurons cultured from rat Trigeminal Ganglia, we have identified a pathway by which ET activates secondary Ca^{+2} channels to maintain neuronal depolarization. Inhibitors to ligand-gated ion channels and calcium release activated calcium (CRAC) channels abrogated ET effects on sensory neuronal Ca^{+2} accumulation measured in real time. Indeed, under these circumstances, the previous significant differences in pharmacological desensitization of BK and ET responses became identical. Furthermore, the withdrawal of Ca^{+2} from extracellular buffer also stunted any prolonged response to ET, indicating that plasma membrane channels contribute

to ET effects. Taken together, these ongoing studies highlight an important mechanistic difference between ET and BK signaling pathways in sensory neurons that may support why ET nocifensive behavior is significantly greater. Research support provided by NIH NS082746.

Title: Complement C5a contributes to inflammatory heat hyperalgesia via TRPV1 and macrophage-dependent mobilization of NGF in mouse

Authors: L. P. SHUTOV[1], C. A. WARWICK[1], R. P. GUPTE[1], A. J. SHEPHERD[1], D. J. CLARK[2], T. M. WOODRUFF[3], D. P. MOHAPATRA[1], *Y. M. USACHEV[1]

Abstract: The complement system is a principal component of innate immunity. It consists of more than 30 proteins that are rapidly recruited through a cascade of enzymatic reactions to contribute to host defenses through diverse mechanisms. In spite of growing evidence implicating the complement system in the development of pain hypersensitivity, the underlying mechanisms are not understood. We found that heat hyperalgesia induced by intraplantar injection of complete Freund's adjuvant (CFA) was markedly reduced in C5a receptor (C5aR) knockout (KO) mice and by administering the C5aR antagonist PMX53. Our data suggest the CFA-induced mechanical sensitization is also diminished in C5aR KO mice. Injection of 500 ng C5a into a mouse hind paw produced strong thermal and mechanical sensitization that lasted for at least 3 hrs, and fully recovered to pre-injection levels within 24 hrs. Heat hyperalgesia produced by C5a was blocked by the TRPV1 antagonist AMG9810 and was strongly reduced in TRPV1 KO mice. Somewhat surprisingly, C5a-induced mechanical sensitization was also inhibited by AMG9810 or by TRPV1 deletion. Examination of inflammatory mediators in the skin induced by intraplantar C5a injection showed a rapid increase in the levels of nerve growth

factor (NGF). Moreover, pre-injection of NGF-neutralizing antibody blocked the C5a-induced heat hyperalgesia. Immunohistochemical analysis of plantar skin sections showed prominent expression of C5aR in macrophages. Drug-induced macrophage depletion in transgenic MAFIA (macrophage Fas-induced apoptosis) mice abolished the C5a-induced heat hyperalgesia. Notably, intraplantar injection of NGF was still able to produce heat hyperalgesia in the macrophage-depleted mice. We propose that the complement fragment C5a contributes to inflammatory heat hyperalgesia by inducing macrophage-dependent production/release of NGF and consequent sensitization of TRPV1 to heat. Our findings highlight the importance of macrophage-to-neuron signaling in the pathogenesis of inflammatory pain and identify C5a and NGF as key mediators in this cross-cellular communication.

Abstract: Aim of investigation: Recently, some evidence for activated microglia being key-players in chronic pain persistence were described. Moreover both microglia and astrocytes have been proposed as critical actors in opiate-induced hyperalgesia and tolerance. The opioid receptors which are G protein-coupled receptors can be found under three different types, mu, delta and kappa, all of them being involved in analgesia. Delta opioid receptors (DOR) are of prime interest as potential therapeutic targets for chronic pain, besides the mu-opioid receptor that represents the main target of the clinically used opiates. Methods: In the present study, we focused on the role of microglial DOR, by generating a new conditional knockout mouse line with a specific deletion of specific DOR in microglia. We crossed the previously described DOR-floxed mice (Gaveriaux-Ruff et al. 2011) with microglia deleter LysM-Cre mice (Clausen et al. 1999). Results: We characterized this new mouse model by molecular and cellular approaches in both brain and spinal cord, followed by behavioral pain tests. In addition, we study the impact of the DOR deletion in microglia on inflammatory pain, following Complete Freund's Adjuvant (CFA) injection into hindpaw, as a model for inflammation-induced pain, and neuropathic pain induced by partial sciatic nerve ligation. Conclusion: Taken together, these results provide information of microglial DOR implication in pain perception, and suggest that microglial DOR are of prime interest in studying neuropathic pain.

Title: B vitamins suppress serine protease and protease-activated receptor 2 as well as behaviorally expressed hyperalgesia in Achilles tendonitis rats

Authors: W. B. SONG[1], Z.-J. HUANG[1], *X.-J. SONG[1,2]
[1]Dept. of Neurobiology, Parker Univ. Res. Inst., Dallas, TX; [2]Peking Univ., Beijing, China

Abstract: We have recently shown that activation of Protease-activated receptor 2 (PAR2) is critical to development of hyperexcitability of dorsal root ganglion (DRG) neurons after nerve injury and the serine protease proteolytic activity and PAR2 activation may play an important role in development of inflammation and pain after Achilles tendonitis. Here we report that i.p. B vitamins can relieve tendon injury-induced hyperalgesia and its accompanied inflammation as well as suppress serine proteases activity and PAR2 activation. Achilles tendonitis was induced by a subcutaneous injection of collagenase in the hind limbs (500 units per rat). Collagenase-induced tendonitis resulted in a rapid-onset (within a day) and long-lasting (at least two weeks) mechanical allodynia and thermal hyperalgesia, in addition to the morphological manifestations of inflammation and tissue damage, e.g., the lesion site was largely filled with loose fibrous tissue, granulation tissue and connective tissues and intensive inflammatory cells accumulation. During the tendonitis, the serine protease proteolytic activity was increased and level of expression of trypsin and tryptase, the two major serine proteases, as well as the PAR2 protein are increased. The proinflammatory cytokines IL-1β and TNF-α were also greatly increased in the inflamed tendon. Repeated intraperitoneal injection of vitamin B1 (100 mg/kg), B6 (100 mg/kg), B12 (2 mg/kg), B vitamin complex (VBC) containing vitamin B1, B6 and B12 (33/33/0.5 mg/kg) (for consecutive 7 days), respectively, significantly reduced the thermal hyperalgesia and the histological signs of inflammation. ELISA assay showed that B6 and VBC greatly suppressed the increased levels of IL-1β and TNFα. Repetitive treatment of B6 and VBC (7 consecutive days) inhibited the tendon injury-induced increase of levels of serine protease proteolytic activity and upregulation of expression of PAR2, trypsin and tryptase. This study indicates that B vitamins can relieve tendon injury-induced thermal hyperalgesia and its accompanied inflammation probably through inhibiting serine proteases activity and PAR2 activation.

Title: The small GTPase Ras mediates Epac-induced sensitization of rat sensory neurons

Authors: *B. SHARIATI[1,2], E. L. THOMPSON[2], R. WANG[2], G. D. NICOL[2,3], M. R. VASKO[2,3]
[1]Dept. of Pharmacol. and Toxicology, Indianapolis, IN; [2]Dept. of Pharmacol. and Toxicology, [3]Program in Med. Neurosciences, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Activation of a class of guanine nucleotide exchange factors (GEFs) known as exchange proteins directly activated by cAMP (Epacs) elicits hypernociception in animal models of pain presumably through a sensitizing effect on sensory neurons. However, the question remains as to the downstream signaling pathways in sensory neurons that mediate sensitization secondary to activation of Epacs. To address this question, we employed as endpoints of excitability the evoked release of calcitonin-gene related peptide (CGRP) and the number of action potentials (APs) generated in response to a ramp of depolarizing current. Pretreating sensory neurons with 3 μM of the acetoxymethyl-conjugated Epac agonist, 8-CPT-2'-O-Me-cAMP-AM (8CPT-AM) prior to and during a 30 nM capsaicin or 30 mM KCl stimulus augments the release of CGRP without affecting resting release. Relative to 3 μM of a PO_4AM_3 control, the 8CPT-AM compound increases capsaicin- and potassium-stimulated release of CGRP from 182 ± 9 to 284 ± 23 and 108 ± 7 to 240 ± 9 fmol/well/10 min, respectively. In current-clamp recordings where small-diameter sensory neurons are injected with a ramp of depolarizing current sufficient to elicit 2-4 APs under control conditions, superfusion with 3 μM 8CPT-AM over a 10 minute period increases the number of APs evoked by the ramp from 2.7 ± 0.4 to 9.5 ± 0.9. Internal perfusion with a pipette solution, wherein 3 mM of GDP-βS substitutes for 0.3 mM GTP, completely blocks sensitization produced by 3 μM 8CPT-AM. In contrast, the ability of 3 μM of the PKA agonist, N^6-Benzoyladenosine-3′,5′-cAMP-AM (6BNZ-AM) to augment AP number was unaffected by internal perfusion with GDP-βS. These data suggest that Epac-induced sensitization is a G-protein mediated phenomenon. Stable infection of isolated sensory neurons with a lentiviral (LV) construct containing the sequences to dominant negative Ras (DN-Ras), an internal ribosome entry site (IRES), and green fluorescent protein (GFP) also blocked the increase in AP firing produced by 3 μM 8CPT-AM, but did not block the increase in AP firing produced by 3 μM 6BNZ-AM**.** When small-diameter sensory neurons are internally perfused with 30 μg/mL of a Ras-neutralizing antibody over a 20 minute period, exposure to the Epac agonist does not augment the number of APs evoked by the ramp of current. Altogether, these data demonstrate that Epac-induced sensitization of sensory neurons is mediated by activation of the small GTPase, Ras.

Title: Tumor Necrosis Factor alfa rapidly modulates gating properties of tetrodotoxin-resistant sodium channels, leading to acute nociceptive hyperexcitability

Authors: S. GUDES[1,2], B. KATZ[1,2], S. LEV[1,2], *A. BINSHTOK[1,2]
[1]The Hebrew Univ. Med. Sch., Jerusalem, Israel; [2]The Edmond and Lily Safra Ctr. for Brain Sci., The Hebrew University of Jerusalem, Israel

Abstract: Sodium channels are key players in determining the input-output properties of peripheral nociceptive neurons. Changes in gating kinetics or in expression levels of sodium channels by proinflammatory mediators, lead to increased neuronal gain and to direct activation of nociceptors. These effects could account for the pain hypersensitivity observed during inflammation. Proinflammatory mediator tumor necrosis factor α (TNFα) is secreted during inflammation and is strongly associated with the rapid onset, as well as long lasting, inflammation-mediated increase in nociceptive excitability via its effect on sodium channels. However, the underlying mechanism of the rapid component of TNFα-mediated nociceptive hyperexcitability and acute pain hypersensitivity is still not fully unraveled. Here we show, that TNFα rapidly increases excitability of peripheral nociceptive neurons and leads to acute pain hypersensitivity in adult rats, via a complex modulation of nociceptive sodium channels. TNFα primarily affects the slow and persistent tetrodotoxin-resistant (TTX-r) fractions of the sodium current, but also moderately increases TTX-sensitive (TTX-s) currents. TNFα leads to increase in availability of TTX-r sodium channels by partial relief of voltage dependence of slow inactivation, via p38 mitogen-activated protein kinase (p38 MAPK), thereby increasing nociceptive gain. Furthermore, TNFα in a p38 MAPK-dependent manner, increases current density and shifts the activation of the persistent fraction of the TTX-r current in a hyperpolarized direction, producing a substantial inward current around the threshold potential. Thus, during acute inflammation, TNFα-mediated p38MAPK-dependent increase in the availability of TTX-r sodium channels modifies the excitability of peripheral nociceptive neurons.

Title: Tnfα is involved in paclitaxel-induced chemotherapy-induced painful peripheral neuropathy

Authors: *Z. WU[1], M. MATA[2], D. FINK[2]
[1]The Dept. of Neurol., [2]Dept. of Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: Treatment with the chemotherapeutic drug paclitaxel causes an early pain syndrome beginning shortly after the start of therapy and characterized by severe mechanical and cold allodynia followed later in the course with the development of neuropathy characterized by sensory loss. We have previously reported that paclitaxel administration to rats induces expression and release of soluble TNFα (sTNFα) in satellite cells of the dorsal root ganglion (DRG) through activation of the TLR4, and that activation of TNFR in DRG neurons by sTNFα results in increased expression of the pain-related ion channels TRPA1 and TRPV4. In the current study, we found that continued administration of paclitaxel (16mg/kg*)* for 5 weeks resulted in an increase in TNFα expression in the nerve that coincided with the emergence of electrophysiological abnormalities (decreased sensory nerve amplitude and reduced conduction velocity) and with increased in calpain activity in peripheral nerve. Expression of the soluble p55 TNF receptor in nerve *in vivo* using a herpes simplex virus-based vector blocked the increase in expression of TNFα and activation of calpain in sciatic nerve in paclitaxel animals, and prevented the reduction in sensory amplitude and conduction velocity. Taken together with our previous observation, the current results suggest that early entry of paclitaxel into DRG causes neuropathic pain by inducing expression of TRPA1 and TRPV4, while prolonged treatment results in nerve damage through induction of calpain activity. Both processes are triggered by paclitaxel activation of TLR4 in glial cells to trigger expression of TNFα.

Title: Effects of alpha-7 nicotinic positive allosteric modulator on mechanical allodynia and TNF-alpha following LPS-induced neuroinflammatory pain in mice

Authors: *M. ABBAS, S. RAHMAN
Pharmaceut. Sci., South Dakota State Univ., Brookings, SD

Abstract: Evidence indicates that inflammatory immune activation contributes to pathophysiology and maintenance of neuroinflammatory pain involving central nervous system alpha7 nicotinic acetylcholine receptors (nAChRs). Here, we examined the effects of TQS, an alpha7 nAChR positive allosteric modulator, on mechanical allodynia, hyperalgesia, tumor necrosis factor-α (TNFα) and norepinephrine (NE) following lipopolysaccharide (LPS)-induced neuroinflammation in mice. Pretreatment of TQS (1 or 4 mg/kg, i.p.) reduced LPS-induced increased mechanical allodynia in a dose-dependent manner. The effect TQS (4 mg/kg) was significantly ($p<0.05$) different from control. Similarly, pretreatment of TQS (1 or 4 mg/kg) significantly ($p<0.05$) reduced LPS-induced increased hyperalgesia in a dose-dependent manner. Furthermore, pretreatment of TQS (1 or 4 mg/kg) reduced LPS-induced increased TNFα level in hippocampus. In addition, pretreatment of TQS (1 or 4 mg/kg.) reversed the LPS-induced reduction of NE level in hippocampal tissue. Taken together, these results suggest that TQS decreases LPS-induced neuroinflammatory pain by modulating hippocampal TNFα and NE levels. Therefore, alpha-7 nicotinic positive allosteric modulatory site could be a potential target for the treatment of neuroinflammatory pain.

Title: Time-course of local release of inflammatory cytokines in a plantar incision model in rats

Authors: *M. A. MEDEIROS[1], N. M. SOUZA[2], L. L. CASTRO[2], F. A. VANDERLINDE[2]
[1]Physiological Sci., UFRRJ, Seropédica, Brazil; [2]Physiological Sci., Federal Rural Univ. of Rio de Janeiro, Seropédica, Brazil

Abstract: Postoperative pain is a common and unique form of acute pain and despite advances in their study, it remains undertreated. Tissue adjacent surgical incisions undergoes inflammation and nociceptive sensitization. Recent studies demonstrate that several cytokines may participate in the enhancement of nociception near these wounds. Thus, before analyze the time-course of local release of inflammatory cytokines in the plantar incision model in rats, we analyzed the pattern of thermal and mechanical hyperalgesia using the nociceptive tests of von Frey test and Hargreaves, respectively. Plantar incision surgery produced a reduction of the withdrawal thresholds in both tests from 1 hour to 96 hours after surgery. Therefore, we analyzed the local release of pro-inflammatory (IL-1β, IL-6 and TNF-α) and anti-inflammatory cytokines (IL-10 and IL-4) by chemiluminescence at 2, 6, 8, 24, 48, 72 and 96 hours after the plantar incision. Plantar incision surgery produced a significant increase in the concentrations of IL-1β and IL-6 six and 8 hours after incision. The concentrations of TNF-α were not statistically different from controls at any time-points studied. The concentrations of IL-10 significantly increased only 2 hours after incision. IL-4 was reduced 24 and 48 h after surgery. The maintenance of hyperalgesia does not appear to be associated with a sustained increase in the local concentrations of these cytokines. Different mechanisms and mediators must contribute to the maintenance of the hyperalgesia in this model of postoperative pain.

Title: TNF-alpha overexpression in the tooth pulp and root results in painful pulpitis

Authors: B. HALL[1], *E. UTRERAS PURATICH[2], M. PROCHAZKOVA[1], A. TERSE[1], J. DOLAN[3], A. KULKARNI[1]
[1]Natl. Inst. of Dent. and Craniofacial Res., Bethesda, MD; [2]Univ. of Chile. Fac. of Sci., Santiago, Chile; [3]New York Univ., New York, NY

Abstract: TNF-alpha is a proalgesic cytokine that is commonly expressed following tissue injury and inflammation, leading to pain hypersensitivity in nociceptors. Chronic inflammation in tooth pulp can cause painful pulpitis, and in bone an imbalance in bone formation and resorption that often results in bone loss. Considering the known link between TNF-alpha and inflammatory pain, we utilized a transgenic mouse to conditionally overexpress TNF-alpha in both odontoblasts and osteocytes in order to study oral pain that would result from subsequent development of pulpitis and bone loss. A transgenic mouse line was engineered that requires Cre-mediated recombination to overexpress TNF-alpha. These mice were bred with a Dentin Matrix Protein 1 (DMP1) Cre line to overexpress TNF-alpha in both tooth pulp and bone. The resulting mice show inflammation in tooth pulp that resembles pulpitis, as well as periodontal bone loss. We detected increased TNF-alpha in the mandible of these mice and active TNF-alpha signaling in both tooth and bone. In the tooth pulp and alveolar bone, inflammatory infiltrates were seen that were comprised of CD3+ lymphocytes and Mac2+ macrophages. Lastly, we were able to demonstrate masticatory dysfunction in these mice, which can indicate oral pain. Using this mouse model displaying these inflammatory disorders, we can dissect out the molecular changes within the primary afferent nociceptors that innervate teeth and bone that occur due to inflammatory pain signaling.

Title: Pharmacologic blockade of the cannabinoid enzyme monoacyglycerol lipase attenuates hyperalgesia induced by inflammatory arthritis

Authors: *S. R. NASS, S. G. KINSEY
West Virginia Univ., Morgantown, WV

Abstract: Rheumatoid arthritis (RA) is the most prevalent chronic inflammatory joint disease characterized by pain, stiffness, swelling, and breakdown of cartilage in synovial joints. Current RA analgesic treatments are ineffective or induce negative side effects. Cannabinoids have antihyperalgesic and anti-inflammatory properties; however, the challenge remains to harness the medical potential of cannabinoids without inducing negative psychomimetic effects. An alternative approach focuses on manipulating endogenously produced cannabinoids (i.e., endocannabinoids). The most prevalent endocannabinoid, 2-arachidonoyl glycerol (2-AG), is catabolized by the enzyme monoacylglycerol lipase (MAGL). Pharmacological inhibition of MAGL increases brain levels of 2-AG and significantly decreases acute inflammatory pain. The present study tested the hypothesis that MAGL inhibition decreases hyperalgesia, and pain suppressed behavior, caused by collagen-induced arthritis (CIA), a well-established animal model of inflammatory arthritis. To induce CIA, male mice were immunized with an emulsion of collagen and complete Freund's adjuvant. CIA causes arthritic symptoms (i.e. paw redness and swelling), and significantly decreases spontaneous locomotor activity. We investigated the antihyperalgesic and decreased pain suppressed behavioral effects of the selective MAGL inhibitor JZL184 on CIA-induced thermal hyperalgesia in the hotplate and tail immersion assays, and spontaneous locomotor activity, respectively. Thermal hyperalgesia was significantly attenuated by JZL184 (8 or 40 mg/kg, ip) on both the hotplate and tail immersion assays. The pain suppressed spontaneous locomotor activity was reversed by JZL184 (8 mg/kg, ip). These results suggest that MAGL inhibition may be a promising strategy for the treatment of pain caused by inflammatory arthritis.

Title: Effect of glutamate on carrageenan-induced acute pleurisy in rat

Authors: S. DAS[1], Z. ZHANG[1], M. B. ANDERSON[1], *K. S. CURTIS[2], K. E. MILLER[1]
[1]Dept. anatomy and Cell Biol., [2]Dept. Pharmacol & Physiol, Oklahoma State Univ. Ctr. For Hlth. Sci., TULSA, OK

Abstract: Carrageenan-induced pleurisy is a well-established model of acute inflammation yet the pleural innervation and its role in inflammations is not well studied. In this project we are interested to understand the pleural innervation and its modulation of acute pleurisy by the neurotransmitter glutamate pathway. Rat models of glutamate and carrageenan-induced acute pleurisy were investigated to study the effect of glutamate. Our preliminary results suggested an increase in total cell count (almost 10 fold) as well as total exudate volume (up to 3 ml) in carrageenan-induced pleurisy. The transcript levels of glutamatergic genes in dorsal root ganglia (DRG) T1-4, e.g., glutaminase (GLS), is down-regulated in carrageenan-induced pleurisy while in glutamate-induced pleurisy, there is no effect on GLS message levels. Vesicular marker, VGLUT2, is down-regulated in both glutamate-induced as well as carrageenan-induced pleurisy models. Aspartate aminotransferase (AST) message levels did not show any significant changes in either treatment. Exitatory amino acid transporter EAAT3 is upregulated in glutamate-induced pleurisy while in carrageenan-induced pleurisy, it is downregulated. We further investigated to characterize the effect of glutamate on carrageenan-induced pleurisy in rat models. In these rats, glutamate pretreatment increased the carrageenan-induced total cell count while glucocorticoid (GC) pretreatment reduced the total cell count. At the same time, the visceral pleural membrane was extracted by shaving the frozen-lung very superficially and total RNA as well as total protein was isolated from these samples. Preliminary data indicates that carrageenan-induced pleurisy rescues the glutamate- and GC-induced down-regulation of AST and GLS message levels in visceral pleura. Contrary to message levels, carrageenan attenuated the expression of AST and VGLUT proteins in both glutamate- and GC-induced pleurisy models. Glutamate treatment increased the expression of all glutamatergic marker proteins, VGLUT2, AST as well as PGP9.5. Visceral pleural extraction was also isolated from different locations of lung namely, apical, basal and interlobar. VGLUT2 protein expression did not show site specific expression except in glutamate treated animals; VGLUT2 expression was increased on inter-lobar sections. The same was true for neuronal marker PGP 9.5 and Peripherin. Our future directions aim at further characterizing the glutamate dose response and their respective inhibitors on these proteins and their respective pathways which guide the neuroimmunomodulation of innervation in acute pleurisy in rat models.

Title: Activity dependent upregulation of Cav3.2 channels by USP5 - implications for pain

Authors: ***P. STEMKOWSKI**, A. GARCÍA-CABALLERO, V. M. GADOTTI, L. CHEN, A. CHEN, N. D. BERGER, T. K. LAPOINTE, C. ALTIER, P. PODGORNY, G. ZAMPONI
Dept. of Physiol. and Pharmacol., Univ. of Calgary, Calgary, AB, Canada

Abstract: BACKGROUND: Cav3.2 T-type calcium channels are essential contributors to the transmission of nociceptive signals in the primary afferent pain pathway. In various pathological conditions linked to pain, including diabetic neuropathy, intestinal inflammation and nerve injury, Cav3.2 channel expression (and activity) in nociceptive neurons is upregulated. Our laboratory has shown that this aberrant T-type channel expression involved an interaction with USP5, a deubiquitinating enzyme highly expressed in dorsal root ganglion (DRG) neurons and whose action is to decrease ubiquitination of Cav3.2, thereby leading to greater T-type channel stability in the cell membrane. Since the enhanced association between USP5 and Cav3.2 channels occurs in response to peripheral inflammation or nerve ligation, we hypothesized that the increase in neuronal activity, common to both injuries, is critical to this process. To test this possibility, we have adopted a new optogenetic method that allows for the transcutaneous activation of nociceptors with light without physical injury (Daou et al., 2013; J. Neurosci. 33: 18631-18640). METHODS: Mice homozygous for the Rosa-CAG-LSL-ChR2(H134R)-EYFP-WPRE conditional allele (*loxP*-flanked STOP cassette) were crossed with mice that express cre recombinase in TRPV1 cells. Thermal thresholds to radiant heat were determined in F1 males (8 - 12 weeks old) before and 40-60 min following prolonged (10 min) transcutaneous stimulation of the right hindpaw with suprathreshold (10 mW/mm^2) blue light (473 nm) under 2.5% isoflurane-induced anaesthesia. The laser was pulsed at 10 Hz with light delivered through a 200

μm fibre optic cannula at a distance of 0.5 cm from the plantar surface. The non-stimulated left hindpaw served as an internal control. Mice were then euthanized and L5 DRG harvested for a co-immunopreciptiation assay where Cav3.2 immunoprecipitates were probed for USP5 binding. RESULTS: We observed an ipsilateral 70% decrease hindpaw withdrawal latency to radiant heat (n=3), along with a 2.5 fold increase in binding of USP5 to Cav3.2 channel protein in L5 DRG (n=2). CONCLUSION: Neuronal activity in the absence of peripheral injury is sufficient to activate USP5 dependent enhancement of Cav3.2 channel activity. This in turn may reduce the firing threshold of afferent fibers, leading to a prolonged increase in neuronal excitability and thus a self-propagating sensitization. Although this scenario may involve the release of mediators, these experiments have the propensity to identify a novel form of activity-dependent plasticity in the primary afferent pain pathway.

Title: Hyperphosphorylation of Kv3.4 channels in DRG neurons as a putative mechanism of peripheral pain sensitization induced by spinal cord injury

Authors: *B. ZEMEL, T. HALA, A. LEPORE, M. COVARRUBIAS
Thomas Jefferson Univ., Philadelphia, PA

Abstract: The high-voltage activated A-type Kv3.4 channels are robustly expressed in dorsal root ganglion (DRG) neurons, where they regulate spiking and the repolarization of the action

potential (AP) in putative nociceptors (Ritter et al., J Physiol, 2012). The effects on AP repolarization depend on direct slowing/elimination of Kv3.4 fast inactivation following protein kinase C (PKC) activation. In addition, persistent PKC activation induces slow downregulation of the Kv3.4 current in heterologous cells and DRG neurons (unpublished). Calcineurin inhibition accelerates this downregulation. These modulations phenocopy changes induced by spinal cord injury (SCI) in putative rat DRG nociceptors exhibiting increased proportions of small (<16 pA) and slow inactivating currents. It is therefore possible that these changes are in part responsible for the SCI-induced hyperexcitability of the nociceptors and the associated pain sensitization (Ritter et al., submitted). Suggesting a peripheral mechanism of pain sensitization in SCI, we hypothesize that hyperphosphorylation of Kv3.4 channels might play a significant role in the SCI-induced hyperexcitable state of DRG neurons. The SCI-induced downregulation does not result from changes in gating, transcription, splicing and translation (Ritter et al. submitted). Consistent with Kv3.4 internalization, anti-Kv3.4 immunostaining demonstrated reduced surface expression in DRG neurons from SCI rats. Interactions between Kv3.4, PKC and related signaling molecules are further supported by the membrane-delimited nature of the elimination of Kv3.4 fast inactivation upon activation of G-protein coupled receptors in DRG neurons suggesting the presence of a Kv3.4 signaling microdomain (Ritter et al., J Physiol, 2012). Accordingly, immunostaining and confocal imaging demonstrated colocalization of Kv3.4 with the calcineurin α-subunit and PKCγ. To further probe the signaling microdomain hypothesis, we will present AKAP79/Kv3.4/PKC/calcineurin colocalization studies and high-resolution stimulated emission depletion (STED) imaging. We will also report validation of these results by co-immunoprecipitations and electrophysiology. Based on these studies, the current working hypothesis proposes that SCI promotes PKC activation and/or calcineurin inhibition, which renders Kv3.4 channels hyperphosphorylated and primed for internalization.

Title: Facilitation of hyperpolarization-activated cyclic nucleotide-gated channel by Prostaglandin E1 in dorsal root ganglion neurons in mice

Authors: *S. LEE, P. CHO, I. AN, S. JUNG
physiology of department department medicine of college Hanyang university, Physiol. of Dept. Dept. Med. of Col. Hanyang Univ., Seoul, Korea, Republic of

Abstract: Facilitation of hyperpolarization-activated cyclic nucleotide-gated channel by Prostaglandin E1 in dorsal root ganglion neurons in mice Sang Hoon Lee, Pyung Sun Cho, In Kyung An, Sung Jun Jung Department of Biomedical Science, Graduate School of Biomedical Science & Engineering, Hanyang University Hyperpolarization-activated cyclic nucleotide-gated (HCN) ion channels and their current, I_h have been suggested to play an important role in neuropathic pain by involvement in spontaneous ectopic discharges after peripheral nerve injury. Prostaglandin E1 (PGE1) has been well known as a therapeutic agent for lumbar spinal stenosis in clinical fields. The present study investigated the cellular action of PGE1 on HCN channel in primary dissociated neurons of dorsal root ganglion (DRG) in mice and pain behavioral responses. Amplitude of I_h increased about 130% by PGE1 in a dose-dependent manner in the medium-sized (30 - 40 μm) DRG neurons. Adenylyl cyclase inhibitor and 8-Br-cAMP inhibited the facilitation of I_h current by PGE1. EP2 receptor antagonist inhibited the facilitation of I_h induced by PGE1. Exposure of HCN-expressing DRG neurons to PGE1 increase in action potential frequency. In behavioral test, hind paw injection of PGE1 to hindpaw reduced the threshold to mechanical stimuli, indicating allodynia. In addition, PGE1-induced allodynia was blocked by CsCl and EP2 antagonist. In conclusion, PGE1 facilitated I_h current in medium-sized DRG neurons in mice, which was mediated by EP2 receptors that transmit a signal to adenylyl cyclase and increase the intracellular concentration of cAMP. Exposure to PGE1 would control action potential firing by enhancing their excitability in HCN-expressing DRG neurons. This molecular mechanism might be associated with PGE1-induced allodynia. Title: Participation of cation channels in the peripheral pronociceptive effect induced by hydrogen sulfide in hyperglycemic rats

Authors: *J. E. ROA-CORIA[1], F. FLORES-MURRIETA[1,2], V. GRANADOS-SOTO[3], H. ROCHA-GONZÁLEZ[1]
[1]Sección de Estudios de Posgrado e Investigación, Superior Sch. of Med. IPN, México, D.F., Mexico; [2]Inst. Nacional de Enfermedades Respiratorias, Mexico, D.F., Mexico; [3]Cinvestav Sede-Sur, Mexico, D.F., Mexico

Abstract: Hydrogen sulfide (H2S) is considered a gasotransmitter that produces a pronociceptive effect in several pain models, but little is known about the molecular targets involved in such effect. The aim of this study was to establish the participation of TRPV1, TRPA1, ASIC, T-type calcium and L-type calcium channels in the nociception induced by H2S in peripheral neuropathy associated with diabetes. Hyperglycemia was induced by streptozotocin (50 mg/kg, ip) in Wistar rats, which had values of glucose >350 mg/dL within 3 weeks. Nociception was assessed by injection of 0.5 % formalin into the right hind paw of the rat. Local peripheral ipsilateral, but not contralateral, injection of H2S (3-100 µg/paw) increased nociceptive behavior in a dose-dependent manner. Moreover, pronociceptive effect of H2S was prevented by local administration of capsazepine (TRPV1 receptor antagonist; 3,10µg/pata), HC-030031 (TRPA1 receptor antagonist; 316,1000 µg/paw), mibefradil (T-type calcium channel blocker; 0.3,10 µg/paw), amiloride (ASIC blocker; 0.001,0.1 µg/paw) or bezamil (ASIC blocker; 0.0001,0.01 µg/paw), but not amlodipine (L-type calcium channel blocker; 1,30 µg/paw). These data suggest that the local pronociceptive effect induced by H2S in rats with peripheral neuropathy could be mediated by activation of TRPV1,TRPA1, ASIC and T-type calcium channels, so the use of blockers of these channels may be a useful strategy to treat painful peripheral neuropathy associated with diabetes.

Title: Increased expression of Nav1.7, TRPV1 and Peizo2 channels contribute to the diabetes-induced hyperexcitability of dorsal root ganglion neurons

Authors: *M. E. O'LEARY[1], C. HO[2]
[2]Biomed. Sci., [1]Cooper Med. Sch., Camden, NJ

Abstract: The hindpaws of STZ-treated diabetic rats display increased sensitivity to thermal and mechanical stimulation consistent with the development of neuropathic pain. To further characterize the underlying mechanisms we used a combination of electrophysiology and single-cell RT-PCR to investigate changes in ion channel function and expression in small-diameter (<25 μm) sensory neurons isolated from dorsal root ganglia (DRG). In response to supra-threshold stimulation, the neurons of diabetic rats displayed a parallel increase in the frequency of action potential firing and TTX-S Na^+ current amplitude. Single-cell analysis of potential TTX-S Na^+ channel isoforms revealed a selective increase in Nav1.7 mRNA in the neurons of diabetic rats that correlated with the observed increased Na^+ current. Auxiliary β subunits are known to regulate voltage-gated Na^+ channels and altered expression could also contribute to changes in Na^+ currents. Although β_1 and β_4 were found to predominate in small-diameter neurons their expression was not altered by diabetes. A piezoelectric probe was used to directly apply mechanical stimulation to the neuronal cell bodies. The peak mechanical currents measured in diabetic neurons were 2-fold larger than those of controls. Transcript analysis of this population revealed a significant increase in Piezo2 expression but no change in TRPA1. Screening revealed that TRPV1 was the predominant thermosensitive TRPV channel present in small-diameter neurons and its mRNA was upregulated in neurons of diabetic rats. Increased expression of TRPV1 is further supported by an increase in the capsaicin-activated currents in this population of neurons. These findings suggest that the upregulation of TTX-S Nav1.7, mechanotransducing Peizo2 and thermosensitive TRPV1 channels in small-diameter sensory neurons contribute to the increased mechanical and thermal sensitivity of diabetic rats.

Title: Expression of alpha-2-delta-1 subunit at the lumbar spinal cord in spinal cord injury rats

Authors: K. KUSUYAMA[1], *T. TACHIBANA[1], H. YAMANAKA[2], K. NOGUCHI[2]
[1]Orthopaedic Surgery, [2]Anat. and Neurosci., Hyogo Col. of Med., Nishinomiya, Japan

Abstract: Spinal cord injury (SCI) commonly results not only in motor paralysis but also in the emergence of neuropathic pain, both of which can impair the quality of life of SCI patients. In clinical fields, it is well known that pregabalin, which binds to the voltage-gated calcium channel alpha-2-delta-1 subunit (Cava2d-1) has therapeutic effect on neuropathic pain after SCI. Previous study has demonstrated that SCI increased Cava2d-1 in L4-6 dorsal spinal cord of SCI rats demonstrated by Western blot and that the increase of Cava2d-1 was correlated with tactile allodynia of the hind paw. However, the mechanisms of effects of pregabalin on SCI-induced neuropathic pain are poorly understood. In this study we examined the cellular distribution of Cava2d-1 expression in L4-6 spinal cord of SCI rats using immunohistochemistry. Spinal cord contusion injury was produced in male Sprague- Dawley rats (180-200 g). Rats were anesthetized by intraperitoneal pentobarbital administration and the lamina of the T10 vertebrate was then removed. A contusion injury was generated using the IH impactor devise that emulates a 100-kilodyne weight-drop onto the dura mater from a distance of 3-4 mm(N=5). Sham control rats received laminectomy without the contusion injury (N=5). During pentobarbital anesthesia, perfusion fixation was performed using 1-4% paraformaldehyde and 0.1 M phosphate buffer solution (at pH 7.4) and the spinal cord (L4-6) was removed. The transverse sections were cut and processed for immunohistochemistry. Quantitative analysis was performed by NIH image software. Locomotor function recovery post SCI was monitored using the Basso, Beattie, and Bresnahan locomotor rating scale (BBB scale). Following SCI, the BBB scale was 2.4±0.6 at day 1, and increased to 12.4±0.6 four weeks after SCI, indicating the improvement of motor function. In the naïve rats we detected the expression of Cava2d-1 immunoreactivity mainly in lamina I and II in the dorsal horn. SCI significantly increased Cava2d-1 immunoreactivity in lamina I and II in the dorsal horn at four weeks after SCI significantly. These findings suggested that increase of Cava2d-1 in the L4/5 of dorsal horn after thoracic SCI was involved in the development of neuropathic pain in hindlimb. The increase of Cava2d-1 in superficial dorsal horn after SCI may be related to the pregabalin's effect on central neuropathic pain.

Title: Role of NaVβ4 regulatory subunit and resurgent current in development of pathological pain

Authors: W. XIE[1], Z. TAN[2], C. M. BARBOSA-NUNEZ[2], *J. A. STRONG[1], T. R. CUMMINS[2], J.-M. ZHANG[1]
[1]Dept Anesthesiol, Univ. Cincinnati, CINCINNATI, OH; [2]Dept Pharmacol & Toxicol, Indiana Univ. Sch. Med., Indianapolis, IN

Abstract: Abnormal spontaneous activity (SA) of sensory neurons plays a key role in many pain models. We previously showed that local inflammation of the L5 DRG (LID) causes mechanical and cold hypersensitivity and increases high frequency bursting SA in medium/large cells with high conduction velocities. Many neurons that express the Na channel isoform NaV1.6 pore-forming subunit have resurgent Na currents, which allow high frequency firing. *In vivo* knockdown of NaV1.6 with siRNA completely blocks pain behaviors and abnormal SA induced by LID. In expression systems, NaV1.6 does not exhibit resurgent currents, which in some neurons require the regulatory NaVβ4 subunit. We examined the role of NaVβ4 in the LID model. siRNA directed against NaVβ4, or nontargetting control siRNA, was injected into the L4 and L5 DRG in rats at same time of L5 DRG inflammation. Knockdown was verified with immunohistochemistry. NaVβ4 but not control siRNA reduced or abolished mechanical hypersensitivity (von Frey test) and allodynia (cotton wisp stroke test) on all days tested (POD1 - 28). Cold allodynia (acetone test) was not affected. Electrophysiological effects were first examined in isolated whole DRG with microelectrode current clamp. Cells were classified as C (unmyelinated), or A (myelinated) based on conduction velocity. On POD 3, SA incidence in A cells from NaVβ4 siRNA treated inflamed DRG was only 6.5%, similar to normal uninflamed DRG, reduced from 24% in inflamed DRG treated with control siRNA. DRG inflammation also reduced the rheobase and increased the fraction of cells showing multiple action potentials or subthreshold oscillations in response to supratheshold currents; these effects were largely blocked by NaVβ4 siRNA. Few effects of DRG inflammation or NaVβ4 siRNA were observed in C cells. Next, whole-cell patch clamp methods were used to record resurgent and transient Na currents in medium-sized DRG neurons (diameter: 35-45 μm) acutely cultured from normal DRG or DRGs isolated 3 days after local inflammation. In neurons with predominantly TTX-S

Na current, the transient current increased 27% after inflammation, resurgent current increased by 50%, and the ratio of resurgent to transient current increased 24%. In neurons with combined TTX-S and TTX-R currents (which generally lack TTX-S resurgent current), the TTX-S transient current density after LID was increased by 28% while the TTX-R transient current density was not altered. The results are consistent with a key role of spontaneous repetitive firing, and suggest that NaVβ4 mediated resurgent currents may play an important role in the hyperexcitability observed in this pain model.

Title: Roles of Acid-Sensing Ion Channels in neuropathic pain induced by experimental autoimmune encephalomyelitis

Authors: *I.-C. WANG[1], C.-H. LEE[2], S.-H. LIN[2], C.-Y. CHUNG[2], F. LIAO[2], C.-C. CHEN[2]
[1]Dept. of Life Science, Natl. Taiwan Univ., Taipei, Taiwan; [2]Inst. of Biomed. Sciences, Academia Sinica, Taipei, Taiwan

Abstract: Multiple Sclerosis (MS) is an inflammatory demyelinating disease in which neuropathic pain is now recognized as one of the major symptoms. To date, the underlying mechanism of neuropathic pain in MS is still a mystery. Previous studies have shown that tissue acidosis is induced by inflammation in a MS animal model. Furthermore, it's known that acidosis activates acid-sensing ion channels (ASICs) on the nociceptors. However, the relationships between ASICs and neuropathic pain in MS animal model remain unclear. Therefore, we hypothesize that ASICs may play a role in pain development in MS. We utilize experimental autoimmune encephalomyelitis (EAE), a well-established MS rodent model, to assess clinical deficits, mechanical response and pathological alterations in different ASIC subtypes knockout mice. All of the mice showed clinical deficits and mechanical hypersensitivity after EAE induction. Also, pathological studies demonstrated that dorsal root ganglion (DRG) neurons are injured after EAE induction by staining with neuron injury marker, ATF3. These results suggested that peripheral nerve may participate in the nociceptive

hypersensitivity in EAE. Moreover, analgesic drug application indicated that EAE-induced neuropathic pain is modulated by ASIC3 mediated anti-nociceptive pathway.

Title: Discovery of a novel T-type calcium channel blocker for the treatment of neuropathic pain

Authors: *Y. HIRAI[1], T. KAWAZU[1], K. YASUTAKE[1], M. ADACHI[2], T. NAITOH[1], D. IKEGAMI[3], M. NARITA[3,4]

Industries, Ltd., Funabashi-shi, Chiba, Japan; [3]Dept. of Pharmacology, Sch. of Pharm., Hoshi Univ., Tokyo, Japan; [4]Life Sci. Tokyo Advanced research center (L-StaR), Tokyo, Japan

Abstract: T (transient)-type calcium channels (TCCs) are low-voltage activated channels that open during a small depolarization of the cell membrane, which allows them to function at near-resting membrane potentials. TCCs are expressed in dorsal root ganglia (DRG), dorsal horn of the spinal cord and thalamus which related to pain signals. The excitability of the sensory neurons in DRG and dorsal horn caused by abnormal burst firing, has a critical function for hyperalgesia and allodynia. In diabetic neuropathy and the chronic nerve injury model of neuropathic pain, TCC current density is increased, and gene knockout or antisense knockdown of the Cav3.2 isoform, one of 3 subunits of TCCs, results in hyposensitivity to pain due to reduced excitability of neurons. Efonidipine is a dihydropyridine calcium channel blocker discovered by Nissan Chemical Industries, Ltd. We have investigated that efonidipine (racemate) blocks both TCC and L-type calcium channels (LCC), and R(-)efonidipine is reportedly a potent T-type calcium channel blocker (TCCB). We revealed that intrathecal administration of R(-)efonidipine reduced neuropathic pain behaviors, i.e., thermal hyperalgesia and mechanical

allodynia in the partial sciatic nerve ligation (Seltzer) model mouse. To further discover novel TCCBs, we conducted a high-throughput screening (HTS) campaign. Nissan Chemical's original focused library including about 20,000 small molecular compounds was assayed based on calcium influx assay using human Cav3.2 over-expressing HEK293 cells. Several active compounds (IC_{50} < 1 μM) were hit, and one of them was efficacious for the Seltzer model by intraperitoneal administration (30 mg/kg). Using these hit compounds, we started to perform optimization research for TCCB through SAR to improve their potency, selectivity, and effect in the formalin model. Finally, we discovered P11520031, a selective TCCB (IC_{50} for TCC: 0.20 μM, IC_{50} for LCC: 2.8 μM), which suppressed pain behaviors in the formalin test (55% inhibition @10 mg/kg p.o.) with no significant motor dyscoordination in the modified Irwin test (100 mg/kg p.o.). In conclusion, we eventually discovered a novel TCCB, which may be considered as a promising analgesic.

Title: Thrombospondin-4 increase mediates disruption of intracellular calcium signaling in injured primary sensory neurons

Authors: *Y. GUO[1], H.-E. WU[1], Z. LUO[2], Q. HOGAN[1], B. PAN[1]
[1]Dept. of Anesthesiol., Med. Col. of Wisconsin, Milwaukee, WI; [2]Dept. of Pharmacol., Univ. of California Irvine, Irvine, CA

Abstract: Painful nerve injury disrupts calcium signaling in primary sensory neurons, including loss of sarco-endoplasmic reticulum Ca^{2+}-ATPase (SERCA) function, elevated plasma membrane Ca^{2+}-ATPase (PMCA) function and decreased endoplasmic reticulum (ER) Ca^{2+} storage. In the neuropathic pain model of spinal nerve ligation, expression of the extracellular matrix glycoprotein thrombospondin-4 (TSP4, non-glycosylated form) is increased, and TSP4 blockade can reverse or prevent behavioral hypersensitivity after SNL. TSP4 can decrease

calcium currents (I_{Ca}) through high-voltage-activated calcium channels and increase I_{Ca} through low-voltage-activated calcium channels in dorsal root ganglion (DRG) neurons, which mimic the change in axotomized peripheral sensory neurons. This study examines whether TSP4 can cause the disrupted levels of cytoplasmic and stored Ca^{2+} in primary sensory neurons that happened after injury. Concentration of intracellular calcium in dissociated DRG neurons was measured by microfluorometry (Fura-2). We find that TSP4 enhanced the store operated calcium entrance function, inhibited the SERCA function, accelerated the PMCA function and depleted calcium store in ER. Taken together, these findings indicate that TSP4 changes calcium signaling similar to that which happens in DRG neurons after injury, which suggests that TSP4 elevation may contribute to the pathogenesis of neuropathic pain.

Title: Discovery and characterization of novel, potent and selective P2X4 receptor antagonists for the treatment of pain

Authors: *C. A. BOWEN[1], J. NEWCOM[1], W. YANG[1], M. ORSINI[1], L. HARDY[1], L. SCARABOTTOLO[2], A. DI SILVIO[2], J.-F. ROLLAND[2], F.-Y. ZHAO[3], H. WEI[3], D. C. SPANSWICK[3,4], T. LARGE[1]
[1]Sunovion Pharmaceuticals Inc., Marlborough, MA; [2]Axxam SpA, Milan, Italy; [3]NeuroSolutions Ltd., Coventry, United Kingdom; [4]Warwick Med. School, Univ. of Warwick, Coventry, United Kingdom

Abstract: Purinergic P2X4 receptors (P2X4R) are trimeric, ATP-activated cation channels that are widely distributed anatomically. Preclinical data indicate roles for P2X4R on CNS microglia and peripheral macrophages, respectively, in neuropathic and inflammatory pain. Consequently, P2X4R antagonists may be beneficial for the treatment of these pain conditions. Few potent and selective P2X4R antagonists have been described previously, and nonselective purinergic antagonists are reported to show species differences at P2X4R. Therefore, a campaign was

initiated to identify novel, potent and selective small-molecule antagonists that inhibit P2X4R across species and that have effects in multiple experimental pain models. Compounds were discovered which displayed a wide range of *in vitro* antagonist potencies (IC_{50}: <1 nM to >1 uM) with similar activities on human, mouse and rat P2X4R using FLIPR and electrophysiology assays, suggesting pharmacological similarities across species. Potent compounds were advanced into mouse models of neuropathic pain or peripheral inflammation after demonstrating selectivity against a broad panel of targets, including other P2X receptor subtypes. To assess potentially discrete roles of P2X4R in the CNS and periphery, two compounds (Compound 1: 280 nM and Compound 2: 12 nM IC_{50}) with low CNS exposures were chosen for further evaluation *in vivo*. Single intrathecal administration of Compound 1 at 3 and 10 nmol/5 uL selectively and significantly increased withdrawal thresholds of ipsilateral paws in a mouse spinal nerve ligation model, indicating a spinal anti-allodynic action. Repeated intraperitoneal dosing of Compound 2 at 100 mg/kg significantly attenuated intraplantar carrageenan-induced prostaglandin E2 concentrations, suggestive of peripheral anti-inflammatory action. In summary, novel, potent and P2X4R-selective small-molecule antagonists were discovered. Importantly, these molecules displayed similar *in vitro* potencies across species. Finally, two of these highly selective P2X4R antagonists demonstrated activity in experimental models of neuropathic pain or peripheral inflammation. Our data strongly support the hypothesis that P2X4R inhibition holds therapeutic promise for both centrally and peripherally mediated pain.

Title: Sigma-1 receptor regulates sarco-endoplasmic reticulum Ca2+-ATPase and store-operated Ca2+ entry activity in axotomized sensory neurons

Authors: *H.-E. WU[1], Y. GUO[1], B. PAN[1], Q. HOGAN[2]
[2]Anesthesiol., [1]Med. Col. Wisconsin, Dept. Anesthesiology, Res. M4280, MILWAUKEE, WI

Abstract: Activation of the sigma-1 receptor (s1R) diminishes I_{Ca} and intracellular Ca^{2+} stores, which are also features of axotomy of primary sensory neurons, suggesting that sR1 actively regulates intracellular Ca^{2+} in painful nerve injury. The sarco-endoplasmic reticulum Ca^{2+}-ATPase (SERCA), plasma membrane Ca^{2+}-ATPase (PMCA), and store-operated Ca^{2+} entry (SOCE) are three critical pathways by which sensory neurons maintain cytoplasmic Ca^{2+} homeostasis. We therefore examined whether s1R activation modulates activity-induced cytoplasmic Ca^{2+} ($[Ca^{2+}]_c$) transients via regulating SERCA, PMCA or SOCE in injured sensory neurons. Sensory neurons were dissociated from dorsal root ganglia (DRGs) and recorded with Fura-2 microfluorometry. (**A**) SERCA function was isolated by blocking PMCA with pH8.8 bath solution and limiting mitochondrial Ca^{2+} buffering by evaluating small K^+-induced transients (35mM, 0.5s, without transient shoulder) in low bath Ca^{2+} (0.25mM). In uninjured neurons, s1R blocker BD1063 (10microM) and agonist (PTZ, 100microM) had no effect compared to vehicle.

Injured neurons (ligation of 5th lumbar spinal nerve, SNL) had slowed transient recovery (increased tau), which was further prolonged by BD1063 (10microM). (**B**) PMCA function was isolated by blocking SERCA with thapsigargin (TG, 1microM). Although injury slowed SERCA function (prolonged tau), there was no effect of BD1063 or PTZ on uninjured or injured neurons. (**C**) SOCE function was examined by Ca^{2+} readdition with bath change (0 to 2mM). A greater increase in $[Ca^{2+}]_c$ upon Ca^{2+} readdition was seen in injured neurons after BD1063 treatment compared with vehicle-treated neurons, indicating amplified SOCE function. These findings indicate that sR1 activity supports SERCA and SOCE function after injury, but has no affect on PMCA of injured neurons.

Title: A novel T-type calcium channel blocker P11520031 is effective for neuropathic pain without CNS-linked side effects

Authors: *Y. HAMADA[1], D. IKEGAMI[1], A. HAMADA[1], Y. HIRAI[2], T. KAWAZU[2], M. NARITA[1,3]
[1]Dept.pharmacology, Hoshi Univ., Tokyo, Japan; [2]Pharmaceut. Res. Dept., Biol. Res. Lab., Nissan Chem. Industries, Ltd., Saitama, Japan; [3]Life Sci. Tokyo Advanced research center (L-StaR), Tokyo, Japan

Abstract: Recently, we newly synthesized a triazinone-derivatived T-type channel blocker (P11520031, IC50 = 0.20 ± 0.02 μM, calcium influx assay in hCav3.2/HEK293). We investigated the analgesic effect and the CNS-related side effects of P11520031 compared to pregabalin using the neuropathic pain model. Systemic administration of P11520031 (3, 10, 30, 100 mg/kg, p.o.) dose-dependently reduced neuropathic pain behaviors, i.e., mechanical allodynia and thermal hyperalgesia in PSNL (Seltzer's) model. Administration of P11520031 (3, 10 mg/kg, p.o.) also significantly reduced oxaliplatin-induced peripheral neuropathic pain. Next, we investigated the effect of P11520031 on somnolence and dizziness, known as adverse effects of pregabalin. In order to evaluate sleep liability, we analyzed electroencephalogram (EEG) and electromyogram in mice administered with pregabalin or P11520031. Analysis of EEG showed

that pregabalin at 10 mg/kg (p.o.) had a sleep-promoting profile with increased non-rapid eye movement (non-REM) and decreased wakefulness, whereas, P11520031 at 10 mg/kg (p.o.) had no effect on non-REM and wakefulness. In order to evaluate the effect on motor coordination, we performed the beam-walking test in rats. Administration of pregabalin (30 mg /kg, p.o.) prolonged the walking time and increased slipping counts, whereas P11520031 even at 100 mg/kg (p.o.) did not affect them. In conclusion, oral administration of P11520031 significantly reduced the neuropathic pain-like state without CNS-related side effects in rodents. These results suggest that this novel TCCB may be an attractive anti-neuropathic pain agent with better pharmacological profiles than pregabalin.

Title: Thrombospondin-4 elevates sensory neuron excitability by decreasing N-type and increasing T-type calcium currents

Authors: *B. PAN[1], Z. LUO[2], Q. H. HOGAN[1]
[1]Dept. of Anesthesiol., Med. Coll Wisconsin, MILWAUKEE, WI; [2]Departments of Anesthesiol. and Perioperative Care, Univ. of California, Irvine, CA

Abstract: Changes in both high-voltage–activated (HVA) and low-voltage–activated (LVA) calcium channels in primary sensory neuronsmay contribute to the generation of chronic neuropathic pain, and could be valuable targets for the development of novel analgesic drugs. Loss of HVA current and gain of LVA current cause elevated excitability in primary sensory neurons. Expression of the extracellular matrix glycoprotein thrombospondin-4 (TSP4, non-glycosylated form) in dorsal root ganglion (DRG) is increased after injury, and TSP4 blockade can reverse or prevent behavioral hypersensitivity after injury.TSP4 can decrease calcium currents (I_{Ca}) through HVA calcium channels and increase I_{Ca} through LVA calcium channels in DRG neurons, which mimic the change in axotomized peripheral sensory neurons.We therefore

investigated whether TSP4 regulates excitability of dorsal root ganglion neurons. We find that TSP4 decreased action potential generation following high frequency depolarization stimuli and both N-type and T-type calcium channel blockers attenuated TSP4's effect. In the neuropathic pain model of spinal nerve ligation, TSP4 application did not further increase the elevated excitability of injured DRG neurons. Taken together, these findings indicate that TSP4 elevation following peripheral nerve injury contributes to hypersensitivity of peripheral sensory systems by decreasing HVA and increasing LVA I_{Ca} in DRG neurons, making TSP4 in peripheral sensory neurons a potential target for analgesic drug development for neuropathic pain.

Title: Differential activation of cutaneous sensory neurons by optical activation of keratinocytes

Authors: *P. C. ADELMAN, K. M. BAUMBAUER, J. J. DEBERRY, R. H. MILLER, B. M. DAVIS, K. M. ALBERS, H. R. KOERBER
Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: It has long been hypothesized that keratinocytes could play a significant role in the transduction of cutaneous stimuli. In order to test this hypothesis we developed a transgenic mouse model expressing channelrhodopsin-2 (ChR2) in keratinocytes by crossing Ai32 mice expressing ChR2 driven by the Rosa-26 promoter (ChR2-EYFP) with K14- keratin Cre mice. These mice exhibited robust expression of the EYFP tagged ChR2 in basal keratinocytes and hair

follicles of hairy skin and basal and suprabasal keratinocytes of glabrous skin. In addition intense staining was also found in Merkel Cells. Behavioral testing revealed that 10 applications of blue light (473nm; 39.7mW; 30s) per mouse elicited nocifensive responses in approximately 30% of the applications. This stimulation never evoked these responses in control groups (i.e. K14 Cre, Ai32 or WT). We next used an *ex vivo* skin/nerve/DRG/spinal cord preparation to record from individual cutaneous sensory neurons and characterize their sensitivity to mechanical and thermal stimuli. Fiber conduction velocities and the responses to natural stimuli were used to identify different types of nociceptors (e.g. CMH - C-fiber responding to mech., heat and cold stimuli). Next blue light (39.7mW; 5-10s) was applied to the cell's receptive field to determine whether keratinocyte activation elicited action potential (AP) firing in the nociceptive fiber. If no response was elicited, we paired blue light stimulation and natural stimuli (mechanical or thermal) to determine if keratinocyte activation potentiated responses in the nociceptive fibers. We found that keratinocyte activation elicited either suprathreshold or subthreshold responses in most types of cutaneous nociceptors. These included both C-fibers (CMH (5/5), CMHC (6/6), CH (4/7), CM (1/1), CMC (1/1), but not in CC (0/2) or CLTMR (0/1) and A-fiber nociceptors (A-HTMR (7/14)). Interestingly keratinocytes evoked responses in both polymodal nociceptors (mechanical and thermal) as well as those responding to a single modality. For A-LTMR fibers only the SA1 population responded to blue light stimulation. These results show that light activation of epidermal keratinocytes alone produces APs in multiple types of cutaneous sensory neurons, demonstrating that sensory transduction mechanisms may also reside in skin keratinocytes.

Title: Optogenetic control of neuromodulator release from keratinocytes

Authors: *R. H. MILLER, K. M. BAUMBAUER, P. C. ADELMAN, H. R. KOERBER, B. M. DAVIS, K. M. ALBERS
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Recent studies have shown that the skin releases neuroactive substances that influence cutaneous afferent activity. Many of these substances, such as adenosine triphosphate (ATP), calcitonin gene related peptide (CGRP), acetylcholine, glutamate and neurotrophic growth factors are produced by epidermal keratinocytes. Evidence suggests these compounds directly and indirectly modulate the activity of sensory fibers that innervate the skin. Keratinocytes also express ligand gated and voltage-gated ion channels and growth factor/cytokine receptors, suggesting complex autocrine and paracrine signaling between epithelial and neural tissues. To advance understanding of the mechanisms regulating keratinocyte-neuronal communication we developed an optogenetic mouse model in which the light activated cation channel channelrhodopsin (ChR2) is targeted to K14 keratin expressing keratinocytes. Interestingly, K14-ChR2 mice exhibited nocifensive behaviors in response to blue light stimulation of the skin. Using an *ex vivo* skin-nerve preparation we found light activation of the skin also elicited action potentials (APs) in cutaneous sensory neurons. To investigate how activation of keratinocytes stimulates AP firing in sensory afferents, we established cultures of primary keratinocytes from K14-ChR2 expressing mice in order to assay neuroactivator release in response to light stimulation. We first measured the level of ATP, a neuroactivator released from keratinocytes that modulates afferent firing via activation of purinergic receptors. Results show that ChR2 activation results in a significant increase in ATP release following a brief (5s) blue light exposure. These findings suggest ATP contributes to the keratinocyte driven AP firing in afferents of K14-ChR2 mice.

Abstract: Approximately 1/3 of the U.S. population suffers from a chronic orofacial/headache pain condition. Trigeminal neuropathic pain is one such unilateral orofacial pain syndrome characterized by constant aching and burning thought to be caused by unintentional injury or vascular mechanical irritation of the trigeminal nerve. Patients with this type of pain are currently treated with analgesics combined with anticonvulsants and/or antidepressants due to their anxiety related to pain. However, these drugs are proving to be unsatisfactory in relieving pain. The proposed studies demonstrate alleviation of chronic neuropathic orofacial pain- and anxiety-like behaviors by administering peroxisome proliferator-activated receptor gamma (PPARγ) agonist, pioglitazone (PIO), and NMDA receptor (NMDAR) partial agonist, D-Cycloserine (DCS) in the Trigeminal Inflammatory Compression (TIC) injury mouse model we devised to mimic chronic neuropathic orofacial pain. PIO is FDA approved as Actos® for treatment of Type II diabetes. Recent studies show that this drug is effective in reducing inflammation and other types of neuropathic pain. Likewise, DCS is FDA approved under the name Seromycin® as a broad spectrum antibiotic for tuberculosis which coincidentally also has unique binding ability for the glycine binding site of NMDAR. Studies show that DCS reduces hypersensitivity as well as anxiety through an NMDAR blocking mechanism in pre-limbic forebrain in certain neuropathy models. However, PIO and DCS have never been used to treat orofacial pain. Our findings determined that Pioglitazone and D-cycloserine each reduce trigeminal neuropathic pain in mice when administered solely and have a super additive effect when combined.

Title: The effects of repeated forced exercise and/or caffeine on analgesia and analgesic tolerance

Authors: *J. W. PICKEL, V. SVYSTUN, G. PHANEUF, M. SHIELDS, E. GAUMER, J. A. SCHROEDER
Connecticut Col., New London, CT

Abstract: Caffeine containing supplements are widely and repeatedly used by athletes to enhance performance and resist fatigue. Caffeine has also been shown to be an effective analgesic adjuvant. In the current study, for ten consecutive days, rats received caffeine (5, 7.5 or 10 mg/kg, ip) or saline 5 minutes prior to being subjected to a 10 minute forced swim or no exercise. Tail flick nociception was measured at 15 (immediately post-swim), 30 and 45 minutes post injection. Results suggest that exercise alone significantly enhances analgesia immediately after swimming, however the effect dissipated by 15 minutes following exercise. Tolerance to exercise's analgesic effect did not develop over the course of ten days. Caffeine administered at 5.0 mg/kg did not enhance exercise induce analgesia. Preliminarty data suggests that higher doses of caffeine acts synergistically with exercise to enhance analgesia to tail flick nociception.

Title: Optogenetic tools for control of primary afferent neurons

Authors: *S. M. IYER[1], S. R. YOUNG[1], C. GORINI[1], K. L. MONTGOMERY[1], H. SCUTT[2], A. J. CHRISTENSEN[3], C. RAMAKRISHNAN[1], K. DEISSEROTH[1], S. L. DELP[1]
[1]Bioengineering, [2]Mechanical Engin., [3]Electrical Engin., Stanford Univ., Stanford, CA

Abstract: Primary afferent neurons are critical to how we perceive the world, mediating sensations ranging from touch to pain. Optogenetic tools have been used to great effect in controlling primary afferent sensory neurons, using both transgenic and virally mediated approaches. We have previously reported how intra-sciatic injections of AAV6-hSyn-ChR2-eYFP and AAV6-hSyn-NpHR3.0-eYFP may be used to optogenetically stimulate or inhibit pain perception respectively (Iyer, Montgomery, et al. 2014). The wide diversity of viral tropisms exhibited by adeno-associated viral vectors indicates that other AAVs may potentially be used to enable virally mediated optogenetic control over different classes of primary afferent neurons. We discuss preliminary results following intra-sciatic injection of scAAV8-CMV-GFP, which demonstrate that AAV8 transduces a largely non-overlapping set of primary afferent neurons when compared with AAV6. Neurons transduced by AAV8 project to the deep laminae in the dorsal horn of the spinal cord, send central projections rostrally through the dorsal columns in the spinal cord, and have large-diameter cell bodies and myelinated peripheral projections. We describe the immunohistological profile of these transduced neurons and effects of optogenetic activation of these neurons. We then extend our attempts to optogenetically control primary afferent nociceptors. We describe how the bicistronic vector AAV6-hSyn-NpHR-p2A-ChR2-eYFP may be used to achieve bidirectional control over pain perception through co-expression of ChR2 and NpHR in nociceptors in the same animal. Future studies using virally delivered ChR2 to optogenetically stimulate primary afferent nociceptors will require improved characterization of ChR2 expression. We describe dose-response curves for AAV6-hSyn-ChR2-eYFP injections, and discuss how sufficiently high titer viral injections (~1e11 vg) achieve persistent expression as late as 12 weeks following injection, while also characterizing the immune response that results from AAV6 injection.

Title: Exposure of early-life stress changes smechanical allodynia and depression-like behavior following nerve injury in mice

Authors: *T. NISHINAKA, K. NAKAMOTO, S. TOKUYAMA
Dept. of Clin. Pharm., Kobe Gakuin Univ., Kobe, Japan

Abstract: Early life stress has recently been reported to be involved in the pathogenesis of psychiatric disorders and chronic pain in adult life. Maternal separation or deprivation is a widely used model of early life stress and induces abnormal behavior, such as an anxiety- or depression-like behavior in the adulthood of the offspring. In rats, maternal separation or deprivation has been shown to induce the change in the pain sensitivity and enhance the mechanical allodynia after nerve injury. However, there is a lack of information about the effect of early life stress on the pain modulation system in mice. In the present study, we evaluated the effect of early life stress on the pain sensitivity and mechanical allodynia induced by nerve injury in male and female mice. Furthermore, since chronic pain has been reported to induce emotional dysfunction, such as anxiety and depression, we evaluated the impact of early life stress on the emotional dysfunction after nerve injury. Maternal separation and social isolation (MSSI) used as early life stress. Mice were separated from dam and littermate for 6 h per day during postnatal days 15-21 and then were housed individually until the end of study. In 7 weeks of age, an anxiety-like behavior was evaluated by elevated plus maze test. In 9 weeks of age, the sciatic nerve was partially ligated to elicit neuropathic pain. Mechanical sensitivity and nerve injury-induced mechanical allodynia was evaluated by using von Frey test. Depression-like behavior was evaluated by using forced swim test at 3 weeks after nerve injury. Results revealed that in the elevated plus-maze test, anxiety-like behavior was enhanced in only female mice with MSSI. The von Frey test showed that the MSSI had no effect on mechanical sensitivity before nerve injury. However, nerve injury-induced mechanical allodynia in ipsilateral paw was enhanced by MSSI in male and female mice. Furthermore, the increasing response to mechanical stimulation in contralateral paw is observed in MSSI male and female mice. The forced swim test showed that depression-like behavior is observed in stressed female mice after nerve injury. Our findings suggested that neuropathic pain was exacerbated by MSSI in adult male and female mice. Overall, this mouse model may be useful for the understanding of the molecular mechanisms underlying the reciprocal relationship between early life stress and chronic pain.

Title: Cholinergic mechanism in posterior hypothalamus: Affects on neural activity in the forebrain and animal behavioral responses to noxious stimuli

Authors: *Z. WANG, M. ARIFFIN, S. KHANNA
Natl. Univ. of Singapore, Singapore, Singapore

Abstract: It has been proposed that the posterior hypothalamus is part of an arousal system. Indeed, acutely inactivating different areas of the region, including the supramammillary nucleus (SuM), attenuates electrophysiological indices of hippocampal and cortical information processing, prevents behavioral arousal during general anesthesia and prolongs the duration of anesthetic effect. Interestingly, we have earlier reported that cholinergic manipulation of the lateral SuM region (lSuM), affects neural activity in the dorsal hippocampus field CA1. In the present study, we have investigated whether (a) cholinergic activation of lSuM affect index of neural activity in cortex and hippocampus, and (b) alters animal behavioral responses to salient/affective stimuli. Using the induction of c-Fos, a transcription protein, as marker of synaptic excitation, we observed that unilateral microinjection of the cholinergic agonist, carbachol (0.156μg/μl, 0.1μl), into the lSuM region in anesthetized animals evoked a robust neuronal activation in ipsilateral cortex, and an increase in the hippocampus and the dentate gyrus. In experiments in awake animals, microinjection of cholinergic nicotinic-receptor antagonists, mecamylamine (2μg/μl, 0.1μl), into the lSuM on left partly attenuated nociceptive behaviors to hind paw injection of the algogen, formalin, into the contralateral hind paw. Thus, a decrease in nociceptive flinching, but not licking was observed in the 2nd phase of the formalin test. The cholinergic muscarinic-receptor antagonist, atropine (0.0068μg/μl, 0.1μl), however had no effect on nociceptive behaviors. Crucially, trends suggest that mecamylamine microinjected into the lSuM region also attenuates peripheral hypersensitivity in the contralateral hind paw in the complete Freund adjuvant (CFA) model of persistent inflammatory pain. However, mecamylamine did not affect reflexive withdrawal per se. Collectively the foregoing data (a)

points to a potential for cholinergic transmission in posterior hypothalamus in the mediation of neural activity in forebrain areas and (b) suggests that nicotinic-cholinergic mechanisms in the region modulate affective-motivational behaviors and tissue damage-induced peripheral hypersensitivity. The peripheral hypersensitivity is suggested to reflect an interaction between the external stimuli and the intrinsic state of brain activity (i.e. responsivity salience) that is altered due to the pain state.

Title: Inhibition of anandamide hydrolysis reduces nociceptor sensitization through CB1 receptors in a murine model of chemotherapy-induced peripheral neuropathy

Authors: *M. L. UHELSKI[1], C. HARDING-ROSE[2], D. SIMONE[2]
[1]Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Painful chemotherapy-induced peripheral neuropathy (CIPN) is the major dose-limiting side effect of chemotherapy, which impacts the efficacy of therapy for patients who are unable to tolerate increasing doses. In addition, many patients continue to experience neuropathic symptoms for months or years after treatment has ended. The mechanisms underlying neuropathic pain due to chemotherapy has been explored in animal models. The platinum compound cisplatin produces mechanical, heat, and cold hyperalgesia in rodents and is associated with damage to primary sensory neurons. Cisplatin has been shown to sensitize nociceptors, evidenced by an increase in spontaneous discharge among both Aδ- and C-fiber nociceptors and an increase in evoked responses. Cannabinoids and drugs that inhibit hydrolysis of endocannabinoids reduce neuropathic pain, including pain from CIPN. Here we examined the effects of URB597, which inhibits the breakdown of anandamide by FAAH, on sensitized C-

fiber nociceptors following cisplatin treatment. Male C3H/HeJ mice (n = 53) received daily IP injections of cisplatin (1mg/kg) for 7d prior to electrophysiology experiments. A 10µl injection of URB597 (9µg, n = 19) or vehicle (n = 14) was administered into the receptive field of well-isolated, sensitized C-fibers. The CB1 and CB2 antagonists AM281 (10µg, n =10) and AM630 (10µg, n = 6), respectively, were administered 5 min prior to URB597 in order to determine the contribution of each receptor subtype to the drug effect. Fibers treated with URB597 demonstrated significant attenuation of spontaneous discharge (from 0.20±0.04 Hz to 0.03±0.01 Hz at 2 hr post-injection), an increase in response thresholds (from 19.6±6.9 mN to 147.1±54.0 mN at 2 hr post-injection), and a decrease in responses evoked by a standard suprathreshold mechanical stimulus (147 mN force; from 44.5±6.4 impulses to 8.2±2.7 impulses at 2 hr post-injection). These changes were mediated by CB1 receptors, as shown by inhibition of these effects in fibers pre-treated with AM281 but not AM630. These results provide evidence that the antihyperalgesic effect of URB597 demonstrated in behavior studies is mediated by effects of CB1 receptor activation. Continued research into the mechanisms underlying the involvement of the peripheral endocannabinoid system in the attenuation of cisplatin-induced hyperalgesia could contribute to the identification of novel targets for the treatment of chronic pain in CIPN patients.

Title: Optimization of a cisplatin model of chemotherapy-induced peripheral neuropathy in mice: Use of vitamin C and sodium bicarbonate pretreatments to reduce nephrotoxicity and improve animal health status

Authors: *J. GUINDON[1], L. DENG[2], B. FAN[2], J. WAGER-MILLER[2], A. G. HOHMANN[2]
[1]Dept. of Psychological and Brain Sci., [2]Indiana Univ., Bloomington, IN

Abstract: Background: Cisplatin, a platinum-derived chemotherapeutic agent, produces antineoplastic effects coupled with toxic neuropathic pain and impaired general health status. These side-effects complicate long term studies of neuropathy or analgesic interventions in animals. We recently demonstrated that pretreatment with sodium bicarbonate (4% $NaHCO_3$) prior to cisplatin (3 mg/kg i.p. weekly up to 5 weeks) was associated with improved health status (i.e. normal weight gain, body temperature, creatinine and ketone levels, and kidney weight ratio) in rats (Guindon et al., 2013). To reduce the nephrotoxic effects of cisplatin treatment in mice, we compared pretreatments with sodium bicarbonate (4% $NaHCO_3$ s.c.), vitamin C (25 mg/kg s.c.), resveratrol (25 mg/kg s.c.) and saline (0.9 % NaCl). **Results:** Cisplatin-treated mice receiving saline pretreatment exhibited elevated ketone, creatinine and kidney weight ratios, representative of nephrotoxicity. Vitamin C and sodium bicarbonate lowered creatinine/ketone levels and kidney weight ratio whereas resveratrol normalized creatinine levels and kidney weight ratios similar to saline pretreatment. All pretreatments were associated with decreased ketone levels compared to saline pretreatment. Cisplatin-induced neuropathy (i.e. mechanical and cold allodynia) developed equivalently in all pretreatment groups and was similarly reversed by either morphine (6 mg/kg i.p.) or ibuprofen (6 mg/kg i.p.) treatment. RT-PCR showed that mRNA levels for IL-1β were increased in lumbar spinal cord of cisplatin-treated groups pretreated with either saline, $NaHCO_3$ or resveratrol/cisplatin-treated groups. However, IL-6 and TNF-alpha were elevated in the kidneys in all cisplatin-treated groups. Our studies also demonstrate that 60 days after the last cisplatin treatment, body weight, body temperature, kidney functions and mRNA levels have returned to baseline although the neuropathic pain (mechanical and cold) is maintained. **Conclusions:** Studies employing cisplatin should include $NaHCO_3$ or vitamin C pretreatment to improve animal health status and reduce nephrotoxicity (lower creatinine and kidney weight ratio) without affecting the development of chemotherapy-induced neuropathy or analgesic efficacy.

Title: *In vitro* electrophysiological screening with dorsal root ganglion neurons for pain related assays

Authors: A. M. NICOLINI, M. W. BROCK, C. M. ARROWOOD, *D. C. MILLARD
Axion Biosystems, Atlanta, GA

Abstract: The sensation of pain is transmitted from nociceptive nerve endings to the central nervous system along axons of neurons in the dorsal root ganglion (DRG). Damage to these primary afferents, or inherited defects in the proteins underlying their electrical or sensory function, can cause neuropathic pain, a persistent sensation of pain caused by increased spontaneous activity of DRG neurons. Pain research has thus far been predominantly based on animal models, in part due to a lack of predictive *in vitro* screening methods. The development of a high throughput *in vitro* assay for pain thus stands to significantly impact the discovery of therapies for chronic pain. Here, we present a non-invasive technique for directly monitoring electrical responses in commercially-available rat primary DRG neurons cultured in 12- and 48-well microelectrode array (MEA) plates. PEI-Laminin coating of the MEA wells yielded excellent cell adhesion, clear neurite outgrowth, and a low rate of spontaneous action potential spikes between days 3 and 10 post-plating. Increased spike activity in DRG neurons could be reproducibly evoked with temperature changes, electrical stimulation, and application of the TRPV1 agonist capsaicin, demonstrating that cultured neurons recapitulate characteristic *in vivo* nociceptor electrophysiological phenotypes. Consistent with *in vivo* function, individual neurons displayed sensitivity to different temperature ranges, including cold, heat, and noxious heat. The response to capsaicin contained transient and persistent components, was dose-dependent, and could be blocked by the TRPV1 antagonists DHEA or capsazepin, illustrating the utility of this assay for screening potential pain inhibitors. In summary, we present an *in vitro* MEA-based model of nociceptor function that exhibits characteristic electrophysiological phenotypes and has applications in pain research and drug screening.

Title: Development and characterization of a primate model of central post stroke pain

Authors: K. NAGASAKA[1,2], I. TAKASHIMA[2], K. MATSUDA[2], *N. HIGO[2]
[1]Grad Sch. Comp Human Sci., Univ. of Tsukuba, Tsukuba, Japan; [2]Systems Neurosci Group, Human Tech. Res. Inst, AIST, Tsukuba, Japan

Abstract: Central post stroke pain (CPSP) occurs after damage in the somatosensory system of the brain including thalamus. CPSP-induced allodynia, in which innocuous stimuli perceived as painful, decreases the quality of life of the affected patients. The development of animal models of CPSP is essential to investigate the underlying mechanisms. Animal models of thalamic CPSP are recently developed in rodents (Wasserman and Koeberle, 2009, Neuroscience 161, 173-183; Hanada et al., 2014, Neuroscience Research, 78, 72-80), while the model using nonhuman primates is also a favorable model to understand neural structures and circuits involved in the production of CPSP because of its close similarity with humans. Therefore, we attempted to establish a nonhuman primate model of thalamic CPSP using macaque monkeys. The location of ventral posterolateral nucleus (VPL) of the thalamus was determined by magnetic resonance imaging (MRI) and extracellular recording of neuronal activity during a tactile stimulation. Collagenase type IV, a proteolytic enzyme, was then injected to induce a hemorrhagic lesion in the identified VPL. T2- MRI imaging and histological analysis using Nissl staining confirmed that the lesion is localized to a small region within VPL. A mechanical withdrawal test using von Frey filaments showed a significant attenuation of the withdrawal threshold in the hand contralateral to the lesion at several weeks after the lesion. A thermal stimulation test also showed a significant decrease in the withdrawal latency to the thermal stimulation of 50℃. These changes lasted for at least 3 months after the lesion induction. The behavioral analyses indicated that both tactile and thermal allodynia were induced in the VPL-lesioned monkey. In addition, we investigated the brain areas with significantly increased activities for thermal stimulation at 50℃ compared with control thermal stimulation at 37℃ using functional MRI (fMRI). The fMRI analysis indicated that the thermal stimulation at 50℃ showed significantly increased activity in the cortical areas that are identical to those observed in the fMRI investigations of CPSP patients,

such as the primary (S1) and secondary somatosensory cortices (S2) and the insular cortex of the lesional hemisphere. The present CPSP model using macaque monkey is useful for studying plastic changes of neural structures and activities that underlie CPSP, especially those occurred in the cortical neurons after thalamic hemorrhage.

Title: Mentha Piperita (peppermint) anti-nociception: Measurement in rats in the hotplate assay of the nociception

Authors: ***W. MICHNO**, E. P. WIERTELAK
Neurosci. Studies, Macalester Col., Saint Paul, MN

Abstract: Mentha piperita (peppermint), a cross-hybrid of Mentha Aquatica (water mint) and Mentha Spiciata (spearmint), is an aromatic herbaceous plant from the Labiatae family that for centuries has been used in folk medicine for the treatment of various disorders. Peppermint has been shown to possess anti-microbial, anti-fungal, and anti-inflammatory properties; possible anti-nociceptive properties of peppermint have also been suggested. The main constituent of the plant, menthol, is often used to counteract pain, typically due to its cooling effect, however peppermint oil has also reduced symptoms of post-herpetic neuralgia. Previous work in mice suggests dosages 200mg/kg and 400mg/kg of peppermint solutions (either ethanol extraction or decoction) produce an anti-nociceptic effect to thermal stimulation. The present study aimed to investigate whether peppermint exhibits the same anti-nociceptive properties in rat models of nociception. The fresh plant was first air-dried away from sunlight, then freeze-dried; the handpicked and selected for quality leaves were then extracted with 99.5% ethanol. Animals received either of the two dosages that have been shown to be effective in mice, or vehicle, using a blinded method. Nociceptive sensitivity was tested via the hotplate assay of nociception. Animals receiving either of the dosages exhibited significantly longer latencies in the hotplate test compared to controls. Further studies employing the five main bioactive constituents of the plant are ongoing; elucidation of the nociceptive effect of peppermint and the underlying nociceptive circuitry involved might lead to novel treatments for the control of pain in humans.

Title: Kappa-Opioid receptor agonist analgesia and antianxiety: Effects of Salvinorin A in rat

Authors: ***E. P. WIERTELAK**, S. A. ANDERSON, Jr., H. C. GEMRICH, T. M. NICHOLS-MEADE, S. SANGGAARD
Neurosci. Studies, Macalester Col., SAINT PAUL, MN

Abstract: Salvinorin A is the main active component of Salvia Divinorum, a plant indigenous to Oaxaca, Mexico. The subjective effects of S. Divinorum are described as being akin to lysergic acid diethylamide (LSD) and other classical hallucinogens that interact with the serotonin 5-HT2A receptor subtype. However, Salvinorin A does not interact with this receptor (Listos et al., 2011). Therefore, Salvinorin A can be defined as a structurally unique, non-nitrogenous, highly selective kappa opioid receptor (KOR) agonist (Roth et al, 2002). Results from various studies exemplify a range of effects similar to known KOR agonists, although reports of analgesia from Salvinorin A have been somewhat varied and collectively limited (McCurdy et al., 2006). Braida et al. (2009) found no dose-dependent effects of Salvinorin A in the Elevated Plus Maze, which tests for anxiety. Their results suggest that Salvinorin A could possess a slight anxiolytic effect. This present study expands upon previous work by testing the analgesic and anxiolytic effects of Salvinorin A on rats using the hot plate, tail-flick, formalin and Elevated Plus Maze assays at three different dosages of Salvinorin A: 0.25 mg/kg, 0.50 mg/kg, and 0.75 mg/kg. Significance was found in open-arm time between the control and 0.50 mg/kg and between 0.50 mg/kg and 0.75 mg/kg. Behaviorally, rats given the 0.50 mg/kg dosage exhibited exploratory activity, as opposed to the 0.75 mg/kg, which induced hypolocomotion and avoidance of the open-arms. These results suggest that 0.50 mg/kg of Salvinorin A has a significant anxiolytic effect in rats. Studies of the potential analgesic effects are currently ongoing. In the future, Salvinorin A could serve as a template for non-addictive opioids, provided dose-dependent dysphoria and hallucinations are eliminated. More research needs to be done to understand the mechanisms behind Salvinorin A, in order to utilize its possible anxiolytic and analgesic therapeutic effects.

Title: Use of a light dark choice paradigm for defining migraine like pain in mice after mast ell degranulation

Authors: ***T. L. YAKSH**, R. RAMACHANDRAN
Univ. California, LA JOLLA, CA

Abstract: Background: Photophobia leading to light-averse behavior is commonly reported by migraineurs during acute attacks and, to a lesser degree, between attacks. Therefore as an alternative to the measurement of tactile thresholds, we sought to assess the development of light aversive behavior in mice as a surrogate of photophobia. **Methods:** Mice (male and female, C57Bl6) were placed in a test system composed of two equally sized chambers. Animal could move freely between the two chambers through a small portal. One chamber was exposed to light from the top (100 lux) while the other chamber was completely dark. The animals were acclimatized for 20 min in the chamber one day before testing. On the day of testing, mice were tested for 10 min prior to the injection with saline or the drug i.p. Following saline/drug administration, animals were tested for 10 mins at different time points (15 min, 1 hr, 2 hrs and 4 hrs). The following parameters were tested using the software: 1) Time spent in the light and dark box 2) Transition of animals from dark to light. Presence and time spent in each chamber was assessed by the obscuration by the animal of red light LEDs. On test day, mice received i.p injections of vehicle (control), the NO donor sodium nitroprusside (1 mg/kg) or the mast cell degranulating agent compound 48/80 (2mg/kg) which has been shown to induce a prolonged state of excitation in primary afferent nociceptors followed by activation of second order neurons. **Results:** After adaptation, the animal's relative time in the light / dark chambers was approximately 40/60 at each time point. After the injection of sodium nitroprrusside, the relative time spent in the light dark chamber over the 4 hrs period did not differ from saline control. In contrast, after compound 48/80, there was a significant decrease in the time spent in the light

chamber and a reduction in the number of crossing between the light dark chamber through 2 hrs with a complete reversal to the 40/60 ratio by 4 hrs but not the longest time points. **Significance:** These findings suggest the utility of the mouse in the light averse behavioral end point. (RR fellowship funded by Migraine research foundation).

Title: Different types of ROS are involved in opposing forms of synaptic plasticity in the spinal cord

Authors: *J. JUN, J. WANG, A. BITTAR, K. CHUNG, J. M. CHUNG
Neurosci. and Cell Biol., Univ. of Texas Med. Br., Galveston, TX

Abstract: The synaptic plasticity in the spinal dorsal horn neurons is an important factor producing central sensitization and thus pain. Our previous studies demonstrated that the direction of synaptic plasticity in dorsal horn neurons in response to nociceptive inputs are cell-type specific by showing long term potentiation (LTP) in spinothalamic track neurons (STTn) and long term depression (LTD) in GABAergic neurons (GABAn). We also demonstrated reactive oxygen species (ROS) are critically involved in both forms of synaptic plasticity. We hypothesize that the opposing forms of neuronal plastic changes are due to the involvement of different types of ROS - superoxides in LTP in STTn and hydroxyl radicals in LTD in GABAn. To test this hypothesis, the effects of specific ROS scavengers are examined on the LTP in STTn and the LTD in GABAn by using whole-cell patch-clamp recordings. From young naïve mice (GAD67-GFP mice, FVB-Tg(GadGFP)45704Swn/J; male, 2-3 week old), spinal cord slices are prepared and excitatory postsynaptic currents (eEPSCs) are recorded from identified STT and GABA neurons. The test stimuli (0.5 ms, 30-70μA) and the afferent conditioning stimuli (ACS; 2Hz for 40 sec, 80 pulses, 30-70μA) with a holding potential of +30mV) are applied to the dorsal root entry zone. GABAn are identified by green fluorescent in GAD67-GFP mice. STTn are identified by labeling with FAST-DiI, a retrograde tracer which was injected into the thalamus.

Three different types of ROS scavengers were used: a superoxide scavenger, TEMPOL (1mM); two hydroxyl radical scavengers, dimethyl sulfoxide (DMSO, 100mM) and dimethylthiourea (DMTU, 20mM). The scavengers were applied through the perfusion solution. LTD is consistently induced in GABAn following ACS application. Pretreatment with DMSO or DMTU prevented development of LTD after ACS. Furthermore, an application of TEMPOL also blocks LTD development in GABAn. In STTn, LTP is consistently induced following ACS. While an application of TEMPOL blocks LTP development in STTn, either DMSO or DMTU had no effect on LTP development in STTn. The results indicate that development of LTP in STT neurons requires the presence of superoxides but not hydroxyl radicals. On the other hand, the development of LTD in GABA neurons depends on both superoxides and hydroxyl radicals. Hydroxyl radicals in GABA neurons could have originated from superoxides. In summary, the results indicate that the different types of ROS may determine the direction of synaptic plasticity in spinal dorsal horn neurons: superoxides on LTP in STTn and both superoxides and hydroxyl radicals on LTD in GABAn.

Title: Treatment of neuropathic pain with a highly selective monoclonal antibody targeting sodium channel NaV1.7

Authors: *R.-R. JI[1,2], J.-H. LEE[3], C.-K. PARK[1], G. CHEN[1], R.-G. XIE[1], S.-Y. LEE[3]
[1]Pain Res. Division, Anesthesiol., Duke Univ. Med. Ctr., Durham, NC; [2]Neurobio., [3]Biochem., Duke Univ., Durham, NC

Abstract: Human genetic evidence from both gain-of-function and loss-of function studies suggests a critical role of voltage-gated sodium (NaV) channel subtype 1.7 (NaV1.7) in human pain sensation. Furthermore, NaV1.7 is expressed by nociceptor neurons in dorsal root ganglion (DRG) and their central terminals in the spinal cord dorsal horn. Thus, NaV1.7 represents one of the most attractive targets for pain medicine. However, it has been a real challenge to develop specific therapeutics against NaV1.7, due to high sequence homology among the nine NaV subtypes. Instead of using a traditional small molecule screening method, we have come up with a unique strategy of developing monoclonal antibodies (mAbs) to target a previously unexplored voltage sensor paddle of NaV1.7 channels. We have successfully raised a monoclonal antibody (SVmab1) that not only inhibits NaV1.7 with high selectivity in isolated heterologous cells but also effectively (70-300 nM) suppresses transient and persistent sodium currents and action potentials in isolated small-sized DRG neurons. Furthermore, application of SVmab1 to spinal cord slices inhibits excitatory synaptic transmission (spontaneous EPSCs) in lamina II neurons. In contrast, the control antibody targeting different domains of NaV1.7 (CTmab) had no effects on sodium currents and EPSCs. Interestingly, SVmab1 is more effective in suppressing persistent sodium currents and EPSCs in a mouse model of neuropathic pain following chronic constriction injury (CCI). Systemic injection of SVmab1 (50 mg/kg, i.v.) attenuated CCI-induced mechanical allodynia for 24 hours. Intrathecal injection of SVmab1 (50 μg) also reduced CCI-induced neuropathic pain. Taken together, our data suggest that NaV1.7-targeting monoclonal antibody (SVmab1) can attenuate neuropathic pain via both peripheral and central mechanisms. Given the specificity and long-lasting effects of monoclonal antibody therapies, humanized NaV1.7-targeting monoclonal antibody could be developed for treating neuropathic pain as well as other chronic pain conditions.

Title: Preserved antinociceptive efficacy following chronic administration of a brain impermeant inhibitor of the anandamide hydrolyzing enzyme fatty-acid amide hydrolase (FAAH) in a mouse model of chemotherapy-induced peripheral neuropathy

Authors: *R. SLIVICKI[1], L. DENG[2], A. HOHMANN[2]
[1]Psychological and Brain Sci., Indiana Univ., Bloomington, ; [2]Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: We recently reported that Δ9-tetrahydrocannabinol (THC), the major psychoactive ingredient in cannabis, produces anti-allodynic efficacy in a model of chemotherapy-induced peripheral neuropathy induced by paclitaxel treatment in mice (Deng et al. (2014) Biological Psychiatry, in press). However, with repeated dosing, tolerance developed to anti-allodynic efficacy of the cannabinoid. By contrast, inhibitors of the endocannabinoid hydrolyzing enzyme fatty-acid amide hydrolase (FAAH) exhibit antinociceptive efficacy in animal models of chronic pain without producing cardinal signs of CB1 receptor activation. Previously, our lab showed that inhibition of FAAH can reverse behavioral sensitivities to mechanical and cold stimulation in a neuropathic pain state induced by administration of the chemotherapeutic agent cisplatin (Guindon et. al (2013) Pharmacol Res. 67: 94-109). In the present study, we asked whether efficacy of a peripherally restricted FAAH inhibitor would be preserved following chronic administration in a mouse model of chemotherapy-induced neuropathy induced by paclitaxel. Paclitaxel induces a neuropathic pain state when administered systemically and produces behavioral hypersensitivities to both mechanical and cold stimulation. Acute treatment with URB937 produced a long duration of anti-allodynic efficacy that was maintained for at least 4 h following administration of the drug. URB937 suppressed paclitaxel-induced hypersensitivity to both mechanical and cold stimulation and normalized cold responsiveness to pre-paclitaxel levels. Moreover, anti-allodynic efficacy of URB937 was preserved throughout the chronic dosing regimen, suggesting that tolerance did not develop to the therapeutic effects of peripheral FAAH inhibition. Finally, the CB1 antagonist rimonabant (10 mg/kg i.p.) did not precipitate CB1-dependent withdrawal signs in animals subjected to chronic dosing with URB937. Our results suggest that inhibition of FAAH outside the central nervous system produces preserved anti-allodynic efficacy without unwanted CNS side-effects in a mouse model of paclitaxel-induced neuropathic pain.

Title: Paclitaxel sensitizes trpv1 via activation of tlr4 contributing to chemotherapy induced peripheral neuropathy

Authors: *Y. LI, H. ZHANG, A. K. KOSTURAKIS, P. M. DOUGHERTY
MD ANDERSON CANCER CENTER, Houston, TX

Abstract: Peripheral neuropathy is dose limiting in cancer chemotherapy with paclitaxel and can often induce persistent pain and discomfort in cancer survivors. This project tested the hypothesis that chemotherapy agents produce this side effect by sensitization of TRPV1 through Toll-like receptor 4 signaling. Immunohistochemistry showed that TLR4 is expressed in TRPV1 positive DRG sensory neurons and western blot studies showed that membrane TRPV1 in DRG and spinal cord is increased in rats treated with paclitaxel. TRPV1 sensitization in DRG neurons was evaluated using calcium imaging and whole cell patch clamp recordings in dissociated DRG neurons. Perfusion of paclitaxel directly activated DRG neurons in both types of experiments and showed an acute sensitization of TRPV1 via a TLR4-mediated mechanism in naïve rats. Moreover, paclitaxel significantly sensitized TRPV1 to capsaicin measured by calcium image and dissociated DRG patch clamp. In paclitaxel treated rats, the acute sensitization of capsaicin evoked increases in intracellular calcium accumulation and inward currents by paclitaxel co-administration was not apparent, but capsaicin responses alone were sensitized and did not show desensitization with repeated application as observed in vehicle treated rats. Paclitaxel-induced behavioral hypersensitivity to mechanical stimuli was prevented and reversed by systemic administration of a TRPV1 antagonist (AMG9810). In summary, Toll-like receptor (TLR) 4 is activated by paclitaxel and leads to sensitization of TRPV1. This mechanism could contribute paclitaxel-induced painful neuropathy.

Title: Dorsal root ganglia transcriptome profile of early painful diabetic neuropathy in a rat model of type-i diabetes

Authors: *M. P. ATHIÉ[1], A. S. VIEIRA[2], F. C. PRADO[1], E. V. DIAS[1], C. A. PARADA[1]
[1]Biol. Institute, Estructural and Functional Biol. Dept., [2]Med. Genet. Dept., Univ. Estadual De Campinas, Campinas, Brazil

Abstract: Peripheral Diabetic Neuropathy (PDN) manifests in 50-60% of types I and II diabetic patients and is the major cause of limb amputation. Although electrophysiological and morphological aspects are well described, little is known about its development and progression, undermining effective therapies. Hyperglycemia and insulin signaling impairment are considered the triggering events of oxidative stress production observed in the dying nerves. Several hypotheses try to explain the phenomenon, but until now there are many gaps in the pathogenesis and the plastic changes it generates. Transcript changes can help understand the plethora of symptoms and molecular events observed in DPN. We studied a rat model for type I diabetes, treated with low-dose of Streptozotocin to explore, by Next-Generation Sequencing of transcriptome, the main pathways and molecules differentially expressed in dorsal root ganglia (DRG) cells in early painful diabetic neuropathy. Glucose concentration and an electronic analgesimeter were used detect diabetes onset and the first modifications in mechanical sensitivity during 28 days after drug injection in STZ-treated rats and its respective controls. RNA from L4 and L5 DRG was submitted to transcriptome sequencing at Illumina HiSeq2500 System. STZ treatment induced hyperglycemia already in day 3, which persisted throughout the duration of experiment, while mechanical hypersensitivity started to appear two weeks after first STZ injection. Although transcriptome mapped ~ 20.000 genes for control and diabetic rats, comparative analysis found a great similarity between transcriptomes, with only 66 differentially expressed genes between the groups (43 down and 23 up-regulated in diabetic group). Molecular function enrichment showed a significant alteration in pathways related to cholinergic nicotinic transmissions, which are enrolled in pain modulation. Some genes encountered may relate to new altered pathways in the context of early painful diabetic neuropathy, and need to be further investigated. Nonetheless, the small number of differentially expressed genes between diabetic and control groups suggests that other mechanisms, such as post-transcriptional changes, may play an important role in this phase of DPN and complement the transcriptome information in explaining sensorial alteration.

Title: Involvement of the opioid system in the analgesic effect of celecoxib in rats with diabetic neuropathy

Authors: *I. E. JUAREZ-ROJOP, JR[1], C. A. TOVILLA-ZARATE[2], H. AGUILAR-MARISCAL[1], D. Y. BERMUDEZ-OCAÑA[2], T. RAMON-FRIAS[1], J. L. BLE-CASTILLO[1], J. C. DIAZ-ZAGOYA[3]

Abstract: Diabetic neuropathy is one of the most frequent complications of diabetes mellitus. In patients with diabetic neuropathy pain relief is incomplete even taking high doses of analgesics and modulators. Furthermore, it is known that celecoxib, a selective inhibitor cyclooxygenase-2 (COX-2) attenuated pain in rats with diabetic neuropathy. Previous studies suggest that celecoxib can be attached to other cellular targets that are different from COX. In this regard, ion channels and the opioid system are identified as new markers for the molecular basis of some of the pharmacological actions of celecoxib. The purpose of this study was to assess the participation of naltrexone (a non-selective opioid receptor antagonist) in the anti-nociceptive and anti-allodynic effect of Celecoxib in rats with diabetic neuropathy. Streptozotocin (60 mg/kg; intraperitoneal) injection caused hyperglycemia within 1 week a Wistar rats. After 4 weeks the pain behavior was assessed using tactile allodynia and formalin test (Formalin 0.5%). Four to six weeks after diabetes induction, hyperalgesia and tactile allodynia was observed in the streptozotocin-injected rats. Results indicate that Intraperitoneal (i.p.) administration of celecoxib (0.3-100 mg/kg) is able to produce a dose-dependent decrease formalin-induced nociception and tactile allodynia in streptozotocin-injected rats. Moreover, on this condition, i.p administration of naltrexone (3 mg/kg) significantly reverses anti-nociceptive and anti-allodynic effects of Celecoxib in diabetic rats. These results suggest that the analgesic effect of Celecoxib in rats with diabetic neuropathy

is mediated through opioid receptors. In conclusion, Celecoxib (i.p) has beneficial effects for the management of diabetic neuropathic pain.

Title: Modulation of spinal AMPA receptor phosphorylation by PI3-Kinase activation in a rat model of neuropathic pain

Authors: J. JUN[1], S. JUNG[1], H. KIM[1], *J. W. LEEM[2]
[1]Dept. of Physiol., [2]Yonsei Univ. Col. Med., Seoul, Korea, Republic of

Abstract: Reactive oxygen species (ROS) in the spinal cord, which plays a crucial role in sensitization of dorsal horn neurons, has been implicated in neuropathic pain. ROS is an important mediator for regulating spinal AMPA receptor phosphorylation to induce persistent pain. ROS is involved in inducing neuropathic pain via PI3-kinase activation in spinal dorsal horn. In this work, we investigate whether PI3-kinase activation modulates the phosphorylation of spinal AMPA receptors in the neuropathic state. Mechanical hyperalgesia of hind paw, evaluated by measuring paw withdrawal threshold upon the application of von Frey hairs, was induced by L5 spinal nerve ligation (SNL). PI3-kinase activity was analyzed by western blotting, and PIP_3 protein level by ELISA. L5 SNL-induced mechanical hyperalgesia was attenuated by pretreatment with either ROS scavenger alpha-phenyl-N-tert-butyl nitron (PBN) or PI3-kinase inhibitor wortmannin. Both PIP3 level and PI3-kinase activity in the lumbar spinal dorsal horn were increased in rats with L5 SNL, and such increases were attenuated by pretreatment with either PBN or wortmannin. In rats with L5 SNL, the phosphorylation of spinal AMPA receptors at GluA1 (S831) and GluA2 (S880) subunits was increased. The increased AMPA receptor phosphorylation was reversed by inhibition of PI3-kinase. The results suggest that PI3-kinase-

dependent changes in the phosphorylation of spinal AMPA receptors, through the action of ROS, are crucial for the development of neuropathic pain.

Title: Anti-hyperalgesic effects of ROS scavengers in neuropathic mice

Authors: ***A. BITTAR**, J. JUN, J. WANG, K. CHUNG, J. M. CHUNG
Dept Neurosci & Cell Biol, Univ. Texas Med. Br., Galveston, TX

Abstract: Our previous study has shown that the direction of neural plasticity in the spinal cord is cell-type specific in that afferent conditioning stimulation produces long term potentiation (LTP) in spinothalamic tract neurons (STTn) and long term depression (LTD) in GABAergic neurons (GABAn). We hypothesize that intense afferent stimulation induces LTP in excitatory STTn, which contributes to persistent pain. Furthermore, simultaneous production of LTD in inhibitory GABAn further intensifies persistent pain. We further hypothesize that two different types of reactive oxygen species (ROS) are involved as intracellular signaling molecules and produce these two opposing synaptic plasticity. To test this hypothesis, the effects of scavengers for specific ROS on pain behaviors are examined in the spinal nerve ligation (SNL) model of neuropathic pain in mice. SNL are produced by a tight ligation of the left L5 spinal nerve in C57/B6 mice. Mechanical hypersensitivity of the hind paw is assessed by measuring the frequencies of foot lifting and shaking in response to mechanical stimulation with Von Frey filaments (VF #2.44 and #3.00) to the affected paw. Sham operated mice are used as the control group. The effects of 4 different ROS scavengers injected intrathecally (i.t., 5μl) on mechanical hypersensitivity are examined at various times after neuropathic surgery. The tested drugs include PBN (nonspecific ROS scavenger, 100μg), TEMPOL (superoxide scavenger, 100μg), DMSO (hydroxyl radical scavenger, 0.55mg) and DMTU (hydroxyl radical scavengers, 1.04mg). To test whether the effect of ROS scavengers is related to GABA dysfunction, the effects of GABA receptor inhibitors (Bicuculline, 0.5μg; CGP46381, 0.25μg) in combination with ROS

scavengers are also examined. The results show that SNL mice produce mechanical hypersensitivity evidenced by increasing the frequencies of foot lifting and shaking of the affected hind limb. An intrathecal injection of ROS scavenger reduces all those measured behaviors representing the mechanical hypersensitivity. All tested ROS scavengers reduce pain behaviors at different degrees of magnitude. The GABA receptor inhibitors reverse the DMSO- and DMTU-induced anti-hyperalgesic effect. The results show that ROS scavengers reduce neuropathic pain behaviors. The data also suggest that an important component of the ROS scavenger-induced anti-hyperalgesic effect is by restoring impaired GABA inhibitory function.

Title: Phosphorylation of transcriptional factors CREB and C/EBPβ was mediated by mitochondrial ROS in the HIV gp120 neuropathic pain model in rats

Authors: *S. HAO, H. YI, W. ZHENG, W. HUANG, S. LIU, R. LEVITT, K. CANDIOTTI, D. A. LUBARSKY
Dept Anesthesiol., Univ. Miami, Miami, FL

Abstract: Despite the wide research of HIV/AIDS, the mechanisms underlying the manifestation of HIV neuropathic pain remain poorly understood. HIV neuropathic pain may be initiated by gp120 and sustained by spinal neuropathology. Mitochondria are the primary source for the generation of reactive oxygen species (ROS), a byproduct of oxidative phosphorylation. The production of ROS is known to be upregulated under inflammatory conditions and can induce

nociceptor sensitization. Transcriptional factor CREB is involved in the neuropathic pain state. However, the role of C/EBPβ (a downstream factor of CREB) is not clear in the HIV pain state. Here, we investigated the neurochemical mechanisms of HIV neuropathic pain in rats. HIV neuropathic pain was induced by gp120 peripheral application into sciatic nerve. Mechanical allodynia was evaluated using Von Frey fibers. HIV gp120 peripheral application into sciatic nerve increased spinal mitochondrial superoxide, upregulated phosphorylation of CREB and C/EBPβ, and lowered the MnSOD (mitochondrial SOD) activity. Either intraperitoneal PBN (a pan-ROS scavenger) or intrathecal PBN suppressed mechanical allodynia induced by HIV gp120. Intrathecal injection of a new mitochondria-targeted superoxide scavenger (Mito-Tempol) suppressed mechanical allodynia and reversed the lowered MnSOD activity. Intrathecal Mito-Tempol also suppressed the upregulated pCREB and pC/EBPβ. Double Immunostaining show the co-localization of MnSOD or pCREB and pC/EBPβ with NeuN, suggesting that MnSOD or pCREB and pC/EBPβ were located in the spinal neurons. The results suggest that mitochondrial ROS, and transcriptional factors pCREB and pC/EBPβ are involved in the HIV pain model, and that mitochondrial ROS mediate the phosphorylation of transcriptional factors CREB and C/EBPβ in the rat model.

Title: Resolution of chemotherapy-induced neuropathic pain by protectin D1 via peripheral and central mechanisms

Authors: *Z. XU, R. XIE, S. BANG, G. CHEN, R.-R. JI
Anesthesiol. and Neurobio., Duke Univ. Med. Ctr., DURHAM, NC

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) is the dose-limiting toxicity for many commonly used classes of anti-cancer agents. CIPN can lead to dose reductions or

discontinuation of cancer therapy. Taxanes, such as paclitaxel, are among the most effective and extensively used drugs in human chemotherapy; unfortunately, they cause painful neuropathy in most cancer patients receiving chemotherapy. Currently, there are no FDA-approved interventions or prevention strategies for CIPN. CIPN results in peripheral and central sensitization, neuroinflammation in the PNS and CNS, and loss of epidermal innervations. Protectin D1 (PD1) is a novel pro-resolution and anti-inflammatory lipid mediator biosynthesized from omega-3 fatty acid DHA. Our previous studies showed that PD1 potently inhibited inflammatory pain and nerve trauma-induced neuropathic pain. In this study, we investigated whether PD1 could prevent and reverse chemotherapy-induced neuropathic pain and further address the underlying mechanisms. We found that pretreatment with PD1 largely prevented chemotherapy-induced neuropathic pain. Mechanistically, PD1 protected chemotherapy-induced axonal degeneration *in vivo* and promoted axonal outgrowth *in vitro*. PD1 also prevented chemotherapy-induced neurochemical changes in DRGs. Interestingly, chemotherapy-induced hyperexcitability in large-sized DRG neurons, as revealed by whole-cell patch clamp recordings in whole-mount DRGs, was normalized by PD1. Furthermore, post-treatment of PD1, via intrathecal route, dose-dependently attenuated chemotherapy-induced neuropathic pain. Patch clamp recordings in spinal cord slices showed that PD1 also reversed chemotherapy-induced spinal cord synaptic plasticity (sEPSC increase). Collectively, our data suggest that pre- and post-treatment of PD1 can effectively attenuate chemotherapy-induced neuropathic pain, by resolving chemotherapy-induced axonal degeneration, neuroinflammation, DRG neuronal hyperexcitability, and spinal cord synaptic plasticity. Thus, PD1 and its mimetics may offer novel therapeutics for preventing and treating neuropathic pain following chemotherapy.

Title: Pentoxifylline decreases Paclitaxel-increased free radicals level in the primary dorsal root ganglia cells in culture

Authors: *H. KIM, S. ABDI
Dept. of Pain Med., MD Anderson Cancer Ctr., Houston, TX

Abstract: Chemotherapy agents including taxanes, vinca alkaloids, and platinum complexes are used to treat cancer patients, however, their neurotoxic side effect has a detrimental impact on the quality of life of patients. We previously reported that pentoxifylline (PTX), phosphodiesterases 1-5 inhibitor, ameliorates paclitaxel (PAC)-induced neuropathic pain in rats. The purpose of this study is to investigate the effects of PTX on the PAC-induced free radicals production using primary cultured rat dorsal root ganglion (DRG) cells. The lumbar DRGs were dissected from adult male Sprague-Dawley rat and then dissociated with collagenase and mechanical trituration. Isolated DRG cells were placed in poly-D-lysine and laminin coated 24-well plate and cultured with complete culture medium (DMEM, 10% FBS, 1% antibiotics, 4 mM glutamine) in a CO2 incubator for 1 weeks. To measure the free radicals level, DRG cells was treated with PAC solution for 1 day and the free radicals level was measured by flow cytometry using CellROX Deep Red Reagent. PAC (10 uM, 1 day) significantly increased the fluorescent intensity by 46% compared to vehicle (0.5% DMSO in culture medium) treated group. Further, PAC-induced increase fluorescent intensity was decreased by PTX (1, 10 mM). This result indicates that PAC increases the production of free radicals in the DRG cells and inhibition of PAC-induced free radicals level in DRG cells may be the mechanism underlying the analgesic effect of PTX on chemotherapy-induced neuropathic pain in rats.

Title: Regulator of G protein signaling – 9 modulates the actions of analgesic drugs in neuropathic pain models

Authors: *V. MITSI[1], S. GASPARI[1], D. TERZI[1], L. MANOURAS[1], G. DESCALZI[2], J. FENG[2], I. PURUSHOTHAMAN[2], L. SHEN[2], V. ZACHARIOU[3]

[1]Basic Sci., Univ. of Crete, Heraklion, Greece; [2]Neurosci., [3]Neurosci. and Pharmacol. and Systems Therapeut., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Regulator of G protein signaling 9-2 (RGS9-2), is a striatal enriched modulator of GPCR signal transduction, which has been shown to be a potent modulator of monoamine and mu opioid receptors. Rgs9-2 modulates the actions of several clinically applied medications, including opiate analgesic, antipsychotic and antiparkinsonian drugs. Our previous work revealed a potent role of signal transduction complexes containing RGS9-2 in the nucleus accumbens in the rewarding and analgesic actions of opiates. Here, we use the Spared Nerve Injury (SNI) paradigm of neuropathic pain, to determine the role of RGS9-2 in neuropathic pain related symptoms and in responses to antidepressant medications used for the treatment of this disorder. Our findings suggest that while Rgs9-2 plays a minor role in the expression and intensity of neuropathic pain symptoms, it is a potent modulator of anxiety and depression behaviours induced by neuropathic pain. Specifically, Rgs9-2 plays a protective role in neuropathy - related depression, as indicated by the social interaction and the forced swim phenotypes of Rgs9 knockout mice. Notably, knockout of the Rgs9 gene accelerates the onset of the antiallodynic actions of monoamine targeting antidepressants used for the treatment of neuropathic pain symptoms. Specifically, Rgs9 knockout mice show an earlier and enhanced response to the tryciclic antidepressant desipramine (DMI) compared to their wildtype controls. Respectively, overexpression of RGS9-2 in the nucleus accumbens (NAc) via viral mediated gene transfer, blocks the antiallodynic effects of DMI. Western blot and immunoprecipitation assays indicated that the mechanism of DMI action in this brain region involves changes in RGS9-2 complexes as well as in downstream signal transduction events, including nuclear shuttling of G beta subunits and changes in protein kinase A (PKA) mediated phosphorylation of protein phosphatase 2A (PP2A). We finally applied RNA sequencing methodology in order to understand the impact of RGS9-2 on gene regulation induced by chronic antidepressant treatment and/or neuropathic pain. The RNA-sequencing studies revealed that modulation of GPCR activity by RGS9-2, controls the expression of several molecules with a key role in the long term actions of antidepressant medications, including several GPCRS, transcription factors and ion channels. Together our findings illustrate a dynamic role of RGS9-2 in the actions of monoamine targeting antidepressants and point to new intracellular targets for the treatment of neuropathic pain.

Title: Behavioral characterization of ZDF rat as model for neuropathic pain

Authors: *N. GORODETSKAYA, A. PEKCEC, L. CORRADINI, H. N. DOODS
Boehringer Ingelheim Pharma Gmbh&Co. KG, Biberach, Germany

Abstract: Neuropathic pain is a severe late complication of diabetic polyneuropathy which is diagnosed within 15-20 years after onset of diabetes. Preclinical evaluation of novel analgesics is mostly based on the rat Streptozotocin-induced model that mimics features of diabetes type 1 and is characterized by an acute severe development. However, there are currently no rodent models that reflect a more chronic phase of diabetic polyneuropathy. Objective of the current study is the evaluation of evoked pain-like and natural behaviors in Zucker Diabetic Fatty (ZDF) rat, a genetic model of spontaneously developed diabetes type2, from onset until the late phase of the diabetes using age-matched genetically linked Zucker Lean (ZL) and genetically independent Wistar rats as controls. Methods Six weeks old male ZDF, ZL and Wistar rats (n=32 per group) were used. Hind paw sensitivity (mechanical allodynia and hyperalgesia) and non-evoked behavior (burrowing and locomotor activity) were measured at 4 time points: at the age of 6-8, 15-17, 31-33 and 37-38 weeks. Blood glucose concentration were measured weekly during diabetes development and every second week after diabetes had been established. Results All but two ZDF rats developed diabetes at the age of 8 weeks. Withdrawal thresholds to tactile stimuli did not differ between ZDF and ZL rats (3.3±0.7g vs. 3.2±0.6g, respectively) but were significantly lower as in Wister rats (10±1.1g) starting already at the first time-point measurement and continued throughout the study. Sensitivity to mechanical pressure stimuli at onset of the study was similar in all 3 groups (withdrawal thresholds for ZDF, ZL and Wistar rat: 140±10.5g, 141±7.9g and 145±8.9g). At the follow up measurements at the age of 17 and 33 weeks the withdrawal threshold to pressure stimuli in ZDF rat was significantly lower than in ZL and Wistar rats (115±3.5g and 107± 4.8g vs 164±7.6g and 168± 9.5g, respectively) and was again increased to 157±11g at 38 week of age. Burrowing did not differ between groups at the age of 8 weeks (ZDF, ZL, Wistar: 800±78g, 1026±58g, 1266±85g), but was significantly lower in diabetic ZDF rats compared to ZL and Wistar rats at all later evaluation time-points (e.g. at age of 16 weeks for ZDF, ZL and Wistar: 783±88g, 1463±55g, 1409±52g). Locomotor activity as assessed by distance moved and rearing frequency was at all evaluation time points high in ZL rats compared to ZDF and Wistar rats. ZDF rats differ from Wistar rats only in rearing frequency at the age of 31 weeks. Conclusions Both kind of read-outs, based on reflex-withdrawal reactions

and on innate behavior have revealed a significant difference between diabetic and age-matched control rats.

Title: Painful nerve injury reduces mitochondrial calcium buffering in axotomized sensory neurons but elevates calcium buffering in adjacent sensory neurons

Authors: ***Q. H. HOGAN**, C. SPRICK, Y. GUO, S. MUELLER, M. BIENENGRAEBER, B. PAN, H.-E. WU
Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Mitochondria play a critical role in coordinating neuronal energy metabolism and cytoplasmic Ca2+ concentration ([Ca2+]c). Initial observations have suggested that mitochondrial dysfunction may be a causative factor contributing to neuropathic pain. Mitochondrial uptake, storage, and release of Ca2+ is engaged by activity-induced [Ca2+]c transient elevation, but the effects of injury have not been examined. Using the application of FCCP (1μM) to eliminate mitochondrial Ca2+ uptake combined with oligomycin (10μM) to prevent ATP depletion, we first identified features of the depolarization-induced neuronal [Ca2+]c transient that are sensitive to blockade of mitochondrial Ca2+ buffering in order to assess mitochondrial contribution to [Ca2+]c regulation. This established the loss of a shoulder (plateau phase) during the recovery of the depolarization (K+)-induced transient, increased transient peak and area, and elevated level of the shoulder as evidence of diminished mitochondrial Ca2+ buffering. We then examined transients in Control neurons and neurons from the 4th lumbar (L4) and L5 dorsal root ganglia after spinal nerve ligation (SNL) at the L5 level. The SNL L4 neurons showed decreased transient peak and area compared to control

neurons, while the SNL L5 neurons showed increased shoulder level. Additionally, SNL L4 neurons developed shoulders following transients with lower peaks than Control neurons. Application of FCCP/Oligo elevated resting [Ca2+]c in SNL L4 neurons more than in Control neurons. Whereas application of FCCP/Oligo 2s after neuronal depolarization initiated mitochondrial Ca2+ release in most Control and SNL L4 neurons, this usually failed to release mitochondrial Ca2+ from SNL L5 neurons. For comparable cytoplasmic Ca2+ loads, the releasable mitochondrial Ca2+ in SNL L5 neurons was less than Control while it was increased in SNL L4 neurons. These findings show diminished mitochondrial Ca2+ buffering in axotomized SNL L5 neurons but enhanced Ca2+ buffering by neurons in adjacent SNL L4 neurons.

Title: Netrin acts as a pain-inducing factor in the adult spinal cord

Authors: *Y. HAYANO[1], K. KITADA[2], T. YAMASHITA[1]
[1]Dept. of Mol. Neurosci., Grad. Sch. of Medicine, Osaka Univ., Suita City, Osaka, Japan; [2]Dept. of Biol. Sciences, Grad. Sch. of Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Neuropathic pain, a debilitating syndrome that occurs post-nerve damage, can lead to hypersensitivity in the peripheral and central nervous systems. The underlying mechanism is poorly understood, and currently available treatments remain inefficient. Here, we demonstrated that Netrin-4, a member of axon guidance molecule family, enhances the sensitivity to sensory input and contribute to neuropathic pain. A lack of the Netrin-4, which was expressed in dorsal horn lamina IIi neurons of the adult spinal cord, attenuated allodynia in neuropathic pain. In contrast, intrathecal administration of Netrin-4 to naïve rats induced allodynia, being mediated by Unc5B and intracellular tyrosine phosphatase SHP2. These findings suggest that suppression of Netrin-4-Unc5B-SHP2 signal may prove as an efficient strategy for the treatment of

neuropathic pain. Our findings provide evidence for the previously unidentified function of Netrin in adult nervous system.

Title: Deletion of Sox11 in nociceptive neurons inhibits nerve regeneration and prolongs neuropathic pain after nerve injury

Authors: ***L. LEI**[1], M. ANDERSON[1], B. ROY[1], L. CAO[2], E. BILSKY[3]
[1]Biol., [2]Biomed. Sci., [3]Univ. of New England, Biddeford, ME

Abstract: The transcription factor Sox11 is highly expressed in sensory neurons in dorsal root ganglia (DRG) and trigeminal ganglia during development, and controls the survival and axonal growth of embryonic sensory neurons *in vivo* and *in vitro*. In adult mice, Sox11 is highly up-regulated in DRG after peripheral nerve injury. We hypothesize that the upregulation of Sox11 after peripheral nerve injury is an adaptive change on the part of the nervous system to promote axonal regrowth and reinnervation of distal territories, thus protecting against neuropathic pain. To test this hypothesis, we generated nociceptor-specific Sox11 conditional knockout (CKO) mice using the Cre-loxP-mediated gene targeting system with the Nav1.8-Cre line that expresses the Cre recombinase specifically in nociceptors. These Sox11 CKO mice were viable, fertile and grossly normal. We tested these Sox11 CKO mice in two neuropathic pain models - sciatic nerve crush (SNC) which allows for axonal growth and nerve regeneration, and L5 spinal nerve transection (L5Tx) which does not allow for nerve regeneration. The ablation of Sox11 in nociceptors led to a prolonged period of hypersensitivity in the SNC model, while had no effect in the L5Tx model. Furthermore, retrograde tracing experiment indicated that axonal growth and regeneration was inhibited in the Sox11 CKO mice after SNC.

Title: Electrophysiological characterization of the ZDF rat model of type 2 diabetes using conventional nerve conduction studies and microneurography

Authors: E. GARCIA[1], N. GORODETSKAYA[2], A. PEKCEC[2], R. SOLA[1], M. SUMALLA[1], *J. SERRA[1]
[1]Neurosci. Technologies, Barcelona, Spain; [2]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany

Abstract: Painful neuropathy is a prevalent condition in type 2 diabetic patients. However, existing animal models of the disease are poorly characterized. We have used electrophysiological techniques to examine peripheral nerve function in the Zucker diabetic fatty (ZDF) rat model of type 2 diabetes Conventional nerve conduction techniques and microneurography were used to evaluate the electrophysiological features of both large and small caliber nerve fibers in ZDF, ZDF lean, and normal Wistar rats; animals were obtained from Boehringer Ingelheim Pharma GmbH & Co (see companion poster). All animals were maintained on high fat diet until recordings were made at age 38-41 weeks. Under urethane anesthesia, amplitude and conduction velocity of sensory nerve action potentials (SNAP) and compound motor action potentials (CMAP) were recorded from the tail. Alternatively, microneurographic recordings of unmyelinated C-fibers were obtained from the sciatic nerve. Eleven ZDF rats (336±6g), 14 ZDF lean rats (454±8g), and 15 Wistar (492±12g) age-matched rats were used in the study. ZDF rats had significantly reduced weights and higher blood glucose levels (499.5±17.9mg/dl; $P<0.001$). No differences in blood glucose levels were detected in ZDF lean (135.93±4.03mg/dl) and Wistar (129.47±10.44 mg/dl) rats. ZDF rats exhibited significantly reduced conduction velocities but normal amplitude of the SNAP and CMAP. The difference in conduction velocity was more prominent for sensory than motor fibers. A total of 605 C-fibers were recorded using microneurography: 104 (17.2%) mechano-sensitive nociceptors, 367 (60.7%) mechano-insensitive nociceptors, and 134 (22.1%) other types (including sympathetic and thermoreceptor fibers). Overall, abnormal spontaneous activity in nociceptors was observed

in 56 (15.26%) mechano-insensitive C-nociceptors from which 25% were recorded in the ZDF group, 11.9% in ZDF lean and 12.9% in Wistar rats. Although the ZDF group had a higher percentage of spontaneously active fibers, this difference did not reach statistical significance. In summary, we have found altered functional properties in peripheral nerves in the ZDF rat model of type 2 diabetes. The reduction in conduction velocities parallel changes found in other diabetic models and patients. Furthermore, C-nociceptors become hyperexcitable and spontaneously active in old hyperglycemic ZDF rats, but also in age-matched and apparently normoglycemic ZDF lean and Wistar rats fed with a high fat diet.

Abstract: Synthesis and degradation of synaptic proteins mediated reorganization of synaptic structure, which in turn partly regulate synaptic strength. Change in synaptic strength is believed to be the fundamental mechanism of pain. In the present study, we examined whether change of synaptic proteins in the ACC is involved in chronic pain. To do this, we investigated the effect of protein synthesis/degradation blockade in pain response, immunoblot analysis, spine structure analysis and electrophysiological measurements in the ACC suffering from chronic pain.

Title: Sensory neuron subpopulation specific dysregulation of intracellular calcium in a rat model of chemotherapy-induced peripheral neuropathy

Authors: *E. YILMAZ[1,2], M. S. GOLD[1,2,3]
[1]Ctr. for Neurosci., [2]Ctr. for Pain Res., [3]Dept. of Anesthesiol., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) is a common side effect of cancer treatment responsible for dose limitation if not cessation of therapy. CIPN is initially manifest with numbness and tingling followed by persistent pain typically localized in distal appendages. Current explanations for CIPN include the primary mechanisms of chemotherapeutic action, immune cell activation, and mitotoxicity. Unfortunately none of these mechanisms alone can explain stocking-glove manifestation of CIPN and the sensory neuron selectively. We and others have previously documented the heterogeneity among subpopulations of sensory neurons including those defined by target of innervation. Ca^{2+} regulatory mechanisms are one of the many differentially distributed properties that contribute to this heterogeneity.

Given recent evidence implicating dysregulation of intracellular Ca^{2+} ($[Ca^{2+}]_i$) as a mechanism of peripheral neuropathy and the importance of mitochondria in the regulation of $[Ca^{2+}]_i$ we hypothesized that the clinical signs of CIPN are due, at least in part, to a dysregulation of $[Ca^{2+}]_i$ in subpopulations of sensory neurons. We therefore assessed the impact of paclitaxel administration *in vivo*, on the regulation of $[Ca^{2+}]_i$ in subpopulations of sensory neurons *in vitro* defined by target of innervation and the presence of criteria used to identify putative nociceptors. There were differences among subpopulations of sensory neurons defined by the presence of nociceptive properties as well as by target of innervation with respect to resting, magnitude, and decay of high K^+-evoked Ca^{2+} transients. Two weeks after paclitaxel administration, when hypersensitivity was fully manifest, there was no detectable influence of target of innervation or paclitaxel treatment on putative non-nociceptive neurons. However, there was a significant influence of paclitaxel on the decay of the high K^+-evoked Ca^{2+} transient in putative nociceptive neurons. Transients decayed faster with a trend toward a larger decrease in transient duration in neurons innervating the glabrous skin on the hindpaw relative to the hairy skin on the thigh and the dorsal surface of the hindpaw. Preliminary results of experiments to identify the basis for the paclitaxel effects suggest an increased activity of sarco-endoplasmic reticulum Ca^{2+} ATPase (SERCA) may contribute to these differences in putative nociceptors from paclitaxel treated rats. Our results suggest a model whereby neurotoxicity may reflect a decrease in the transport of mitochondria that results in neurotoxicity in distal endings of putative nociceptors as a result of a decrease in SERCA-mediated Ca^{2+} reuptake.

Title: Activation of cAMP-PKA signaling pathway in rat dorsal root ganglion and spinal cord contributes to development of bone cancer pain

Authors: X. TAN[1], *G. ZHU[2], X.-M. HE[1], P. CHEN[1], X.-J. SONG[1]
[1]Ctr. for Clin. Res. and Translational Med., Lianyungang City Oriental Hosp., Lianyungang City, China; [2]Dept. of Anesthesiol., Lianyungang East Hosp., Jiangsu, China

Abstract: Treating cancer pain possesses a major clinical challenge and mechanisms underlying cancer pain remain elusive. The cAMP-PKA signaling pathway, which impinges on many essential cellular processes and is crucial for synaptic plasticity, is widely involved in inflammatory and neuropathic pain. Here we report that activation of cAMP-PKA signaling in rat dorsal root ganglion (DRG) and the spinal cord contributes to the development of bone cancer pain. Studies were performed on adult, female, Sprague−Dawley rats. Bone cancer pain in rats was produced by tumor cell (1×10^5 cells/μl, 5μl) implantation (TCI) into the intramedullary space of the right tibia. TCI treatment induced significant painful behaviors manifested as thermal hyperalgesia and mechanical allodynia. TCI treatment also increased the expression of PKA mRNAs in DRG and increased levels of cAMP concentration and PKA activity in both DRG and the spinal cord. *In vivo* delivery of PKA inhibitor Rp-cAMPS (1 mM/ 20 μl) intrathecally to interfere cAMP-PKA signaling pathway in the early (3-5 day) and late phase (9-10 days) after TCI treatment, respectively, significantly delayed and suppressed TCI-induced thermal hyperalgesia and mechanical allodynia. The increased level of cAMP concentration and PKA activity was also greatly suppressed by the PKA inhibitor. These findings indicate that TCI treatment activates the cAMP-PKA signaling pathway and continuing activation of this pathway is required for TCI-induced hyperalgesia and allodynia. This study reveals a critical role of the cAMP-PKA signaling pathway in the production and maintenance of bone cancer pain and suggests that targeting the activated cAMP-PKA pathway may be an effective therapeutic approach for suppressing cAMP-dependent neural hyperexcitability and bone cancer-induced behaviorally expressed hyperalgesia and allodynia.

Title: Ventrobasal thalamic burst firing after selective spinal cord tractotomies

Authors: J. OVELMEN-LEVITT[1], *P. G. SHINKMAN[2]
[1]Dept Neurobio. and Anat., Wake Forest Baptist Hlth. Ctr., Winston-Salem, NC; [2]Dept Psychology, Univ. North Carolina, CHAPEL HILL, NC

Abstract: In human subjects, spontaneous dysaesthetic sensations, often described as painful, frequently follow spinal cord injury. Peripherally-evoked dysaesthesias are also reported, referred to the same or different body locations. Monkeys and rats also show signs of chronic spontaneous and evoked dysaesthesias following midthoracic spinal tractotomies that involve the anterolateral column (ALC). Our ALC lesions included primarily the spinothalamic tract. These signs are shown by sensory testing, neurological testing, and behavioral observation. Sprague-Dawley rats were observed chronically for over a year for signs of dysaesthesia. After these observations were complete, various spinal cord lesions led to different changes in firing patterns in the hindlimb area of the middle ventral posterolateral thalamic nucleus (mVPL), including burst firing as indicated by the burst index (BI) and the distribution of interspike intervals (ISI). Five groups were studied with extracellular unit recordings in anesthetized animals: intact control (C), dorsal column section (DC), anterolateral column (ALC), DC+ALC, and hemisections (Hemi). Large increases (10-50%) in long-duration (25-50 msec) multispike (7-10 APs) burst firing in hind-limb mVPL was found in ALC subjects when compared to C subjects (Mann-Whitney $U = 14$, $p<0.01$) in the hindlimb area. There was a high correlation between burst firing and the presence of objective signs of dysaesthesias, measured many months post-op (Pearson's correlation, $r = 1.00$). In DC subjects there was a marked increase in firing frequency compared to C ($U = 2.5$, $p<0.001$), with no accompanying spontaneous dysaesthesias. Overall, spinal cord lesions resulted in significant long-term changes among groups in the BI and ISI (chi-square = 17.6 and 18.9, respectively, with 4 df; $p<0.005$ and 0.001). We conclude that spinothalamic tract deafferentation (ALC) produces increased bursting in mVPL neurons. Based on ISI criteria and known mechanisms of burst discharges in thalamic nuclei, we interpret these bursts as consistent with the involvement of T-type calcium channel activation. This disruption in firing pattern occurs coincident with spontaneous behavioral dysaesthesia.

Title: Contribution of dorsal root ganglion myeloid zinc finger protein 1 to neuropathic pain in rats after nerve trauma

Authors: *Y. TAO, Z. LI, X. GU, L. SUN, S. WU, L. LIANG, B. M. LUTZ
Dept. of Anesthesiol., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Peripheral nerve injury-induced changes in gene transcription and translation in primary sensory neurons of the dorsal root ganglion (DRG) are considered to contribute to neuropathic pain genesis. Transcription factors control gene expression. Peripheral nerve injury increases expression of myeloid zinc finger protein 1 (MZF1), a transcription factor, in the injured DRG. However, whether DRG MZF1 participates in neuropathic pain is unknown. Here, we report that pre-knockdown of DRG MZF1 prevents nerve injury-induced mechanical, cold, and thermal hypersensitivities in rats. Post-knockdown of DRG MZF1 also markedly reduces established neuropathic pain. Mimicking nerve injury-induced increase in DRG MZF1 produces neuropathic pain symptoms in naïve rats. Mechanistically, MZF1 blocks Kcna2 mRNA and protein expression, reduces total potassium current, and increases neuronal excitability through activation of Kcna2 antisense RNA gene in DRG neurons. Thus, MZF1 might serve as a potential target for preventing and treating neuropathic pain.

Title: Wnt5a signaling pathway in the pathogenesis of HIV-associated pain

Authors: *S.-B. YUAN, B. LI, G. JI, V. NEUGEBAUER, S.-J. TANG
Dept of Neurosci. and Cell Biol., Univ. of Texas Med. Br., Galveston, TX

Abstract: Pain is a high incidence neurological complication in HIV-1/AIDS patients, but the underlying pathologic mechanism is unclear. We recently found that Wnt5a was aberrantly up-regulated in the spinal cord dorsal horn (SDH) in HIV patients who developed neuropathic pain. Further, intrathecal injection (i.t.) of HIV gp120, a protein implicated in HIV-1-associated pain, rapidly up-regulated Wnt5a expression in the SDH of C57BL6 mice. The objective of this study was to investigate the role of Wnt5a in the pathogenesis of HIV-associated pain. Using a HIV-related pain mouse model generated by i.t. gp120, we found that a Wnt5a-specific antagonist (Box5) attenuated gp120-induced mechanical allodynia. Conversely, either a Wnt5a agonist (Foxy5) or purified Wnt5a facilitated gp120-induced allodynia. Next, we tested the role of the JNK/TNF-α pathway, which can be activated by gp120 in the SDH in a Wnt5a-dependent manner. We found that a specific JNK inhibitor (SP600125) prevented the expression of allodynia induced by gp120 and Foxy5. Similarly, a specific TNF-α antagonist (Enbrel) was able to reverse gp120 and foxy5 induced allodynia. These data suggest that JNK and TNF-α are the downstream proteins that mediate the biological effects of Wnt5a in regulating gp120-induced pain. To determine neuronal effects, we performed extracellular single-unit recording on the SDH neurons in anesthetized mice. Gp120 increased background activity (action potentials) and responses to brief innocuous and noxious test mechanical stimuli applied to the hindpaw. Box5 or SP600125 blocked the facilitatory effects of gp120. Foxy5 also increased background and evoked activity, and this effect was blocked by SP600125 or Enbrel. The electrophysiological data suggest that Wnt5a, JNK and TNF-α mediate the facilitatory effects of gp120 on SDH neurons. Collectively, our findings implicate the Wnt5a-JNK-TNF-α pathway as a critical signaling mechanism in the development of gp120-induced pain.

Title: A spinal analogue of memory reconsolidation enables the reversal of hyperalgesia

Authors: *R. P. BONIN, Y. DE KONINCK
Unite de neurosciences cellulaires et moleculaire, CR-IUSMQ, Univ. Laval, Quebec, QC, Canada

Abstract: The development of persistent pain through the sensitization of pain relays in the spinal cord dorsal horn shares many mechanistic and phenotypic parallels with memory formation. Memory reconsolidation, in which the reactivation of memories renders them labile and susceptible to erasure by inhibition of protein synthesis, may thus be of particular relevance to the treatment of persistent pain. Here we test the hypothesis that the reactivation of sensitized pain pathways initiates a process similar to memory recall and reconsolidation to render hyperalgesia labile and erasable. We find that both acute and long-lasting mechanical hyperalgesia could be reversed after reactivation of the sensitized pain pathway and the concomitant inhibition of spinal protein synthesis. This process was dependent on the activation of spinal AMPA, NMDA, and NK1 receptors during reactivation of the sensitized pain pathways, and on the activation of CaMKII and ERK. Additionally, the activation of spinal AMPA or NMDA receptors without peripheral stimulation was sufficient to render hyperalgesia labile, suggesting this process was mediated by post-synaptic activation of dorsal horn neurons. In electrophysiological experiments, synaptic LTP in the superficial dorsal horn, a cellular model of hyperalgesia, was similarly rendered labile and reversible by reapplying the LTP induction stimulus in the presence of the protein synthesis inhibitor anisomycin. These findings provide the first demonstration of a reconsolidation-like phenomenon in spinal pain processing pathways and the sensory system in general, suggesting that reconsolidation may exist more broadly throughout the CNS than previously known. These findings may further provide a novel therapeutic strategy for the treatment and erasure of persistent pain.

Title: Painful hypersensitivity is attenuated by treatment with a novel CSE inhibitor in a rat model of chemotherapy induced peripheral neuropathy

Authors: *S. SYDSERFF, B. FRANCHINI, T. SACH, S. DURON, J. CHAPMAN
Sova Pharmaceuticals, La Jolla, CA

Abstract: Chemotherapy induced peripheral neuropathy (CIPN) is a significant treatment limiting side effect of taxane or platinum based chemotherapeutics. CIPN develops in around 40% of patients during a course of chemotherapy and is the dose-limiting toxicity. Initially presenting as a tingling or burning sensation in the extremities it can quickly develop into a painful debilitating condition. Reducing the onset of CIPN or alleviating the symptoms would both enable the continuation of aggressive cancer therapy for longer periods and reduce the painful sequelae. We have developed novel inhibitors of Cystathionine-γ-lyase (CSE), an enzyme involved in the production of hydrogen sulfide gas (H2S). H2S has been implicated in the regulation of ion channel pharmacology in pathophysiological states and has been shown to sensitize or activate both TRP and voltage gated ion channels involved in the nociceptive pathway. We hypothesize that inhibiting H2S production will remove this molecular sensitizer and effectively reset the pain pathway to a normal/baseline state. In order to test this hypothesis we have developed a dual chemotherapeutic model of CIPN in the rodent, which we describe here. Male SD rats were administered 2 mg/kg Paclitaxel on alternate days for 1 week and 10 mg/kg Carboplatin daily for 4 days. 23 days after beginning chemotherapy, hypersensitivity to von Frey hairs was assessed. The novel CSE inhibitor SV250 was administered either daily for 1 week prior to testing or acutely 5 hours prior to testing. Paclitaxel + carboplatin treated animals were extremely sensitive to the application of von Frey filaments, much more so than in animals treated with Paclitaxel alone. The 50% withdrawal threshold (g) being approximately a sixth of that seen in naïve rats. SV250 normalized the withdrawal response in both hind paws when administered for 7 days prior to testing at 3 mg/kg daily or when administered at a dose of 30 mg/kg 5 hours prior to testing. In the latter instance reduction in hypersensitivity to filaments was observed up to 48 hours post dosing. We have demonstrated that inhibiting CSE is highly effective at reducing painful hypersensitivity associated with chemotherapy induced peripheral neuropathy in the rat.

Title: AKAP-dependent cAMP-PKA signaling maintains pain-related spontaneous activity in nociceptor somata after spinal cord injury

Authors: A. BAVENCOFFE[1], Z. WU[2], Q. YANG[1], J. DU[3], Y. LI[1], E. J. KENNEDY[4], S. M. CARLTON[3], C. W. DESSAUER[1], *E. T. WALTERS[1]
[1]Dept Integrative Biol & Pharmacol, Univ. Texas Med. Sch. At Houston, HOUSTON, TX; [2]Scripps Res. Inst., La Jolla, CA; [3]Univ. Texas Med. Br, Galveston, TX; [4]Univ. of Georgia, Athens, GA

Abstract: Chronic, intractable pain is a major problem for many patients with spinal cord injury (SCI), but the underlying mechanisms are not understood. In a rat model of contusive SCI at T10 we found that pain-related behavioral changes were associated with persistent hyperexcitability and spontaneous activity (SA) in the cell bodies of primary nociceptors recorded *in vitro* and *in*

vivo (Bedi et al. J Neurosci, 30:14870, 2010; Wu et al. Pain, 154:2130, 2013). Because prolonged activation of cAMP-PKA signaling has been linked to persistent nociceptor hyperexcitability and pain (e.g., Song et al., J Neurophysiol 95:479, 2006) and nociceptor responsiveness involves the complexing PKA and associated proteins to AKAP scaffolds (e.g., Efendiev et al., J Biol Chem 288:3929, 2013), we are testing the hypothesis that AKAP-dependent cAMP-PKA signaling continuously contributes to SA in nociceptor cell bodies acutely and chronically after SCI. Neurons from L4 and L5 DRG dissociated between 3 days and 3 months after SCI showed increased incidence of SA (21 of 39 cells showed SA, 72% incidence) compared to neurons from sham-operated (3 of 15, 20%) or naive animals (5 of 30, 17%), without apparent changes in incidence across this period (replicating Bedi et al., 2010). Blocking PKA activation with Rp-cAMPS blocked the increase in SA (4 of 21 with SA, 19%). Disrupting the binding of PKA to AKAP with two different blocking peptides, Ht31 and a novel stapled peptide STAD-2, blocked the increase in SA (5 of 24, 21% for Ht31; 3 of 16, 19% for STAD-2) compared to the effect of a corresponding inactive peptide, Ht31P (6 of 10, 60%) or STAD-2scr (8 of 11, 73%). A peptide that specifically blocks binding of adenylyl cyclase to AKAP also blocked the increase in SA (2 of 13, 15%) compared to the effect of a corresponding inactive peptide (8 of 12, 67%). Moreover, application of forksolin to capsaicin-sensitive DRG neurons from naive animals depolarized resting potential (9 of 9, 100%; 1,9-dideoxyforskolin, 0 of 9). To test whether PKA-AKAP association is also necessary for chronic SA generated in DRG neuron cell bodies *in vivo*, we have begun to test the effects of blocking peptides delivered locally to lumbar DRG in anesthetized rats. Preliminary results suggest that exposure to stearated Ht31 reduces SCI-induced SA generated in neurally isolated but otherwise intact DRG *in vivo*. These observations support the hypothesis that continuing activation of an AKAP-dependent cAMP-PKA signaling pathway maintains nociceptor SA that promotes pain in acute and chronic phases after SCI.

Title: Functional MRI reveals emotional modulation of pain processing in the human brainstem and cervical spinal cord

Authors: *T. A. MCIVER[1], J. KORNELSEN[2], S. D. SMITH[3], R. L. BOSMA[1], H. S. KHAN[1], A. I. COTOI[1], R. H. Y. LEUNG[1], P. W. STROMAN[1]

Abstract: Emotions can modulate pain perception. In line with Motivational Priming Theory, painful stimuli are generally experienced as more painful when accompanied by, or associated with a negative emotional influence, while pain ratings decrease with positive emotional influence. Functional magnetic resonance imaging (fMRI) has been used to investigate pain and its underlying neural mechanisms throughout the central nervous system. Although fMRI studies have examined emotional modulation of pain processing in the brain, this provides an incomplete representation of the process. Pain processing areas are widely distributed across the brain, brainstem, and spinal cord. To gain a complete understanding of how emotion influences pain, we need to characterize the neural response in the brainstem and spinal cord. The present study used fMRI of the spinal cord and brainstem to examine the effect of emotional modulation on thermal pain processing and neural function at this level. Behavioral testing identified healthy, heterosexual, right-handed adult females who exhibited emotional modulation of pain perception. Painful heat stimulation (via Medoc® TSA-II Thermal Sensory Analyzer) was calibrated for each participant to produce a moderately painful sensation and applied on the thenar eminence of the right hand, corresponding to the C6 dermatome. Imaging sessions entailed 12 functional runs, with the painful stimulus applied in a block paradigm. For the duration of each run, participants viewed images selected from the International Affective Picture System of negative, neutral, or positive valence, with image valence held constant throughout each run. Participants reported the sensation's intensity and unpleasantness using pain rating scales ranging from 0 -100. Data analysis for fMRI included use of a general linear model, with subsequent contrasts to compare BOLD responses between conditions. We observed significant differences in pain perception, reflecting the influence of emotional valence of the visual stimuli on pain intensity and unpleasantness. Similarly, contrast analysis revealed significantly greater BOLD percent signal change, in the ipsilateral dorsal horn (C6) corresponding to the painful stimulus during negative picture viewing, relative to both positive and neutral picture viewing conditions. Image valence and arousal appear to have varying effects on BOLD responses to pain in different regions of the brainstem, including the periaqueductal gray, rostral medulla, and the nucleus tractus solitarius. These results provide evidence for descending emotional modulation of brainstem and spinal mechanisms involved in pain processing.

Title: Nanotheranostics as a tool for search, rescue and discovery: Understanding chronic pain processing in the peripheral nervous system

Authors: *M. SALEEM[1,2,3], J. M. JANJIC[4,5,3], K. VASUDEVA[1,2,3], K. ANDERSEN[1,2,3], B. ZEYZUS-JOHNS[1,2,3], T. K. HITCHENS[6], S. K. PATEL[4,5,3], J. POLLOCK[1,2,3]

Abstract: Chronic pain has been an inadequately managed condition in the clinic, for a number of reasons: the cause is not always apparent, it is complex in terms of its pathogenesis, the cognitive processing of pain is highly variable in individuals, and current treatments are not yet targeting underlying pain mechanisms. Hence, new ways of tracking and manipulating the biology of chronic pain – in a personalized context - is critical for developing therapies that treat, rather than mask chronic pain. Combining diagnostics with therapeutics, the field of nanotheranostics provides both potent imaging capabilities and a directed therapeutic delivery modality, following systemic administration. In certain chronic pain conditions, there is a dynamic interplay between the nervous and immune systems. By way of mechanisms currently under intense research, the immune system and glia play a role in initiating and maintaining aspects of neuropathic pain - which is characterized by allodynia (normally innocuous stimuli causing pain), among other symptoms. Learning more about the way that chronic pain develops in the context of this multi-system cross-talk will offer the best strategy for its treatment. To explore the relationship between the immune system and neuropathic pain, – a type of chronic

pain that affects the nervous system - we have adapted a nanotheranostic 'search' tool, with the aim of imaging the inflammation associated with chronic pain. We intravenously injected a novel nanotheranostic emulsion – using a chronic constriction injury (CCI) rat model of neuropathic pain – which enables neuroinflammation to be imaged by a near infrared (NIR) lipophilic fluorescence reporter (DiR) and separately by a 19F fluorine MRI tracer. The nanotheranostic emulsion is internalized by circulating inflammatory cells, such as monocytes and macrophages. We have demonstrated NIR fluorescence, a 19F MRI signal, as well as the infiltration of CD68 positive macrophages at the site of CCI tissue damage. Our work paves the way for utilizing nanotheranostics to target the inflammatory events involved in chronic pain initiation, progression and maintenance - both in the context of treatment, as well as furthering our understanding of pain biology in the neuron-glia network.

Title: Neuromodulation of conditioned placebo/nocebo cue effect in heat pain: Anodal vs. cathodal tDCS to the right DLPFC

Authors: *N. EGOROVA[1,2], R. YU[1,2], J. A. CAMPRODON[1,2], N. KAUR[1], D. D. DOUGHERTY[1,2], R. L. GOLLUB[1,2,3], J. KONG[1,2,3]

Abstract: Placebo and nocebo play an important role in clinical practice and medical research. Modulating placebo/nocebo responses using noninvasive brain stimulation methods, such as transcranial direct current stimulation (tDCS), offers a great potential for harnessing these effects

in a clinical setting. Right dorsolateral prefrontal cortex (DLPFC) has been previously implicated in both placebo and nocebo effects. Its excitability can be successfully modulated by tDCS, as reported in several studies, in which anodal tDCS enhanced learning and consolidation. In the present study we assessed the effect of anodal and cathodal tDCS over the right DLPFC on conditioned placebo/nocebo cue response to heat pain. Two matched groups of healthy volunteers (N=15 per group) were subjected to an identical 30-minute session of conditioning, during which low and high cues (abstract images) were associated with low and high pain levels, respectively. Following the conditioning phase, 20-minute 2mA tDCS (either anodal or cathodal) over the right DLPFC (F4 in 10-20 coordinate system) was applied. The influence of tDCS current polarity (anodal vs. cathodal) on placebo/nocebo cue effect was assessed, using the change in subjects' pain ratings in response to identical pain stimuli preceded by the conditioned high or low cues. A significantly greater difference ($p=0.045$) between the high and low cue ratings was observed in the anodal tDCS group compared with the cathodal tDCS group, where the effect was reduced. This study provides evidence that it is possible to modulate conditioned placebo/nocebo cue effect by changing the brain excitability of the right DLPFC using tDCS.

Title: Changes in the functional connectivity of pain related brain areas during mental stress

Authors: ***R. RINGLER**[1], P. V. KEYLEN[2], K. DETMAR[4], R. LOOSE[4], C. FORSTER[3]
[1]Dept of Med. Physics, Univ. of Appl. Sci., Weiden, Germany; [2]Inst. of Anat., [3]Inst. of Physiol., Univ. of Erlangen-Nuremberg, Erlangen, Germany; [4]Dept. of Radiology, Clin. Ctr. of Nuremberg, Nuremberg, Germany

Abstract: Introduction: The cold pressure test (CP) induces a long lasting pain which changes during its application from an acute sensation to a deep and dull pain. It has been shown that mental stress as it is induced by a false color stroop task (ST) changes the pain perception. This is expressed by a change in the activation pattern of the affected brain areas. In this work we further studied these changes regarding the functional connectivity between these brain areas and

hypothesized that the connectivity of pain related brain areas will be diminished when the subjects were distracted from the pain by mental stress. Materials and methods: 14 healthy subjects were included in the study. They participated on psychophysical pre-examination where pain rating, blood pressure and heart rate were recorded. In the second run fMRI was assessed using a block design with alternating stimulus and baseline. Each stimulus lasted 2 minutes and was either CP alone or CP with ST (CP+ST). Each combination was given twice. For CP the right foot was immersed into cold water (4°C = 40°F), during the baseline periods it was changed to warm temperature (14°C = 57°F). Whole brain fMRI EPI sequences (TR=3000ms) were acquired on a 1.5 T Siemens MAGNETOM Espree. Predefined anatomical regions (ROI) were used and the mean MRI time courses in these regions were extracted for each subject. These signals were z-transformed and Pearson's correlation coefficients (r) were calculated between the ROI for the periods CP and CP+ST, respectively. Results: The psychophysical studies and the fMRI showed significant lower pain ratings during CP+ST as compared with CP. Blood pressure was increased during the painful stimuli of CP. Nearly all connectivity values were higher during CP than during CP+ST. The highest r values were found between S1 and S2 (BA 40) on both hemispheres ($r>0.8$, $p<0.00$) with only little decrease during CP+ST as compared with CP. There were also high connectivity values ($r>0.6$, $p<0.00$) between the areas of the medial system (insular cortex, anterior cingular cortex, amygdala). The most prominent decreases of connectivity (CP+ST compared to CP) were found in the network consisting of amygdala, caudate and BA 40. These areas are known to be involved in processing of the affective components of pain. Conclusion: CP activates the previously described network of pain related brain areas which is reflected by an increased functional connectivity between these areas. Distraction from the pain by a stroop task reduces the synchronism. This effect is pronounced most in areas which are known to be involved in processing of the affective components of pain.

Title: An objective human brain biomarker of target engagement by gabapentin in central sensitization

Authors: *V. WANIGASEKERA, M. MEZUE, Y. KONG, I. TRACEY
Univ. of Oxford, Oxford, United Kingdom

Abstract: Aim Development of new analgesics for neuropathic pain is hindered by translational failure of their efficacy from animals to patients. Detecting such failures in large phase III studies is expensive and unsustainable. Demonstrating target engagement objectively in mechanism-based models in early phase II studies might avoid such failures. Functional magnetic resonance imaging (FMRI) is a powerful tool for providing such objective evidence. Resting state (RS) functional connectivity (Fc) between different brain regions can be gathered over a few minutes with little effort from individuals, making it an ideal tool for patient studies. We used Fc in a human model of central sensitization (CS) to study target engagement of a clinically effective drug, gabapentin (Gb) in neuropathic pain; CS being a key mechanism that contributes to neuropathic pain. We hypothesised that CS induced Fc between nociceptive processing areas would be modulated by Gb but not by ibuprofen (Ib), a drug that is ineffective in neuropathic pain or by placebo (Pl), irrespective of changes in subjective pain ratings which are influenced by context and expectation. Method We used a double blind placebo controlled crossover study design with 3 visits. In 24 healthy volunteers we induced CS using 1% topical capsaicin on the right leg, 90 min after 600mg of Ib, 1200mg Gb or Pl (balanced for order). Subjects rated spontaneous ongoing pain (OGP) 60 and 100 min after capsaicin using a visual analogue scale (anchors “no pain” and “severe pain”). RS data were acquired 90 min after capsaicin over 6 min using a 3T MRI scanner and analysed using FMRIB Software Library. We used a whole brain Fc analysis with the contralateral (left) thalamus (Th) as the seed region as it is a structure that is central to nociceptive impulse transmission. Plasma drug levels were measured 3.15 hrs after dosing. Results There were no significant differences between the visits in OGP scores but Gb significantly reduced CS induced Fc between the left Th and the left somatosensory cortex (SII) when compared to Ib and to Pl (mixed effects analysis; cluster corrected; $z > 2.3$; $p<0.05$). This Fc during Gb showed a significant -ve correlation (rho 0.59; $p = 0.002$) with Gb plasma levels. There were no significant differences in Fc between Pl and Ib. Conclusion Only Gb suppressed CS induced Fc between left Th and SII; key nociceptive processing areas implicated in chronic neuropathic pain patients, in a plasma drug level dependent manner. RS Fc in a relevant human model differentiated Gb, an effective analgesic from Ib, an ineffective analgesic in neuropathic pain despite low subject numbers, while the subjective pain scores did not.

Title: Temporal summation of sensory and affective dimensions of pain in humans: A fMRI study

Authors: *X. LIU[1], W. XIAO[2], L. LI[1], H. WANG[1], H. SU[3], Y. WANG[4], Y. QIU[1]
[1]Res. Ctr. for Neural Engneering, Shenzhen Inst. of Advanced Technol., Guangdong, China; [2]Loudi hospital, Hunan, China; [3]Ohio State Univ., Columbus, OH; [4]Shenzhen Middle Sch., Shenzhen, China

Abstract: Aim of investigation: To explore temporal summation (acute, tonic) of sensory and affective dimensions of deep muscle pain by using functional magnetic resonance imaging (fMRI). Methods: 16 healthy subjects participated to this study. We used fMRI to measure BOLD signal changes between acute and tonic pain condtions. Acute pain anticipation followed by pain are induced by masseter injection of a single bolus of isotonic saline (0.9% 0.2ml) and hypertonic saline (5% 0.2ml), respectively. A 20 min tonic pain state is induced by masseter injection of hypertonic saline by the application of a computer-controlled closed-loop system which could adjust the hyper saline infusion rate based on the VAS pain intensity rating score. And tonic pain of anticipation followed by the tonic pain, which induced by masseter injection of isotonic saline with a constant rate of 75ul/min. The visual analog scale (VAS) and SF-McGill pain questionnaire (MPQ) are used to assess the sensory and affective dimensions of pain. Results The significant difference was only found in the MPQ affective subscale in comparisons the subjective rating scores of the MPQ, PANAS and POMS scales between acute pain and tonic pain. The fMRI BOLD signal differences were found in regions of ipsilateral mid-prefrontal cortex, contralateral hippocampus and ipsilateral cerebellum in the tonic pain compared to acute pain conditions, and the signal differences were found in regions of bilateral insula, bilateral primary somatosensory (SI) and contralateral primary motor cortex (MI) in the acute pain compared to tonic pain conditions. Conclusions Temporal summation of muscle pain can affects sensory and affective dimensions of pain. Comparing with acute pain, the fMRI signal of tonic pain has more correlation with sensory and affective dimensions of pain in human brain areas such as mid-prefrontal cortex, hippocampus and cerebellum.

Title: Motor cortex stimulation on neuropathic pain with positron emission tomography

Authors: ***J. KIM**[1], S. LEE[2], J. SHIN[1], H. JUNG[1], S. KIM[2], J. CHANG[1]
[1]Neurosurg., Yonsei Univ. Coll of Med., Seoul, Korea, Republic of; [2]Sch. of Electrical Engin. and Computer Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Neuropathic pain is one of severe diseases. Neuropathic pain is induced by direct or indirect nerve damage. Neuropathic pain is different from the other types of pain. It cannot be easily modulated by general pain treatments. The Motor cortex stimulation (MCS) is one of the treatment modalities for neuropathic pain. However, the mechanism of MCS is still unclear. We have studied to find the action mechanism of MCS using positron emission tomography (PET). We used Sprague-Dawley rats and induced neuropathic pain. To measuring tactile allodynia, behavior tests were carried on. We carried on immunohistochemical study, imaging study using PET. MCS modulates secretion of c-Fos and Serotonin (5-HT). In mPET study, the brain activity of the Striatum, Thalamic area and Cerebellum was changed. From this study, we can demonstrate that MCS suppresses neuropathic pain effectively, and we suggest that MCS modulates the ascending and descending aspects of the pain pathway in modulating pain.

Title: A magnetoencephalography study of pain anticipation in patients with thalamic pain syndrome

Authors: *R. GOPALAKRISHNAN[1], R. BURGESS[2], A. MACHADO[1]
[1]Ctr. for Neurolog. Restoration, [2]Epilepsy Ctr., Cleveland Clin., Cleveland, OH

Abstract: Thalamic pain syndrome (TPS) may occur after thalamic strokes or lesions, with numbness and pain in the contra-lateral side of the body. Not purely a somatosensory experience, chronic pain has significant affective components, including anticipatory phenomena (Melzack 1990). Evaluation of the neural mechanisms underlying pain anticipation is important to avoid maladaptive pain conditioning and injury, in addition to serving as biomarker to evaluate the results and progress of therapy. In this study we evaluated for the first time, with magnetoencephalography (MEG), the neurophysiological activity during pain anticipation in patients with TPS using visual countdown cues. Patients were evaluated before and after DBS therapy targeting affective sphere of pain (Plow et al 2013). Testing was performed with 7 adult patients seated upright in a 306 channel MEG array (Elekta AB). The paradigm (Machado et al 2014) consisted of 4 blocks of 60 randomized trials of distinct visual cues signaling the arrival of a painful stimulus (60% chance) or of no stimulus. Each trial was 9s long with 1s of baseline, 3s of pre-stimulus countdown and 5s post-stimulus period. All data analysis was performed at the sensor level using Fieldtrip (Oostenveld et al 2011) software in the time (power) domain. Data (from 204 orthogonal gradiometers) were tSSS filtered, parsed, down-sampled, anomalies rejected and filtered to 1-70 Hz. Additionally, head movement confounds were corrected. Here, we looked at the 300 ms response (P300) to the first visual cue as predictor of anticipation to upcoming painful stimulus. Data show high anticipatory phenomena around P300 both in control population (n=10) and patients with DBS OFF (n=7) stimulated on the painful limb. Data in 2 patients with DBS ON show this anticipatory phenomena was disrupted.

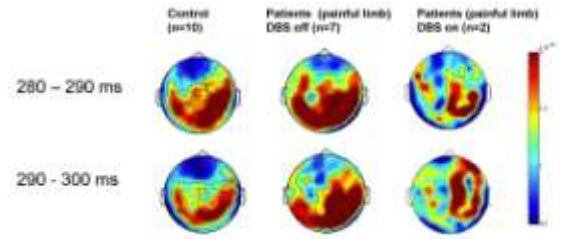

Fig.1. Topographies of MEG data at 300ms after the first visual cue preceding painful stimulus. Negativity in the anterior regions and positivity in the posterior regions is indicative of anticipatory behaviour. Dotted sensor locations showed significant activity ($p<0.05$) compared to a condition when visual cue indicated upcoming non-painful stimulus.

Title: Neurophysiological correlates of bottom-up and top-down mediated modulations of pain

Authors: L. TIEMANN[1], E. MAY[1], M. POSTORINO[1], E. SCHULZ[1], M. NICKEL[1], U. BINGEL[2], *M. PLONER[1]
[1]TU Muenchen, Munich, Germany; [2]Univ. Hosp. Essen, Essen, Germany

Abstract: The perception of pain is highly variable. It depends on bottom-up mediated factors like stimulus intensity and top-down mediated factors like expectations. In the brain, pain is associated with a complex pattern of neuronal responses including evoked potentials and induced

responses at alpha and gamma frequencies. Although they all covary with stimulus intensity and pain perception, responses at gamma frequencies can, under certain conditions, be particularly closely related to the perception of pain. It is, however, unclear whether this generalizes to fundamentally different modulations of pain. Here, we used electroencephalography to directly compare bottom-up and top-down mediated modulations of pain, which were implemented by changes in stimulus intensity and placebo analgesia, respectively. The results show that stimulus intensity modulated pain-evoked potentials and pain-induced alpha and gamma responses. In contrast, placebo analgesia was associated with changes of evoked potentials, but not of alpha and gamma responses. These findings reveal that pain-related neuronal responses are differentially sensitive to bottom-up and top-down modulations of pain indicating that they provide complementary information about the perception of pain. The results further show that pain-induced gamma oscillations do not invariably encode pain perception but may rather represent a marker of local sensory processing whose influence on pain perception varies with behavioral context.

Title: Investigation of the neural processes involved in cognitive modulation of pain in the human cervical spinal cord and brainstem using functional MRI

Authors: *R. H. LEUNG, A. I. COTOI, R. L. BOSMA, T. A. MCIVER, H. T. KHAN, P. W. STROMAN
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Pain is a highly subjective sensory experience involving elaborate neural pathways, and the perception of pain can vary across and even within individuals. Studies have shown that descending pathways originating from cortical regions can modulate ascending nociceptive stimuli. For example, engaging executive functions, such as working memory can alter the

salience and intensity of pain, and behavioural studies have shown that increased attentional load reduces the perception of pain. This cognition-dependent suppression of pain perception illustrates a mechanism of modulation in which top-down attentional selection can mitigate the bottom-up salience of noxious stimuli via increased distraction or cognitive load. This study aims to assess the neural correlates of cognitive modulation of pain within the brainstem and cervical spinal through blood-oxygenation level dependent (BOLD) responses during functional magnetic resonance imaging (fMRI). Cognitive modulation of pain was behaviourally confirmed in a group of 13 healthy, female adults ages 18 to 45 using a robust heat pain paradigm and the N-back working memory cognitive task. All participants completed questionnaires regarding social desirability, depression, anxiety, and pain catastrophizing as a means of control. Calibrated thermal pain was applied to the right thenar eminence, which corresponds to the C6 dermatome, via a Medoc® TSA-II Thermal Sensory Analyzer as participants performed the task pseudo-randomly varied between three levels (no-, 1-, and 2-back). Participants rated their pain intensity according to a rating scale ranging from 0 (no sensation) to 100 (intolerable pain). The no-back yielded the highest pain ratings while the 2-back yielded the lowest pain ratings, and pair-wise comparisons between each condition was significant with Bonferroni adjustment. Task performance also differed significantly between the 1- and 2-back levels. To investigate this further, ongoing fMRI studies are examining the neural correlates involved in cognitive modulation of pain. BOLD responses in the brainstem and spinal cord are recorded while participants perform a cognitive task and undergo thermal stimulation. We hypothesize significant differences in subjective pain responses as well as signal intensity changes in key regions such as the periaqueductal gray, rostral ventral medulla, and the dorsal horn of the C6 spinal cord segment, when comparing between N-back levels. The results of this study will help us better understand how pain experiences are formed in healthy individuals by elucidating the role cognitive function plays in the neural processing of pain.

Title: Effects of visual body image on pain perception

Authors: *M. OSUMI, R. IMAI, K. UETA, S. MORIOKA
Dept. of Neurorehabilitation, Grad. Sch., Nara, Japan

Abstract: [Objective]In recent years, there has been a rise in changing the visual body image as a method of rehabilitation for chronic pain. However, there are inter-individual differences in the analgesic effect changing the visual body image. We made a hypothesis that negative emotion on self-body perception associated with changing the visual body image. Now we investigated, using a rubber hand illusion, whether these unpleasant caused by changing the visual body image of a healthy person are able to modulate pain. [Methods] Twenty-three healthy subjects participated in this study (8 male, 15 females, mean age 21.6; SD 1.5years). To evoke negative emotion on self-body perception associated with changing the visual body image, we applied the method of rubber hand illusion. In order to create these unpleasant, we created a "injured rubber hand", a "hairy rubber hand", and a "twisted rubber hand". We also created a “normal rubber hand” as a control. The both of participant’s real hand and rubber hand were touched synchronously with paint brush to elicit body ownership experience for rubber hands in each condition. After that, the pain threshold of the hidden real hand was measured while the participant observed the rubber hand using a device that measured pain caused by thermal stimuli. In the between conditions, values of illusory ownership, unpleasantness on self-body perception and pain threshold were analyzed using one-way repeated-measures ANOVA. The Bonferroni method was used for post hoc comparisons. An alpha level of 5% was considered as statistically significant. [Result]Body ownership experiences were elicited by observation of the injured rubber hand and hairy rubber hand as well as the normal rubber hand. Participants felt more unpleasantness by observing the injured rubber hand and hairy rubber hand than the normal rubber hand and twisted rubber hand ($p < 0.001$). The pain threshold was lower under the injured rubber hand condition than with the other conditions ($p < 0.001$). [Conclusions] This result supports the view that negative emotion on the visual body image associated with pain can increase pain sensitivity. We can conclude that rehabilitation for pain by changing the visual body image will succeed if there is no negative emotion associated with the pain.

Title: Cathodal transcranial direct current stimulation over primary somatosensory cortex increases joint flexibility

Authors: ***T. MIZUNO**[1,2], Y. ARAMAKI[1]
[1]Grad. Sch. of Hlth. and Sport Sci., Chukyo Univ., Toyota, Japan; [2]Res. Fellow of Japan Society for the Promotion of Sci., Toyota, Japan

Abstract: Is the primary somatosensory cortex (S1) involved in joint flexibility? Joint flexibility is dependent on both mechanical and neural factors. However, the contribution of neural factors is not fully understood. Transcranial direct current stimulation (tDCS) can modulate excitability of the cerebral cortex; anodal tDCS can upregulate excitability of the cerebral cortex under the electrode, whereas cathodal tDCS can downregulate excitability. Herein, we assessed whether tDCS over the S1 of the lower limb can modify the joint flexibility of the ankle joint in healthy subjects. In eight male subjects, range of motion (ROM) of the left ankle joint and left wrist joint were measured during the passive-dorsiflexion test. The ankle and wrist were passively dorsiflexed at a speed of 1°/s to the maximal dorsiflexion angle. We defined the ROM as the angle at which the subject felt discomfort in the calf or the wrist. To determine changes of due to mechanical factors, the passive torque, which represents involuntary resistance torque to dorsiflexion, was also measured at the ankle joint. Subjects performed the left ankle and the left hand passive-dorsiflexion tests before and after anodal, cathodal and sham-controlled tDCS over the S1 of the lower limb. The current was applied for 10 min with an intensity of 2.0 mA during anodal and cathodal tDCS. Cathodal tDCS was significantly increased by 10.5% (from 26.5 ± 7.7° to 29.4 ± 8.1°) of ROM for the ankle joint, but not for the wrist joint. Both anodal and sham tDCS had no significant effect. Cathodal tDCS over the S1 of the lower limb might have changed neural factors such as perception of joint angle or pain, because the mechanical factors indicated by the passive torque at 0°, 5°, 10° and 15° were not changed. These results suggest that the S1 is involved in joint flexibility.

Title: Pain facilitation in the spinal cord and brainstem of patients with fibromyalgia syndrome: An fMRI study

Authors: *R. BOSMA[1], E. MOJARAD[1], L. LEUNG[1], C. PUKALL[1], R. STAUD[2], P. STROMAN[1]
[1]Queen's Univ., Kingston, ON, Canada; [2]Univ. of Florida, Gainsville, FL

Abstract: Fibromyalgia syndrome (FMS) is a highly prevalent wide-spread chronic pain condition, which afflicts primarily females. Although the etiology of this disease is not completely understood, FMS pain is believed to be maintained by both peripheral mechanisms, through tonic deep muscle inputs, and central mechanisms, by facilitation of the spinal cord and brain. Temporal summation of second pain (TSSP) paradigms evoke a C-fiber transmitted enhancement (or "wind-up") of the dorsal horn neurons that coincides with an increase in pain perception. Abnormal behavioral responses to temporal summation paradigms in patients with FMS indicate central pain processing abnormalities. Using this paradigm and spinal cord functional MRI, we can, for the first time, non-invasively probe the central mechanisms of this pain response in the spinal cord and brainstem of patients with FMS. The aim of this study is to characterize the fMRI BOLD responses in the spinal cord and brainstem that correspond to TSSP in patients with FMS and in healthy controls. Healthy female adults (N = 15) and females with FMS (N = 15) completed a quantitative sensory testing session and two imaging sessions. In the first session, heat pain thresholds were determined, and participants became familiar with the study procedures, as well as the MRI environment. As a measure of control, participants completed questionnaires to assess depression, anxiety, pain catastrophizing and social desirability. Functional MRI studies of the spinal cord and brainstem were conducted at 3T. A thermode was placed on the right thenar eminence (C6 dermatome) and TSSP (0.33 Hz) and non-TSSP (0.17 Hz) heat pain paradigms were employed. The stimulus intensity was calibrated for each individual in order to produce the wind-up effect and achieve comparable TSSP ratings of moderate pain at 0.33 Hz. Participants rated the pain on a scale from 0 (no sensation) to 100 (intolerable). Data were analyzed by means of the general linear model. In the TSSP condition, all participants rated the pain intensity of the last stimulus (FMS M_{rating} = 51, Control M_{rating} = 50) more painful than the first (FMS M_{rating} = 24, Control M_{rating} = 18). Temporal summation to a final rating of moderate pain (~50) was achieved at lower temperatures in the FMS group compared to the controls. Preliminary fMRI results in both groups indicate that, compared to the

non-TSSP condition, the BOLD response to the TSSP condition was more robust and was sustained beyond the duration of the stimulation block. Results from this study indicate the presence of wind-up in the human dorsal horn and will provide more information about changes in pain processing in patients with FMS.

Title: Chronic non-resolving nerve injury in the rat causes behavioral changes and global and cellular abnormalities in brain morphology

Authors: *L. A. LOW[1], B. WANG[1], S. J. THOMPSON[2], M. BUSHNELL[1]
[1]Natl. Ctr. for Complementary and Alternative Med., Natl. Inst. of Health/NCCAM, Bethesda, MD; [2]Dept. of Dent., McGill Univ., Montreal, QC, Canada

Abstract: Aim: To monitor nerve injury-induced changes on behavior in the rat, and investigate global and cellular changes in the brain 7 months after nerve injury. **Methods:** 12 male Sprague-Dawley rats received a spared nerve injury, where 2 of the 3 branches of the sciatic nerve are ligated and cut. 12 males received sham surgery. From 3 to 7 months, animals were regularly tested for sensory hypersensitivity (mechanical and cold hypersensitivity), as well as exploratory behaviors in the open field and elevated plus maze. At 7 months, rats were euthanized and post-mortem MRI scans were performed on a 7T Bruker Pharmascan machine, then MR signal intensity across the whole brain compared using AFNI software. In addition, brains were retained for histological analysis. Initially, prefrontal cortex was sectioned and stained for GFAP (astroglia) immunofluorescence. **Results:** Nerve-injured rats remained significantly hypersensitive to both mechanical and cold (acetone) stimulation at all time points ($p<0.0001$), with no resolution of sensory hypersensitivity. Additionally, nerve-injured rats showed reductions in rearing in an elevated plus maze and open field ($p<0.05$), suggesting decreased exploratory behaviors. 7 months after nerve injury, post-mortem MR analysis showed reductions

in MR signal intensity in 4 clusters (>20 voxels) in primary somatosensory areas, dentate gyrus and ventral tegmental area (VTA) in nerve-injured animals compared to controls ($t=3.64$, $p=0.003$). Contralateral prefrontal cortex (infralimbic and prelimbic) also showed increases in GFAP immunofluorescence ($p<0.05$, $n=8$ per group), suggestive of the presence of activated astrocytes (gliosis). **Conclusions:** Chronic (7 months) nerve injury causes non-resolving sensory hypersensitivity and long-lasting changes in exploratory behaviors. Reductions in MR signal are seen in brain areas involved in pain processing and changes in cellular morphology are seen in prefrontal brain regions. Ongoing work is characterizing further cellular changes in brain integrity in ROIs suggested by MR results.

Title: Measuring the effect of pain on sensorimotor integration using short-latency afferent inhibition

Authors: *L. J. BOUYER[1], M. GAGNÉ[2], J.-A. BEAUMONT[2], C. MERCIER[1]
[1]Rehabil. Dept- CIRRIS, Univ. Laval Fac Med., Quebec, QC, Canada; [2]CIRRIS-Université Laval, Quebec city, QC, Canada

Abstract: INTRODUCTION: The effects of pain on the motor system are not yet well described. In the presence of pain, motor cortex excitability is reduced. In the context of rehabilitation, where pain is often present during motor re-training, such reduced excitability could potentially have a negative impact on sensorimotor integration and thereby reduce treatment effectiveness. The aim of the present study was therefore to measure if a pain-induced decrease in motor cortex excitability interferes with sensorimotor integration. METHODS: Ten healthy subjects (aged 25.8 +/- 4.1) came to the laboratory for a single session. They were exposed to the same sensorimotor integration protocol either in the presence or absence of pain. Sensorimotor integration was assessed with a short latency afferent inhibition (SAI) paradigm. SAI consisted in measuring the amount of inhibition of a cortically evoked motor response in the

first dorsal interosseus muscle (FDI) with transcranial magnetic stimulation (TMS) when preceded by a brief transcutaneous electrical stimulation of the ulnar nerve (200μs pulse). The intervals between electrical and magnetic stimulations were based on the latency of the afferent sensory volley measured with electroencephalography (N20) in each subject and were set to N20-5ms, N20+2ms, N20+4ms and N20+10ms. TMS intensity was set to induce a 1mV FDI motor evoked potential (MEP) in the no Pain condition and ulnar nerve stimulation intensity was set at 5-10% Mmax in FDI. Pain was induced by applying heat pulses (50°C) with a thermode to the lateral border of the stimulated hand. Statistical analysis consisted of a two-way repeated measures ANOVA with factors Condition and Stimulation and a Sidak adjustment for multiple comparisons was used in post-hoc tests. RESULTS: show a main effect of Condition ($p=0.005$) as overall, MEPs in the NoPain condition had a larger amplitude (0.91 vs. 0.59 mV). There was also a main effect of Stimulation ($p=0.012$). Pairwise comparisons revealed that MEPs at N20+2 were inhibited compared to Test ($p=0.016$). These results support that: 1) heat pain reduces corticospinal excitability; and 2) as there were no interaction effects, pain does not interfere with sensorimotor integration as measured with SAI. CONCLUSION: While pain reduces corticospinal excitability, these results suggest that under controlled conditions, such reduction in excitability does not interfere with sensorimotor integration.

Title: Investigating the neural processing of Conditioned Pain Modulation (CPM) in the human brainstem and spinal cord using functional MRI

Authors: *A. COTOI, R. H. Y. LEUNG, R. L. BOSMA, T. A. MCIVER, M. VALENCIA, H. S. KHAN, P. W. STROMAN
Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada

Abstract: Pain is an unpleasant experience that varies in perception depending on the degree of activity in neural pain networks that span the entire central nervous system (CNS). Studies

suggest that when a noxious “conditioning” stimulus is applied to a remote area of the body prior to the onset of a “test” stimulus, the perception of pain is diminished. This phenomenon, termed Conditioned Pain Modulation (CPM), is suggested to activate descending inhibitory pathways which dampen the sensation of pain. Although functional MRI studies have shown cortical responses related to the CPM effect, pain inhibition by means of this paradigm is yet to be studied in the spinal cord and brainstem. This study investigates the neural processing at the level of the brainstem and spinal cord by means of blood-oxygenation level dependent (BOLD) responses to CPM with functional MRI. Studies of 11 healthy, adult women, confirmed the behavioral effect of CPM on pain perception. As a measure of control, all participants completed a series of questionnaires regarding depression, anxiety, pain catastrophizing, and social desirability. Two Medoc® TSA-II Thermal Sensory Analyzers were used to deliver cold and hot pain to the left and right thenar eminence, respectively, as the conditioning and test stimuli. Participants received either the test stimulus alone, or both test and conditioning stimuli, and were instructed to focus their attention either towards the hot (test) or cold (conditioning) pain. Participants then rated the heat pain intensity according to a visual scale ranging from 0 (no sensation) to 100 (intolerable) at the end of each pseudo randomized trial. The results indicate a significant reduction in heat pain ratings when the conditioning and test stimuli were applied simultaneously and focus was directed on the cold pain (CPM condition), compared to receiving the test stimulus only, with focus directed on the hot pain (control condition). To investigate BOLD responses in the brainstem and spinal cord, participants underwent functional MRI while exposed to the CPM paradigm described above. We hypothesize that a decrease in pain perception will correspond to the BOLD signal change in the dorsal horn of the spinal cord at the C6 segment, the periaqueductal gray matter of the midbrain, and in the rostral ventromedial medulla in the CPM condition compared to the control condition. We further hypothesize that the connectivity between these regions will be greater during CPM. This study elucidates the neural mechanisms of pain modulation and pain inhibition, furthering our understanding of pain processing.

Title: Demonstration and validation of a new MRI-safe pain tolerance device

Authors: ***T. A. DANIEL**[1], M. T. DAVIS[2], T. K. WITTE[2], J. Z. WILLIS[3], R. J. BEYERS[3], Y. WANG[3], T. S. DENNEY, Jr[2,3], N. SALIBI[3,4], J. S. KATZ[2], G. DESHPANDE[2,3]
[2]Dept. of Psychology, [1]Auburn Univ., AUBURN UNIVERSITY, AL; [3]AU MRI Res. Center, Dept. of Electrical and Computer Engin., Auburn Univ., Auburn, AL; [4]Mr r&d, Siemens Healthcare, Malvern, PA

Abstract: One of the barriers to studying the behavioral and emotional effects of pain using functional Magnetic Resonance Imaging (fMRI) is the absence of a commercially available, MRI compatible pressure-based algometer to elicit pain. The present study sought to address this barrier through creation and validation of a novel MRI-safe apparatus capable of delivering incremental, measurable amounts of pressure inside a scanning bore. This device was created using a sphygmomanometer, sealed plastic tubing (to allow for metal portions of the device to be kept outside the scanner room), and a hard plastic disc with attached round nub. The disc was attached to participants' downward facing right hand such that the nub was positioned to touch the skin between middle and pointer fingers with the sphygmomanometer cuff wrapped around it. During each of 10 consecutive trials the experimenter systematically increased the pressure applied to the participant's hand by inflating the cuff at a rate of roughly 10 mmHg per second. A timer and the pressure gauge attached to the sphygmomanometer were used to standardize application of pressure across participants. Participants were instructed to signal when the "pain was too uncomfortable to continue," at which point, air pressure was released from the cuff. If participants did not signal to discontinue pressure was released at 2000 kPa, a cutoff selected following consultation with previous literature (e.g. Neziri et al., 2013). Using the noted procedure the device was first tested outside the scanner to ensure that its functioning was comparable to the AlgoMed, a portable, electronic algometer widely used in literature exploring pain-tolerance (N = 308). Results of this initial study will be presented to support the validity and reliability of the novel device. The device was then piloted inside a MAGNETOM 7T Siemens MRI scanner (Siemens Healthcare, Malvern, PA, USA), where participants' (N = 10) blood-oxygen level dependent (BOLD) signal was recorded while pressure was administered using the noted procedure with the addition of an infrared button-box used to signal when participants reached their pain threshold. The use of this device yielded BOLD activation within the insula (BA 13) and the anterior cingulate gyrus (BA 24); with each increase in pressure, activation in these areas parametrically increased. These findings correspond to other studies using thermal, electrical, mechanical, or pin-prick pain applications. This behavioral and functional data demonstrates that this new device is a valid method of administering pressure-related pain in MRI environments.

Title: An fMRI study of estrogen-dependent visceral hypersensitivity following stress in rats

Authors: D. A. SEMINOWICZ, *C. S. HUBBARD, A. FURMAN, J. M. KARPOWICZ, R. J. TRAUB
Neural and Pain Sci., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Irritable bowel syndrome (IBS) is a functional, multifactorial disorder characterized by abdominal pain, altered bowel habits, and visceral hypersensitivity, which can be influenced by psychological factors including stress and/or anxiety. Even after accounting for health-care seeking differences, this condition is more prevalent among females, suggesting hormonal influences on visceral pain sensitivity may, in part, underlie the etiology of IBS. Moreover, recent imaging studies have demonstrated that patients with IBS have altered brain activity in emotional-arousal and stress-related circuitry and subchronic stress (forced swim, FS) has been shown to induce visceral hypersensitivity that is estrogen (E2) dependent in a rat behavioral model. The major aim of the current study was to use a novel fMRI paradigm to examine brain activation associated with colorectal distension (CRD) and the role of gonadal hormones in a model of visceral hypersensitivity. Ten female, Sprague Dawley rats (10-12 weeks) were ovariectomized 15 days prior to the baseline scan and singly housed following surgery for the duration of the study. E2 or vehicle was injected s.c. every 4 days. Stress was produced by a 3 day FS paradigm (26°C water, 10 min first day, 20 min on following 2 days). Three scans were performed for each rat: baseline (no visceral hypersensitivity), 2 days post-stress (E2-dependent visceral hypersensitivity), and 18 days post-stress (no visceral hypersensitivity). Rats were fasted for 24 hrs prior to undergoing MRI in a Bruker BioSpec 70/30USR Avance III 7-Tesla scanner (Bruker Biospin MRI GmbH, Germany). Rats were sedated with ≤ 1.5% isoflurane for the entire scanning session. fMRI scans were performed during CRD (80 mmHg for 15 s with a 60 s

interstimulus interval, 15 trials, ~15 min, TR = 1.5 s, resolution = 0.35 x 0.35 x 1 mm). All image preprocessing and statistical analyses were conducted using SPM8. Across all rats, CRD resulted in activation of bilateral insula, bilateral hippocampus, retrosplenial cortex, anterior cingulate cortex (ACC), periaqueductal gray (PAG), and hypothalamus. E2-dependent hypersensitivity was associated with an enhanced response of the right amygdala and bilateral insula, indicating an upregulation in stress-related emotional-arousal circuitry may be estrogen-dependent. Understanding the brain circuitry involved in the IBS model could allow us to define targets for pharmacological and nonpharmacological therapies in humans.

Inst. of Hlth., Bethesda, MD; [3]Div. of Intramural Research, Natl. Inst. of Biomed. Imaging and Bioengineering, Natl. Inst. of Hlth., Bethesda, MD

Abstract: Introduction: Human brain imaging studies using positron emission tomography (PET) have demonstrated that the cerebral opioid system is altered in patients with chronic pain. With the view of investigating rodent pain models in the future, we investigated the *in vivo* distribution of opioid receptors in the rat brain using PET imaging and compared it to the distribution in humans to elucidate potential species differences. Methods: Each rat (n=10, male Sprague-Dawley) was briefly anesthetised with sevoflurane and received a tail vein injection of [18F]-fluoroethyl-diprenorphine ([18F]-FDPN), a PET tracer with comparable affinity for mu,-

kappa-, and delta opioid receptors, and a subcutaneous hind paw injection of saline (acting as a control for a different experiment). Anesthesia was removed and each rat was placed in an observation chamber for 35 minutes. After behavior observation, each rat was anesthetised with sevoflurane and placed in a Siemens Inveon preclinical PET scanner. At minute 45, the scan began and the rat remained anesthetized for 30 minutes of dynamic image acquisition. Using SPM8 brain imaging tools, PET data were aligned to a common space and coregistered to an anatomical MRI of a weight-matched rat. Data were normalized to the visual cortex, a region relatively devoid of opioid receptors, using the reference tissue method. A set of regions known to be involved in the processing of nociceptive stimuli were defined on the anatomical MRI in Paxinos space and used to calculate the mean tracer binding within each region. Results: The highest levels of [18F]-FDPN binding were seen in the thalamus, caudate putamen, anterior cingulate cortex and amygdala. The level of tracer binding within these regions was in alignment with the human literature. Conclusion: The level of [18F]-FDPN binding in the rat brain is similar to levels seen in the human brain for multiple brain regions of interest for pain-related research.

Title: Human nerve growth factor mutation alters neural pathways for behavioral responses to acute pain

Authors: *I. MORRISON[1], I. PERINI[2], M. CEKO[3]
[1]Neurosci & Physiol, [2]Clin. and Exptl. Med., Linköping Univ., Linköping, Sweden; [3]Natl. Ctr. for Alternative and Complementary Med., NIH, Bethesda, MD

Abstract: Acute pain coding goes beyond sensory processing to encompass the selection and modification of behavioral responses to a noxious event. We used fMRI and white matter tractography (tract-based spatial statistics, TBSS) to investigate such pain-action. We compared

healthy subjects to patients with a rare nerve growth factor beta (NGFB) mutation that results in a reduction in unmyelinated and thinly-myelinated afferent nerves (including nociceptive C and Aδ afferents). These patients show impaired pain sensitivity and indifference to pain, and have been diagnosed with hereditary sensory and autonomic neuropathy type V (HSAN-V; Minde et al 2004). However, they are able to report thermal pain thresholds, which do not differ from those of controls. During fMRI, participants pressed a button at the appearance of a visual cue during painful or nonpainful thermal stimulation, with task instructions changing by block. This allowed modeling of voluntary motor responses and painful stimulation separately (Perini et al, J Neurosci, 2013). For the main effect of pain regardless of motor response, the neurologically healthy control group showed a robust bilateral activation of anterior insula (AI). The main effect of motor action activated the midcingulate/anterior cingulate cortex (MCC/ACC). This activation pattern suggests that anterior insula signals motor-independent aspects of the noxious stimulus, whereas MCC/ACC is more closely tied to the production of a voluntary motor response. In contrast, the mutation carrier group's AI responses were markedly reduced for the main effect of pain, and their MCC/ACC responses were absent for the main effect of motor action. Carriers also rated the "urge to move" their hand away from the painful thermal stimulus as significantly lower than controls. When this "urge to move" was included as a covariate in the statistical model for the healthy group, pain-related signal changes revealed activation in the posterior insula contralateral to stimulation. "Urge" itself covaried with responses in the AI contralateral to stimulation. In carriers, fractional anisotropy (FA) in ACC positively correlated with the density of C afferents in the cornea, which more generally indexes nerve density in the skin. These results suggest a caudal-rostral coding of pain and "urge" information in insula which culminates in action-related processing in the MCC/ACC. The NGFB mutation's consequences in the brain may not affect pain perception per se but lead to less efficient translation of pain information into action, resulting in failure to make appropriate behavioral adjustments in potentially tissue-damaging situations.

Title: Intrinsic brain networks normalize with treatment in pediatric complex regional pain syndrome

Authors: *L. BECERRA[1], L. SIMONS[2], A. LEBEL[3], S. BORSOOK[3]
[1]P.A.I.N. Group, [2]Psychology, [3]Anesthesia, Boston Children's Hosp., Waltham, MA

Abstract: Complex regional pain syndrome (CRPS) is a neuropathic pain condition affecting the peripheral and central nervous system characterized by the continuing presence of pain that is disproportionate to the inciting event and it is not curable in adults. Pediatric patients with CRPS typically recover with standard medical treatment. In this study, we evaluated intrinsic brain networks measures in the CRPS disease state and after an intensive multidisciplinary pain treatment program to delineate (a) network abnormalities in the disease state and (b) changes induced by treatment. Twelve patients with unilateral lower extremity CRPS were recruited (n=12; 14.1 ± 0.7 yrs.) and 12 age/sex matched controls (n=12; 14.2 ± 0.8 yrs.). Patients and Healthy Controls were scanned twice, before treatment (patients-Visit 1) and at discharge (3 weeks later: Visit 2). A 3T Siemens Tim Trio was used. Subjects underwent a structural scan (MPRAGE, 256x256 mm 192-1.33 mm slices) and a RSN scan (EPI, 41 slices isotropic 3.5 mm3 voxels, TR/TE=3s/30ms 200 volumes). fsl tools were used for preprocessing and an ICA analysis was done. Group ICA were first calculated and then dual regression was applied to determine differences. The main contrasts of interest were: (i) Patients vs. Controls visit 1 (Disease Effect); (ii) Patients visit 1 vs. Patients visit 2 (Treatment Effect) (iii) Patients vs. Controls Visit 2 (Residual Effects). Patients indicated a reduction of pain symptoms and functional disability. Disease Effect: Intrinsic networks associated with chronic pain in adults displayed abnormal connectivity: salience network: increased connectivity with prefrontal (PFC), cingulate and insula cortices. Default mode network: increased connectivity with frontal, postcentral and precuneus. Central executive network: increased connectivity with PFC, post central and temporal areas. Sensorimotor network: increased connectivity with frontal and parietal areas, decreased connectivity with cingulate and cerebellum. Following treatment, abnormalities in most of these networks tended to be non-significant, however, in some networks (sensorimotor network), they still persisted (Residual Effects). Pediatric pain imaging studies are very sparse and difficult to perform. This is one the first studies of a chronic pain condition in children. We detected changes in intrinsic brain networks in children suffering from CRPS. After a relatively short treatment of 3 weeks, most of the observed changes were diminished. The plasticity of a young brain could be a significant factor in the recovery, as it does not occur in adults.

Title: White matter neuroplasticity following cognitive behavioral therapy for chronic pain

Authors: J. BISHOP[1], G. LIEBERMAN[1], M. SHPANER[1], T. ANDREWS[2], R. WATTS[3], M. DAVIS[1], C. FILIPPI[4], *M. R. NAYLOR[1]
[1]Psychiatry, Clin. Neurosci. Res. Unit, Univ. of Vermont, BURLINGTON, VT; [2]Phillips Healthcare, Best, Netherlands; [3]Radiology, Univ. of Vermont, BURLINGTON, VT; [4]Radiology, Columbia Univ., New York, NY

Abstract: Objectives: Chronic musculoskeletal pain is a leading cause of disability in the United States, however, efforts to provide patients with therapeutic relief have remained insufficient. Novel biobehavioral and psychotherapeutic interventions such as cognitive behavioral therapy (CBT) may provide a more successful long-term treatment option. In this study we hypothesize that changes in potentiation due to CBT intervention will act to neuroplastically alter white matter pathways in the pain matrix measured by diffusion tensor imaging (DTI). Furthermore, we speculate that there will be an increase in fractional anisotropy (FA) and a decrease radial diffusivity (RD) that will correlate with clinical self-efficacy behavioral scores. **Methods:** 49 adult patients with a primary diagnosis of chronic musculoskeletal pain were evaluated by a physician to confirm eligibility. Additionally, 33 age and gender matched controls were recruited. Chronic pain patients were randomized to one of two groups: group 1 received an 11 week CBT intervention, and group 2 received educational mailings pertaining to healthier living habits but not pain coping mechanisms. Magnetic resonance imaging (MRI), including DTI assessment, was acquired before and after 11 week CBT. Furthermore, behavioral self-efficacy questionnaires were completed before and after completion of CBT. DTI analysis was conducted using FSL tract based statistical software (TBSS) followed by subsequent region of interest (ROI) cross-group voxel-based statistical analysis using behavioral clinical measures as covariates. **Results**: There were significant group by time interactions between CBT and education. A decrease in FA was observed in the right

cingulum adjacent to the hippocampus (p<0.01), the right superior longitudinal fasciculus (SLF) (p=0.03) as well as an increase in RD in the left cerebral peduncle (p=0.04). Additionally, significant improvements in self-efficacy behavioral scores were correlated with a decrease in FA and increase in RD. **Conclusions**: CBT intervention showed decreased FA and increased RD in pain matrix white matter tracts, however, the same trend was also noted in the education group. Antithesis to our hypothesis, these changes indicate a further amplification of both FA and RD post-intervention opposed to attenuation. These changes may be attributed to learning to cope with chronic pain over time. Alternatively recent molecular mechanisms have been proposed implicating ATP release by tonically active neurons modulating astrocyte cytokine activity that could have downstream effects on myelinating oligodendrocytes.

Abstract: Low Back Pain (LBP) is one of the most common chronic conditions affecting millions of people worldwide with significant economic impact. Currently, there is no clear understanding of how nociceptive regions of the brain respond to different pain stimuli. Nociceptive brain region reactivity has been examined with functional magnetic resonance imaging (fMRI) to thermal or noxious stimuli. Critically, patients with back pain report pain with mechanical stress. Understanding how the brain responds to mechanical stress could improve our understanding of nociception in LBP. In this study we used fMRI to investigate brain activation patterns resulting from a mechanical stimulus applied to the lumbar spine via fMRI. We developed a MRI compatible device capable of delivering a range of pressures. Thirteen healthy and thirteen LBP subjects (average duration of pain: 8 months) were included in this preliminary study. Using a block design, subjects received 3 levels of mechanical pressure to the lower back with our custom-made pressure device. Whole-brain voxel-wise t-tests comparing each pressure condition to rest were used to examine brain responses to mechanical pressure in healthy and LBP patients separately. Results show significant differences in brain activation patterns between healthy and LBP subjects. Healthy subjects demonstrated increased brain activation in the cerebellum and parts of the frontal and parietal lobes, and decreased activation in the hippocampus, pre and post central gyrus compared to rest. In contrast, LBP subjects demonstrated decreased activation in cingulate, caudate and post central gyrus compared to rest. Our preliminary results suggest that subjects with LBP have altered sensory processing and respond differently to mechanical stimuli compared to healthy subjects.

Title: Cortical thickness change following acupuncture therapy predicts long-term pain improvement in idiopathic hand pain patients

Authors: *Y. MAEDA[1,2], N. KETTNER[2], J. KIM[1], S. CINA[1], C. MALATESTA[3], J. GERBER[1], C. MCMANUS[3], A. LIBBY[1], R. ONG-SUTHERLAND[3], P. MEZZACAPPA[1], L. R. MORSE[4], J. AUDETTE[5], V. NAPADOW[1]

Hosp., Medford, MA; [4]Harvard Med. School, Spaulding Rehabil. Hosp., Boston, MA; [5]Harvard Vanguard Med. Associates, Atrium Hlth., Boston, MA

Abstract: Introduction: Patients with carpal tunnel syndrome (CTS) and idiopathic hand pain (IHP) both suffer from pain and paresthesia over median-nerve innervated regions of the hand. While CTS presents with decreased median nerve conduction, IHP does not. We have previously shown maladaptive structural neuroplasticity in CTS, and acupuncture has been reported to relieve symptoms associated with hand pain and paresthesia, as well as producing brain plasticity (Napadow et al. 2006, 2007). However, the effects of acupuncture on symptomatology and structural brain plasticity in hand pain disorders devoid of peripheral nerve pathology have not been reported. Moreover, the link between structural brain plasticity and long-term outcomes in such patients is also unknown. Methods: We evaluated the brains of 19 IHP patients with structural T1-weighted MRI at 3T (Siemens Trio) before and after 8 weeks of acupuncture treatment. Pain and paresthesia were evaluated with the Boston Carpal Tunnel Syndrome Questionnaire (BCTSQ, 0-5 scale) before and after acupuncture, as well as 3 months following therapy. Acupuncture treatment included 2Hz electrical stimulation at acupoints PC7 and TW5 near the affected wrist, with an additional 3 acupoints, manually stimulated, chosen by the acupuncturist. Structural data were preprocessed using specific algorithms for longitudinal cortical thickness measurement (Freesurfer, ver. 5.3). Gray matter thickness data were contrasted before versus after acupuncture, and a paired difference map was calculated, cluster corrected for multiple comparisons at $p=0.05$. Cortical thickness data from the most significant vertex were correlated with BCTSQ change. Result: BCTSQ pain (baseline: 3.0±0.6, post-acup: 2.1±0.7, 3-months: 1.9±0.7, mean±SD) and paresthesia (baseline: 2.6±0.7, post-acup: 1.7±0.5, 3-months: 1.5±0.3) decreased following acupuncture treatment and at 3-month follow-up ($p<0.01$). Following acupuncture, cortical thickness was significantly reduced in primary somatosensory cortex (S1) contralateral to the most affected hand. Furthermore, S1 thickness change after acupuncture was negatively correlated with long-term change in BCTSQ pain (3month follow-up vs. post-acupuncture, $r=-0.78$, $p=0.01$). Therefore, greater increase in S1 cortical thickness rate,

the greater the continued reduction in BCTSQ pain at long-term follow-up. Conclusions: Acupuncture reduced pain and paresthesia, while S1 thickness change was correlated with long-term follow-up reductions in pain. Thus, longitudinal cortical thickness change following acupuncture therapy may serve as a predictor for long-term treatment outcome in IHP.

Inst. of Biomed. Engin., Natl. Central Univ., Taoyuan, Taiwan; [5]NINDS, Dept Psychology, Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Laser acupuncture (low level Laser) stimulated on acupoint Yongquan (K1) with the different modulation induced different brain activations in the human study. However, according to the higher heart rate and respiratory rate of rodents, we hypothesis the effect of modulated laser acupuncture would conduct similar results in the low frequency modulation in a rodent study. In this study, we are testing the hypothesis by stimulating 10Hz modulated laser acupuncture on the rat K1 located at right backpaw. All the MR experiments were conducted on a 7T Biospec MRI system (Bruker, Germany). Six male Sprague Dawley rats were scanned under institutional approval. During fMRI, rats were anesthetized with α-chloralose. The functional data were analysis by using SPM8 (UCL, U.K.). Our results demonstrated the greater brain activation at right somatosensory cortex S1 in the hind limb region, left motor cortex M1, thalamus and paraventricular thalamic nucleus. Firstly, the activation founded in R-S1 suggested the undefined ipislateral pathway that conducted by laser acupuncture. Secondly, the activation

in thalamus suggested the similar activation to the human 2Hz modulation laser acupuncture study. In conclusion, this study firstly demonstrated the laser acupuncture effect on the rodent K1. The ipislateral activation area and the similar activation of human study suggested under discover pathway conducted by laser acupuncture.

Title: Structural and functional network topologies of the limbic system shape chronic pain

Authors: *E. VACHON-PRESSEAU, M. N. BALIKI, P. TETREAULT, T. J. SCHNITZER, A. V. APKARIAN
Northwestern Univ., Chicago, IL

Abstract: Neuroimaging studies in humans show that limbic brain properties are involved in motivation, aversive learning, and memory, and might predispose individuals to develop chronic pain. Here we test the role of functional and anatomical properties of the limbic brain in the transition to chronic back pain. We collected fMRI and DTI in 69 subacute back pain (SBP, pain duration < 12 weeks), repeatedly over one year, and examined the functional and structural topological properties of the limbic brain. We constructed structural brain graphs of 1068 nodes (4 mm3 voxels) belonging to the frontal cortex, nucleus accumbens, amygdala, and the hippocampus with edges drawn between nodes representing white matter tracks. Edges were thresholded at a density of 0.1 and binarized. Functional brain graph was also constructed from Pearson correlation coefficients, thresholded at a density of 0.1 and binarized. Both structural and functional networks were sparse and displayed small world properties. A modularity analyses on the structural limbic network revealed the presence of three modules, with dense

within module interconnections and sparse across module interconnections. These modules corresponded to the corticostriatal circuit, the orbitofrontal cortex and the hippocampo-amygdala complex. Over one year, 39 of SBP persisted with back pain (SBPp) and 30 recovered (SBPr). SBPp showed stronger structural connectivity in the corticostriatal module than SBPr at all visits ($F = 9.7$; $p = .003$) and no group differences or interaction were observed in the other modules. SBPp showed stronger functional connectivity in the corticostriatal module compared to SBPr ($F = 4.6$; $p = .04$) and an interaction of time by group was observed in the orbitofrontal module ($F = 3.3$ $p = .02$) and the hippocampo-amygdala module ($F = 4.3$ $p = .007$). These findings suggest that the density of structural and functional connectivity in the corticostriatal circuit predispose individuals to chronic pain; while the density of functional connections in the other two limbic modules change in time in relation to the clinical profile of the patients. Therefore, these results indicate the critical role of the limbic brain in transition to chronic pain.

Title: Resting state and stimulus evoked brain activity in awake or isoflurane-anesthetized rat

Authors: *P.-C. CHANG, D. PROCISSI, A. APKARAIN
Northwestern Univ., Chicago, IL

Abstract: Functional imaging in rodents generally uses anesthetics to control stress levels and excessive motion. However, the use of anesthetics or paralyzers introduce confounds that can hamper our ability to assess brain network properties and/or stimulus representation. In this work, we describe an innovative design for assessing resting state and task related fMRI in awake, conscious rats. To demonstrate the value of the awake rat fMRI, we compare within animal fMRI results in the awake and anaesthetized conditions. To reduce the stress of the animals in the MRI environment, the rats were trained seven continuous days prior to MRI scans. Each day half hour training with fMRI scanning sound and head-post constraint conditioning

was administered. Custom made snuggle were adjustable around the rats for effective yet comfortable restraint, with an opening that provided access to the rat's hindpaw. A resting state fMRI (rs-fMRI) and stimulus-evoked fMRI were first acquired when the rats were in awake state, followed by repeat scans under isoflurane anesthesia. Rs-fMRI was acquired when rats were resting in the scanner for 8 minutes with no external stimulation. Air-puff stimuli, applied to the hindpaw, were used as mechanical stimulation to examine somatosensory activity. Stimulus-evoked fMRI had 10 repetitive stimulus blocks. Each block consisted of stimulation alternated with 15s-off/15s-on/10s-off. While the rats were awake, Nucleus of Accumbens (NAc) core and shell showed significant connection to various cortical regions, including the cingulate (ACC), somatosensory (S1, S2) and motor cortices (M1, M2). After the rats went under anesthesia, the core and shell mainly display local connections. In the awake state, we observed a significant activation in contralateral S1, S2, thalamus (Tha), and deactivation in ipsilateral S1, and bilateral amygdala (Amy). While anesthetized, the same stimulus only resulted in deactivations in ipsilateral S1, and bilateral Amy. In summary, NAc core and shell in the awake rats show more widespread functional connectivity, compared to the state when the rats were anesthetized; in addition, rats had more fMRI activation in response to air-puff stimulation. These results demonstrate that awake rat fMRI will permit better evaluation of brain networks and brain responses to external stimuli.

Title: Cell to cell coupling in dorsal root ganglion (DRG) neurons amplifies pain sensation

Authors: *Y. KIM[1], K. PARK[2], S. JILAFU[2], L. HAN[2], Z. LI[2], L. YOUNG[2], P. LAVINKA[2], S. HE[2], F. ZHOU[2], Y. GUAN[2], M. CATERINA[2], X. DONG[2]
[1]Neurosci., [2]Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Hyperalgesia/allodynia, heightened pain sensitivity in uninjured and/or injured tissues, is widely accepted to be mediated primarily by sensitization of spinal cord and brain neurons, a process called central sensitization. The contribution of peripheral sensitization of primary sensory neurons to hyperalgesia/allodynia remains controversial and largely unknown. Here we

have generated Pirt-GCaMP3 mice in which GCaMP3, a genetic-encoding Ca2+ sensitive indicator, is expressed robustly and specifically in almost all primary sensory neurons. The advantages of GCaMP3 imaging using these mice include facile, parallel direct visualization of activity in many afferents, excellent spatial resolution, and preservation of somatotopic organization. Application of this technique to DRG hyperalgesia/allodynia and inflammatory model permitted us to visualize robust increase of neuronal hypersensitivity in cell bodies of DRG neurons *in vivo* in an anesthetized Pirt-GCaMP mouse. Peripheral sensitization was observed not only as of increasing activated number of neuronal cell bodies in DRG but also as of apparently increasing cell to cell coupling events. Gap junctions are specialized transmembrance channels that allow rapid electrical signaling and direct intercellular communication for maintenance and coordination of normal cellular activities and homeostasis. Strikingly, augmentation in cell to cell coupling in DRG was mediated by the dynamic plasticity of gap junctions in response to nervous system injury and modulated neuronal hypersensitivity and pain in animal models of inflammatory and/or sciatic nerve chronic constriction model (SN-CCI). Blockade of gap junction modulated DRG cell to cell coupling and also chronic and inflammatory pain and is the potential target as a novel modality for the treatment of intractable pain syndromes. Pirt-GCaMP3 mice thus represent a unique tool with which to visualize primary sensory neuron activity under physiological and pathological conditions of pain, itch, and any somatosensations *in vivo* and to reveal peripheral sensitization mechanisms associated with hyperalgesia, allodynia, and possibly referred pain. Therefore, this study creates a new way of characterizing the physiological properties and functions for developing new pain- or other modality-specific drug target for a treatment with few side effects.

Title: A bivalent ligand that targets μ opioid and mGluR5 receptor heteromers reduces neuropathic pain responses when given intrathecally to mice

Authors: *C. PETERSON[1], K. F. KITTO[2], E. AKGUN[3], M. LUNZER[3], P. S. PORTOGHESE[4], C. FAIRBANKS[2]
[1]Pharmaceutics, [2]Neuroscience, Pharmaceutics, Pharmacol., [3]Medicinal Chem., [4]Medicinal Chemistry, Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Background: Both the mu opioid receptor (MOR) and mGluR5 receptor are expressed in the spinal cord and are involved in analgesia and pain. The association of the two receptors as MOR-mGluR5 heteromers has been noted in HEK293 cells coexpressed with MOR and mGluR5. Therefore, it is possible that this putative heteromer may be present in the central nervous system (CNS). Such a heteromer could be involved in the hyperalgesia associated with chronic pain given the known functional interaction of mGluR5 with the NMDA receptor. Thus, a bivalent ligand (MMG22) that contains both mGluR5 antagonist and mu agonist pharmacophores should antagonize the mGluR5 protomer and activate the MOR protomer of the putative MOR-mGluR5 heteromer. In fact, intrathecal MMG22 has recently been reported to produce profound antinociception without tolerance in mouse models of inflammatory pain (Proc. Nat Acad Sci. USA, 2013, 110, 11595). In the present studies, we show that MMG22 also reduces nerve-injury-induced tactile hypersensitivity. **Methods:** Baseline responses to electronic von Frey apparatus were collected in ICR-CD1 male mice, after which they were subjected to the spared nerve injury model of neuropathic pain. Several weeks post injury, multiple doses of MMG22 were intrathecally injected at a wide dose range (0.01-10 nmol). Time points assessed included 5, 12, 20, 90, 120 minutes post-injection. Additionally, morphine, mGluR5 antagonist (MPEP), and the combination of morphine + MPEP were assessed for interactions. **Results:** This study demonstrated that intrathecal delivery of the bivalent ligand MMG22 attenuates nerve-injury induced hypersensitivity with high potency. This effect was clear at 5 minutes post injection. Higher doses (1, 3, 10 nmol) demonstrated a longer duration of action. The monovalent ligands, morphine and MPEP (upon which the bivalent structure is based), both reduced hypersensitivity in nerve-injured mice when given individually at 1, 3, and 10 nmol. The potency of coadministered monovalents was substantially less than that of MMG22. **Conclusion**: These results suggest that the MMG22 compound targets a heteromer that likely is comprised of both mu opioid and mGluR5 protomers expressed in the spinal cord.

Abstract: Background: An endogenous antinociceptive peptide, which highly binds to mu- and delta-opioid receptors, is β-endorphin. These opioid receptors regulate the neurotransmitter release from primary afferents and hence control analgesia in spinal dorsal horn. The aim of this study is to disclose an ability of intrathecal β-endorphin on acute pain induced behavior and neurotransmitter release from primary afferents. Materials and methods: Rats (male Holtzman Sprague-Dawley, 250g) with intrathecal (IT) catheter administrated IT saline, β-endorphin (1, 3 and 10μg), β-endorphin (10μg) + intraperitoneal (IP) naltrindole (3mg/kg) or β-endorphin (10μg) + IP naloxone (3mg/kg). Animals received intraplantar formalin (50μl) to the left hindpaw. Formalin-evoked flinches were counted for an hour by an automated machine. Rats were transcardially perfused at 2 hours after formalin and c-Fos expression in the lumbar spinal dorsal horn were measured by immunohistochemistry. In separated groups, rats were perfused at 10 min after formalin and the incidence of neurokinin 1 receptor (NK1r) internalization in the superficial dorsal horn were quantified by fluorescent immunohistochemistry. Results and discussion: Formalin injection to the paw resulted in an intense, bi-phasic flinching behavior in the injected side paw, which was reduced by IT β-endorphin pretreatment dose-dependently. Robust NK1r internalization in the ipsilateral L3 to L5 dorsal horn was showed following formalin injection. IT β-endorphin significantly decreased NK1r internalization. Formalin also caused c-Fos expression in the superficial and deep dorsal horn neurons, which reversed by IT β-endorphin. The regulations of IT β-endorphin on formalin-induced flinching behavior, NK1r internalization and c-Fos were demised by naltrindole. Conclusion: IT β-endorphin displayed potent antinociceptive effects in acute pain model. At the dose of analgesia, IT β-endorphin suppressed the release of substance P from primary afferents likewise c-Fos expression in dorsal horn neurons. The effects were at least in part regulated through the delta-opioid receptors.

Title: SEO-16: An orally active opioid analgesic with rapid onset of activity and reduced CNS-side effects

Authors: ***S. D. HARRISON**[1], N. ANAND[2], I. CHOI[2], J. EVANS[2], K. GOGAS[2], M. HENNESSY[2], H. GURSAHANI[2], G. KIM[2], M. LEE[2], P. QUACH[2], W. RUBAS[2], J. RIGGS[2]
[1]Nektar Therapeut. Inc., San Francisco, CA; [2]Nektar Therapeut., San Francisco, CA

Abstract: Opioids are widely prescribed for the treatment of moderate to severe acute pain but are limited by their CNS-mediated side effects. Stable polymer conjugation technology has been successfully applied in the development of NKTR-181. NKTR-181 is an opioid receptor agonist intended for the chronic treatment of moderate to severe pain. The molecule is designed to have a slow rate of entry into the CNS, to markedly reduce abuse liability and CNS side effects. Nektar is also developing a novel opioid molecule intended to have low CNS side-effects (SEO-16). This program targets treatment of acute pain, hallmarked by rapid onset of analgesic activity. SEO-16, binds to the mu opioid receptor (Ki = 191 nM) and displays full agonist efficacy *in vitro*. Oral SEO-16 produces full efficacy in the mouse acetic acid writhing model of pain (ED50 = 7 mg/kg po). Activity in the formalin paw test was seen within 15 min, consistent with rapid attainment of plasma exposure (concentrations peak 20 mins after oral dosing in rats), suggesting a rapid onset of analgesic effect. Doses of SEO-16 that produced a greater than 50% reduction in the time spent on the rotarod were 60-80 times higher than ED50 doses that were associated with efficacy in the acetic acid writhing models, suggesting a significant separation of the analgesic and CNS side effects. These data were consistent with *in vivo* pharmacokinetic and *in situ* brain perfusion data in rats showing a 40 fold reduction in brain:plasma ratio and a 4-fold reduction in brain entry rate compared with marketed opioids. These preclinical data suggest that SEO-16 is a mu-opioid agonist with low CNS side effects that produces a rapid onset of analgesic activity. The reduced brain entry rate may also lead to reduced abuse potential compared to currently marketed products for this indication. Taken together, these data indicate

that Nektar's polymer conjugation technology can be used to alter opioid pharmacology to enable treatment of both chronic and acute pain while minimizing undesirable CNS side effects.

Title: Valpronic acid attenuated the development of morphine withdrawal syndrome in mice

Authors: T. SHINOZAKI, M. ARAKI, *T. YAMAMOTO
Kumamoto Univ. Hosp., Kumamoto-shi, Japan

Abstract: Background: Valpronic acid has been used for the treatment of epilepsy, bipolar disorder and migrane, but the precise mechanisms of action of valpronic acid is not fully understood. Valpronic acid has many actions, such as the enhancement of GABA-mediated neurotransmission, the involvement of signaling systems like the Wnt/β-catenin and ERK pathways and interference of inositol and arachidonate metabolism. Recently, valpronic acid has been known to have the property of HDAC inhibitor. Recently, a selective HDAC inhibitor, suberoylanilide hydroxamic acid, has been reported to enhance naloxone-induced morphine withdrawal syndrome. On the other hand, other HDAC inhibitor, such as trichostatin A, has been reported to attenuate naloxone-induced morphine withdrawal synderome. In the present study, we examined whether valpronate attenuates the development of naloxone-induced morphine withdrawal syndrome. Methods: Valpronic acid was injected three times daily (900 mg/kg/day) for 5 days. Morphine withdrawal syndrome was induced by ip injection of 3 mg/kg of naloxone after 5 days infusion of 24 mg/kg/day morphine. Level of morphine withdrawal syndrome was evaluated by counting the number of jumping during 10 min after naloxone injection. Results: Valpronic acid attenuated the development of naloxone-induced morphine withdrawal syndrome. Conclusion: HDAC may play an important role in the development of morphine withdrawal syndrome and the inhibition of HDAC by valpronic acid is a useful technique to prevent morphine withdrawal syndrome.

Title: Activation of the mu opioid receptor stimulates the binding of RGS4 to the receptor/G protein complex in a GTP-dependent manner

Authors: R. SANTHAPPAN[1], *T. E. COTE[2]
[1]Pharmacol., [2]Uniformed Services Univ., Bethesda, MD

Abstract: The conditions that cause RGS4 to associate with the mu opioid receptor/G-protein complex in rat brain membranes were examined. Solubilized mu opioid receptors (MOP-r), that retained high affinity, guanine nucleotide-sensitive agonist binding, were immunoprecipitated with antibodies directed against either the N-terminal or the C-terminal of the rat mu opioid receptor. Stimulation of MOP-r with [D-ala^2, N-Me-Phe^4, Gly5-ol]-Enkephalin (DAMGO), a selective MOP-r agonist, caused a 2-fold increase in the amount of the G-proteins that co-immunoprecipitated with MOP-r and also increased by 35% the amount of recombinant RGS4 that associated with the MOP-r/G protein complex. Interestingly, MOP-r activation by DAMGO in the presence of 10 μM GTP further increased the association of RGS4 with the MOP-r/G-protein complex by 72% (unpaired t test, p=0.003). Direct activation of G-proteins with GTPS, a nonhydrolyzable analog of GTP, increased by 2-fold the association of RGS4 with the MOP-r/G-protein complex (unpaired t test, p=0.013). The amount of RGS4 co-immunoprecipitating with MOP-r was determined by comparing the densities of RGS4 bands to the densities of known standard amounts of RGS4 in western blots. The presence of MOP-r in immunoprecipitates was detected by western blotting using anti-MOP-r$_{349\text{-}398}$. Quantification of MOP-r in immunoprecipitated material was determined by saturation [^{3}H]DAMGO binding. It was determined that the ratio of RGS4 to MOP-r was 1 to 1 when the G-proteins associated with MOP-r were fully activated. In Ni^{2+}-resin pull down experiments, it was determined that activation of Goa with GTPS tripled the amount of Goa bound to His_6RGS4 while GTP and GDP were without effect. In SHSY5Y cell homogenates, RGS4 caused a concentration-dependent, noncompetitive attenuation of DAMGO-mediated inhibition of adenylyl cyclase activity but had no effect on GTPS-mediated inhibition of adenylyl cyclase activity. Conclusions: Agonist activation of MOP-r causes Gi/o-type G proteins to bind to MOP-r and causes GTP to activate Gi/o-type G-proteins. GTP-activated G-proteins trigger downstream signaling and also cause RGS4 to bind to the MOP-r/G-protein complex and to cause a noncompetitive attenuation of MOP-r signaling by increasing the rate of GTP hydrolysis by Gi/o-type G-proteins.

Title: Intrathecal pretreatment with AAV5 carrying the gene for human arginine decarboxylase (hADC) inhibits the development of opioid analgesic tolerance

Authors: *C. C. CHURCHILL[1], S. SCHNELL[2], M. RIEDL[2], C. PETERSON[3], K. KITTO[4], J. WEINHOLD[2], L. VULCHANOVA[2], C. FAIRBANKS[5]
[1]Exptl. & Clin. Pharmacol., Univ. of MN, Minneapolis, MN; [2]Neurosci., [3]Exptl. & Clin. Pharmacol., [4]Neuroscience, Pharmaceutics, Pharmacol., [5]Neuroscience, Pharmaceutics, Pharmacology, Exptl. & Clin. Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Background: The decarboxylated form of L-arginine (agatmine) has been shown to reduce opioid analgesic tolerance, as well as other manifestations of neuroplasticity. Agmatine inhibits NMDA receptor activation and the production of nitric oxide synthase; consequently the mechanism by which agmatine acts to reduce neuroplasticity likely involves that cascade. Since agmatine has a synthetic pathway an opportunity presents itself to increase expression of the synthetic enzyme (arginine decarboxylase, ADC) and potentially local agmatine levels. Toward this end, we have developed an adeno-associated viral vector (AAV) to provide gene transfer of human ADC following intrathecal delivery. We then compared the development of systemic opioid analgesic tolerance in subjects treated with this vector (AAV5-hADC) or saline controls. Methods: ICR-CD1 male mice were pre-treated with either AAV5-hADC vector or saline eight weeks prior to testing. Baseline tail flick responses were collected using the warm water tail flick immersion test (52.5°C). Opioid tolerance was induced with seven subcutaneous (s.c.) injections of either morphine (3 mg/kg (4 times) and 5 mg/kg (3 times)) or saline over the course of 3 days. On day four, cumulative dose-response curves to s.c. morphine (1, 3, 10, 20 mg/kg) were constructed in each of the four pre-treatment groups (Saline-Saline, Saline-Morphine, AAV5-hADC-saline, AAV5-hADC-morphine.) Relative potency (Tallarida 1987) was calculated for

each dose-response curve and the development of morphine tolerance assessed in each of the two primary treatment groups. Following completion of the experiment, mice were euthanized and spinal cord, dorsal root ganglia, periaqueductal grey, and choroid plexus tissues assessed for mRNA expression. Results: A significant four-fold rightward shift in the morphine dose-response curve was observed in control subjects, as expected. However, in subjects pre-treated with AAV5-hADC, the ED50 values were equivalent between the morphine and saline treatment groups, indicated that morphine tolerance did not develop. Expression of hADC mRNA was confirmed in 15 out of 16 animals in any of the following tissues: Choroid plexus, spinal cord, dorsal root ganglia, periaqueductal gray. Conclusion: We interpret the observed inhibition of morphine analgesic tolerance in the AAV5-hADC treatment group as suggestive of agmatine produced endogenously from the over expression of hADC.

Title: Identification of new opioid receptor variants

Authors: ***M. H. PILTONEN**[1], L. DIATCHENKO[2]
[1]Dept. of Anaesthesia, Fac. of Dent., [2]Dept. of Anaesthesia, Fac. of Dent. and Fac. of Med., McGill Univ., Montreal, QC, Canada

Abstract: Mu-opioid receptor (MOR) is the main target for opioid analgesics. The gene OPRM1 encodes for a number of alternatively spliced variants of the receptor -over 20 alternatively spliced mRNA constructs are known in human, and over 50 in mice. The functional significances of different splice variants are still poorly understood, but there is some evidence for isoform-specific differences in cellular signalling, contributing to certain adverse effects related to use of opioid drugs. Surprisingly, despite high homology, much less splice variants have been described for the other members of the opioid receptor family: delta- and kappa-opioid receptors and opiate receptor-like (DOR, KOR and OPRL, respectively). Identification of new variants of these

receptors, and understanding their signaling pathways could reveal similar diversity as is seen with MOR, and could lead to discovery of novel specific drug targets. Therefore, we aimed to find new isoforms of all four opioid receptors. We first treated cultured Be2C human neuroblastoma cells with 100 nM deltorphin II (DOR selective agonist), 1 uM IBNtxA (MOR1-K selective agonist) or 1 uM morphine (non-selective opioid receptor agonist) for 1, 3, 8 or 24 h to observe changes in mRNA expression of DOR1, MOR1 or MOR1-K (a 6-transmembrane variant of MOR). We also used the spinal cords of DOR exon 1-knockout and wild type mice, chronically treated with morphine or vehicle. Total RNA was extracted from the cells using the guanidinium thiocyanate-phenol-chloroform extraction method, and from the spinal cords using a special column extraction kit for lipid-rich tissues. The quality of the RNA was verified with Agilent Bioanalyzer. The mRNA was processed for determination of the expression levels of the receptors by qPCR (junctions of exons were amplified: 1-2 for MOR1, 13-2 for MOR1-K and 1-2 for DOR1) We observed an up-regulation of all three receptors mRNA in a ligand-specific pattern. The most robust up-regulation was observed for with 100 nM deltorphin II and 1 uM IBNtxA treatments after 1h. Morphine dependent mRNA up-regulation was most prominent in 3 hours. mRNA from these time points were processed for 5'RACE PCR to map possible new 5' splice variants. Multiple PCR-products generated by a gene-specific primers targeting 5' end of selected exons in all four opioid receptor genes were generated, suggesting multiplicity of 5'alternatively spliced isoforms. Hi-seq sequencing approach is applied to map the fine substructure of these alternatively-spliced isoforms.

Title: Ligand biased differences in morphine and fentanyl antinociception following microinjection into the ventrolateral periaqueductal gray of the rat

Authors: R. L. WESCOM, K. N. CAMPION, K. A. SAVILLE, E. N. BOBECK, *M. M. MORGAN
Dept Psychology, Washington State Univ., VANCOUVER, WA

Abstract: Mu-opioid (MOP) receptors in the periaqueductal gray (PAG) contribute to the antinociceptive effects of opioids such as morphine and fentanyl. We recently found that relative to morphine, the antinociceptive efficacy of fentanyl is much lower when administered into the ventrolateral PAG as opposed to systemically (Bobeck et al., 2012). This loss of antinociceptive efficacy could be caused by diffusion of fentanyl to sites outside the PAG. Experiment 1 tested this hypothesis by comparing the ability of morphine and fentanyl to produce antinociception when injected in and adjacent to the ventrolateral PAG. It also is possible that morphine and fentanyl antinociception are mediated by differential activation of pre- and postsynaptic MOP receptors in the PAG. MOP receptors are located on both pre- and postsynaptic elements and are coupled to unique signaling pathways at each site. Given that presynaptic receptors have greater control over transmitter release, morphine may produce antinociception by a predominantly presynaptic mechanism and fentanyl via a predominantly postsynaptic mechanism. Experiment 2 tested this hypothesis by determining whether blocking presynaptic Kv+ channels with alpha-dendrotoxin or postsynaptic GIRK channels with tertiapin-Q preferentially attenuates the antinociceptive effect of microinjecting morphine or fentanyl into the ventrolateral PAG. Experiment 1 revealed that morphine and fentanyl were most likely to produce antinociception when microinjected into the ventrolateral PAG as opposed to adjacent sites or into the dorsal raphe nucleus. Although antinociception was evident at injection sites adjacent to the PAG, the present data suggest this antinociception is caused by diffusion into the PAG. Experiment 2 showed that blocking presynaptic Kv+ or postsynaptic GIRK channels by injecting alpha-dendrotoxin or tertiapin-Q into the ventrolateral PAG caused a significant reduction in morphine antinociceptive potency. In contrast, microinjection of alpha-dendrotoxin or tertiapin-Q into the ventrolateral PAG had no consistent effect on fentanyl antinociception. These data demonstrate that the PAG is the primary site for antinociception when morphine or fentanyl are injected in this region. In contrast, morphine and fentanyl differ in their reliance on pre- and postsynaptic potassium channels on antinociception. Morphine antinociception is much more sensitive to inhibition of potassium channel currents than the antinociception produced by fentanyl.

Title: A possible role of peripheral mu-opioid receptors in DALDA-induced inhibition of ongoing neuropathic pain and persistent inflammatory pain in rats

Authors: *V. TIWARI, S.-Q. HE, F. YANG, Q. XU, R. SHECHTER, A. CARTERET, Y. GUAN, S. RAJA
The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Abstract: Peripherally acting mu-opioid receptor (MOR) agonists, which generally do not cause the central nervous system (CNS) side effects known to centrally penetrating mu-opioids (e.g., morphine), attenuate both mechanical and heat hypersensitivity in rodent models of inflammatory and neuropathic pain. Yet, it is unclear whether they provide analgesic effects for ongoing, persistent pain. Ongoing pain is the most common and bothersome symptom in patients suffering from tissue or nerve injury. However, because most pain behavioral assays in preclinical studies rely heavily on reflex response to evoked sensations, they may not reflect whether a drug is effective in alleviating ongoing pain. Recent studies show that inhibition of ongoing pain in animal models may be examined by a conditioned place preference (CPP) assay. We used a CPP assay to examine the effects of dermorphin [D-Arg2, Lys4] (1-4) amide (DALDA), a potent and highly selective MOR agonist with restrictive penetration into the CNS after subcutaneous (s.c.) administration. We subjected rats to L5 spinal nerve ligation (SNL) to induce ongoing neuropathic pain and tested DALDA at 2-3 weeks after injury. Compared to the preconditioned state, SNL rats spent significantly more time (e.g., preference) in the DALDA-paired chamber after receiving two conditioning sessions of DALDA treatment (45 min/session, 1 session/day; 5 and 10 mg/kg s.c., n=8-12/dose). Importantly, neither dose of DALDA (5 and 10 mg/kg, s.c., n=8) induced CPP in naive rats, suggesting that DALDA-induced CPP in SNL rats is likely due to the reward of pain relief, not from penetration into CNS and direct activation of CNS reward circuitry, an action known to morphine. Further, intraperitoneal (i.p.) pretreatment with methylnaltrexone (5 mg/kg), a peripherally restricted MOR-preferring antagonist, at 10 min before DALDA injection blocked DALDA-induced CPP in SNL rats, suggesting a peripheral mechanism for DALDA-induced relief of ongoing pain. Gabapentin (60 mg/kg, i.p), which we used as a positive control, also induced CPP in SNL rats (n=8), but not in naive rats (n=8). Moreover, DALDA pretreatment (10 mg/kg s.c, 30 min, n=10) significantly inhibited ongoing pain behavior in rats at 15-60 min (phase II) after intraplantar injection of formalin (50 µL, 1%, n=10) and attenuated the subsequent development of mechanical hypersensitivity at 4-6 h after formalin injection. Our studies suggest that peripherally acting mu-opioids may ameliorate ongoing pain associated with neuropathic injury. Further studies are required to examine the underlying neurophysiologic mechanisms.

Title: How do biased u-opioid receptor and non-biased agonists differ on receptor desensitization and downstream signaling?

Authors: ***S. P. ARNERIC**, T. W. STINNETTE
Pain/Migraine Neurosci. Res., Eli Lilly and Co., INDIANAPOLIS, IN

Abstract: Background: u-opioid receptor (MOR) agonists are the standard of care treatment for severe pain. DeWire et al. (2012) reported reduced GI effects and respiratory depression with TRV130, a biased MOR agonist that couples with G-protein and bypasses beta-arrestin-2 signaling pathways. While it had been reported to have reduced receptor phorsphorylation, data had not been shown regarding effects on functional, acute desensitization to prolonged receptor activation, or its recovery. This study characterized these responses to non-biased (morphine & fentanyl) versus biased (buprenorphine & TRV130) MOR agonists previously shown to lack beta-arrestin-2 engagement using hMOR-1 CHO cells (DiscoveRx™). Results: Different cellular and receptor phosphorylation profiles were observed between the biased and non-biased agonists. Concentration response curves (0.1- 1,000 nM) demonstrated all four agonists inhibited cAMP with EC50= 1-10 nM at time points < 4 hrs; buprenorphine and TRV130's inhibitory G-protein activity were completely lost by 24 hr and failed to recover back to control EC50 levels post a 1-4 hr washout/recovery period (N=3). In contrast, morphine and fentanyl continued to exhibit inhibition at 24 hr, although CRCs where significantly rightward shifted. Both morphine and fentanyl rapidly, and completely, recovered EC50 levels within 1-2 hrs. The biased agonists had significantly lower phosphorylation (pSer375; LSBio #LS-C17026) levels (2-to 5-fold less) when compared to morphine or fentanyl. While all agonists rapidly reduced p-MOR by 1 hr exposure, functional recovery to p-MOR occurred with morphine and fentanyl despite continued ligand exposure, an effect that did not occur with buprenorphine and TRV130. Suprisingly, p-MOR levels elicited by morphine and fentanyl declined during the 4 hr recovery phase, while

cAMP responses were restored. Both responses to TRV130 and buprenorphine were unchanged. MOR activation induces several fold higher levels of AKT and ERK phosphorylation in comparison to p38a and p70S6, although differences between biased and non-biased ligands were not apparent. Conclusions: Our data suggest that the degree of G-protein mediated cAMP response initially tracks with p-MOR375 levels overall, and that loss of cAMP responses (acute desensitization) is more susceptible to agonists with a lower potential to phosphorylate MOR. In contrast, recovery of non-biased ligands requires less pMOR375 to elicit the same G-protein mediated cAMP response. Whether these observations are only relevant to recombinant engineered cells, or correspond to *in vivo* responses, remains to be established.

Title: Involvement of radixin in the attenuation of morphine analgesia through the small intestinal P-glycoprotein

Authors: *S. TOKUYAMA, T. KOBORI, S. HARADA, K. NAKAMOTO
Dept. of Clin. Pharmacy, Sch. of Pharmaceut. Sci., Kobe Gakuin Univ. Library Yakugaku, Kobe, Japan

Abstract: Aims: Many cancer patients suffer from cancer-related pain around the world. The World Health Organization recommends oral administration of opioids to treat pain from palliative care setting. Hence, the number of patients receiving opioids in conjunction with cancer chemotherapy is expected to increase, giving rise to drug-drug interactions between these agents during absorption process in the small intestine. Note that various anticancer drugs and opioid analgesics are recognized as substrate drugs of P-glycoprotein (P-gp), a drug efflux transporter. Previously, we have reported that repeated oral administration of etoposide (ETP), a

typical substrate of P-gp, attenuates oral morphine analgesia with decreases in serum and brain levels of morphine through increased expression of small intestinal P-gp. We have also proposed that activation of ezrin/radixin/moesin (ERM), scaffold proteins for P-gp, mediated by RhoA/ROCK signaling may have an impact on this mechanism. However, it has yet to be determined which one of three contribute to the alteration in the small intestinal P-gp. Here, the purpose of this study is to determine which ERM contributes the most to the increased expression of P-gp in the small intestine after treatment with ETP. Methods: Each protein expression levels in the plasma membrane fraction of small intestine or localization analysis were conducted by western blotting or immunofluorescence study. The protein-protein interaction between P-gp and each ERM proteins was determined by immunoprecipitation assay. The analgesic effect of morphine (50 mg/kg, p.o.) was evaluated by tail-flick test. Results: On 24 hr after completing repeated treatment with ETP (10 mg/kg/day for 7 days, p.o.), protein expression of radixin but not ezrin or moesin in the small intestinal membrane was significantly increased compared with that of vehicle-treated mice. Additionally, the amount of radixin but not ezrin or moesin co-immunoprecipitated with P-gp was also dramatically increased in the same fraction. The increased expression of radixin and P-gp by ETP treatment was significantly suppressed by concurrently administered rosuvastatin (an inhibitor of RhoA; 5 mg/kg/day for 7 days, p.o.) or fasudil (an inhibitor of ROCK; 5 mg/kg/day for 7 days, p.o.), respectively with inhibitory effect against an attenuation of oral morphine analgesia seen after repeated treatment with ETP. Conclusion: Activation of radixin via RhoA/ROCK signaling by repeated oral treatment with ETP may at least, in part, be involved in an increase in the protein expression of small intestinal P-gp, leading to attenuation of oral morphine analgesia.

Title: β–arrestin–2–biased agonism of delta opioid receptors sensitizes transient receptor potential vanilloid type 1 (TRPV1) in primary sensory neurons

Authors: *A. P. DOYLE[1], M. P. ROWAN[2], R. GOMEZ[2], K. SZTEYN[2], M. A. HENRY[3], N. A. JESKE[2,4,5]
[1]Dept. of Pharmacol., [2]Oral and Maxillofacial Surgery, [3]Endodontics, [4]Pharmacol., [5]Physiol., UTHSCSA, San Antonio, TX

Abstract: The clinical significance of chronic pain is overwhelming and treating pain and the related loss of productivity in America costs society upwards of $635 billion annually. Morphine and other agonists acting at the mu opioid receptor (MOR) remain first line drugs for the treatment of moderate to severe chronic pain. However, prolonged use of MOR agonists can lead to opioid-induced hyperalgesia (OIH), characterized by exaggerated pain sensitivity. Recent data from our lab demonstrate that chronic activation of peripheral MOR with β-arrestin2-biased agonists sensitizes TRPV1, producing behavioral symptoms of OIH. Delta opioid receptors (DOR) are gaining considerable attention as promising new targets in the treatment of chronic pain. DOR agonists demonstrate antinociceptive properties and are reported to have fewer side effects than traditional opioids; however, no studies have evaluated whether or not agonists at DOR are capable of producing OIH following chronic administration. In the present study, immunocytochemical analyses demonstrate DOR colocalization with TRPV1 in peptidergic and non-peptidergic rat peripheral sensory neurons. Additional experiments in heterologous expression systems show that treatment with DOR agonist SNC80, not ARM390, reduce β-arrestin2 association with TRPV1 and recruit β-arrestin2 to DOR. Peripheral sensory neurons from rat trigeminal ganglia (TGs) were nucleofected with YFP-tagged DOR or YFP control vector and were assessed for TRPV1 activation following stimulation by capsaicin. DOR-YFP and YFP had no effect on basal TRPV1 response. However, pretreatment with β-arrestin2-biased DOR agonist SNC80, not ARM390, significantly sensitizes TRPV1. Interestingly, this sensitization is species-dependent, as cells expressing human or rat DOR display significantly greater enhancement than those expressing mouse DOR. In addition to cellular sensitization of TRPV1, chronic administration of SNC80 *in vivo* produces behavioral signs of OIH in rats, but not mice. This supports the concept that DOR-TRPV1 cross-talk is species-dependent. Together these data suggest that species-dependent β-arrestin2 recruitment to DOR, away from TRPV1, may play a peripheral role in OIH.

Title: The prototypical kappa opioid receptor (KOR) antagonist, norBNI, uniquely regulates KOR function in peripheral sensory neurons

Authors: *R. J. JAMSHIDI, B. A. MCGUIRE, L. C. SULLIVAN, T. A. CHAVERA, W. P. CLARKE, K. A. BERG
Pharmacol., UT Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: KOR couples to a variety of intracellular signaling cascades, including inhibition of adenylyl cyclase (AC), activation of Extracellular Signal-Regulated Kinase (ERK), and c-Jun N-terminal Kinase (JNK). Previous studies with norbinaltorphimine (norBNI) show that this selective KOR "antagonist" is an "agonist" for activation of JNK. Activation of JNK by norBNI results in a long-term reduction in KOR function in HEK cells and in brain following a single administration. Similarly, we have found that local administration of norBNI leads to long-lasting, JNK-mediated, reduction of KOR function in peripheral sensory (pain-sensing) neurons. Using a rodent behavioral model of nociception, we found that peripheral KOR-mediated antinociception in the ipsilateral paw was abolished 2 and 7 days following a single intraplantar (i.pl.) injection of norBNI. The KOR responsiveness of the contralateral paw was unaffected. The long-term inhibition of KOR-mediated antinociception was completely abolished by the JNK inhibitor, SP600125, injected i.pl., prior to norBNI. Long-term inhibition of KOR function by norBNI also occurred when norBNI was applied directly to adult rat peripheral sensory neurons in culture (*ex vivo*). Treatment of neuronal cultures with norBNI for 1h, followed by washing, abolished KOR-mediated inhibition of AC activity (in a JNK-sensitive manner), however KOR-mediated activation of ERK was unaffected. Since JNK is a well-known activator of transcription factors, ultimately leading to protein synthesis, we sought to determine if protein synthesis was required for the long-term effects of norBNI. In hindpaws treated (i.pl.) with the protein synthesis inhibitor, cycloheximide (CHX), prior to norBNI administration (i.pl.), the long-term effect of norBNI on peripheral KOR-mediated antinociception was completely abolished. Similarly, the inhibitory effect of norBNI on KOR-mediated inhibition of AC activity in peripheral sensory neuron cultures was abolished completely with CHX pretreatment. Additionally, inhibiting protein translation with rapamycin, an mTOR inhibitor, also completely abolished the long-term effects of norBNI *in vivo* and *ex vivo*. Taken together, these results

suggest that activation of JNK by norBNI leads to increased protein synthesis of an unknown protein that subsequently leads to prolonged reduction in some, but not all, KOR functional responses in peripheral sensory neurons. Moreover, these data provide strong evidence that norBNI is a protean ligand which has powerful capacity to regulate peripheral KOR function.

Title: Differential effects of various opioids on the development of allodynia and abuse in the context of pain

Authors: ***M. A. EMERY**, M. L. S. BATES, P. J. WELLMAN, S. EITAN
Psychology, Texas A&M Univ., College Station, TX

Abstract: The use of opioids has been associated with altered responses of D2-like dopamine receptors (D2DRs) that contribute to the pathology of addiction and other mental illnesses. Our recent studies demonstrate that this effect of opioids on the response of D2DRs is markedly pronounced during adolescence. In addition, our recent studies demonstrate that the effects of opioids on D2DRs' responses are ligand-selective. Specifically, in a rodent model of recreational use, buprenorphine, methadone, hydrocodone, oxycodone, and morphine differentially alter the responses of the dopaminergic system in adolescents. Burn injuries are very common in the pediatric population, representing the fifth most common cause of non-fatal childhood injuries. Burn injuries have greater than 98% survival rate among people below age 20, but they are known to be extremely painful. In addition to acute pain, 18% of burn survivors experience persistent pain long after healing was complete. The need to use opioids to manage severe pain in burn victims is ultimately unavoidable, but currently results in a problematic increase in prescription opioid abuse. Additionally, there is evidence that morphine may paradoxically result in hyperalgesia/allodynia following chronic use for pain. Thus, this study examined the effect of hydrocodone, oxycodone, and morphine on the development of allodynia symptoms and

subsequent alteration of D2DRs responses and opioid reward in a rodent model of burn injury. A burn or sham injury was induced on the dorsal portion of the hindpaw of adolescent mice. The resulting pain was treated orally with various opioids administered twice daily for 14 days. During these 14 days, mice were tested for the development of mechanical and cold allodynia. Each time, mice were tested for baseline pain sensitivity followed by the antinociceptive response to the various opioid. Subsequently, mice were tested for the response to the D2/D3 receptor agonist quinpirole, or the acquisition of morphine conditioned place preference (CPP). Our results demonstrate a complex interaction between the specific opioid administered and the experience of burn pain. Specifically, the development of allodynia and the subsequent alteration in the response to a D2/D3 agonist and morphine CPP are both ligand-selective (i.e. dependent on the specific opioids used) and altered by the experience of pain. These findings suggest that the use of various opioids for pain management in burn victims carry differential risks for the development of hyperallodynia, altering the neurochemistry of adolescents' brain, especially the dopaminergic system, and the development of opioid addiction.

Title: Increased response to glutamate in small dorsal root ganglia neuron of morphine tolerant rats

Authors: *K. GONG[1], P. OHARA[2], L. JASMIN[3]
[1]Dept. of Oral and Maxillofacial Surgery, [2]Anat., [3]Oral and Maxillofacial Surgery, Univ. of California San Francisco, San Francisco, CA

Abstract: The hyperalgesic effects of opiates are one of most intriguing aspect of these widely prescribed drugs. Our lab has focused on changes that occur in primary sensory neurons of rats rendered tolerant to morphine. We conducted patch clamp recordings on neurons in intact dorsal

root ganglia (DRG) and found that 5 days after twice-daily injection of an escalating dose of morphine (10 to 40 mg/kg/s.c.), small DRG neurons consistently showed increased excitability. The rheobase was reduced from 267.7± 29.8 pA to 203.7 ± 13.6 pA ($p < 0.05$, $n = 30$). The membrane threshold was reduced from -13.3 ± 1.7 mV to -20.3 ± 1.1 mV ($p < 0.001$, $n = 25$). While these results are consistent with previous reports, we also found that after morphine injection, small diameter primary sensory neurons showed a greatly increased response to puff application of 1mM glutamate, 686.5 ± 127.5 pA vs. 227.4 ± 25.7 pA in controls. Though this result suggest an enhancement of glutamate receptor function, analysis of individual glutamate receptors did not reveal any increase in receptor response to selective agonist application. Responses to puff application of KA (100 μM), AMPA (100 μM), and DHPG (group I mGluR specific agonist, 1 mM) on small sensory neurons were similar in morphine treated and control rats. Unexpectedly, there was a marked decrease response to NMDA (100 μM) in the small sensory neurons of morphine treated rats (33.4 ± 7.9 pA in morphine group vs. 554.0 ± 174.1 pA in control group, $n = 12$, $p < 0.01$). To control for opiate withdrawal, we included morphine (5 μM) in the perfusate bathing the DRGs during the recordings. These results suggest that the increased response of small DRG neurons to glutamate is involved in morphine-induced hyperalgesia but the mechanism remains to be determined.

Title: Curcumin attenuates thermal hyperalgesia in a rat full thickness thermal injury model

Authors: ***M. M. SALAS**[1], L. N. PETZ[2], M. FOWLER[2], J. CLIFFORD[2]
[1]United States Army Inst. of Surgical Res., Ft Sm Houston, TX; [2]Battlefield Pain Mgmt., United States Army Inst. of Surgical Res., Fort Sam Houston, TX

Abstract: Introduction: The nature of recovery and healing from severe burn injuries involve intensely painful procedures including wound debridement, dressing changes, and strenuous physical and occupational therapy. In fact, procedural pain is the most common grievance

reported by the burn population. Although opioids are available to treat severe pain, a multitude of side effects including development of tolerance accompany routine use of opioids for severe pain. In order to reduce the amount of opioids necessary for burn patients, alternative analgesics with reduced side effect profiles deserve exploration. Curcumin, the active compound in turmeric, which has been utilized in ancient medicine for centuries, has potential to be utilized as an analgesic or as an adjuvant that has potential for use in burn pain management. Objective: To assess the effect of curcumin on inflammatory signaling *in vitro*, and to asses curcumin's effect on mechanical allodynia and thermal hyperalgesia in a full thickness thermal injury model *in vivo*, and to measure curcumin's effect on calcitonin gene-related peptide (CGRP)in human dental pulp. Methods: *In vitro* assays were performed on heat shocked human keratinocyte-derived cells and phosphorylation levels of NF-kB and p38 MAPK were assessed. Utilizing a rat model of full thickness thermal injury model in Sprague Dawley male rats, curcumin was injected into the thermally injured hind paw for 5 consecutive days post thermal injury and both thermal hyperalgesia and mechanical allodynia was assessed. Finally, human dental pulp was collected and CGRP levels were assessed after inflammatory stimulation either with or without pretreatment with curcumin. Results: Curcumin treatment suppressed phosphorylation levels of NF-kB and p38 MAPK in heat shocked keratinocytes-derived cells. Curcumin also, when delivered locally, attenuates thermal hyperalgesia in a full thickness thermal injury rat model. Conclusions: Curcumin has been shown to alter gene expression, modulate several signaling pathways, and may interact directly or indirectly with target molecules to produce anti-inflammatory effects as well as alter thermal hyperalgesia and mechanical allodynia. Therefore curcumin has potential to aid in reducing the amount of opioids necessary for burn procedures in burn patients.*The opinions or assertions contained herein are the private views of the author and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.*

Title: Local anaesthesia reduces the acute inflammatory edema and early elevation of glutaminase in dorsal root ganglion neurons during adjuvant induced arthritis

Authors: *Z. ZHANG, B. BOLT, S. DAS, M. ANDERSON, K. MILLER
Anat. & Cell Biol., Oklahoma State Univ-CHS, TULSA, OK

Abstract: Glutamate, released from peripheral afferents, is implicated as a sensitizer of peripheral nociceptive terminals during inflammation. Glutamate is synthesized from glutamine in peripheral terminals via the enzyme phosphate-activated glutaminase. In rat adjuvant induced arthritis (AIA) model, an early elevation of glutaminase was observed in the ipsilateral dorsal root ganglion (DRG) neurons during acute (24h) phase of inflammation. We hypothesize that electrical activity mediates, in part, this increase of DRG glutaminase in response to acute peripheral inflammation. In this study, unilateral AIA was induced with a single subcutaneous injection of complete Freud's adjuvant (CFA) into the rat hindpaw. Sciatic nerve blockade was performed by concurrent injection of 1% lidocaine with epinephrine into the sciatic nerve at the mid-thigh level. Paw thickness was measured as an index of the severity of inflammation. At 24 h of AIA, rats were anesthetized and transcardially perfused with fixative. Ipsilateral L4 DRGs were collected and GLS was localized in DRG neuronal cell bodies with immunofluorescence microscopy. Mean grey intensity of GLS was evaluated with image analysis software Image J. Local anesthetic blockade of neuronal conduction in sciatic nerve partially alleviated the acute hindpaw edema and suppressed the elevation of glutaminase at 24 h post CFA injection. As no changes were observed in DRG of the non-inflamed side within 24 h, the elevation of glutaminase at this time point was systemically mediated. The partial relief of edema and suppressed glutaminase expression indicate that increased neuronal electrical activity may be one of the mechanisms that drive the increase of glutaminase expression in the DRG in response to peripheral inflammation. Our result supports the notion that increased nerve activity at the inflamed nerve terminal contributes to the early alteration of glutamate metabolism in the DRG neuronal cell body during acute inflammation. Further studies are needed to evaluate the effect of sciatic nerve blockade during the chronic phase of AIA.

Title: Antinociceptive properties of the mastoparan peptide Agelaia-MP I from social wasps

Authors: ***M. RANGEL**[1,2], J. C. GONÇALVES[2], A. B. MAYER[2], E. S. ALVES[2], K. G. MOREIRA[3], L. P. SILVA[4], M. R. MORTARI[2]
[1]Butantan Inst., SAO PAULO, Brazil; [2]Physiological Sci. Ctr., Biol. Sci. Institute, Univ. of Brasilia, Brasilia, Brazil; [3]Univ. Federal de Goiás, Catalão, Brazil; [4]Lab. of Mass Spectrometry, PBI, Embrapa Genet. Resources and Biotech., Brasilia, Brazil

Abstract: The current analgesic therapy is based on the sequential prescription of pain killers, which has as last resource drugs that act on opioid receptors, such as morphine, known to be very effective but also to produce undesirable systemic side effects, tolerance and addiction. Therefore, the search for new drugs with alternative targets became necessary in order to minimize side effects and enhance the efficacy of treatment. The wasps, arthropods of the order Hymenoptera, contain a great diversity of bioactive toxins in their venom that have antimicrobial, anticonvulsant, anxiolytic and antinociceptive properties. Mastoparans are an abundant class of peptides in the venom of wasps which has shown potential as new antimicrobial drugs and are excellent tools for the study of G protein coupled receptors. The main objective of this work is to study the antinociceptive activity of the mastoparan peptide Agelaia - MP I and the mechanisms involved. Agelaia-MP I (MW 1565 Da) was isolated from an active fraction of the venom of the social wasp Parachartergus fraternus, sequenced by De novo MS/MS using MALDI-TOF/TOF and identified as a mastoparan identical to the previously described from other wasp specie, Agelaia pallipes pallipes. The peptide was synthesized and then tested in the bioassays. Agelaia-MP I presented a dose-dependent antinociceptive activity in mice injected i.c.v. at concentrations of 3.2, 4.8 and 6.4 mM in two different models: hot plate and tail flick. The largest dose reported maximum antinociceptive effect for up to four hours and kept the nociception reduced three days after i.c.v. injection. The antinociceptive effect of the peptide in the hot plate model was about 2.5 times stronger than in the tail flick experiment, indicating a possible action in the pain ascending pathway. Further experiments with isolated sciatic frog nerve in sucrose gap assay showed that Agelaia-MP I induced partial (80%) and reversible blockade of action potential amplitude at 1mM. Since voltage dependent sodium channels (Nav) are also an important target for pain treatment, additional patch clamp experiments with hNav 1.1 to 1.7 will be performed to determine if the peptide is a sodium channel blocker. Taken together, these results revealed the great potential of the study of compounds isolated from wasp venoms with activity in the central nervous system. In addition, the antinociceptive effect described here is a novel activity for the mastoparan class of peptides.

Title: Thermal hyperalgesia is offset by top-down inhibition in offset analgesia

Authors: E. IKEDA, H. KOBINATA, S. ZHANG, T. LI, K. MAKITA, *J. KURATA
Anesthesiol., Tokyo Med. and Dent. Univ. Sch. of Med., Tokyo, Japan

Abstract: Offset analgesia (OA) is defined as a disproportionate decrease of perceived pain intensity after a brief temporary increase in pain stimulus, and is considered mediated by the descending pain inhibitory system. The extent of OA might potentially be influenced by the other pain modulatory mechanisms at the spinal cord or the other neural systems. Here we examined whether the extent of OA be influenced by hyperalgesia or adaptation to pain using thermal stimulation and continuous recording of perceived pain intensity. We also examined the effects of different ramp rates on adaptation to pain. [Methods] After IRB approval and informed consent, we recruited 14 healthy volunteers including 8 men and 6 women with the age range from 23 to 51 years old. We used a Peltier-type thermal stimulator (PATHWAY, Medoc, Israel) and a digital visual analogue scale (VAS) recorder (CoVAS, Medoc, Israel). We applied a painful heat stimulus via a 27 mm-diameter probe on the ventral surface of the left forearm and simultaneously recorded perceived pain intensity continuously. The baseline temperature of the probe was set at 32°C and stimulus intensity calibrated for each individual at the 60/100 mm of VAS (Tv6). "OA5" and "OA15" blocks consisted of a three-temperature stimulus train of 30s: T1 = Tv6 for 5 s, T2 = Tv6+1°C for 5 and 15 s, and T3 = Tv6 for 20 s, respectively, at a ramp rate of 56°C/s. A "constant stimulus (CS)" block consisted of a constant Tv6 stimulus of 30 s at a ramp rate of 56°C/s (Fast) or 6°C/s (Slow). The OA5, OA15, Fast CS, and Slow CS blocks, 3 for each, were given at a pseudorandom order. Statistical analysis was performed with analysis of

variance at a significance threshold of $P < 0.05$. [Results] The peak VAS (48.7 ± 20.0 vs. 68.0 ± 18.0; $p = 0.01$) and its latency (4.4 ± 0.7 vs. 9.7 ± 3.5; $p = 0.01$) were significantly higher and longer in OA15 than in OA5. That is, a 15-s thermal stimulus caused hyperalgesia followed by possible adaptation 10 s after the beginning. We observed a comparable decrease in perceived pain during T3 in both OA5 and OA15 blocks (65.1 ± 16.2 vs. 66.2 ± 22.3, respectively; $p = 0.88$). On the other hand, between Fast CS and Slow CS, there were no differences in either the peak VAS, its latency, and the extent of adaptation (23.8 ± 3.6 vs. 31.9 ± 4.8, respectively; $p = 0.19$). [Discussion] Although we observed hyperalgesia followed by 15 s of continuous thermal stimulation at the VAS of 6, it did not affect the extent of OA. It implied that descending pain inhibition by OA might have offset "wind-up" hyperalgesia at the dorsal horn of the spinal cord. We also found that a ramp rate at faster than 6°C/s did not affect adaptation to pain.

Title: Epinephrine dose not worsen histological damage induced by lidocaine neurotoxicity in the rats

Authors: *T. TAKENAMI[1], Y. NARA[2], H. OKAMOTO[2]
[1]Kitasato Univ., Sagamihara, Japan; [2]Kitasato Univ. Sch. of Med., Sagamihara, Japan

Abstract: Backgound: Epinephrine has a risk to increase the local anesthetics neurotoxicity in spite of the popular use in patients undergoing spinal anesthesia. The strong vasoconstrictive property of epinephrine possibly reduces dural, and spinal blood flow and decreases clearance of local anesthetics from the spinal cord, resulting in a prolongation of stagnant time of the anesthetics in the subarachnoid space. Therefore, we examined whether additional epinephrine deteriorates histological damage and neurofunctional impairment induced by lidocaine neurotxicity in rats. Methods: Thirty rats were randomly received 40μl/g from 1ml solution which included 7.5%lidociane or 5%lidocaine dissolved in 10%glucose with or without 0.1mg, or 0.5mg epinephrine. Another 10 rats were received 0.1mg or 0.5mg epinephrine dissolved in 1ml of 10% glucose. Seven days after the injection, L2 spinal cord with both anterior and

posterior roots and dorsal ganglion as well as cauda equina were excised for light and electron microscopic examination. The neurological function of hind limbs was evaluated by walking behavior, and the responses to the radiant heat stimulation. Results: Histological abnormality was observed in the posterior root only in rats received 7.5%lidocaine both with and without epinephrine. The lesion was almost restricted in posterior root just entrance into the spinal cord. The incidence of the lesion at 7.5%lidocaine was not significantly different between the rats with epinephrine (25%) and those without epinephrine (33%). Other areas and other groups did not show any histological abnornality. There was no significant difference in sensory threshold among the groups. Disturbance of hindlimb movement prolonged in rats receiving 5% and 7.5% lidocaine with epinephrine (3hours), which was significantly longer than rats receiving 5% and 7.5% lidocaine without epinephrine (1hour). All the rats received intrathecal 0.5mg epinephrine alone could walk normally within 15minutes. Conclusion: Both 5% and 7.5% lidocaine with epinephrine prolonged anesthetic effect compared to those additional epinephrine, its incidence and primary lesion is the same to our previous study on lidocaine. Moreover, the incidence of the lesion in 7.5% lidocaine with epinephrine was not significant different from 7.5% lidocaine without epinephrine. Apparent sensory impairment did not occur in all groups. Thus, intrathecal epinephrine did not deteriorate histological damage and functional impairment even if the prolonging effect on the action of intrathecal lidocaine, suggesting that the use of epinephrine is not associated with augmentation of local anesthetic neurotoxicity.

Abstract: Neuropathy is the most common and debilitating complication of diabetes and results in hyperalgesia and allodynia. Hyperglycemia clearly plays a key role in the development and progression of diabetic neuropathy. Current therapeutic approaches are only partially successful and they are only thought to reduce the pain associated with peripheral neuropathy. Some natural products offer combined antioxidant, anti-inflammatory and antineuropathic properties that may help to treat in a more integrative manner this condition. The purpose of this study was to investigate the antineuropathic effect of 7-hydroxy-3,4-dihidrocadalin in streptozotocin-induced diabetic rats and mice; as well as, the possible mechanism of action involved in this effect. Rats and mice were injected with 50 or 200 mg/Kg streptozotocin, respectively, to produce hyperglycemia. The formalin test and von Frey filaments were used to assess the nociceptive activity. Rota-rod was utilized to measure motor activity and malondialdehyde assay to determine anti-oxidative properties. After 3 weeks of diabetes induction, chemical hyperalgesia was observed in the streptozotocin-injected rats. Oral acute administration of 7-hydroxy-3,4-dihidrocadalin (0.3-30 mg/kg) decreased in a dose-dependent manner the formalin-evoked hyperalgesia in diabetic rats. In addition, methiothepin (5-HT_1 receptor antagonist, 1 mg/kg, i.p.) and ODQ (guanylate cyclase inhibitor, 2 mg/kg, i.p.), but not naltrexone (opioid receptor antagonist, 1 mg/kg, s.c.),prevented 7-hydroxy-3,4-dihidrocadalin-induced antihyperalgesic effect. The anti-hyperalgesic effect of 7-hydroxy-3,4-dihidrocadalin was similar to that produced by pregabalin (10 mg/kg, p.o.). Furthermore, oral acute administration of 7-hydroxy-3,4-dihidrocadalin (30 mg/kg) reduced streptozotocin-induced changes in malondialdehyde concentration from plasma samples. Unlike pregabalin, 7-hydroxy-3,4-dihidrocadalin did not affect motor activity. Six weeks after diabetes induction, tactile allodynia was observed in the streptozotocin-injected rats. At this time, oral administration of 7-hydroxy-3,4-dihidrocadalin (30 mg/kg) or pregabalin (10 mg/kg) reduced in a similar way tactile allodynia in diabetic rats. Data suggests that 7-hydroxy-3,4-dihydrocadalin has therapeutic potential for diabetic neuropathy treatment. This effect seems to involve activation of 5-HT_1 receptors and inhibition of guanylate cyclase enzyme, as well as antioxidant properties.

Title: Remembering dynamic changes in acute pain: Effects of pain intensity and memory delays

Authors: *M. KHOSHNEJAD[1], M. FORTIN[2], G. DUNCAN[1], P. RAINVILLE[1]
[1]Univ. of Montreal, Montreal, QC, Canada; [2]Rutgers Univ., Piscataway, NJ

Abstract: This psychophysical study investigated the effects of pain intensity and post-stimulus delays on the short-term memory of dynamic changes in acute pain. The intensity of pain induced by 8-sec noxious contact-heat stimuli of varying temperatures (47.5, 48, 48.5, 49 °C) was rated continuously during the stimulus or after a delay of 6, 10 or 14 sec, using an electronic visual analog scale in ten healthy volunteers. Principal component analysis (PCA) was applied to the raw time courses, consistent with our previous work (Khoshnejad et al. Pain, 2013). Three components explained about 90% of the total variance in perceptual temporal profiles across all trials and subjects with the first, second, and third components accounting for 53%, 31% and 7% of the overall variance, respectively. ANOVA showed main effects of temperature on component 1 ($p=0.006$) and of memory on components 1 and 2 ($p's<0.001$). However, there was no significant difference between the 3 memory delays ($p's>0.5$) and no interaction between memory and temperature ($p's=0.99$). Reconstruction of the mean curves from the first two components shows an underestimation of both time and overall pain felt in memory; however, this effect is comparable across the four temperatures tested and the three memory delays. These effects were confirmed using standard parameters extracted from the raw time-courses: area under the curve (AUC), maximum pain (MP), and total time (TT). ANOVA showed main effects of temperature on AUC and MP and of memory on AUC and TT ($p's<0.01$), but no interaction ($p's=0.99$). These results confirm a systematic distortion of pain magnitude and temporal information in short-term memory, with an overall preservation of the maximum pain felt (*i.e.*, no main effect of, or interaction with, memory on MP). These effects appear inconsistent with a simple decay of a sensory memory trace and may reflect the conversion of the dynamic pain experience into a more stable but distorted template underlying memory encoding, storage and recall.

Title: Gonadal hormone modulation of antinociceptive tolerance to delta-9-tetrahydrocannibinol

Authors: *R. M. CRAFT[1], A. A. WAKLEY[2]
[2]Psychology, [1]Washington State Univ., Pullman, WA

Abstract: We have previously shown that cannabinoid agonists, including delta-9-tetrahydrocannabinol (THC), are more potent and in some cases more efficacious in female than in male rats, in terms of their antinociceptive effects (Tseng & Craft, Eur J Pharmacol 430:41, 2001). Moreover, females develop greater antinociceptive tolerance than males when given THC chronically (Wakley et al., submitted). In the present study, we determined whether activational effects of gonadal hormones are responsible for sex differences in the development of tolerance to THC. Adult Sprague-Dawley rats were sham-gonadectomized or gonadectomized (GDX); females were implanted s.c. with estradiol-filled (1-mm capsule/rat) or blank capsules, and males were implanted with testosterone-filled (10-mm capsule/100 g body weight) or blank capsules. Additionally, oil or progesterone (500 micrograms/rat) was administered s.c. every 5 days starting on the 4th day post-surgery. On Day 14 post-surgery, THC was administered cumulatively and rats were tested for antinociception on the warm water tail withdrawal and paw pressure tests (pre-chronic test). Vehicle or THC was then administered twice-daily for 9 days, and the next day THC dose-effect curves were redetermined (post-chronic test). At the pre-chronic test, THC's antinociceptive potency was significantly greater in sham-GDX females than in sham-GDX males on the tail withdrawal test ($p=0.001$) but not on the paw pressure test ($p=0.16$). Gonadectomy did not significantly affect THC's antinociceptive potency on either test (sham-GDX vs. GDX, within sex); however, progesterone decreased THC potency in GDX females, on the paw pressure test ($p=0.006$). Antinociceptive tolerance developed to THC in all groups treated twice-daily with THC, on both tests. Sham-GDX females developed more tolerance than sham-GDX males ($p=0.015$) on the tail withdrawal but not paw pressure test. Overall, estradiol increased females' THC sensitivity ($p<0.001$). However, neither testosterone in males nor estradiol or progesterone in females significantly influenced the magnitude of tolerance development in GDX rats. These results suggest that sex differences in the development of antinociceptive tolerance to THC are not due to activational effects of gonadal hormones.

Title: Characterization of 2-261, a novel positive allosteric modulator of GABAA receptor β2/3 subunit, in experimental neuropathic pain

Authors: *C. QU[1], J. Y. XIE[1], M. H. OSSIPOV[1], T. B. JOHNSTONE[2], K. GEE[2], F. PORRECA[1]
[1]Univ. of Arizona, Tucson, AZ; [2]Univ. of California, Irvine, Irvine, CA

Abstract: Loss of inhibition due to attenuation of GABA tone has been suggested to play an important role in the development and maintenance of chronic neuropathic pain. Potentiation of GABAA receptor function via direct activation by agonists or positive allosteric modulation has been proposed as a potential mechanism for new analgesics. Previous drug discovery efforts have been hampered by severe central nervous system side effects related to modulation of GABAA receptors, including sedation, ataxia, amnesia, and addiction/withdrawal. Compound 2-261 is a novel β2/3 subunit-selective GABAA positive allosteric modulator (PAM). We have previously shown that spinal nerve ligation (SNL) produces an aversive state that reflects spontaneous (i.e., stimulus-independent) pain and that can be captured using conditioned place preference (CPP), likely reflecting negative reinforcement. In addition, relief of spontaneous pain may be reflected by increased dopamine efflux in the nucleus accumbens (NAc). Here, male Sprague-Dawley rats received L5/L6 SNL or sham surgery and intrathecal (i.th.) catheterization and were allowed to recover for 2 weeks. Spinal administration of 2-261 (0.2 μg in 5 μl, i.th.) reversed evoked tactile and thermal hypersensitivity in nerve-injured rats. It also produced robust conditioned place preference in nerve-injured, but not in sham-operated, rats. Additionally, spinal 2-261 significantly increased dopamine efflux in the NAc selectively in nerve-injured rats, likely reflecting that the reward of pain relief. Spinal 2-261 didn't produce any effects on CPP or NAc DA efflux in sham-operated rats, indicating that this compound delivered by this route is not intrinsically rewarding. Importantly, no motor side effects were observed in 2-261-treated rats. The data show that spinal 2-261 alleviates nerve injury-induced evoked and spontaneous pain and increases NAc DA release selectively in injured rats. Therefore, GABAA β2/3 subtype-selective PAMs represent a promising new mechanism for the development of novel analgesics

without producing undesirable side effects in the central nervous system and/or intrinsic rewarding effects.

Title: The oral administration of trans-caryophyllene attenuates mechanical hypernociception in chronic pain induced by sciatic nerve injury and sleep restriction

Authors: *L. G. FREIRE[1], G. R. MOLSKA[2], A. A. F. Z. LOPES[1], D. SUCHECKI[1]
[1]Psychobiology, [2]Preventive Med., Univ. Federal De São Paulo, São Paulo, Brazil

Abstract: The bidirectional relationship between sleep and pain has been the topic of interest in recent investigations, since patients with pain disorders sleep poorly and poor sleepers exhibit higher pain sensitivity. Likewise, animals with peripheral nerve injury, submitted to sleep restriction or sleep deprivation, show reduced pain threshold. Usually, pain treatment involves chronic administration of anti-inflammatory compounds, which usually produces numerous side effects. For this reason, natural products may represent an important contribution for the development of new therapeutic strategies. Trans-caryophyllene (TC) is the major compound of essential oil of several medicinal plants, such as Cannabis sativa, with pronounced antinociceptive activity; therefore the aim of this study was to evaluate whether sleep restriction (SR) led to worsening of mechanical hypernociception induced by chronic contrition injury of the sciatic nerve (CCI) and whether TC was capable to prevent hypernociception and/or to reverse SR effect. Male Wistar rats (3 month-old, n = 5) were submitted to CCI or sham surgery and after recovery (2 to 3 days), they were distributed in two main groups: 1) control, non sleep-restricted (CTL) and 2) SR for 15 days, 18 h/day (from 4 pm to 10 am). These groups were treated either with vehicle (corn oil, groups CTL+VEH, CCI+VEH, SR+VEH, CCI+SR+VEH)

or TC (20 mg/kg; groups CCI+TC, SR+TC, CCI+SR+TC). Thus, comparison of data was done with the following groups: CTL, Non sleep-restricted Sham, CCI+VEH, SR+VEH, CCI+SR+VEH, CCI+TC, SR+TC, CCI+SR+TC. TC antihypernociceptive potential effect was assessed by von Frey test before surgery (baseline measurement), 5 days (before onset of SR), and 8, 14 and 21 days after surgery. CCI and SR alone or in combination resulted in reduced pain threshold compared to CTL group at all time-points; reduction of pain threshold in SR+VEH group was observed after onset of restriction period ($p < 0,005$). CCI+SR+VEH group showed a trend for higher pain sensitivity compared with CCI+VEH and SR+VEH groups. Treatment with TC for 21 consecutive days significantly inhibited mechanical hypernociception in CCI ($p < 0.03$), SR ($p < 0.05$), and CCI+SR animals ($p < 0.004$) compared with their respective non-restricted groups. These findings confirm the antinociceptive effect of trans-caryophyllene in experimental neuropathic pain associated with sleep restriction. The evidence for biological activity of trans-caryophyllene encourages further studies, particularly regarding its mechanisms of action.

Title: Store-operated calcium channels play an important role in neuropathic pain via the ERK signaling pathway

Authors: *H. HU, X. GAO, R. GAO, Y. TIAN, J. E. BARRETT
Pharmacologe and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Store-operated calcium channels (SOCs) are calcium-selective cation channels and are implicated in various functions of many types of cells. Our previous study has shown that YM-58483, a potent SOC channel inhibitor, strongly attenuates spare nerve injury (SNI)-induced pain hypersensitivity, suggesting a potential role of SOCs in neuropathic pain. We recently demonstrated that SOCs are expressed in dorsal horn neurons and identified STIM1, STIM2 and

Orai1 as key components of SOCs that mediate the SOC entry and SOC currents in dorsal horn neurons. However, the functional consequence of SOC activation remains elusive. In the present study, we demonstrated that activation of SOC entry (SOCE) by thapsigargin (TG) leaded to phosphorylation of extracellular signal-regulated kinase (ERK). Inhibition of SOCE by YM-58483 or $GdCl_3$ blocked TG-induced ERK activation. SNI induced robust ERK activation, which was significantly reduced by YM-58483. Knockdown of STIM1, STIM2 or Orai1 decreased SNI-induced ERK activation. Importantly, knockdown of STIM1, STIM2 or Orai1 attenuated spare SNI-induced pain hypersensitivity. Our findings reveal that the SOC signaling plays an important role in neuropathic pain via the ERK pathway.

Title: Activation of NK1 receptors leads to store-operated calcium entry in mouse spinal cord dorsal horn neurons

Authors: *J. XIA, R. GAO, Y. TIAN, J. E. BARRETT, H. HU
Drexel Univ., Philadelphia, PA

Abstract: We have previously demonstrated that store-operated calcium channels (SOCs) are expressed in mouse spinal cord dorsal horn neurons and inhibition of SOC entry (SOCE) by YM-58483 (an inhibitor of SOCs) attenuates pain hypersensitivity, indicating that SOCs may be involved in pain processing. It is well known that substance P (SP) play an important role in pain transmission through the stimulation of neurokinin 1 (NK1) receptor, which results in calcium release from ER calcium stores. Previous studies demonstrated that reduction of the ER calcium can activate SOCE. We therefore hypothesized that activation of NK1 receptors leads to SOCE. To test this hypothesis, we performed Ca^{2+} imaging, siRNA knockdown and evaluated pain sensitivity using a behavioral assay. We found that application of 100 nM SP induced a transient calcium response in the absence of extracellular Ca^{2+}, representing the calcium released from intracellular Ca^{2+} stores; the subsequent addition of 2 mM $CaCl_2$ caused sustained responses. To

determine whether the SP-induced $[Ca^{2+}]_i$ changes were mediated by NK1 receptors, we pretreated neurons with 1 μM RP 67580, a potent and selective NK1 receptor antagonist. SP-induced calcium release and calcium entry were both blocked by RP 67580. To determine whether this Ca^{2+} entry was through SOCs, we pretreated neurons with 3 μM YM-58483 or 1 μM $GdCl_3$, and found that SP-induced Ca^{2+} release was not affected by YM-58483 or $GdCl_3$; however, Ca^{2+} influx was blocked by both YM-58483 and $GdCl_3$. To confirm that this effect was mediated by Orai1, a key component of SOCs, neurons were transfected with the specific Orai1 siRNA. Knockdown of Orai1 abolished SP-induced Ca^{2+} entry, but had no effect on Ca^{2+} release. Finally, behavioral data showed that intrathecal injection of 0.25 nmol SP induced robust spontaneous nociceptive behavior, which was drastically reduced by YM-58483 in a dose-dependent manner. Taken together, our results demonstrate that SOCs are involved in NK1 receptor-mediated Ca^{2+} signaling in spinal cord dorsal horn neurons. These findings provide a potential mechanism underlying YM-58483-induced central analgesia.

Title: A quantitative analysis of Meissner's corpuscles in the fingertips of humans, chimpanzees and monkeys

Authors: ***A. VERENDEEV**[1], C. THOMAS[1], S. C. MCFARLIN[1], W. D. HOPKINS[2,3], K. A. PHILLIPS[4], C. C. SHERWOOD[1]
[1]Dept. of Anthrop., George Washington Univ., Washington, DC; [2]Div. of Developmental and Cognitive Neurosci., Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [3]Neurosci. Inst. and Language Res. Ctr., Georgia State Univ., Atlanta, GA; [4]Dept. of Psychology, Trinity Univ., San Antonio, TX

Abstract: Meissner's corpuscles (MCs) are tactile mechanoreceptors found in the hairless skin of mammals, including fingertips. They are characterized by sensitivity to light touch and therefore might be associated with the evolution of manipulation abilities of the hands in primates. We examined MCs in different primate species, including common marmoset (*Callithrix jacchus*, n=5), baboon (*Papio anubis*, n=2), rhesus macaque (*Macaca mulatta*, n=3), chimpanzee (*Pan troglodytes*, n=1) and human (n=8). Fingertips of the first, second, and fourth digits were collected from both hands of specimens, dissected and histologically stained using hematoxylin and eosin. The density (counts of MCs per mm^2 of dermis) and the size (width of MCs) were quantified. Overall, there were no differences in MCs density or size among the digits or between the hands (all *p*s nonsignificant). When averaged across hands and digits for each individual, one-way ANOVA revealed significant species differences in both the density ($F(4,14)=4.027$; $p=0.022$) and the size ($F(4,14=22.696$; $p<0.001$) of MCs. We found that apes (i.e., humans and chimpanzees) had a higher density of MCs per mm^2 of epidermal length than the monkeys ($t(17)=3.431$; $p=0.003$). However, there were no difference in MCs sizes between apes and monkeys ($t(17)=1.443$; $p=0.172$). We further correlated the density and size of MCs to an index of dexterity as reported previously (Iwaniuk et al., 1999). Spearman correlation coefficient analysis revealed a significant positive relationship between dexterity and MCs density ($\rho=0.616$; $p=0.005$) as well as MCs size ($\rho=0.552$; $p=0.014$), such that more dexterous species had both higher densities and larger MCs.

Title: Somatosensory innervation in the skin of humpback whales (Megaptera novaeangliae)

Authors: *S. A. ELDRIDGE[1,2], F. MORTAZAVI[2], V. HERRERA[3], F. L. RICE[4], D. KETTEN[5], D. L. ROSENE[2]
[1]Biol. Dept., Univ. of Massachusetts Dartmouth, Dartmouth, MA; [2]Dept. of Anat. and Neurobio., [3]Boston Univ. Sch. of Med., Boston, MA; [4]Integrated Tissue Dynamics, Albany, NY; [5]Biol. Dept., Woods Hole Oceanographic Inst., Woods Hole, MA

Abstract: Underwater physical cues provide critical information to cetaceans (whales, dolphins and porpoise) for finding prey, navigating migrations, assessing dive depth, and interpreting and triangulating communication signals. Auditory and visual systems of marine mammals have been studied, however, little is known about somatosensory reception in cetaceans. Here, we describe innervation in skin biopsies from the flanks of humpback whales (*Megaptera novaeangliae*) (NMFS permit 15240). Immunohistochemistry (IHC) was optimized to visualize antibodies specific for highly conserved molecules of axons, neural support cells, myelination, and the low-threshold mechanoreceptors (LTMRs) that transduce stretch, indentation and vibration into action potentials. Results were compared with the prototypical, glabrous skin of mice, macaque monkeys, and humans. The exceptionally thick cetacean epidermis is densely interdigitated with long pencillate dermal papillae, creating an extensive epidermal-dermal interface. IHC revealed axons immunoreactive to α-brain sodium channel I (BNaC) running along this boundary. In prototypic mammalian skin, BNaC is specific to LTMRs of dorsal root ganglia neurons. Other LTMRs, marked by α-calcitonin gene-related peptide (CGRP), formed clusters of fine-caliber neurofilaments and cells in the epidermal stratum basale, along the lateral wall of dermal papillae. In prototypic glabrous skin, this formation is found at the deep end of epidermal pegs, and is the tactile Merkel cell-neurite complex (MCNC), a slowly-adapting ending associated with heavily myelinated axons. In whale skin, the orthogonal orientation and lateralized location suggests a novel MCNC. Colocalization among antibodies to neurofilament-H (sensory fibers), PGP 9.5 (neurons and glia), the glial (Schwann cell) marker S100, BNaC, and CGRP differentiated fiber types in the subepidermal neural plexus and dermal papillae. Axons had a particularly large caliber compared to that in other species, consistent with the higher conduction velocity necessary to traverse distances up to 5m to the spinal cord. Another remarkable feature, not reported in any other mammal, is that axons in nerve fascicles appeared suspended within a large non-cellular space. Molecular homology of cutaneous innervation in whales and prototypic mammals suggests that whale skin contains a wide variety of unique innervation patterns and structural adaptations. These results will guide future work assessing how whale integument may be tuned to amplify signals or filter noise, protect axons from the pressures of deep dives, and triangulate signal sources in an aquatic environment.

Title: Ion channels/receptors expressed along group IV sensory afferent fibers within rat skeletal muscle

Authors: *R. RAMACHANDRA[1], K. S. ELMSLIE[2]
[1]Dept. of Pharmacol., A.T. Still Univ., Kirksville, MO; [2]Pharmacol., A.T.Still Univ. of Hlth. Sci., Kirksville, MO

Abstract: Exercise Pressor reflex (EPR) is activated by mechanical distortion and the metabolic by-products of exercising skeletal muscle, which stimulates receptors and ion channels to generate action potentials in thinly myelinated group III and unmyelinated group IV. This activity helps to increase cardiac output in response to exercise. The EPR can be inappropriately activated in disease states, such as peripheral vascular disease, leading to increased risk of myocardial infarction. We are investigating the receptors and ion channels expressed by group IV muscle afferent neuronal that could be involved in EPR. In this study, we utilize immunohistochemistry to identify receptors and ion channels expressed in the sensory afferent nerve fibers within rat skeletal muscles (gastrocnemius and soleus). Group IV afferent fibers were identified by using an antibody to label peripherin. Some of these fibers were co-labeled with antibodies targeting P2X3 (ATP) and α7 nACh (choline) receptors. We are also investigating the voltage-gated sodium (NaV) channels that are expressed along these afferent fibers. We have found that α7 nACh receptors are co- labeled with P2X3 on group IV nerve terminals that provides support for the idea that choline could be an activator of the EPR. The visualization of these receptors and channels along the afferent fibers compliments data from electrophysiological and whole-animal studies to provide a more complete understanding of their role in generating the EPR.

Title: Encoding temperature valence

Authors: L. POGORZALA, M. ISAACSON, H. SOLINSKI, *M. HOON
NIDCR, BETHESDA, MD

Abstract: Temperature changes trigger characteristic sensations of cooling, or warming, but how these thermal percepts are produced is still not fully understood. We wanted to study how the feeling of temperature, or the emotive valence generated by temperature, is formed. We devised a new method to investigate how peripheral sensory neurons and molecular receptors prompt these responses. Previously, behavioral tests have utilized passive assays such as the two plate preference and reflex response tests. However, these tests are incapable of determining the affective component in the animal being tested; they do not define the quality of the stimuli being sensed. Therefore, we developed an operant assay which allowed examination of an animal's ability to cognitively recognize temperature change. We established a novel apparatus capable of generating a rapid change in temperature in the skin of mice and linked this to a training regime in which mice learn to recognize specific thermal cues and quantitatively display a decision about the quality of thermal sensation they sense. A simple go/no go paradigm allowed water restricted mice to be trained to form a strong association between a specific temperature change and a water reward. Subsequently, trained animals were tested with novel thermal cues. This method allowed us to 1) examine whether thermal salience is retained in different temperature ranges (i.e. are temperature changes generalized? For example, does cooling from 20-15°C cause a similar sensation to that produced by cooling from 40-35°C?) 2) Determine how thermal acuity changes across a range of temperature. Lastly, we exploited this new approach to evaluate the effect, of the selective perturbation of different subsets of peripheral neurons, and of the elimination of receptors expressed in these neurons.

Abstract: Touch is encoded by a diverse array of receptors that generate unique firing patterns to inform the brain about mechanical stimuli. These receptors are embedded in the skin, which is a dynamic sensory organ that undergoes continual remodeling, including epidermal renewal and cyclical hair growth. This raises a key question: what are the mechanisms by which touch receptors maintain reliable firing during normal skin remodeling? We use Merkel cell-neurite complexes in mice to address this question. Merkel cells localize to skin areas specialized for high tactile acuity such as whisker follicles, fingertips, and touch domes in hairy skin. Merkel cells are contacted by slowly adapting type I (SAI) afferents, which together form gentle touch receptors that encode information about object features and static pressure. In mice, hair-growth cycles occur in synchronous waves, providing an excellent model system to study neuronal remodeling during skin structural changes. Mouse skin mechanical measurements demonstrated that skin becomes thicker and less stiff during hair growth. As skin is pivotal in transferring force to tactile end organs, we hypothesized that touch-evoked firing will change over the hair cycle unless homeostatic mechanisms, such as neuronal remodeling, compensate. To test this hypothesis, we investigated SAI-afferent structure across hair-cycle phases. During hair growth, we found the number of Merkel cells increased by over 50% and the new Merkel cells were incorporated into SAI end organs, suggesting they are functional transduction units. Neuronal branching complexity increased, correspondingly, with 40% more terminal branches in growth phases and higher branching orders. We postulate that this remodeling offsets the skin changes to

maintain consistent signaling. Collectively, these data indicate that tactile afferents remodel during skin changes. To identify molecular cues that govern neuronal remodeling, we focused on Bone Morphogenetic Protein (BMP) pathway signaling because 1) it governs the transition between resting and growth hair-cycle phases in the skin, and 2) overexpression of BMPs causes a decrease in cutaneous innervation density. Thus, we hypothesize that BMP signaling plays a role in afferent remodeling during hair cycling. To test this, we have outlined the timing of hair cycle-induced afferent remodeling and assessed expression of BMP receptors the skin. Together, our findings reveal mechanisms that govern homeostatic touch receptor remodeling in mammalian skin.

Title: Cellular and behavioral characterization of ASIC4 in knockout mouse

Authors: *S.-H. LIN[1], C.-C. CHEN[2]
[1]Academia Sinica, Taipei, Taiwan; [2]Inst. of Biomed. Sci., Taipei, Taiwan

Abstract: Acid-sensing ion channel 4 (ASIC4) is the most recent member of the degenerin/epithelial sodium channel (DEG/ENaC) family and is reported to express mainly in the nervous system. Like all other DEG/ENaC subunits, ASIC4 has a structure characterized by two transmembrane domains, one extracellular loop and intracellular N- and C-terminal domains. However, heterologous expression study indicated that ASIC4 cannot form an ion channel by itself and thus its function is proposed to be a modulator for other ASICs in the nervous system. Since information about ASIC4 is limited in the literature, we generated a knockout mouse line by inserting the CreERT2 coding sequences into the ATG site of Exon1 in the mouse Accn4 gene. ASIC4 homozygous knockouts were viable, fertile, and displayed no obvious defects in appearance. Q-PCR study suggested that in adult wildtype animal, ASIC4 transcript is expressed broadly in the central nervous system, most abundantly in the pituitary gland and barely in the dorsal root ganglion. All these transcripts are eliminated and no evidence of ASIC1a and/or ASIC3 mRNA compensation in the knockout mice. After crossing with CAG-

Td-Tomato reporter mice, we examined the induction of Cre recombination activity in adult ASIC4 homozygous animals by daily intraperitoneal injection of tamoxifen (3mg/day) for 7 days. Td-tomato signals were detected in many CNS regions, including the pituitary gland, olfactory bulb, hippocampus, amygdala, hypothalamus, cerebellum, cortex and the spinal cord. We next screened known behavioural phenotypes that were reported to be effected in the ASIC1a knockout mice. To our surprise, results indicated that ASIC4 knockout behaved normally in the fear conditioning task, their pain threshold for thermal and mechanical stimuli were normal, and the severity for experimental autoimmune encephalomyelitis (EAE) and kainic acid-induced seizure were the same to wildtype control. We concluded that ASIC4 might not be participated in the proposed function to modulate other ASICs in the nervous system.

Title: Vibration detection thresholds in a human cohort with congenital hearing deficits

Authors: *R. MOSHOURAB[1], V. BEGAY[1], J. WALCHER[1], C. WETZEL[1], M. GROSS[2], G. LEWIN[1]
[1]Neurosci., Max-Delbrück Centrum, Berlin, Germany; [2]Audiol. and Phoniatrics, Charité - Universitätsmedizin, Berlin, Germany

Abstract: Mechanosensory senses might share common genes that play a role in the transduction of mechanical energy, such as sound and touch. A recent study revealed that mutations in the USH2A gene, which causes deafness in Usher's syndrome, diminishes tactile sensation 1. We hypothesized that distinct components of tactile sensation, vibration, pressure, temperature, and pain, that pertain to specific mechanoreceptors classes are affected in subjects with congenital hearing deficits. A cohort with congenital deafness (n = 36; 17 females and 19 males; ages 14-21) from a school for the deaf were screened with an extensive battery of tests for deficits in tactile sensation of the dominant hand. The testing protocol determined the vibration detection threshold (VDT) at 10Hz and 125Hz, tactile acuity (using tactile acuity cube), thermal

sensation thresholds, and mechanical detection (von Frey hairs) and pain thresholds (pinprick test). Vibrations were applied below the nail of little finger, and a two alternative forced choice - where amplitude decreased in a logarithmic pattern after 6 correct choices and increased after 2 incorrect choices - was implemented. Data were compared to an age-matched healthy cohort (n=27). Elevated tactile acuity and vibration detection thresholds were observed in deaf subjects. Median values for tactile acuity threshold were significantly higher in the deaf cohort (1.675 mm compared to 1.425 mm in controls, P=0.024). We observe a strong effect on VDT, especially at 10Hz (mean threshold 8.01 μm in deaf individuals, compared to healthy age-matched controls, 4.07 μm, P=0.0003). In a considerable proportion of our deaf subjects 42% (15/36) thresholds found to be above 7.87 μm. Pain thresholds to pinprick in the deaf cohort were not significantly affected. Here we provide evidence of common genetic elements involved in auditory and cutaneous mechanotransduction. Next generation sequencing methods will be used in order to identify gene variants that control both touch and hearing. 1.Frenzel, H. et al. A Genetic Basis for Mechanosensory Traits in Humans. Title: Role of somatic/perisomatic membrane potential of nociceptive neurons in peripheral nociceptive transmission

Authors: ***X. DU**[1], H. HAO[1], S. GIGOUT[2], D. HUANG[1], Y. YANG[1], C. WANG[1], D. SUNDT[3], D. JAFFE[3], H. ZHANG[1], N. GAMPER[1,2]

[1]Pharmacol., Hebei Med. Univ., Hebei, China; [2]Univ. of Leeds, Leeds, United Kingdom; [3]Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Peripheral somatosensory neurons (including pain-sensing neurons, the nociceptors) are pseudo unipolar neurons that convey versatile information about body's environment to the CNS. It is generally accepted that in healthy organism peripheral nerves conduct action potentials from their respective sites of origin (peripheral nerve endings) to the superficial laminae of dorsal spinal cord without interruption and that sensory neuron somata do not contribute significantly to such conduction. Yet, growing evidence suggest that somatic/perisomatic compartment of sensory neurons can influence peripheral sensory transmission, particularly in some chronic pain conditions. Resting membrane potential (E_{rest}) is an important parameter regulating neuronal excitability, however, our understanding of how E_{rest} is regulated in sensory neuron somata or how changes in somatic E_{rest} affect peripheral sensory transmission is insufficient. In this study we evaluated the influence over E_{rest} of several major ion channels expressed in nociceptive neurons. Thus, we characterized contributions of Kv, K_{Na}, ATP-sensitive (K_{ATP}), Kv7 (M-type), and two-pore (K2P) K^+ channels; hyperpolarization-activated cyclic nucleotide-gated channels (HCN), T-type Ca^{2+} channels and TTX-sensitive and TTX-resistant voltage-gated Na^+ channels to E_{rest}. The strongest and most prevalent effect on E_{rest} was achieved by modulating M channels while targeting 4-aminopiridine-sensitive Kv channels, K2P, $K_{ATP,}$ HCN, Na^+ and Ca^{2+} channels also produced some effects. Next, we investigated how modulation of somatic/perisomatic ion channels affects peripheral nociceptive transmission *in vivo*. Acute focal application of M and K_{ATP} channel enhancers and HCN blocker to L5 DRG via the implanted DRG cannula *in vivo* significantly alleviated pain induced by hindpaw injection of bradykinin. Finally, we developed a mathematical model of mammalian C-fibre nocicieptor which supported our finding that hyperpolarization of a somatic/perisomatic compartment of nociceptive neuron can fail propagation of an action potential past the axonal bifurcation. Our study identifies ion channels that set somatic E_{rest} of nociceptive neurons and provides evidence for a robust filtering role for somatic/perisomatic compartment of peripheral nociceptive neuron. Title: Bidirectional modulation of heteromeric acid-sensing ion channel 1a/3 channels by zinc

Authors: *X. CHU[1], X. ZHA[2], Q. JIANG[1]
[1]Basic Med. Sci., Univ. Missouri-Kansas City, Kansas City, MO; [2]Univ. of South Alabama, Mobil, AL

Abstract: Acid-sensing ion channels 1a and 3 subunits are all expressed in sensory neurons, where they are though to play critical roles in pain perception associated with tissue acidosis. Our previous studies have shown that both homomeric ASIC1a and 3 channels are inhibited by physiological concentrations of zinc. ASIC1a and 3 can form functional channels in heterogonous system, which is believed to be expressed in neurons. Here, we found that heteromeric ASIC1a/3 channels are regulated by physiological concentration of zinc with dual effects. Different from homomeric ASIC1a and ASIC3 in response to zinc, co-application of zinc dose-dependently potentiates both the peak amplitude and sustained component of heteromeric ASIC1a/3 channel currents, pretreatment with zinc between 3 to 100 μM exert the same potentiation as co-application. However, pretreatment with zinc induced the significant inhibition of heteromeric ASIC1a/3 channels when concentration of zinc is over 100 μM. The potentiation of heteromeric ASIC1a/3 channels by zinc is pH-dependent, as zinc shifts the pH-dependences of ASIC1a/3 current from a pH_{50} of 6.5 to 6.9; while the inhibition of ASIC1a/3 currents by zinc is pH-independent. The inhibition of ASIC1a/3 currents by pre-applied zinc was independent of pH activation, steady-state desensitization, voltage, or extracellular Ca^{2+}. Further, we showed that the effect of zinc is dependent on the extracellular histidine residue. Systemic mutation of histidine residues in extracellular domain of ASIC1a subunit didn't affect the effect of zinc on heteromeric ASIC1a/3 channels. However, mutating histidine residues, located in the extracellular domain of the ASIC3 subunit abolished the zinc effects on heteromeric ASIC1a/3 channels. These findings suggest that histidines (located in the ASIC3) in the extracellular domain of heteromeric ASIC1a/3 subunit is critical for zinc-mediated effect and provide the basis for future mechanistic studies addressing the functional importance of heteromeric ASIC1a/3 channels in pain modulation.

Title: The novel T-type Cav3 channel biologic probe ML218 produces state-dependent inhibition of T-currents and mitigation of neuropathic and inflammatory pain in rodents

Authors: *B. ZOU[1], C. PASCUAL[1], L. YANG[1], J. XIE[1], X. XIE[1], D. WEAVER[2,3], C. LINDSLEY[2,3]
[1]AfaSci Res. Lab., Redwood City, CA; [2]Dept. of Pharmacol., [3]Vanderbilt Inst. of Chem. Biol., Vanderbilt Univ., Nashville, TN

Abstract: The T-type Cav3 channel (T-channel) plays a key role in pain signaling. The T-channel is involved in at least two key stages of pain pathways: first, in sensory neurons of the dorsal root ganglion (DRG) and second at the thalamic pain relay. Chronic nerve constriction injury and diabetic neuropathy cause upregulation of Cav3.2 subtype protein and augment of its-mediated T currents in the DRG neurons of rats. Conversely, gene knockout, antisense knockdown, or silencing of the Cav3.2 isoform produces pain relief in both neuropathic and inflammatory pain in rodents. To discover a potent and selective T-channel biologic probe that can be available without intellectual property restriction for all research, we completed the T-type Cav3 biologic probe discovery project. We first validated a fluorometric HTS method and then conducted a primary HTS, and followed by a “hit-to-probe” optimization. The lead has been designated as the T-channel probe ML218. The present study was undertaken to character the probe *in vitro* and investigate its efficacy *in vivo*. Using western blot with Cav3.1 and 3.2 antibodies we confirmed that DRG neurons exclusively express Cav3.2, but not Cav3.1 proteins. Under voltage-clamp, ML218 (100 nM) selectively blocks the T-current with approximately 100-fold selectivity over high-voltage activated Ca+, Na+ and K+ currents in the DRG neurons.

ML218 produced a voltage and frequency-dependent inhibition of the T-current. Under current-clamp, ML218 (1 μM) reversibly blocked T-channel triggered bursts without effects on resting potentials and membrane input resistance of the thalamic neurons. ML218 (50 μM) had no effects on NMDA-mediated EPSPs. One hour after administration of ML218 (30 mg/kg, ip), the plasma ML218 concentration was 976±177 nM in rats and 2,430±230 nM in mice. At this dose, acute treatment with ML218 mitigated chronic pain induced by spared nerve injury, streptozotocin-induced diabetic neuropathy and reserpine-induced chronic pain in rats. The 30 mg/kg dose ML218 also reduced hyperalgesia in the Complete Freund's adjuvant (CFA)-induced inflammatory pain in mice; while sparing normal nociception. At 60 and 100 mg/kg, ML218 did not cause significant changes in active/inactive cycle and reduction in locomotion and rearing of mice during 24 hours homecage monitoring using the SmartCage system. These results demonstrate that ML218 is a useful probe for investigation of physiologic and pathophysiologic roles of the T-channel, and can form a basis to develop a novel therapeutic with selective and state-dependent inhibition of the T-channel to treat chronic neuropathic pain.

Title: Control of activity mode and sensory signal processing in the thalamus: The novel role of KCNQ channels

Authors: *M. CERINA[1], H. J. SZKUDLAREK[2], P. COULON[2], T. KANYSHKOVA[2], P. MEUTH[2], K. GOEBEL[3], T. SEIDENBECHER[2], S. G. MEUTH[1], H. C. PAPE[2], T. BUDDE[2]

Abstract: KCNQ channels are slow voltage activated K+ channels. They represent the molecular substrate of the M current (IM), which operates below action potential threshold and limits neuronal excitability. We detected mRNA and protein expression of these channels in the ventrobasal thalamic complex (VB). To determine the contribution of KCNQ channels to thalamic activity modes and to analyse their possible role in somatosensory and noxious stimulus processing, VB neurons were characterized *in vitro*, in silico and *in vivo*. Whole-cell recordings were performed in mouse VB slices. Channel properties were modulated by using the specific KCNQ channel opener retigabine and inhibitor XE991. The consequences of IM activation were investigated in a TC neuron computer model and in mice using hot plate tests. In voltage-clamp, KCNQ channels generated a slow K+ outward current which was sensitive to retigabine and XE991. In current-clamp, retigabine reduced tonic firing and promoted the burst-like firing mode. The same effect was produced by adding an IM component to the TC neuron model. During hot plate testing, intrathalamic injection of retigabine and XE991 significantly increased and decreased the latency to the occurrence of pain behaviour, respectively. These findings indicate that IM limits TC neurons' excitability. Moreover, membrane hyperpolarization induced by KCNQ channel activation represents a new mechanism for the facilitation of LTS-mediated burst firing. Given the analgesic effect induced by retigabine injection and the known anti-nociceptive effect of thalamic burst firing during noxious stimulation, KCNQ channels may represent a novel target to control pain sensation on thalamic level.

Abstract: Nearly all sensory stimuli are conveyed from the periphery to respective cortical processing areas via the thalamus, where initial information processing occurs. Thalamocortical relay (TC) neurons which represent the majority of cells in the thalamus are determining its relaying and gating functions and are characterized by unique electrophysiological properties. Relay of information by the TC neuron is represented by tonic firing of Na+/K+-mediated action potentials where individual action potentials are nearly equally spaced; while gating of the information transfer is reflected by burst firing mediated by a T-type Ca2+ current where few individual action potentials are grouped together and these groups are separated by long quiescence periods. Recent studies indicate that TC neurons express K+ channels belonging to the KCNQ channel family (Kv7.2-Kv7.5). Opening of neuronal KCNQ channels induces a slow outward K+ current activating below the action potential threshold. This current has been termed M-current and typically results in spike frequency adaptation, a feature not observed in TC cells. For that reason involvement of KCNQ channels to firing mode regulation of TC neurons is thought to be of minor consequence and involvement of these channels in thalamic functions is continuously neglected. In the present study we provide evidence that KCNQ channels are functionally expressed in ventrobasal thalamic complex (VB) of mice and evaluate their physiological role. Extracellular single-unit recordings of TC neurons in VB of behaving animals showed that local pharmacological activation of KCNQ channels with retigabine increased the number of burst-associated spikes that were fired at higher frequency. Moreover, when animals were tested in a hot plate paradigm, local thalamic infusion of retigabine increased the latency to the occurrence of aversive behavior while blocking activity of KCNQ channels with XE991 decreased the latency. Simultaneous unit recordings showed that 35% of the VB neurons increased their activity during the hot plate test. Local application of retigabine reduced the number of responsive units to 25%, while XE991 increased it to 50%. On average, the peak activity of responsive units under control conditions occurred ~7 s after exposure to the hot plate. Retigabine increased this to ~14 s and XE991 decreased it to ~3 s. These findings indicate that KCNQ channels contribute to sensory information processing in VB. Their activation in freely

behaving mice mediates an increase in the latency to pain related behavior in response to thermal noxious stimuli paralleled by a decrease of responsive VB units and an increase of burst firing.

Title: TRP channel mediated cross-talk between axotomized and intact neurons in dorsal root ganglia revealed by probing activity with an ion channel photoswitch compound

Authors: *C. HEROLD, R. H. KRAMER
UC Berkeley, Berkeley, CA

Abstract: Transient Receptor Potential (TRP) ion channels play a major role in detecting sensory information and pain. TRP channels have also been shown to function as a key integrators of many pain related signals and TRP channel activation is implicated in the emergence of pain hypersensitivity and chronic pain. Interestingly, some TRP channels exhibit an unusual activation state identified by dynamic changes in ion selectivity after strong and prolonged stimulation. However, the physiological implications of this activation state remain completely unknown. We hypothesized that this activation contributes to physiological changes after peripheral axotomy and is involved in the communication between axotomized and non-axotomized cell bodies in the dorsal root ganglia. Since studying this activation with conventional methods in intact tissues remains hardly feasible, we developed an assay using a reporter molecule to indirectly read out dynamic selectivity over time in intact dorsal root ganglia tissue. In detail, we designed the photoswitch molecule QAQ which constitutes a light sensitive intracellular blocker of voltage-gated sodium, potassium and calcium channels. Block can be regulated by rapid and reversible photoisomerization of the central azobenzene group from trans to cis configuration upon 380 or 500nm light illumination, respectively. QAQ blocks ion channels in its trans configuration and switch to cis relieves the block. Given its double-charged character, QAQ is membrane-impermeable but it can enter cells using certain TRP channels as a conduit. In conclusion, QAQ functions as an activity dependent local anesthetic

inhibiting neuronal excitability in a light-sensitive manner after selective cell entry. Therefore, conferred light sensitivity functions as an indicator of TRP channel activity and reversible silencing of active pain neurons enables a new approach to study nociception. In addition, integrated QAQ entry over time amplifies even small changes in channel activity invisible to other techniques. Using this assay, we could demonstrate that the Spared Nerve Injury (SNI) mouse model for chronic pain leads to elevated TRP channel activity 24 hours after surgery. In contrast, activity levels decrease again in a 7 day post SNI time frame. More interestingly, spared, intact sensory neurons also show increased TRP channel activity. This cross activation is limited to slow conducting C fibers and TRPV1 expression is not essential for this effect. In summary, these findings might have implications for the regulations of neuronal plasticity and dynamic adaptation in the pain system.

Title: Neuropeptides in Sensory Neurons

Authors: *S. K. MISHRA, J. HUANG, M. A. HOON
Natl. Inst. of Dent. and Craniofacial Research/NIH, Bethesda, MD

Abstract: Recently there has been a renaissance in the study of neuropeptides in sensory systems as modulators and transmitters of somatosensory stimuli. We showed previously that the small polypeptide Nppb is expressed in peripheral sensory neurons and is critical for responses to itch-inducing compounds. This raised the issue of the role of a second peptide that had been reported to be expressed in DRG-neurons and had also been thought to be a primary transmitter for itch-behavior, GRP. Here we present evidence for a lack of GRP expression in peripheral sensory neurons while there are high levels of GRP expression in the dorsal horn of the spinal cord. These results indicate that GRP is not acting as a peripheral transmitter, but functions downstream of the DRG. A previous report also suggested that Nppb played a role as an analgesic at the level of the spinal cord. In order to evaluate the latter study we examined the

behavioral responses of mice lacking Nppb to painful stimuli. We found no evidence of deficits to noxious heat or mechanical stimuli either in naïve mutant mice or following intraplantar injection of CFA in Nppb knockout mice. Together these results argue against Nppb being important in pain signaling pathways and instead strongly suggest Nppb is a highly selective peripheral neuromodulator of itch sensation.

Title: KCNS1 as a biomarker for increased pain perception in patients with musculoskeletal pain

Authors: *A. FRENCH[1], J. BISHOP[2], S. ATKINSON[2], V. MAY[2], G. LIEBERMAN[2], M. NAYLOR[2]
[1]Univ. of Vermont, Essex Junction, VT; [2]Univ. of Vermont, Burlington, VT

Abstract: Objectives: The primary goal of this research is to determine whether an allele within the gene encoding for the potassium channel alpha subunit KCNS1 is associated with increased pain perception in patients with chronic musculoskeletal pain. Previous research demonstrated that the potassium channel encoded by this gene plays a role in neuronal excitability and that expression in sensory neurons is substantially down-regulated in patients with neuropathic pain with Val substitution. Specifically those with homogenous Val/Val missense single nucleotide polymorphism (SNP) at the rs734784 KCNS1 allele experience increased pain sensitivity. Given this, we aim to: (1) determine whether the distribution of KCNS1 genotypes differs in our sample of chronic musculoskeletal pain patients compared to the general population, (2) identify physical and psychological characteristics of patients with musculoskeletal pain by KCNS1 genotype, and (3) to investigate whether clinical response to Cognitive Behavioral Therapy (CBT) for coping with chronic pain differs based on KCNS1 genotype. We hypothesize that patients with the Val/Val SNP will report greater pain sensitivity and show greater improvement post-CBT. Methods: 201 adult male and female patients with chronic musculoskeletal pain were recruited to participate in this study. All participants underwent clinical evaluations and saliva samples were collected for DNA analysis. Clinical evaluations included a battery of behavioral inventories. After consenting patients were randomly assigned to either eleven weeks of group

CBT or an attention control group. Ongoing data analysis includes creation of statistical models to determine the interaction of characteristics impacting pain experience. Results: Preliminary analysis of these data revealed that the frequency of Val/Val substitution in our sample closely represents that of the general population (20.4% vs. 20.5%). In addition, at baseline, patients homogenous for the Val/Val substitution had lower pain levels (p=.02), higher SF-36 mental component scores (p=.04) and reported reduced catastrophizing (p=.006) compared to patients with no Val substitution. Conclusion: These findings demonstrate that genetic variations in the KCNS1 allele correlate with pain perception. Contrary to our hypothesis, musculoskeletal pain patients with homogenous Val/Val mutations report lower average pain than those with no Val substitution, suggesting KCNS1 plays a different role in pain perception than in neuropathic pain. Work is underway to assess whether differences in genotype can be correlated with treatment outcomes.

Title: Conditioned taste aversion prevents the long-lasting BDNF-induced enhancement of synaptic transmission in the insular cortex: A metaplastic effect

Authors: A. RIVERA-OLVERA, *M. L. ESCOBAR
División de Investigación Posgrado, Fac Psicol, UNAM, Mexico, D.F., Mexico

Abstract: Metaplasticity is a homeostatic process by which the capacity of synapses to express plastic changes is itself subject to variation depending on previous experience. In particular, training in several behavioral tasks modifies the possibility to induce long-term potentiation (LTP). Recently, we have reported that prior training in conditioned taste aversion (CTA) prevents the subsequent induction of long-term potentiation generated by high frequency stimulation in the projection from the basolateral nucleus of the amygdala (Bla) to the insular cortex (IC). One key regulator of long-term synaptic modifications related to learning and

memory maintenance is brain-derived neurotrophic factor (BDNF). Our previous studies have demonstrated that acute microinfusion of BDNF on the IC induces a lasting potentiation of synaptic efficacy at the Bla-IC projection. The aim of the present study was to analyze whether CTA training modifies the ability to induce subsequent BDNF-induced potentiation of synaptic transmission in the Bla-IC projection *in vivo*. Thus, CTA trained rats received intracortical microinfusion of BDNF in order to induce lasting potentiation 48 h after the aversion test. Our results show that CTA training prevents the induction of *in vivo* BDNF-LTP in the Bla-IC projection. These findings reveal that CTA training produces a change in the ability to induce subsequent *in vivo* BDNF-LTP in the IC, suggesting that changes in the ability to induce subsequent synaptic plasticity in the neocortex contribute to the formation and persistence of aversive memories.

Title: Alterations in neurotrophin expression associated with adult experience-dependent plasticity

Authors: *S. A. MARIK, C. D. GILBERT
The Rockefeller Univ., NEW YORK, NY

Abstract: Plasticity in the adult cortex can be induced by alterations in sensory experience. The representation of the whiskers in the mouse somatosensory cortex can be altered by whisker plucking, which results in remapping of the areas receiving input from the remaining whiskers. This remapping is associated with a parallel process of axonal outgrowth and pruning with a net increase in density of horizontal excitatory axons projecting into the deprived cortex. To determine the molecular mechanisms underlying the axonal changes, we examined the temporal alterations in BDNF expression following whisker plucking. After one day of whisker plucking there is upregulation of BDNF expression throughout the barrel cortex, which then, after two days, becomes more localized to the deprived cortex. One the other hand, the BDNF precursor,

proBDNF, is expressed in the somatosensory cortex before plucking, with particularly high levels in layer V pyramidal somata, and this expression decreases following whisker plucking. The decrease in proBDNF may be related to the elevation in BDNF, with the former being constitutively expressed and then converted into the latter after removal of sensory input. The balance between BDNF and proBDNF may account for the push pull nature of axonal changes involved in experience-dependent plasticity.

Title: Epigenetic regulation of BDNF affects parvalbumin interneuron maturation during experience-dependent plasticity of the mouse barrel cortex

Abstract: During early development, interactions between sensory experience and innate genetic programs are crucial for sculpting neuronal circuits. We used the mouse primary somatosensory cortex (S1) to investigate the molecular mechanisms involved in gene regulation during experience-dependent plasticity. Differences in cortical function and gene regulation were compared between barrel cortices in the same animal that received differential sensory input as a result of unilateral whisker deprivation. 30 days after whisker deprivation at birth, we found that inhibitory transmission between layer II/III parvalbumin interneurons and pyramidal neurons was decreased. We hypothesize that this results from epigenetic mechanisms that regulate genes responsible for maturation of inhibitory circuits. Histone acetylation, an epigenetic mark for gene transcription, is kept in equilibrium by histone acetyltransferases and histone deacetylases (HDACs). We observed that HDAC1 expression decreased during the course of S1 development.

However whisker deprivation caused HDAC1 expression to remain relatively high (34% increase). This was associated with (1) decreased acetylation of histones, (2) increased binding of HDAC1 to promoter I of brain-derived neurotrophic factor (Bdnf), and (3) reduced transcription of the Bdnf gene. Whisker deprivation also delayed maturation of layer II/III inhibitory circuits in S1, evident by a 34% decrease in parvalbumin expression within interneurons and a 17% reduction in perineuronal nets, which have been implicated in maturation and stabilization of inhibitory synapses. Our results are consistent with the hypothesis that HDAC1 activity modulates BDNF expression required for the maturation of parvalbumin interneurons within layer II/III inhibitory circuits.

Title: Post-training changes in the numerical density of CB1 and PV immunoreactive puncta in barrel cortex following fear conditioning in the mouse

Authors: *E. SIUCINSKA, W. BRUTKOWSKI, T. BERNAS
Nencki Inst., Warsaw, Poland

Abstract: In the cerebral cortex immunostaining for the type 1 cannabinoid receptor (CB1) was found in axon terminals, all of which contained GABA and formed symmetric synapses. Parvalbumin (PV) neurons include chandelier and basket cells. Parvalbumin immunopositive chandelier cells synapse on the axon initial segments and basket cells regulate the cell soma of pyramidal cells, regulating output and integration across cortical areas. Previous ultrastructural studies using stereological counting techniques show a 70% increase in the density of inhibitory synapses on spines of neurons located in layer IV barrels that represent the stimulated vibrissae, have suggested synaptic remodeling occurred at least 24hr after fear conditioning. The present study estimates the mean CB1 (Abcam 1:500) and PV- (Sigma 1:12,000) immunoreactive puncta

(CB1-IR, PV-IR) numerical density (Nv) in a region of the mouse the primary somatosensory cortex known to be involved in plastic changes induced 24h following three days fear conditioning. In all experiments precise location of layer IV cells were identified using Hoechst 33258 staining of tangential sections. A confocal microscopy stereological technique, the "disector", was used in the CB1-IR and PV-IR puncta analyses. In barrels belonging to the row of vibrissae stimulated during fear conditioning, the average density of CB1-IR puncta and PV-IR axon terminals in the hollows increased by approximately 25% as compared with the hollow of row on the contralateral control side. The finding suggest that both, endocannabinoid receptor 1 and PV-IR axon terminals may be a key part of processes involved in conditioning-dependent plasticity of the primary somatosensory cortex. The observed increase of PV-IR neuropil may be related to controlling the effectiveness of perisomatic inhibition, or metabolic activation of the population of PV-IR neurons.

Title: Visualization of NMDA receptor-dependent AMPA receptor synaptic plasticity *in vivo*

Authors: ***Y. ZHANG**[1], R. H. CUDMORE[1], D.-T. LIN[1,2], D. J. LINDEN[1], R. L. HUGANIR[1]

Abstract: Regulation of AMPA receptor (AMPAR) membrane trafficking plays a critical role in synaptic plasticity and learning and memory1. However, how AMPAR trafficking occurs *in vivo* remains elusive. Using *in vivo* two-photon microscopy in the somatosensory barrel cortex, we found that acute whisker stimulation leads to significant increases in the expression of surface AMPA receptor GluA1 subunit (sGluA1) in both synaptic spines and dendritic shafts and only small changes in spine size and no changes in spine turnover. Interestingly, initial spine

properties bias changes in spine sGluA1 content and spine size. Changes in spine sGluA1 are positively correlated with changes in dendritic shaft sGluA1, while changes in spine sGluA1 between neighboring spines are negatively correlated. The sensory stimulated increase in spine sGluA1 is NMDA receptor dependent and long lasting similar to major forms of synaptic plasticity in the brain. Our findings shed light on the complexity of AMPAR membrane trafficking and experience-dependent remodeling of synaptic strength *in vivo*.

Title: Synapse-specific plasticity and calcium-permeable AMPA receptors expression in the neocortical layer-5 microcircuit

Authors: *T. LALANNE[1], J. OYRER[2], R. P. COSTA[3], A. J. CHUNG[1], M. FARRANT[2], P. J. SJÖSTRÖM[1]
[1]Neurol. and Neurosurg., McGill Univ., Montreal, QC, Canada; [2]Neuroscience, physiology and pharmacology, Univ. Col. London, London, United Kingdom; [3]Inst. for adaptive and neural computation, Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Although they play critical roles in the neocortical circuitry functions and development, little is known about the plasticity of inhibitory neurons, mainly because they are

difficult to identify. We examined plasticity at excitatory pyramidal cell (PC) synapses onto basket (BCs) and Martinotti cells (MCs), two major inhibitory cell types in layer-5 of visual cortex. In acute slices from postnatal day 12-21 mice, neurons were identified by morphology, and spiking pattern when possible. With a 50-Hz induction protocol that consistently potentiated PC-PC synapses (after/before ± SEM = 120% ± 7%, n = 10, $p < 0.05$, Student's t-test), we observed non-Hebbian depression of both PC-BC (74% ± 7%, n = 7, $p < 0.05$) and PC-MC connections (54% ± 10%, n = 5, $p < 0.05$). In hippocampus, calcium-permeable (cp-) AMPARs underlie non-Hebbian plasticity at excitatory synapses onto some inhibitory neuron types. We thus set out to determine the presence of cp-AMPARs at these three synapse types. With intracellular loading of spermine to specifically block cp-AMPARs at positive voltages, spontaneous release onto BCs showed inward rectification (rectification index RI+60mV/-60mV = 0.40 ± 0.03, n = 6, versus 1.32 ± 0.15, n = 4, for controls without spermine, $p < 0.001$). Similar results were obtained for evoked currents in PC-BC pairs (RI+40/-40 = 0.104 ± 0.04, $p < 0.001$, n = 6), suggesting the presence of cp-AMPARs. In agreement, the cp-AMPAR blocker NASPM reduced both spontaneous (61 ± 5%, n = 5, $p < 0.01$) and evoked currents in BCs (44% ± 4%, n = 5, $p < 0.001$). In contrast, PC-MC connections did not rectify (RI+40/-40 = 1.41 ± 0.15, p = 0.12, n = 4), suggesting the absence of cp-AMPARs. To study the postsynaptic side in isolation, we uncaged NPEC-AMPA. Uncaging-evoked currents were reduced by NASPM in BCs (61% ± 5%, n = 7, $p < 0.001$) but not MCs or PCs (99% ± 10%, n = 4, p = 0.96 for MCs). In addition, uncaging-evoked currents rectified in BCs (RI+40/-40 = 0.10 ± 0.09, $p < 0.001$, n = 8) but not in MCs (RI+40/-40 = 0.97 ± 0.1, p = 0.8, n = 6). Finally, simulations using a computer network model tuned to our Naspm wash-in data suggested that cp-AMPARs impact early BC but not late MC feedback inhibition onto PCs. In conclusion, although both PC-BC and PC-MC synapses show non-Hebbian plasticity cp-AMPARs are specifically expressed at PC-BC connections. This implies that cp-AMPARs do not alone determine non-Hebbian plasticity. However, synapse-specific cp-AMPAR expression may govern early BC and late MC feedback inhibition. Such synapse-specific plasticity may critically influence information processing in cortical networks.

Title: Development of sub- and suprathreshold plasticity in RS and IB cells in layer V of the mouse barrel cortex *in vivo*

Authors: *S. GREENHILL, K. FOX
Dept. of Biosci., Cardiff Univ., Cardiff, United Kingdom

Abstract: We have previously shown that, in layer V of the rat barrel cortex, regular spiking (RS) and intrinsic bursting (IB) cells respond differently to whisker deprivation; RS cells show depression of responses to deprived whisker stimulation and an increase in spike timing fidelity for short latency responses to spared whisker stimulation. IB cells show no depression but do show generalised potentiation of responses to spared whisker stimulation (Jacob et al, Neuron 73, 391-404 (2012)). We tested whether these results generalised to the mouse barrel cortex. Sharp electrode intracellular recordings were made from acutely anaesthetised preparations of both naive mice and mice whose D-row whiskers had been unilaterally clipped for either 3 or 10 days. The D1-D3 barrels were localised before recording using intrinsic optical imaging at 700nm to guide the electrode recordings. Upon penetration and electrophysiological classification of a layer V pyramidal cell, the receptive field and whisker evoked activity of the cell was automatically mapped using a 3x3 piezo matrix stimulator. Cells were classified as RS or IB depending on their response to depolarising current. In wild-type mice (C57BL/6J), RS cells in layer V showed a depression in firing rates (to 71% of control) in response to both principal (deprived) and surround (spared) whisker stimulation after 3 and 10 days D-row spared deprivation. However, subthreshold responses generally displayed increased amplitude with longer latencies, suggesting a complex relationship between subthreshold activity and firing rate. Additionally, the rate of spontaneous firing was reduced in RS cells recorded from deprived animals. In contrast, IB cells displayed spike-rate potentiation (to 212% of control) across all vibrissae types, but only after 10 days of deprivation. Subthreshold IB responses were of larger amplitude and shorter latency after both 3 and 10 days deprivation. These data suggest that in common with rat layer V, RS and IB cells show different plasticity responses to whisker deprivation but in contrast to the input-specific responses observed in rat layer V, mouse layer V neurones show plasticity that is input agnostic. Current studies are underway to identify the molecular substrates underlying these different forms of plasticity.

Title: Role of experience in plasticity outcomes of spatially separate synaptic pathways onto individual neurons in mouse visual cortex

Authors: *O. M. FITCH[1,2], M. J. FRIEDLANDER[1]
[1]Virginia Tech. Carilion Res. Inst., Roanoke, VA; [2]Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: In the neocortex, individual cells of like type can undergo heterogeneous plasticity responses from depression (LTD) to potentiation (LTP), or no change (NC) in response to a common fixed time delay synaptic conditioning protocol. However it is not known whether all synapses onto a common cell have the same plasticity outcome. Nor is it known what role visual experience plays in shaping the distribution of differential plasticity outcomes. Thus, we evaluated the synaptic plasticity responses of separable sets of synaptic inputs onto common layer 2/3 pyramidal neurons in primary visual cortex in response to simultaneous stimulation of distinct sets of afferents in acute brain slices from visually intact mice and from mice reared with binocular deprivation from before the natural time of eye-opening. The two stimulation sites in layer 4 were spatially isolated by occlusion testing followed by alternative activation of each pathway to evoke a post-synaptic potential (PSP) every 10 seconds in an interleaved fashion. After a ten minute baseline period, the activation of both pathways was simultaneously paired with direct post-synaptic activation that preceded the synaptic stimulation by 10 milliseconds resulting in 3-7 post-synaptic spikes over ten minutes at 0.1 Hz followed by reversion to the interleaved stimulation for 30 minutes. The ratio of the evoked PSP post-/pre- conditioning was calculated for each pathway by taking the 5 minute average peak amplitude over 25-30 minutes post-conditioning compared to 5 minute average before the onset of conditioning. Our results from 132 pathways onto 71 neurons validate in the mouse cortex our previous findings from other rodent species demonstrating heterogeneous plasticity outcomes ranging from LTD to LTP for individual cells with a median post/pre ratio of 0.84 in visually intact mice- both naïve and anesthesia controls. Visually deprived mice did not show a significant difference in the change of synaptic strength of individual pathways with a mean 0.89 post/pre ratio for 63 pathways onto 31 neurons (Rank Sum, $p=0.42$). However, the relationship between two pathways onto a common cell differed depending on the level of visual experience with a weak correlation between two pathways in visually deprived mice (median $R= 0.49$, $p= 0.005$, $n= 30$ cells) while no such relationship existed in sighted mice (median $R = 0.023$, $p= 0.9$, $n= 31$ cells) with a significant

difference between correlation coefficients (t-test, p=0.05) as measured by a linear fit to 10,000 random permutations of ordinate and abscissa designation of post/pre ratios of two pathways onto a common cell for each treatment group (Monte Carlo Permutation Analysis).

Title: The role of CaMKII-alpha in experience-dependent structural plasticity of Layer2/3 pyramidal dendritic spines in mouse barrel cortex

Authors: *G. SEATON, K. D. FOX
Cardiff Univ., Cardiff, United Kingdom

Abstract: Most functional plasticity studies to date have focused on Layer2/3 neurons, while structural plasticity remains largely uncharacterised in these layers. It is not clear from the literature on visual and somatosensory cortex whether Layer2/3 neurons show significant levels of structural plasticity in response to sensory deprivation, whilst it is clear that they show substantial CaMKII-dependent functional plasticity (Glazewski et al 2000 Nature neuroscience 3 (9), 911-918). To address this issue we investigated experience-dependent structural plasticity of the basal dendritic spines of Layer2/3 pyramidal neurons in the barrel cortex. C57Bl6-Jax mice were injected intracranially with AAV-Cre(CaMKII)-GFP and AAV-Flex-GFP, to target sparse expression of GFP (under the control of Cre-recombinase and the CaMKII-alpha promoter) in a population of Layer2/3 pyramidal neurons. Using 2-photon laser-scanning microscopy, chronically intracranial windowed GFP mice were then imaged to quantify basal turnover and the proportion of persistent spines (i.e. spines that survive for 8 days or more). Mice were then subjected to sensory (chessboard whisker) deprivation and the imaging paradigm timed so that spines were quantified and characterised 24 hours post deprivation, with subsequent 4 day imaging time points extending up to two weeks post deprivation. To investigate the role of CaMKII-alpha in the structural component of experience-dependent plasticity in the barrel cortex, we imaged double virus injected CaMKII- Threonine-286-Alanine (CaMKII-T286A)

mutant mice, and characterised spine density, morphology, turnover and persistence before and after whisker deprivation. Initial observations suggest that CaMKII-T286A mice have a 2 fold higher basal turnover rate, of 4%, compared to WT control of 2%. 24 hours post deprivation, CaMKII-T286 mice show an increased percentage of new spines compared to WT control, however new spines in WT appear to persist for longer, some lasting over two weeks after formation. Structural morphology and clustering dynamics also appear to be altered compared to WT controls. These data, for the first time, suggest a role for CaMKII-alpha in the initial phases and subsequent maintenance, of structural changes in the basal dendritic spines of Layer2/3 neurons, and therefore support the hypothesis that structural plasticity underlies the functional experience-dependent plasticity observed in the mouse barrel cortex.

Title: Sensory training reorganizes intracortical connections differentially across modalities after a mild TBI

Authors: *S. L. JULIANO[1], E. M. SHINDELL[2], S. SCHWERIN[2]
[1]USUHS, BETHESDA, MD; [2]USUHS, Bethesda, MD

Abstract: Intracortical connections expand over a lengthy period following a controlled cortical impact (CCI) in a mouse model of traumatic brain injury (TBI). To investigate the effects of introducing a training paradigm on cortical architecture, we studied the outcome of a situation where mice with and without CCI were trained on a task involving sensory discrimination with their whiskers. The injury directly affects the barrel cortex, but is flanked on either side by intact sensory and motor cortices. Animals recovered for 2 days and then trained to distinguish between rough and smooth textures for 1, 4 or 12 weeks, to determine if the length of training influenced neuroplastic changes. The mouse used its whiskers to choose a coarse versus smooth texture, cross a gap and receive a food reward. This task was difficult for the mice and they were not all able to learn. Following training, the mouse brains were studied by injecting fluorescent

dextrans into select slices through both barrel and motor cortex. The slices were maintained in a chamber perfused with oxygenated aCSF for three hours post injection. To detect and quantify the labeled intracortical connections we examined microscope images using a Hessian-based edge detection filter in Image J. In particular we measured the density of labeled pixels and determined the distance and dispersion of the apical dendrites, descending axons and medial and lateral projections. We previously reported that in the absence of training, longer recovery durations result in greater expansion in barrel cortex than shorter recovery periods and that few changes were observed in motor cortex. The training task after TBI resulted in an expansion of processes in both sensory and motor cortices, compared to control animals or animals with TBI alone. Specifically, we observed a greater expansion in processes extending AWAY from the injury regardless of cortex injected. In addition, the animals that learned the task showed more expansion in sensory cortex compared with the expansions in motor cortex. In summary, these results have implications for rehabilitation regarding the timing and modality of training and the resulting effects on different cortical regions.

Title: Inhibitory and excitatory spike-timing-dependent plasticity in the auditory cortex

Authors: *J. A. D'AMOUR, R. C. FROEMKE
Mol. Neurosci., New York University, Sch. of Med., New York, NY

Abstract: Inhibition must be carefully calibrated with excitation in neural circuits. This excitatory-inhibitory balance promotes information flow through neural networks while limiting over-excitability and spurious plasticity. However, this means that changes to excitatory synapses should be tracked by corresponding changes to specific inhibitory synapses to preserve overall excitability and excitatory-inhibitory balance. How inhibitory synapses are modified in

parallel with excitatory synapses has remained unclear. Here we study spike-timing-dependent plasticity (STDP) of inhibitory synapses onto layer 5 neurons in slices of young mouse (P12-24) auditory cortex, together with concomitant STDP of excitatory synapses onto the same neurons. Repetitive pairing of extracellular stimulation with single postsynaptic action potentials induced substantial long-term potentiation (LTP) of inhibitory inputs irrespective of the precise temporal order as long as spikes occurred within ~10 msec (162.2±15.3% n=34 for short positive spike timing intervals, and 133.7±15.8% n=26 for short negative intervals), similar to the prediction of a recent theoretical study (Vogels et al., Science 2011). This was in contrast to excitatory inputs onto these neurons, which displayed a conventional asymmetrical time window for STDP induction (132±6.2% n=46 for short positive intervals, and 81.9±2.8% n= 30 for negative intervals). Inhibitory plasticity was linked to excitatory changes, as NMDA receptors were required for modifications of both excitatory and inhibitory synapses. Irrespective of the temporal order of spike pairing, these combined synaptic modifications acted together to normalize the excitatory-inhibitory ratio of events paired together with postsynaptic action potential generation. Moreover, after excitatory and inhibitory STDP, subthreshold events could become suprathreshold, and the temporal integration window between the onset of excitation and inhibition became shorter, potentially improving spike timing precision. These findings demonstrate that cortical inhibitory synapses are highly plastic, and more importantly, indicate that inhibitory plasticity requires interactions with functionally-related excitatory synapses in order to properly regulate excitatory-inhibitory balance.

Warsaw, Poland; [3]Rutgers Univ. Cell Biol. & Neurosci., Piscataway, NJ; [4]Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: Rodent whisker representation in the somatosensory cortex has a clear somatotopic organization in a form of barrel-like neuronal densities in layer IV forming so-called barrel field (BF) and arranged in a pattern strictly corresponding to the organization of whiskers on the snout. We used this model to study experience-dependent plasticity induced by partial sensory deprivation i.e. unilateral clipping of all but row B whiskers. The cortical representation of the sparred row B was investigated electrophysiologically and by 14C-2-deoxy-D-glucose (2DG) brain mapping. We compared evoked field potentials (EP) and metabolic activity changes (2DG incorporation) evoked in both hemispheres by a unilateral and bilateral stimulations of row B whiskers in deprived and undeprived rats. It was shown with 2DG mapping that cortical representation of the spared whiskers was enlarged after one month of everyday whisker trimming. Bilateral stimulation of row B whiskers induced 2DG incorporation in the cortical area over sparred row B representation that was wider by 44% ($p < 0.05$) compared to the control side and control undeprived animals. Interestingly, after unilateral whiskers stimulation the spared to control difference of row B representations was only 20% ($p<0.05$). Preliminary electrophysiological data shows that the amplitude of potentials evoked by the stimulation of spared row B tend to be lower than in control animals, both in contra- and ipsilateral hemisphere. However, the responses recorded in deprived hemisphere after stimulation of row B from ipsilateral (undeprived) whisker pad tend to be enlarged - they can be as large as those induced by contralateral whiskers stimulation at the depth of 500um. Such activation profile supports the hypothesis that the interhemispheric influences from contralateral side may play important role in inducing the enlargement of the 2DG representation of spared row B whiskers in input-deprived barrel field.

Title: Altered microRNAs expression in cortical plasticity after sensory stimulation

Authors: *I. KHADIMALLAH[1], N. WENGER[1], R. KRAFTSIK[1], R. REGAZZI[1], G. KIRSCHMANN[2], E. WELKER[1]
[1]Univ. of Lausanne, Lausanne, Switzerland; [2]Univ. Hosp. Ctr., Lausanne, Switzerland

Abstract: In rodents, sensory experience alters the whisker representation in layer IV of the barrel cortex. Excitatory and inhibitory interneurons, together with the astrocytic network, modify the functional representation in an orchestral manner. Our group showed that continuous whisker stimulation in adult mice induces depression of neuronal responses and insertion of new inhibitory synapses on spines. This form of cortical plasticity is controlled by several gene regulatory mechanisms including the activation of genetic programs controlling the expression of microRNAs. The transitory and localized expression of these small, non-coding RNAs in dendrites and their capacity to respond in an activity-dependent manner make brain-specific miRNAs ideal candidates for the fine tuning of gene expression associated with neural plasticity. To investigate the involvement of miRNAs in cortical plasticity, we selected four microRNAs known to be implicated in other forms of synaptic plasticity: miR-125b, miR-132, miR-137 and miR-138. After unilateral stimulation of three whiskers (C1−3) in the adult mouse, we compared the expression level of these miRNAs in stimulated and adjacent non-stimulated barrels using *in situ* hybridization with digoxigenin-labeled Locked Nucleic Acid probes. Whisker stimulation increases the expression, of miR-132 after 3hours of stimulation ($p=0.02$; $n=6$) and miR-137 ($p=0.03$; $n=6$; 24 hrs of stim.), whereas it reduces the level of miR-125b ($p=0.002$; $n=6$; 9 hrs of stim.). No significant difference was detected for miR-138. In addition to this quantitative comparison, we combined microRNA *in situ* hybridization and immunolabeling for various neuronal markers that were chosen for the localization in both excitatory and inhibitory circuits as well as in astrocytes. Analysis of three dimensional confocal acquisitions showed a colocalization of miR-125b with GAD65/67 and parvalbumin; miR-132 with GAD65/67 and Vglut2, miR-138 with parvalbumin, Vglut1 and PSD95, and miR-137 with Vglut1, GS and S100ß. Stimulation alters the degree of colocalization in the stimulated barrel. For example, double labeling for miR-138 and PSD95 is significantly increased in the stimulated barrel as compared to the level of colocalization in the neighboring non- stimulated barrel ($p=0.012$; $n=3$). Using increased neuronal activity in the whisker-to-barrel pathway, our results indicate that microRNAs have a potential role in sensory activity-dependent cortical plasticity in the adult mouse by acting specifically within the different cellular components of the adult neocortical circuit.

Abstract: Presynaptic NMDARs (preNMDARs) with unclear functional role have been found at several central synapse types. They have often been implicated in increasing the probability of release, but precisely how has remained unknown. We compared evoked and spontaneous release onto layer-5 pyramidal cells (PCs) using whole-cell recordings in acute slices of juvenile mouse visual cortex. AP5 blockade of preNMDARs downregulated responses evoked at firing rates >8 Hz (69% ± 3%, n = 16, p < 0.001) but not <8 Hz (97% ± 2%, n = 19, p = 0.14). Even though spontaneous release rates were <8 Hz (2.4 ± 0.5 Hz, n = 16, p < 0.001), AP5 reduced miniEPSC frequency (66% ± 3%, n = 16 vs. controls 98% ± 2%, n = 4, p < 0.001), seemingly in contradiction. Quantal amplitude was not affected, as miniEPSPC amplitude remained unaltered (96% ± 1% vs. 98% ± 0.4%, p = 0.11). Two-photon imaging revealed that AP5 reduced basal calcium levels in a subset of PC boutons (67% ± 5%, n = 5), which could potentially specifically reduce probability of spontaneous release while leaving evoked release unaffected. PreNMDARs could affect evoked release in several different ways, e.g. by altering probability of evoked release directly, by increasing the readily releasable pool (RRP) size, or by upregulating RRP replenishment rate. We used Schneggenburger-Neher’s approach to examine the RRP, depleting it with 14-pulse trains at 30 Hz every 80 seconds, and then comparing preNMDAR blockade to external [Ca2+] reduction. The GluN2B-specific NMDAR blocker Ro25-6981 reduced both RRP size (-36 ± 7%, n = 11 vs. controls -7.1% ± 5%, n = 11, p < 0.05) and replenishment rate (-

31% ± 7% vs. 18% ± 7%, $p < 0.001$). However, although lowering [Ca2+] decreased the RRP size (-27% ± 4%, $n = 9$, $p < 0.05$ vs. controls), replenishment rates were unaffected (7.8% ± 7%, $p = 0.33$). PreNMDAR upregulation of RRP replenishment rates is thus dissociated from general calcium influx. We next extended the Tsodyks-Markram short-term plasticity model to include preNMDARs and tuned it to control and Ro25-6981 conditions. The model corroborated that replenishment rates were downregulated in preNMDAR blockade, and it also captured the 8-Hz frequency threshold. In conclusion, preNMDARs may elevate the probability of spontaneous release directly by increasing basal calcium levels in boutons, presumably by flickering open at resting membrane potential. However, preNMDARs may upregulate probability of evoked release indirectly as a consequence of increasing RRP replenishment rates. In this view, one functional role of preNMDARs may be to maintain neurotransmission in the face of high-frequency firing.

Title: Imbalanced synaptic plasticity rules lead to energy efficient connectivity

Authors: J. SACRAMENTO[1], *M. C. VAN ROSSUM[2]
[1]Inst. Superior Técnico, INESC-ID, Universidade de Lisboa, Portugal; [2]Univ. Edinburgh, Edinburgh, United Kingdom

Abstract: It is believed that energy efficiency is an important constraint in brain evolution. As synaptic transmission dominates energy consumption, energy can be saved by ensuring that as few as possible synapses are active. It is therefore likely that the formation of sparse codes and sparse connectivity is a fundamental objective of synaptic plasticity. In this work we study how sparse connectivity can result from a synaptic learning rule of excitatory synapses. Information is maximised when potentiation and depression are balanced according to the mean presynaptic activity level and the resulting fraction of zero-weight synapses is around 50%. However, an imbalance towards depression increases the fraction of zero-weight synapses without

significantly affecting discrimination performance. We show that imbalanced plasticity corresponds to imposing a regularising constraint on the L1-norm of the synaptic weight vector, a procedure that is well-known to induce sparseness. Imbalanced plasticity is biophysically plausible and leads to more efficient synaptic configurations than a previously suggested approach that prunes synapses after learning. Our framework gives a novel interpretation to the high fraction of silent synapses found in brain regions like the cerebellum.

Title: Distinct mechanisms of spike timing-dependent LTD at vertical and horizontal inputs onto L2/3 pyramidal neurons in mouse barrel cortex

Authors: *A. RODRIGUEZ-MORENO[1], A. BANERJEE[2], A. GONZALEZ-RUEDA[3], C. SAMPAIO-BAPTISTA[2], O. PAULSEN[3]
[1]Univ. Pablo de Olavide (Edificio 21), Seville, Spain; [2]Univ. of Oxford, Oxford, United Kingdom; [3]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Spike timing-dependent plasticity (STDP) is an attractive candidate to mediate the synaptic changes that support circuit plasticity in sensory cortices during development. STDP is prevalent at excitatory synapses, but it is not known whether the underlying mechanisms are universal, or whether distinct mechanisms underpin STDP at different synapses. Here, we set out to compare and contrast STDP at vertical layer 4 and horizontal layer 2/3 inputs onto

postsynaptic layer 2/3 neurons in the mouse barrel cortex. We find that both vertical and horizontal inputs show STDP, but that they display different time windows for induction of timing-dependent long-term depression (t-LTD). Moreover, whereas t-LTD at vertical inputs requires presynaptic NMDA receptors and is expressed presynaptically, using paired recordings we find that t-LTD at horizontal inputs requires postsynaptic NMDA receptors and is expressed postsynaptically. These results demonstrate that similar forms of plasticity on the same postsynaptic neuron can be mediated by distinct mechanisms, and suggest that these forms of plasticity may enable these two types of cortical synapses to support different functions.

Title: Microglial P2Y12 signaling is critical for visual plasticity

Authors: *G. O. SIPE, A. K. MAJEWSKA
Neurobio. & Anat., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Synaptic plasticity is critical for neurodevelopment and proper function of the adult nervous system. Studies show that microglia play critical roles in neurodevelopment, but mechanisms driving these roles are poorly understood. We explored purinergic signaling as a potential mediator between microglia and neurons during synaptic plasticity. Purinergic signaling has been implicated in microglial behavior, but studies focused on inflammatory roles. Non-inflamed microglia highly and selectively express the purinergic receptor, P2Y12, which functions in microglial chemotaxis. We posited that purinergic signaling contributes to the microglial motility underlying synapse surveillance and may be critical for microglial roles in synaptic refinement. We used P2Y12 knock-out (KO) mice or the P2Y12 antagonist, clopidogrel in wildtype (WT) mice, to disrupt P2Y12 signaling and examined microglia morphology,

microglia motility and functional synaptic plasticity in the visual cortex. We used immunohistochemistry for the microglia specific ionized calcium-binding adapter (Iba-1) protein to stain microglia in fixed sections and confocal imaging to quantify microglial process complexity. We also used 2-photon microscopy to monitor microglial motility in P2Y12 KO mice by crossing them with CX3CR1-GFP knock-in mice. Finally, we used intrinsic optical signaling to measure ocular dominance plasticity in P2Y12 disrupted mice. Our evidence suggests that P2Y12 disruption prevents ocular dominance shifts indicative of synaptic plasticity. P2Y12 disruption also decreases microglial process complexity, without affecting basal microglial process motility. We are now investigating how P2Y12 disruption prevents ocular dominance plasticity by examining changes in microglial-synapse interactions, synaptic turnover, and microglial-synapse phagocytosis. Our studies will explore new non-pathological roles for microglial purinergic signaling in neurodevelopment.

Title: Motor skill learning induced AMPA receptor synaptic translocation in the fmr1 KO mouse

Authors: A. SURESH, *A. DUNAEVSKY
Developmental Neurosci., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Fragile X syndrome (FXS) is the most common inherited form of intellectual disability. Patients with FXS exhibit a range of neurological deficits including motor skill deficits. Previously, we found that fmr1 KO mice have an impairment in motor skill learning in a forelimb reaching task and reduced learning-induced synaptic plasticity in the forelimb area of the primary motor cortex (M1). Specifically, fmr1 KO mice do not exhibit learning induced increases in dendritic spines as seen in the trained hemisphere of wild type mice and show a delay in synaptic insertion of AMPAR subunit GluA1 in the forelimb region of the primary motor cortex. Here we investigated the spatiotemporal expression of AMPAR in order to understand the relationship between AMPAR insertion and dendritic spine formation and

stability. We performed *in utero* electroporation of SEP-AMPAR subunits and the morphological marker tdTomato to label layer 2/3 neurons in M1 of fmr1 KO mice. We then performed repeated *in vivo* two photon imaging of dendritic spines and AMPAR subunits following motor skill training in adolescent mice. Our preliminary data suggest that as in dendrites of layer 5 neurons, motor learning results in a rapid increase in dendritic spines on layer 2/3 neurons in the trained hemisphere. Moreover, an increase in synaptic GluA2 is observed in wild type mice but not in the fmr1KO mice. These studies will help elucidate the relationship between structural and functional synaptic plasticity with learning.

Abstract: Parkinson's disease (PD) affects seven to ten million people worldwide. Human and animal studies have shown that the parkinsonism results from degeneration of midbrain dopaminergic neurons. The majority of research to date has focused on synaptic adaptations in the striatum, a region that receives the highest density of dopaminergic innervation. Cortical

areas have received very little attention, even though the motor cortex, the command center that governs precise fine motor control, also receives rich projections from midbrain dopamine neurons. While it is known that PD patients' motor learning and motor memory are highly impaired, there remain key gaps in our understanding of the cause of these deficits. In particular, we know very little about how dopamine regulates motor cortex physiology and how dendritic spine dynamics are altered by the loss of its dopaminergic innervation. To investigate the process of dopamine depletion-induced synaptic remodeling in the intact motor cortex, we repeatedly imaged the same apical dendrites of layer V pyramidal neurons. Neurons in the forelimb area of the motor cortex and barrel cortex were identified by the expression of yellow fluorescent protein (Thy1-YFP-H line) and monitored using trans-cranial two-photon laser scanning microscopy. We found dramatic increases in both spine formation and spine elimination in two different PD mouse models (MPTP injection, which lesions dopamine neurons; and Reserpine injection, which depletes dopamine). The spine remodeling is region-specific, as the barrel cortex did not show changes in either spine formation or elimination. This rewiring in the motor cortex can be partially rescued by injection of L-Dopa (a drug commonly used to treat PD patients), suggesting this phenomenon is dopamine-dependent. In addition, spine elimination and formation are selectively regulated by D1 and D2 dopamine receptor signaling, respectively. Dendritic spines are the postsynaptic structure where excitatory synapses are located, and changes in spine morphology and dynamism serve as good indicators of synaptic plasticity. Together, our study reveals unique roles of D1 and D2 dopamine receptor signaling in regulating spine dynamism and functional plasticity, and this abnormal spine turnover in the motor cortex may underlie the learning and motor memory deficits seen in PD.

Title: Deprivation-induced strengthening of pre- and postsynaptic inhibitory transmission in layer 4 of visual cortex during the critical period

Authors: *M. NAHMANI, G. G. TURRIGIANO
Dept. of Biol., Brandeis Univ., WALTHAM, MA

Abstract: Inhibition from fast-spiking (FS) interneurons plays a crucial role in shaping cortical response properties and gating developmental periods of activity dependent plasticity, yet the expression mechanisms underlying FS inhibitory plasticity remain largely unexplored. In layer 4 of visual cortex (V1), monocular deprivation (MD) induces either depression or potentiation of FS to star pyramidal neuron (FS→SP) synapses, depending on the age of onset (Maffei et al., 2004; Maffei et al., 2006). This reversal in the sign (- to +) of plasticity occurs on the cusp of the canonical critical period (CP). To investigate the expression locus behind this switch in sign of inhibitory plasticity, mice underwent MD during the pre-CP (eye-opening to postnatal day (p)17) or CP (p22-p25), and FS→SP synaptic strength within layer 4 was assessed using confocal and immuno-electron microscopy, as well as optogenetic activation of FS cells to probe quantal amplitude at FS→SP synapses. Brief MD prior to p17 or p25 did not alter the density of FS→SP contacts. However at the ultrastructural level, FS→SP synapses in deprived hemispheres during the CP, but not the pre-CP or in GAD_{65}KO mice, had larger synapses and increased docked vesicle density compared to synapses from the non-deprived control hemispheres. Moreover, FS→SP evoked miniature inhibitory postsynaptic currents increased in deprived hemispheres when MD was initiated during the CP, accompanied by an increase in the density of postsynaptic $GABA_A$ receptors at FS→SP synapses. These coordinated changes in FS→SP synaptic strength define an expression pathway modulating excitatory output during CP plasticity in visual cortex. Ongoing experiments aim to compliment these findings by exploring the contribution of FS inhibition to visual responsiveness in freely behaving mice.

Title: Cortical neuronal morphology and alteration of Neurexin distribution by Rho GTPases

Authors: *S. K. VALAPPIL[1], H. L. HYNDS[2]
[2]Biol., [1]Texas Womans Univ., DENTON, TX

Abstract: Rho GTPases are a family of small G-proteins that act as a molecular switches by cycling between guanosine triphosphate (GTP)-bound active forms and guanosine diphosphate (GDP)-bound inactive forms. Rho GTPases transduce intracellular signals and regulate a variety of cellular processes. Rho GTPase signaling is best known for their regulation of actin dynamics and thereby regulate neurite outgrowth and networking. At spines forming active synapse, the actin network provides a pushing force on membrane to form spine head and generates increased contact area. Though the roles of Rho GTPases in cellular cytoskeleton is vastly studied, their role in synaptic organization and plasticity is not as completely explored. The intracellular domains of presynaptic membrane protein Neurexin interacts with PDZ-domains of scaffolding proteins and is paralleled by assembly of actin filaments. Hence we speculate that Rho GTPases have a direct or indirect regulatory effect on neurexin distribution and function. To investigate this, we assessed how altering Rho GTPase activity affects the morphology of neurons from neonatal rat cortices, as well as the localization of Neurexin during synaptogenesis. We employed pharmacological activators and inhibitors of Rho GTPase signaling. Using immunocytochemistry and qualitative analysis, we demonstrated morphological changes and distribution of Neurexin in cortical neurons cultured for 7 days *in vitro*. We found that RhoA activation leads to formation of prominent single neural process with few to no minor processes, whereas selective inhibition of Rho-associated protein kinase leads to the formation of extensive process elaboration and fasciculation. Localization of MAP2 towards the cell body and Tau in distal processes was conspicuous in both treated and untreated cells. Neurexin was distributed evenly in cell bodies and neural processes. This finding is supported by the presence of intercellular connections observed both on cell bodies and dendritic extremities. Exploring the specialized neural structures at synapse and understanding synthesis, transport, assembly and interactions of Neurexin is imperative to address neuropsychological disorders such as autism spectrum disorder (ASD), schizophrenia, epilepsy, intellectual disorders (IDs) and Alzheimer's disease.

Title: Immunohistochemical and morphometric characterization of neuropeptide Y positive neurons in the human neocortex during regional chronic ischemia

Authors: *V. AKULININ[1], P. V. BELICHENKO[2], A. V. MYTSIK[1], A. V. SERGEEV[1], S. S. STEPANOV[1]
[1]Histology, Cell Biol. and Embryology, Omsk State Med. Acad., Omsk, Russian Federation; [2]Dept. of Neurosciences, Sch. of Medicine, Univ. of California, San Diego, La Jolla, CA

Abstract: Neuropeptide Y (NPY) is densely localized in the central nervous system. NPY and its receptors take a part in the modulation of different neuronal functions: learning and memory, neuroprotection, mood regulation, and food intake, and they also have anticonvulsant effect. The aim of this study was to define changes in expression of neuropeptide Y (NPY) in human brain during ischemia. Human neocortex biopsy tissues were obtained from patients during operational removal of the brain tumor performed at the Omsk State Medical Academy with the approval of the Ethical Committee. Specimens from 15 different ages, ranging from 23 to 62-year-old specimens were ischemic group. The brain biopsy of 5 patients undergoing non-tumor surgery served as control samples. Layers II-III of neocortical Brodmann's areas 10, 17, and 21 were investigated using indirect immunohistochemical method with antibodies against neuropeptide Y (NPY; Sigma Chemicals, St. Louis, USA; diluted 1:8000) for recognizing NPY positive neurons. Morphometric analysis of neurons was performed using ImageJ 1.46 program with Mann-Whitney test for statistical evaluation. NPY positive cells were identified as basket cells, Martinotti cells and neuroglioform cells and they formed large fiber networks. In control cases, the numerical density of NPY positive neurons was 5.8 ± 1.2 per 1 mm2, without significant differences between areas 10, 17, 21 and they formed a dense network of processes (the distance between the transverse sections labeled dendrites was 8.6 ± 2.2 microns). In chronic ischemia cases, the area of NPY positive immunofluorescence (labeled cell bodies and their processes) was significantly increased: 1.95 fold in area 10, 2.17 fold in area 21, and 2.15 fold in area 17 compared to controls ($p < 0.001$). The abundance of the NPY+ cells in the ischemic group was slightly reduced; and fiber density with varicosity formation were significantly elevated. In conclusion, these differences were mainly due to increases in the amount of NPY positive dendrites but not neurons, indicating new formation, growth and branching dendrites of NPY positive neurons. The present study demonstrates that the NPY neurons display resistance and even hyperplasia during regional chronic ischemia. Supported by the Start-up grant from UCSD, CA, USA (to P.V.B.)

Title: Chronic *in vivo* imaging of synaptic reorganization in visual cortex after traumatic brain injury

Authors: ***E. WITKOWSKI**, G. DEWALT, A. FOSTER, W. ELDRED, I. DAVISON
Biol., Boston Univ., Boston, MA

Abstract: Traumatic brain injury (TBI) impairs the cognitive, emotional, and physical abilities of millions of Americans every year. Despite dramatic increases in prevalence in recent years, the neurobiological mechanisms underlying TBI remain poorly understood. This is particularly true for mild TBI, where cellular and subcellular damage is difficult to detect by human neuroimaging methods but can still cause pronounced impairment. With high-resolution chronic *in vivo* imaging in a rodent model of TBI, we visualized the extent and time course of fine-scale structural changes in cortical networks following injury. To test how mild TBI affects the stability of neural circuits in mouse visual cortex, we examined structural correlates of excitatory synaptic connectivity before and after mild TBI. Imaging of dendritic spines on layer V pyramidal cells revealed a transient phase of elevated turnover lasting approximately 3 days after injury, consisting of balanced loss and formation of spines. In contrast, dendritic branching and spine density remained stable, indicating that mild TBI induced reorganization of the existing cortical network rather than large-scale changes in dendritic anatomy or number of excitatory synapses. High-resolution chronic imaging approaches promise to help establish how trauma affects the structure and function of neural circuits over different phases of injury and recovery.

Title: Dorsal column lesions in monkeys differentially affect widespread activity and response properties of putative inhibitory and excitatory neurons in area 3b

Authors: *J. L. REED, H.-X. QI, J. H. KAAS
Psychology, Vanderbilt Univ., NASHVILLE, TN

Abstract: In our primate model of spinal cord injury, unilateral lesions of the dorsal column (DC) disrupt sensory input from one hand, impairing sensation and motor control. Over time, primary somatosensory cortex (area 3b) reactivates and hand use improves. We hypothesize that response properties of area 3b neurons are consistent with partial recoveries of hand use, and we suggest that response abnormalities may relate to lesion severity. We evaluated 3b neurons in 10 monkeys (Aotus, Saimiri) with or without DC lesions by implanting a 100-electrode array in the hand representation. In 5 monkeys, unilateral DC lesions were made, and 5-13 weeks later the array was implanted contralateral to lesion. Tactile stimuli indented skin at individual locations on the digits and palm to activate area 3b in anesthetized monkeys. Here we expand our previous reports by assessing widespread spatiotemporal activity in area 3b of fast-spiking units (FSUs) and regular-spiking units (RSUs), corresponding to putative inhibitory and excitatory neurons. In monkeys with and without lesions, some neurons show widespread activation to suprathreshold stimuli, firing in response to discrete stimulation on more than one hand location. Paradoxically, minimal receptive field (mRF) sizes of 3b neurons are restricted, while mRFs after DC lesion tend to be large and disorganized. We examined whether neurons fired at consistent latencies to multiple sites and how neuron type and lesion extent affected these responses. In normal monkeys, 50% of FSUs and 38% of RSUs responded to tactile stimulation. In monkeys with DC lesions, 53% of FSUs and 25% of RSUs recorded were responsive. When lesions were nearly complete (~1% DC sparing), activity of RSUs was more spatially restricted and latencies were longer. After partial lesions (~20-50% sparing), response latencies resembled those of normal RSUs, but activity was less widespread. FSUs generally maintained widespread activation similar to normal after partial lesions, but nearly complete lesions resulted in restricted activity

and longer latencies. Thus, we found that hand use recovered even after loss of DC input from one hand restricted 3b activation and delayed latencies. Spatially restricted FSU activity after an extensive DC lesion may reflect a mechanism that reduces suppression. However, RSU activity was even more spatially restricted; suggesting that restricted activity of FSUs and RSUs is a consequence of limited input. Long latencies are likely indicative of alternative pathways providing tactile input to 3b. Thus, treatments to promote neuron activation and function of secondary pathways may augment other interventions for spinal cord injury.

Title: Amplification of synaptic currents without bistability in motoneurons: A tale of two channels modulated by monoamines

Authors: *P. ROSE[1], R. MARATTA[1], K. FENRICH[2]
[1]Queens Univ., Kingston, ON, Canada; [2]Fac. of Rehabil. Med., Univ. of Alberta, Edmonton, AB, Canada

Abstract: CaV1.3 channels on the dendrites of motoneurons are critical components of the mechanisms responsible for amplification of weak synaptic currents and bistability. It is widely assumed that these two functions are inseparable. However, not all motoneurons exhibit bistability, but all motoneurons require amplification of synaptic currents to generate a high frequency discharge. Our goal was to test the hypothesis that the combination of CaV1.3 and CaV1.3 dependent K+ channels can amplify synaptic currents without causing bistability. To test this hypothesis we constructed anatomically realistic compartmental models equipped with CaV1.3 and CaV1.3 dependent K+ channels. These channels were confined to dendritic zones, approximately 100 um long, 250-450 um from the soma on small motoneurons and 700-900 um

from the soma on large motoneurons). In keeping with experimental observations (Lee and Heckman 1998), the densities of these channels were tuned to match experimentally observed differences in the thresholds for activating and deactivating CaV1.3 channels in small and large motoneurons in response to slow triangular voltage commands delivered to the soma. The densities of the CaV1.3 channels determined activation thresholds. The densities of the CaV1.3 dependent K+ channels controlled deactivation thresholds. Amplification and bistability were measured by recording the current delivered to the soma by a 1 second long activation of uniformly distributed excitatory synapses. Depending on the number of synapses activated, the synaptic current was amplified 2 to 7 fold. At the termination of the synaptic activity, the current declined in a series of staircase-like steps lasting 3-4 seconds before reaching a sustained current of 1.4 to 7.1 nA. Reducing the conductance of CaV1.3 channels by 50% or increasing the conductance of CaV1.3 dependent K+ channels by 60% reduced the duration of the staircase-like steps and abolished the sustained currents. In contrast, synaptic amplification was not lost. In large motoneurons, the duration of the stair-case decline was shorter and the sustained currents were smaller (2.6 to 3.4 nA). Synaptic currents were amplified 3 fold. A 25% reduction in the conductance of CaV1.3 channels or increasing the conductance of CaV1.3 dependent K+ channels by 36% eliminated the sustained currents and substantially reduced the duration of the staircase decline. Once again, synaptic amplification was retained. These results suggest that decreasing the modulation of CaV1.3 and CaV1.3 dependent K+ channels by monoamines provides a means of amplifying synaptic currents without causing bistability.

Title: Effect of cannabidiol treatment associated with CB1 and CB2 receptors antagonists after neonatal rat sciatic nerve axotomy

Authors: *M. PEREZ[1], L. P. CARTAROZZI[1], F. S. GUIMARÃES[2], E. A. DEL BEL[2], A. L. R. OLIVEIRA[1]
[1]Unicamp, Campinas, Brazil; [2]Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: The endocannabinoid system is composed by cannabinoid receptors (CB), endogenous ligands (anandamide and 2-Arachidonoylglycerol) and enzymes that synthesize and degrade such molecules. Endocannabinoids and the respective receptors are found in several tissues, including the nervous system. Ligands to CB1 and CB2 act on demand both in response to physiological stimuli or in pathological conditions and can play neuromodulatory actions. Recent studies showed increased levels of endocannabinoids and also cannabinoid receptors after nervous system lesion, suggesting a role on neuroprotective responses. Several exogenous cannabinoids can interact with the endocannabinoid system, thus acting on the nervous system. Among them, the cannabidiol (CBD) arises as a viable drug to treat nerve injuries due to its antioxidant and neuroprotective properties. Thus, the present study aimed to investigate the neuroprotective potential of CBD following acute neonatal peripheral nerve lesion. For that, we used two days old Wistar rats, which were divided into the following experimental groups: sciatic nerve axotomy (crushing at mid-thigh) and CBD treatment (CBD group), axotomy and vehicle treatment (VE group), axotomy + CBD + AM251 treatment (AM251 group - CB1 inhibitor) and axotomy + CBD + AM630 treatment (AM630 group - CB2 inhibitor). Spinal motoneuron survival was evaluated in Nissl stained sections of the lumbar spinal cord, five days following injury. Such analysis showed that CBD treatment was ~40% more effective when compared to the vehicle group. CB1 and CB2 blockage led to partial increase in neuronal degeneration, even after CBD treatment, indicating that neuroprotection is at some extent triggered by ligand/receptor interaction. Glial reaction was evaluated by immunohistochemistry using antibodies against GFAP (glial fibrillary acidic protein - astrogliosis marker) and IBA-1 (Ionized calcium binding adaptor molecule 1 - microgliosis detection). CBD treatment reduced both astroglial (40%) and microglial (62%) reaction at lamina IX, in the surroundings of lesioned motoneurons. Importantly, CB1 but not CB2 blockage completely reversed the positive effects of CBD. Overall, the present results show that CBD is neuroprotective and reduces glial reaction following neonatal axotomy. Such effects possibly require CB1 receptor and downstream signaling to be effective.

Title: Reduction of survival of motor neuron protein in the enteric nervous system impairs neuromuscular transmission to smooth muscle and gastrointestinal function

Authors: *S. E. GOMBASH, K. C. WILLIAMS, J. A. FITZGERALD, C. C. IYER, V. L. MCGOVERN, I. S. GRANTS, F. L. CHRISTOFI, C. C. COWLEY, A. H. M. BURGHES, K. D. FOUST

Abstract: All cells require a basal level of the ubiquitous survival motor neuron (SMN) protein for embryonic development. However, motor neurons in the spinal cord specifically require increased SMN levels for proper maturation of neuromuscular signaling. Like the central nervous system, the enteric nervous system (ENS) is rich in motor neurons, but the requirement for SMN within the ENS has not been investigated. The ENS is found in the walls of the gastrointestinal (GI) tract and is estimated to have as many neurons as the spinal cord. Among its various functions, the ENS controls peristalsis that allows for the passage of materials through the gut. In the present study we investigated whether basal SMN levels are sufficient for proper ENS physiology and function. To accomplish this, Nestin-cre mice were crossed to tdTomato reporter mice to characterize recombination within the ENS. Reporter gene expression was detected in enteric neurons and glial cells within the myenteric plexus, but was absent in both smooth and skeletal muscle and motor neurons within the CNS. Nestin-cre mice were then crossed to mice with a floxed Smn exon 7 allele on a SMNΔ7 background (SMN2+/+;SMNΔ7+/+;SmnF7/-), thereby reducing Smn in targeted cells. Because CNS motor neurons are not subject to recombination, Nestin-F7 mice are long-lived and ambulatory. Neurotransmission to smooth muscle in the distal colon was examined in Nestin-F7 mice using *ex vivo* organ bath assays. Electrical field stimulation of ENS neurons resulted in opposite responses in control (SMN2+/+; SMNΔ7+/+; SmnF7/+) and experimental colons showing defective neuromuscular transmission. The addition of tetrodotoxin to the bath verified that alterations in muscle response were neuronally driven. To determine whether these changes resulted in functional deficits, Nestin-F7 and control littermates were assayed in tests of gastric emptying, constipation, and colonic motility. Gastric emptying and intestinal transit were significantly slower in experimental mice compared to control littermates. In assays of constipation, Nestin-F7 mice produced significantly less stool with reduced moisture content that corresponded to reduced colonic motility in the bead latency test. Collectively, these data show that basal levels of Smn within the ENS impairs neuromuscular signaling within the GI tract.

Title: Direct cutaneous modulation of motoneuron activity: Evidence for a monosynaptic circuit connecting cutaneous afferents with spinal motoneurons

Authors: *P. M. SONNER, M. A. DALLMAN, D. R. LADLE
Wright State Univ., Dayton, OH

Abstract: Sensory information from mechanoreceptors and nociceptors is processed along interneuron pathways prior to modulating motoneuron (MN) output. Here we report a novel pathway in which a subset of cutaneous Saphenous (Saph) nerve sensory afferents monosynaptically connects with spinal MNs. To assess this circuit, an isolated spinal cord preparation was utilized in C57BL6 mice at birth (P0-P2) and one-week postnatal (P7/P8). The peripheral Saph nerve was stimulated at 0.2Hz and the resultant change in membrane potential was recorded from MN axons exiting from the ventral root of lumbar segment 3. A monosynaptic response was observed in all P7/P8 preparations (n=4), upon Saph nerve stimulation. Interestingly, monosynaptic latency responses in P0-P2 preparations were not observed (n=4). The stimulation strength required to elicit these responses were similar to those required to activate low-threshold proprioceptors, and below that for C-fiber activation. A possible explanation for this phenomenon could be that small numbers of proprioceptive afferents are misrouted in the Saph nerve during development. To test whether the monosynaptic MN connections arising from the Saph nerve were proprioceptive in origin, experiments were conducted in genetically altered mice. We first utilized an Er81 KO mouse, in which proprioceptive afferents fail to project into the ventral horn largely eliminating their monosynaptic connections with MNs (Arber et al., 2000). Interestingly, stimulation of the Saph nerve in Er81 mutants still elicited monosynaptic responses in MNs, similar to that observed in control mice. Secondly, we utilized another mouse model (Parvalbumin-Cre; Munc18-1 flox/flox), in which synaptic transmission of proprioceptive axons are blocked, but axonal projections into the ventral horn remain intact, resulting in responses upon Saph nerve stimulation that were very similar to those observed in Er81 mutants and in control animals.

Lastly, we performed anatomical tracing experiments, in which central axons of afferents projecting in the Saph nerve are retrogradely labeled with fluorescent dextran. We show that a limited number of Saph nerve afferents project into the ventral horn and are in close proximity to MNs. In addition, these axons do not express parvalbumin (a protein found in proprioceptive sensory neurons), again suggesting these afferents are unlikely to be proprioceptive. Taken together these data strongly suggest that the subset of Saph afferents that monosynaptically contact spinal MNs are non-proprioceptive and may represent a novel pathway by which cutaneous sensory information can directly modulate MN firing activity.

Title: Stereological and immunohistochemical analysis of inhibitory and excitatory innervation of the cranial motor nuclei that control extraocular muscles in the mouse

Authors: *N. M. DOIG, V. LUCO, J. CORTÉS, A. OÑATE, P. HENNY
Lab. of Neuroanatomy, Pontificia Univ. Católica De Chile, Santiago, Chile

Abstract: The extraocular muscles are responsible for movements of the eyes and are innervated by motoneurons of the oculomotor (III), trochlear (IV) and abducens (VI) cranial nuclei. Extraocular muscles have distinctive patterns of activity during sleep, relative to other groups of cranial muscles, in that they become increasingly active during the rapid eye movement (REM) stage of sleep. The aim of this study is to examine excitatory and inhibitory innervation of the cranial motor nuclei which control eye movement using immunohistochemical and stereological methodology in wild-type adult mice, as this specific pattern of activity during REM sleep could be related to the ratio of inhibitory to excitatory innervation. In order to achieve this we

examined specific markers for inhibitory presynaptic terminals: the vesicular inhibitory amino acid transporter (VIAAT) and the glycine transporter subtype 2 (GlyT2) as well as excitatory presynaptic terminals using the vesicular glutamate transporter subtypes 1 (VGluT1) and 2 (VGluT2). These markers were revealed for light microscopy using a DAB-Nickel reaction and the sections are then counter-stained using Nissl. Using the optical fractionator method, we can estimate numbers of terminals within the IIIrd, IVth and VIth nuclei. Using this data we can assess the total number of excitatory and inhibitory terminals, as well as their relative ratio of innervation. Preliminary data shows the relative densities of terminals in the abducens (VI) nucleus are mainly excitatory with 76% positive for a glutamatergic marker (VGluT1 or VGluT2; n=2) and 24% positive for a marker of inhibitory terminals (VIAAT; n=3). Current analysis is underway to establish the number and proportion of terminals in the IIIrd and IVth nuclei. We are extending our analyses to examine the innervation of these nuclei by neuromodulators using antibodies for the vesicular monoamine transporter subtype 2 (VMAT2) which labels dopaminergic, serotonergic, noradrenergic, and histaminergic terminals; and also for orexinergic terminals (orexin A). The results from this study will provide detailed information about innervation to the motor nuclei which control the activity of extraocular muscles in wild-type mice. This data will then be able to be compared to similar data from other cranial motor nuclei which show different levels of activity during sleep-wake states. Comparison with non-oculomotor cranial motor groups will also be relevant in relation to neurodegenerative diseases that affect motoneuron survival, such as amyotrophic lateral sclerosis, in which oculomotor neuronal groups have been documented to be spared from early degeneration.

Title: Task-specific activation of extraocular motoneurons in Xenopus laevis

Authors: J. M. SCHULLER[1], A. G. KNORR[2], *S. GLASAUER[2], H. STRAKA[1]
[1]LMU Munich - Biocenter Martinsried, Planegg, Germany; [2]Inst. for Clin. Neurosciences, Ludwig-Maximilian-University, Munich, Germany

Abstract: During vertebrate locomotion, visuo-vestibular reflexes and intrinsic efference copy-driven extraocular motor discharge minimize retinal image slip through compensatory eye movements. The presence of different subsets of extraocular motoneurons with a wide range of morpho-physiological properties is essential to generate spatio-temporally adequate eye movements. The horizontal optokinetic reflex with its alternating slow following and fast resetting phases offers an ideal motor behavior to study the potential recruitment of task-specific neuronal units. Here, we studied the optokinetic reflex, functional organization of extraocular motoneurons and influence of active locomotion during optokinetic stimulation in semi-intact preparations of larval Xenopus laevis with an intact visual system and an isolated brainstem/spinal cord. Eye movements, evoked by velocity step and sinusoidal optokinetic stimulation (0.2-50°/s; 0.032-1 Hz) with a vertically striped drum, were captured with a camera at a rate of 50 Hz and quantified by computerized video analysis. Typical responses of pre-metamorphic Xenopus tadpoles during optokinetic step stimulation consisted of slow phases with a horizontal ocular motor range of ~50° and an average gain of ~0.45 at a constant stimulus velocity of 0.5°/s, interrupted by resetting fast phases with velocities of ~300°/s. Simultaneous motion recordings of one eye and multiple-unit discharge of the lateral or medial rectus nerve on the other side during optokinetic stimulation and spontaneous fictive locomotion allowed evaluating the interaction between intrinsically generated motor commands and optokinetic sensory feedback signals. Single spike analysis and determination of activation thresholds, response properties and discharge regularity confirmed a differential recruitment of individual motoneurons and task-specific contribution during extraocular motor behaviors. Preferential activation of individual motor units was observed for slow and fast phase components during the optokinetic reflex as well as for locomotion-related spino-extraocular coupling. While the latter behavior recruited phasic motor units with large spikes, optokinetic slow phases were mediated by low threshold, persistently discharging units with small spikes. The task-specificity of motor units demonstrated only limited integration of intrinsic locomotor efference copies and image motion-derived visual signals at the level of individual motoneurons and rather suggests that part of the effective motor behavior results from a separate activation of muscle fibers by the respective sets of extraocular motoneurons.

Title: Vestibulo-ocular reflexes are mediated by functionally distinct subgroups of extraocular motoneurons

Authors: H. DIETRICH[1], S. GLASAUER[2], *H. STRAKA[1]
[1]LMU Munich - Biocenter Martinsried, Planegg, Germany; [2]LMU Munich, Dept. Neurology, Klinikum Grosshadern, Munich, Germany

Abstract: Vestibulo-ocular and optokinetic reflexes ensure spatio-temporally precise gaze stabilization during passive or self-generated head and body motion. Effective conjugate eye movements in the horizontal plane are generated by synergistic contractions of the lateral and medial rectus eye muscles, innervated by abducens and oculomotor motoneurons, respectively. Task-specific motoneuronal subtypes integrate visuo-vestibular inputs into reactive motor commands that allow a range of dynamically different eye movements from slow, tonic to fast, twitch-like contractions of functionally co-adapted extraocular muscle fiber types. Here, we studied this neuronal diversity in a morpho-physiological approach including the synaptic pharmacology of abducens motoneurons in Xenopus laevis tadpoles. Experiments were performed on isolated semi-intact preparations, which allow in-vitro manipulations within the intact neuronal vestibulo-ocular circuitry from the sensory periphery to the ocular motor plant. Multiple-unit extracellular recordings of the lateral rectus nerve close to its target muscle insertion site during natural stimulation of the vestibular endorgans and subsequent spike shape analysis confirmed the presence of two major subgroups of abducens motoneurons. During horizontal sinusoidal rotation, one group of motoneurons exhibited responses with amplitudes and phase relations independent of stimulus frequency, thus precisely encoding angular head velocity. A second group of motoneurons displayed responses with magnitudes and dynamics that systematically varied with stimulus velocity and frequency, thereby additionally transmitting information about the peak acceleration of head motion. Common to both subgroups were motor units with a range of activation thresholds for rotational stimuli, generating a continuum of tonic to phasic response patterns, respectively. Pharmacological blockade of excitatory neurotransmission of vestibular neurons onto abducens motoneurons by focal application of NMDA and AMPA-receptor antagonists into the abducens nucleus revealed a differential expression of glutamate receptor subtypes that supports a dual motoneuronal organization. In

addition, blocking glycinergic transmission by focal injections of strychnine suppresses modulated inhibitory inputs from the ipsilateral vestibular nucleus. These findings confirm the notion of separate functional subgroups of extraocular motoneurons that differ from each other in several pharma-physiological properties and act in concert to ensure image stabilization over a large range of motion dynamics.

Title: A method to detect silent carriers of spinal muscular atrophy by analysis of human sperm

Authors: M. C. EVANS, M. C. GALLEN, N. J. ROBICHAUD, D. A. HILL, C. D. BRAASTAD, *J. J. HIGGINS, Jr.
Quest Diagnostics, Worcester, MA

Abstract: Spinal muscular atrophy (SMA) is the second most common fatal autosomal recessive disorder after cystic fibrosis, affecting approximately 1 in 6,000 to 10,000 live births. The disorder is characterized by hypotonia, proximal muscle weakness, and respiratory distress due to degeneration of motor neurons in the spinal cord. SMA is caused by mutations in the survival motor neuron 1 (*SMN1*) gene. A nearly identical homolog of the *SMN1* gene, *SMN2*, lies in an inverted orientation in cis- with *SMN1* on chromosome 5q. The molecular diagnosis of SMA is accomplished through the detection of homozygous deletions of *SMN1*. The presence of *SMN2* and the varying numbers of both *SMN1* and *SMN2* complicate molecular testing, but the sequence differences between the two genes allow them to be distinguished. More than 95% of SMA patients have a homozygous deletion of *SMN1* exon 7. The occurrence of two copies of the *SMN1* gene on one allele and zero copies on the other (2+0 genotype or silent carrier) is recognized as a source of false-negative carrier testing results. This genotype is present in about 4% of the carrier population but varies considerably between different ethnic groups. To identify null alleles for *SMN1, w*e used haploid human sperm cells in an end-point limiting dilution assay. The results show the ability to detect sperm that are null for *SMN1* copies. This study addresses a

key limitation in SMA carrier screening and is a step toward using diploid cells to identify silent carriers of SMA.

Title: Active intrinsic properties differ between murine cranial and spinal motoneurons

Authors: ***M. A. TADROS**[1], A. J. FUGLEVAND[2], A. M. BRICHTA[1], R. J. CALLISTER[1]
[1]Univ. Newcastle, Callaghan, Australia; [2]Dept. of Physiol., Univ. of Arizona, Tucson, AZ

Abstract: Motoneurons differ in the motor behaviours they control and their vulnerability to disease. For example, cranial motoneurons such as hypoglossal motoneurons (HMs) are involved in licking, suckling, swallowing, respiration, and vocalization. In contrast spinal motoneurons (SMs) innervating the limbs are involved in locomotor and postural function, tasks requiring comparatively higher loads and lower speed movements. Correspondingly, the contractile speed of tongue muscle is typically faster than that of limb muscle. Nevertheless, little is known about the relative properties of these two motoneuron pools. In this study, we used whole-cell patch clamp recording to compare the electrophysiological properties of HMs and SMs in age-matched mice. Transverse slices (300 μm thick) were obtained from the brainstem or lumbosacral spinal cord of C57Bl/6 mice (P7-10). Whole-cell recordings were made from visualized motoneurons at 23^{o}C using a KCH_3SO_4-based internal solution. Passive membrane properties were remarkably similar in HMs and SMs (n = 28 and 26, respectively). No differences were observed in input resistance, cell capacitance, and resting membrane potential. In addition, action potential (AP)

properties such as rheobase, voltage threshold, spike amplitude, and afterhyperpolarization did not differ between the two populations. In contrast, AP half-width was smaller in HMs (0.95 ± 0.03 vs. 1.49 ± 0.08 ms) and they discharged at higher frequencies in response to square step (1 s duration, 50 pA increments, 450 pA above rheobase; 31.3 ± 1.3 vs. 24.5 ± 2.5 Hz; n = 27 and 15) and triangular ramp current injection (0.3 nA/s, maximum frequency 42.2 ± 4.0 vs. 26.9 ± 2.4 Hz, n = 17 and 10). Therefore, while HMs and SMs have similar passive properties, their discharge in response to similar levels of depolarizing current differs markedly. This suggests each population possess differing suites of ion channels that allow them to discharge at rates that match the different mechanical properties of the muscle fibers underlying their distinct motor functions.

Title: Abnormal migration and functional architecture in zebrafish facial motor neurons

Authors: *K. L. MCARTHUR, J. R. FETCHO
Neurobio. & Behavior, Cornell Univ., Ithaca, NY

Abstract: Developing neurons often arise in one location in the brain and then migrate to another. Normal migration supports proper circuit formation; thus, abnormal migration can be associated with abnormal neural activity and behavior. However, studies of cellular migratory mechanisms have described genetic mutations that disrupt migration but spare behavior - such that mutant animals with unexpected neuronal positioning survive and behave grossly like their wild type (WT) counterparts. This raises the possibility that the developing brain can, under some circumstances, compensate for unexpected cell locations in order to maintain normal function. In recent work with zebrafish larvae, we have revealed the functional properties of WT

facial branchiomotor neurons (FBMNs), which undergo a dramatic caudal migration in the hindbrain early in development. We now present preliminary evidence that at least some of the FBMN functional architecture is preserved in two lines of mutant zebrafish, where these cells fail to migrate caudally. Both calcium imaging with GCaMP5 and whole-cell recordings indicate that mutant FBMN activity is at least qualitatively similar to WT FBMN activity. Although further studies are needed to rigorously determine if more subtle differences exist, this result is not altogether surprising. FBMNs are critical for feeding and respiration, and mutant zebrafish are still viable - gross disruption of FBMN activity would likely kill the fish. Further, using transgenic expression of the photoconvertible protein Dendra, we see that mutant FBMNs adopt a dorsoventral age topography similar to what we have found in WT fish. Thus, FBMNs can arrange themselves by age regardless of which rhombomere they ultimately occupy. However, dye-filled mutant FBMN dendritic arbors ramify in different rhombomeres - though their position relative to the soma generally matches what we have seen in the WT. Therefore, it seems that mutant FBMNs can join functional circuits in ways that preserve gross functional activity, despite the fact that their dendrites are in the wrong place along the rostrocaudal axis. Perhaps key ascending and descending inputs from respiratory and feeding-related centers are able to find target FBMNs at any position along the rostrocaudal hindbrain axis, as long as age order is maintained. This work builds on current knowledge of the fundamental principles guiding circuit formation and has exciting implications for our understanding of how neuronal populations can evolve to shift their location without completely disrupting behavior.

Title: Copper nanoparticles and or ionic copper (II) causes neurotoxicity and cardiotoxicity in Zebrafish embryos

Authors: *E. CUEVAS[1], W. TRICKLER[2], M. G. PAULE[2], S. ALI[2], J. KANUNGO[2]
[1]Neurochemistry Lab. Div. of Neurotoxicology, NCTR-FDA, Jefferson, AR; [2]Neurotoxicology, NCTR/FDA, Jefferson, AR

Abstract: Copper oxide nanoparticles (Cu-NPs) are frequently used in medical devices, paints, fabrics or as antimicrobials. Their industrial applications may lead to the contamination of aquatic ecosystems. The toxicological and human health risks of NPs in the environment are hard to evaluate due to a lack of knowledge about the mechanisms by which NPs interact with biological systems. In this study, we investigated the toxicity of Cu-NPs (60nm) and ionic copper (II) in wild-type (WT) zebrafish embryos and *hb9-GFP* transgenic zebrafish (each *Danio rerio*, AB-strain) embryos. Here, the effects of bare Cu-NPs were compared to those seen after exposure to the mass equivalent ionic form of copper (II) ($CuCl_2$) at various concentrations (1.25-to-20 ug/ml). Toxicity was evidenced by phenotypic changes in zebrafish embryos including survival, heart rate, motor neuron development and absorptive permeability. Both Cu-NPs and $CuCl_2$ were lethal to zebrafish embryos at 20 μg/ml (within 24-hrs) and 10 μg/ml (within 48-hrs), with $CuCl_2$ being more toxic at equivalent mass concentrations. Similarly, the heart rate was significantly reduced following exposure to either Cu-NPs or $CuCl_2$ in a concentration-time dependent manner. Additionally, the embryo permeability studies showed that exposure to either Cu-NPs or $CuCl_2$ (5 ug/ml) for 24-hrs significantly increased the topical absorption of the fluorescent tracer 6-coumarin (6CM). Furthermore, embryos treated with either Cu-NPs or $CuCl_2$ (2.5 μg/ml for 48-hrs) showed a significant reduction (nearly 2-fold) in spinal motor neurons. These results indicate that both $CuCl_2$ and Cu-NPs can be toxic to zebrafish embryos causing significant neurotoxicity and cardiotoxicity at exposure levels that do not cause lethality.

Title: Myelin-Associated Glycoprotein modulates programmed cell death of motoneurons during early postnatal development via NgR/p75NTR receptor-mediated activation of RhoA signaling pathway

Authors: *A. PALANDRI[1], M. V. ROZES SALVADOR[1], J. WOJNAKI[1], A. L. VIVINETTO[1], R. L. SCHNAAR[2], P. H. H. LOPEZ[1]

Abstract: Myelin-Associated Glycoprotein (MAG) is a minor constituent of the nervous system selectively expressed at the periaxonal layer of myelinated axons. By engaging multiple axonal receptors, including Nogo-receptors (NgRs), MAG exerts a nurture effect on axons it ensheaths. Pharmacological activation of NgRs has a modulatory role on p75NTR-dependent postnatal apoptosis of motoneurons (MNs). However it is not clear whether this observation reflects a physiological role of NgRs in MNs development. NgRs are part of a multimeric receptor complex which includes p75NTR, Lingo-1 and gangliosides. Upon ligand binding, this multimeric complex activates RhoA/ROCK signalling in a p75NTR-dependent manner. The aim of this study was to analyze a possible modulatory role of MAG on MNs apoptosis during postnatal development. A time course study showed that Mag-null mice suffer a loss of MNs during the first postnatal week. Also these mice exhibited increased susceptibility in an animal model of p75NTR-dependent MNs apoptosis induced by nerve-crush injury, which was prevented by treatment with a soluble form of MAG (MAG-Fc). The protective role of MAG was further confirmed in *in vitro* models of p75NTR-dependent MN apoptosis including the MN cell line MN1. Lentiviral expression of shRNA sequences targeting NgRs on these cells abolished protection by MAG-Fc. Analysis of RhoA activity using a FRET-based RhoA biosensor showed that MAG-Fc activates RhoA. Pharmacological inhibition of p75NTR/RhoA/ROCK pathway or overexpression of a p75NTR mutant lacking binding to RhoA completely blocked MAG-Fc protection against apoptosis. The role of RhoA/ROCK signaling was further confirmed in the nerve-crush model, where pre-treatment with Y27632 (ROCK inhibitor) blocked pro-survival effect of MAG-Fc. Overall these findings identify a new protective role of MAG as a modulator of apoptosis of MNs during postnatal development by a mechanism involving p75NTR/RhoA/ROCK signaling pathway. In addition our results highlight the relevance of the nurture/protective effect of myelin on neurons.

Title: Developmental changes in dendritic morphology and distribution of excitatory and inhibitory synaptic inputs of mouse hypoglossal motor neurons

Authors: *M. C. BELLINGHAM, R. KANJHAN, M. J. FOGARTY, P. G. NOAKES
Univ. of Queensland, Brisbane, Australia

Abstract: Hypoglossal motor neurons (XII MNs) play a vital role in suckling, eating, vocalization and breathing. XII MNs (n=103) in brainstem slices from C57Bl6 mice (n=36) aged embryonic day 17 (E17) to postnatal day 28 (P28) were filled with Neurobiotin, labeled with Cy3-avidin, and then immunohistochemically labeled with antibodies against pre- and post-synaptic marker proteins at glutamatergic (VGLUT2 and PSD95) and GABAergic (VGAT and GABAα1) neurochemical synapses. The morphology of single XII MNs was digitally imaged and synaptic marker immunofluorescence was processed to visualize postsynaptic puncta within the XII MN, and presynaptic puncta within 1 μm of these postsynaptic puncta. The dendrites of XII MNs from areas thought to innervate different tongue muscles showed similar morphology in most, but not all, features. Morphological properties of XII MNs were established prior to birth, not differing between E17-18 and P0-1. MN somatic volume gradually increased for the first 2 weeks post-birth. The complexity of dendritic branching and dendrite length of XII MNs increased throughout development. MNs in the ventromedial XII motor nucleus, likely to innervate the genioglossus, frequently (42%) had dendrites crossing to the contralateral side at all ages, but their number declined with postnatal development. Unexpectedly, dendritic spines were found in all XII MNs at all ages, and were primarily localized to XII MN somata and primary dendrites at E18-P4, increased in distal dendrites by P5-P8, and were later predominantly found in distal dendrites. Dye-coupling between XII MNs was common from E18 to P7, but declined strongly with maturation after P7. Axon collaterals were found in 20% (6 of 28) of XII MNs with filled axons; collaterals terminated widely outside and, in one case, within the XII motor nucleus. Glutamatergic neurochemical synapses increased in density in distal dendrites with age, while GABAergic neurochemical synapses were common on soma and proximal dendrites at all ages. These results reveal new morphological features of mouse XII MNs, and suggest that dendritic projection patterns, spine density and distribution, dye-coupling patterns, and excitatory and inhibitory synaptic inputs show specific developmental changes in mice. Funded by Australian NHMRC grant APP1065884.

Abstract: Few attempts are in the literature to control a hand prosthesis by means of electroneurographic signals (ENG). However, currently there are still no reliable ENG-driven prosthesis. For this reason, it is important to access the peripheral nerves of humans without surgery in order to investigate the ability to decode features of neural control of the hand motion. Microneurography (MNG) is an established minimally invasive technique for the study of human peripheral nervous system (PNS). However the MNG studies are mainly focused on the afferent PNS, while investigations on the efferent side are lacking. MNG studies on the efferent PNS could potentially allow to identify the best techniques for processing and decoding the ENG signals. We conducted MNG sessions on two healthy volunteers and acquired efferent signals from their median nerve along with the electrical activity of the hand muscles (EMG) innervated by it. In particular, in order to seek for efferent signals, a neurologist placed the electrode in the fascicles that presented ENG correlated with the hand EMGs but not with muscles stretch or skin touch. This expert overview was necessary to minimize and eventually avoid the acquisition of tactile or proprioceptive signals. During the trials the subjects were asked to execute several grasps/movement with hand and wrist, at different forces and velocities while MNG was acquired. The recorded signal was wavelet denoised to find the occurrences of the spikes, which were subsequently projected in the principal component space and clustered with a superparamagnetic classifier. As a result of the sorting, we found a population of 10 neurons

with a firing rate in the range 0-10 Hz. We discovered that from the ENG signal it is possible to detect the type of grasp/movement performed by the subjects (e.g., tridigital, cylindric grasp or rest): indeed, different neuron groups show distinct firing activity during particular grasps. We found, also, that the neurons firing rate have a strong relation with the force exerted during the grasps. This relation has been modeled mathematically. Finally, we observed that when identical tasks are executed at increasing velocities, the average (positive) derivative of the neurons firing rate has a significant increase. These results represent an important neurophysiological insight into the way the PNS decodes the control of different movements, their velocity and force, supporting the idea that MNG could represent a method to deeply investigate the way the motoneurons control the volitional limbs motion.

Title: Stereological estimation of the number of cells and VGluT1, VGluT2 and VIAAT immuno-positive varicosities in the trigeminal, facial and ambiguus motor nuclei of the mouse brain

Authors: *P. HENNY, M. FAUNES, S. FERNANDEZ, A. ONATE
Anatomia Normal, Pontificia Univ. Catolica de Chile, Santiago, Chile

Abstract: Mammalian branchiomeric motor nuclei are involved in vital non-locomotive behaviours such as suckling, mastication, swallowing, whisking, facial expression and the production of vocalizations. Trigeminal (Vm), facial (VIIm) and ambiguus (Amb) brainstem motor neurons innervate the jaw, facial, and pharynx/larynx/oesophagus muscles, respectively. The activity displayed by these neurons is controlled by primary excitatory afferents and various second order sensory brainstem nuclei, as well as premotor neurons from the medullary, pontine

and midbrain reticular formation, most of which are glutamatergic GABAergic or glicinergic. In order to clarify the influence that these neurotransmitters have on controlling the activity of neurons of Vm, VIIm and Amb we estimated the number of varicosities immunopositive for the vesicular glutamate transporter subtypes 1 (VGluT1) and 2 (VGluT2) and for the vesicular transporter for GABA and glycine (vesicular inhibitory amino acid transporter, VIAAT, also known as VGAT), using an unbiased stereological technique, the optical fractionator. To further examine differences in density, we also estimated the volume and cell number for these nuclei and their subdivisions. According to our results, Vm, VIIm and Amb contain ~1,200, ~3,400 and ~800 cells, respectively. Cells in Amb are much more densely packed than in Vm and in VIIm. These nuclei exhibit different patterns of glutamatergic and GABA/glycinergic innervation. Vm receives the highest proportion of VGluT1+ varicosities among the other cranial nuclei, most likely originating from trigeminal mecencephalic nucleus afferents carrying propioceptive activity from jaw closing muscles, associated with the role of Vm in mastication. VIIm shows a surprisingly higher density by VGluT2+ and VIAAT+ varicosities than Vm and Amb. This high degree of innervation likely reflects the numerous and various inputs needed for the VIIm to take part in the wide range of complex behaviours in which it is involved. The high cell density in the Amb, along with a relatively low density of terminals may reflect its more crucial involvement in stereotyped and reflexive type of movements.

Title: Role of subthreshold Ca-dependent potassium currents in motoneuron firing properties

Authors: *R. H. LEE[1,2], C. S. MITCHELL[1]
[1]Dept Biomed Engin., Georgia Tech., ATLANTA, GA; [2]Emory Univ., Atlanta, GA

Abstract: While there is extensive observation and theory regarding the role of Ca-dependent potassium (i.e. SK channel) currents during motoneuron firing, little has been done on the sub-threshold aspect of this current. We have recently hypothesized that this current plays a small but critical role in regulating firing rate stability and input-firing rate (F-I) gain by interacting directly with spike initiating persistent sodium currents. In the work presented here, we examine this hypothesis both experimentally and theoretically. Experimentally, we observe subthreshold outward currents consistent with SK activation and that these currents vary in a manner consistent with decreasing the F-I gain as predicted. On the theoretical side, we demonstrate how this current stabilizes F-I gain to prevent excitotoxic excursions in firing rate as the motoneuron and its innervated muscle fibers fatigue.

Title: Spinal nerve root and rootlet stimulation

Authors: *J. A. NORTON
Surgery, Univ. Of Saskatchewan, SASKATOON, SK, Canada

Abstract: The spinal nerve roots remain functional after a spinal cord injury, and respond to electrical stimulation as well as conducting reflexes. In a previous study we implanted electrodes on the anterior nerve roots between L2 and S2 in individuals with chronic, complete spinal cord injuries. The large number of muscles innervated from each nerve root, often with non-synergistic actions meant that we were unable to generate functional standing or stepping, although good exercise through cycling was achieved. In this study we investigated the innervation pattern of nerve rootlets in a rodent model. The rootlets are the bundles of fibres that exit the spinal cord and coalesce to form the nerve roots. Electrical stimulation, under inhalational anesthesia was performed with multi-channel EMG recordings in the hind limbs.

Using a constant current stimulator (and 200μs pulse widths) we evaluated the thresholds for eliciting the first and second muscle responses. We also looked at whether these muscles were synergistic, and where they were recorded the threshold for non-synergistic muscles. Our previous studies looked at contralateral thresholds and defined these as crosstalk and identified k as the ratio between the 2 thresholds. We use the same parameter for both contralateral thresholds and ipsilateral ratios between 2 muscle responses. Universally we found across all rootlets (221) that there was a k value than we saw on the roots (62) for both ipislateral thresholds, non-synergistic thresholds and contralateral thresholds. Electrical stimulation of nerve rootlets appears to be more selective, and offer more degrees of control than nerve root stimulation. This offers the potential for this type of stimulation to be a part of future multi-modal neural prosthesis.

Title: Estimating the time course of excitatory postsynaptic potential in human motoneuron

Authors: *X. HU[1,2], N. L. SURESH[2], B. JEON[2], W. Z. RYMER[2]
[1]Sensory Motor Performance Program, [2]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: The ability to estimate the time course of excitatory postsynaptic potential (EPSP) permits a systematic characterization of human motoneuron properties. The rising edge of the EPSP is typically estimated from the discharge probability of motoneurons. However, the estimation of the falling phase of the EPSP is insecure because of the absence of discharges due to afterhyperpolarization. In this study, we proposed a more rigorous approach estimating the falling edge of the EPSP using sub-threshold paired electrical stimulations. Specifically, we applied a conditioning electrical stimulation of the median nerve innervating the flexor carpi radialis muscle. The conditioning stimuli were set at a sub-threshold level (i.e., no H-reflex was recorded) to avoid afterhyperpolarization. Test stimuli with the same amplitude were applied with a random latency ranging from 4 to 60 ms with respect to the conditioning stimuli. The

probability of triggering H-reflexes from the test stimuli reflects the time course of the EPSP from the conditioning stimuli. The impulse function was then used to quantify the falling phase of the EPSP. Using this approach, we were able to capture the time course of EPSP in motoneurons non-invasively, which can be used as a potential tool to evaluate the properties of human motoneurons in healthy and disease states.

Title: Synaptic plasticity of two genetically distinct populations of GPe neurons after dopamine depletion

Authors: *K. J. MASTRO[1,2], H. A. HOLT[3], A. H. GITTIS[3,2]
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [3]Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: The basal ganglia (BG) are set of subcortical structures critical for movement and cognition. The external segment of the globus pallidus (GPe) is a central nucleus in the BG and contains a heterogeneous population of neurons. Previously, we identified two genetically distinct populations that express Parvalbumin (PV) or Lim homeobox 6 (Lhx6) protein in healthy transgenic mice. The populations differ in their topographic organization, intrinsic physiology and axonal projections. These results provide tools to study cell-type specific roles of the GPe in BG function during health and disease. Here, we utilized transgenic mouse lines to assess changes in axonal projections and synaptic physiology under control (saline) and dopamine depleted (6-hydroxydopamine) conditions. First, we identified anatomical targets and projections densities of each GPe cell-type by expressing EYFP under viral transfection in Lhx6-cre or PV-cre mice treated with saline or 6-OHDA. Under conditions of low dopamine, downstream BG targets were differentially altered in Lhx6 and PV populations. Specifically, there was a significant decrease in projection densities of the PV-GPe population to the subthalamic nucleus (STN) and parafascicular nucleus but no change in Lhx6-GPe projections to these areas. To

identify alterations in synaptic physiology, we recorded mini inhibitory spontaneous currents (mIPSCs) in acute brain slices from Lhx6 or PV reporter mice. Under control conditions, mIPSC frequency was greater onto Lhx6-GPe than PV-GPe neurons. After dopamine depletion, mIPSC frequency decreased onto Lhx6-GPe neurons and increased onto PV-GPe neurons. To investigate excitatory synaptic inputs, we focused on the major source of excitation from the STN which has been heavily implicated in disease. Here, we recorded the evoked synaptic response of the STN inputs onto the two GPe populations to measure the amplitude and paired pulse ratio. The amount of facilitation in the two populations was altered in the disease condition. Specifically, Lhx6-GPe neurons became more depressive in conditions of low dopamine. The anatomic and synaptic changes that occur after dopamine depletion suggests a reorganization of the circuit that may contribute to the complex symptomology associated with basal ganglia dysfunction.

Title: Differential gabaergic contribution during corticostriatal activation

Authors: *A. B. GARCÍA[1], R. HENÁNDEZ-MARTÍNEZ[1], J. E. PÉREZ-ORTEGA[1], V. G. LÓPEZ-HUERTA[2], J. BARGAS[1], E. GALARRAGA[1]
[1]Inst. De Fisiología Celular UNAM, México, Mexico; [2]Okinawa Inst. of science and Technol., Okinawa Japan, Japan

Abstract: Feed-back inhibition or that arising among striatal projection neurons (SPNs) axon collaterals has been found to be profoundly disturbed during dopamine (DA) depletion in a rodent model of Parkinsonism (Lopez-Huerta et al., 2013). We intend to initiate a similar study with feed-forward inhibition and compare the two. We recorded SPNs in an *in vitro* corticostriatal slice preparation while sensorimotor cortex was stimulated with a concentric

bipolar electrode (50 μm in diameter). Orthodromic corticostriatal synaptic responses were evoked after a train of four pulses of 0.1 ms duration and of increasing intensity. We performed both electrophysiological (whole cell recordings) and calcium imaging recordings (fluo-8) to follow the activity of one to dozens of cells simultaneously with single cell resolution. Corticostriatal axons make convergent mono- and polysynaptic contacts with both SPNs and interneurons (INs). The GABAA receptor antagonist, bicuculline (10 μM) increased orthodromic response in direct SPNs (dSPNs) and decreased the same response in indirect SPNs (iSPNs) along a whole series of stimulus intensities. The reason for this discrepancy is explained in an accompanying poster. Calcium imaging allowed the acquisition of neuronal recruitment curves during increasing stimulus intensities before and after bicuculline application. Blockade of GABAA receptors tripled the number of activated neurons for the same stimulus indicating that cortical transmission reaches SPNs in parallel to interneurons so that SPNs integrate a convergence of cortical excitation and INs inhibition thus allowing quantify the amount of feed-forward inhibition as compared to feed-back inhibition. The goal is to compare these two classes of inhibition in control and DA depleted circuits since it is known that feed-back inhibition is lost during dopamine deprivation while feed-forward inhibition is enhanced. The question is: to what extent a disturbance in the circuit due to DA depletion arises from these unbalanced inhibitory entries?

Title: Striatal microcircuit plasticity

Authors: *E. LARA-GONZALEZ, M. DUHNE, J. BARGAS
Inst. de Fisiología Celular, Univ. Nacional Autónoma de México, México, D.F, Mexico

Abstract: Learning and memory theories propose: 1) that different types of long term synaptic plasticity such as LTP and LTD are capable to shape the synaptic weights of neuronal microcircuits, and 2) That these changes in synaptic weights induce observable changes in functional connectivity and therefore in circuit trajectories for the preferential flow of activity. In addition, for this to happen, neuronal elements conforming the ensembles or neuron pools conforming the network have to recycle. In order to observe whether those phenomena can be revealed in the striatal microcircuit we used dynamic calcium imaging techniques to record the activity of dozens of neurons simultaneously, with single cell resolution, while applying plasticity protocols. Striatal microcircuits consist in the presence of spontaneous peaks of neuronal co-activation (network states) which exhibit recurrence, alternation, and reverberant behavior (Carrillo-Reid et al. 2008). After a plasticity protocol (given in the cortex), we observed that control network states changed their composition, functional connectivity and number of neuronal elements. Previously silent neurons became active, previously active neurons became silent and neurons from one network state migrated to other network state giving as a result a reconfiguration of the microcircuit. We infer that these are the circuit level analogues of the change in synaptic weights and correspond to the circuit correlates of a forming memory trace. Clearly, training stimulus generates a new microcircuit using previous and new neurons and connections while discarding others, suggesting that on coming memory traces are a combination of new connections with previously existing ones.

Title: Network theory applied to living neural circuits distinguish between normal and pathological conditions

Authors: *J. E. PÉREZ-ORTEGA, M. DUHNE, E. LARA, V. PLATA, D. GASCA, A. HERNÁNDEZ-CRUZ, E. GALARRAGA, J. BARGAS
Neurociencias, Inst. De Fisiología Celular - Univ. Nacional Autónoma De México, México, Mexico

Abstract: By using whole-cell recordings, dynamic calcium imaging to visualize the activity of dozens of neurons simultaneously with single cell resolution, and network theory algorithms, the functional configuration of the striatal microcircuit was revealed. The network was visualized as a graph in which the nodes are individual neurons and correlated firing between them represents the links. Differences in activity were used to distinguish hierarchical architectures. It is shown that network topology satisfies a "small world" configuration (Watts and Strogatz, 1998) in that the circuit is highly clustered —it has small communities—, like a regular lattice, and still have a small characteristic path length —or high efficiency— as a random graph. Degree distribution (links per node) could be fitted by a "power law" denoting the hierarchical configuration, where "hub-nodes" improve efficiency by interconnecting different communities conformed by neuron sets. Whole-cell recordings disclosed interneurons as "hub-nodes". This topology depended on corticostriatal feed-forward activation of "hub-nodes" because the decorticated striatal microcircuit failed to keep its hierarchical structure, decreased its resilience, and increased its characteristic path length, diminishing its efficiency. Interestingly, a similar change in circuit topology was found when the striatal network was deprived of dopamine using the 6-OHDA rodent model of Parkinson´s disease. In addition, inverse functional configurations were found in a rodent model of L-DOPA induced dyskinesia. Nevertheless, network measurements suggested that both the Parkinsonian and the dyskinetic microcircuits significantly decreased their efficiency and the slope parameter of their degree distributions. In conclusion, change in hierarchical architecture that causes failures in "hub-nodes" connectivity is one main characteristic of pathological circuits.

Title: Motor deficits induced by a selective loss of dopamine D2 receptors in striatal indirect pathway neurons

Authors: *J. C. LEMOS[1], A. R. KAPLAN[1], D. M. FRIEND[2], J. H. SHIN[1], M. RUBINSTEIN[3], A. V. KRAVITZ[2], V. A. ALVAREZ[1]
[1]Lab. for Integrative Neurosci., NIAAA/NIH, Rockville, MD; [2]Diabetes, Endocrinology, and Obesity Br., NIDDK/NIH, Bethesda, MD; [3]Consejo Nacional de Investigaciones Científicas y Técnicas, Inst. de Investigaciones en Ingeniería Genética y Biología Mol., Buenos Aires, Argentina

Abstract: The direct and indirect pathways are the two main outputs from the striatum that control motor output in complementary and sometimes opposite ways. GABAergic medium spiny neurons that express D1 receptors form the direct pathway (dMSNs) and those expressing D2 receptors (D2Rs) form the indirect pathway (iMSNs). D2Rs on iMSNs may have a critical role in regulating basal striatal circuit function and motor behavior, yet testing these hypotheses have been difficult using conventional pharmacological techniques because D2Rs are present on several different cell types in the striatum. We generated a cell-specific D2R knockout mice that lacks D2R selectively in iMSNs, referred to here as iMSN-D2 KO mice (Drd2loxP/loxP;A2a-cre+/-). Characterization of the cre expression pattern in these mice shows 80% colocalization with a specific marker for iMSNs (met-enkephalin). iMSN-D2 KO mice display a significant suppression in locomotor activity in the homecage as well in an open field. Moreover, iMSN-D2 KOs showed impaired performance on a motor skill task as assayed by the rotarod test. However, this motor impairment was not apparent in animals place in a forced swim test suggesting that these mice are capable of movement in certain contexts. Surprisingly, despite this reduced locomotor activity, they concurrently show enhanced responsivity to novelty. These behavioral phenotypes were not due to decreased evoked dopamine release in the striatum. The observed motor deficits were rescued by selective activation of Gi coupled DREADD receptor (hM4Di) expressed in iMSNs demonstrating that activation of the Gi signaling pathway in iSPNs in critical for facilitating sustained locomotion. *In vivo* recordings made in the dorsal striatum of awake behaving iMSN-D2 KO mice revealed a decrease in firing rate of MSNs compared to controls. In an *ex vivo* slice preparation we observed increased frequency and amplitude of GABA-A mediated mIPSC in both the dorsal and ventral striatum MSNs. There are several sources of GABAergic innervation onto MSNs, one of which is GABAergic axon collaterals emanating from D2-containing iMSNs that synapse onto to neighboring dMSNs and iMSNs. Optogenetic activation of these collateral inputs is sufficient to decrease the excitability of neighboring dMSN. D2-like agonist inhibited the collateral inputs via activation of presynaptic

D2R in iMSNs of WT mice, but not iMSN-D2 Kos mice. Thus, loss of D2Rs from iMSNs abolish the inhibition of GABA release from these collateral inputs and contributes to the increase GABA tone and the reduction in locomotor activity observed in iMSN-D2 KO mice.

Title: Presynaptic active zone proteins RIM1αβ are required for normal corticostriatal transmission and striatal-based behaviors

Authors: *D. A. KUPFERSCHMIDT, D. M. LOVINGER
Lab. for Integrative Neurosci., Natl. Inst. of Alcohol Abuse and Alcoholism, Rockville, MD

Abstract: The presynaptic scaffolding proteins RIM1αβ (RIM1) coordinate key active zone processes involved in fast neurotransmitter release and mediate various forms of presynaptic plasticity. Genetic deletion of RIM1 results in several behavioral abnormalities and learning deficits. Given the near ubiquitous neuronal expression of RIM1, the specific cell types and circuits contributing to the altered transmission and behavior seen following RIM1 deletion are unknown. Using Cre recombinase-conditional RIM1 knockout mice crossed with Emx1-Cre mice that express Cre in the vast majority of excitatory neurons in neocortex and hippocampus (Emx1:RIM1 KO), we find that loss of RIM1 in these excitatory neurons, including corticostriatal projection neurons, alters corticostriatal transmission and striatal-based behaviors. Whole-cell recordings of excitatory transmission in medium spiny neurons of the dorsolateral striatum reveal that Emx1:RIM1 KO mice show enhanced paired-pulse facilitation and reduced synaptic depression during 10-Hz trains, suggestive of impaired release probability at these synapses. Phenocopying global RIM1α KO mice, Emx1:RIM1 KO mice show elevated novelty-induced locomotion but normal motor learning on the accelerating rotarod. In contrast to global RIM1α knockout mice, Emx1:RIM1 KO mice show normal prepulse inhibition of acoustic startle. Preliminary results suggest that Emx1:RIM1 KO mice may also show enhanced

responding for food on random interval and progressive ratio schedules. Our findings implicate cortical pyramidal cells as important mediators of select behavioral impairments seen in global RIM1α KO mice, and reveal novel roles for RIM1-dependent processes in corticostriatal transmission and striatal-based behaviors.

Title: Striatal indirect pathway activity is reduced in a mouse model of dyskinesia

Authors: *A. B. NELSON[1,2], D. NATHANIEL[1], A. KREITZER[1]
[1]Neurol., Gladstone Inst. of Neurolog. Dis., San Francisco, CA; [2]Neurol., UC San Francisco, San Francisco, CA

Abstract: Dystonia is characterized by abnormal activation of normally opposing muscle groups. In most cases here is no neuropathological correlate, suggesting that the symptoms may be caused by abnormal circuit function, rather than frank cell loss. Some models of basal ganglia function suggest dystonia may be associated with aberrant activity in the input nucleus of the basal ganglia, the striatum. One hypothesis is that an imbalance in the striatal direct- and indirect-pathways triggers dystonia. To investigate the circuit basis of dystonia, we have employed a combination of electrophysiology and optogenetics to probe the activity of the striatum in a mouse model of dystonia. Paroxysmal nonkinesigenic dyskinesia (PNKD) transgenic mice carry the human gene mutation associated with human PNKD, and recapitulate the human phenotype, which consists of attacks of dyskinesias, including dystonia, triggered by caffeine, alcohol, or stress. Using optogenetic labeling of striatal medium spiny neurons (MSNs) forming the direct pathway (dMSNs) and indirect pathway (iMSNs) during *in vivo* single-unit recordings in freely moving mice, we have found that dyskinetic attacks are associated with profound decreases in iMSN activity, with more modest changes in direc pathway activity. Dyskinesia can be recapitulated in wild-type mice by optogenetically boosting synchronous activity in dMSNs, suggesting that an imbalance in the activity of the two pathways is sufficient

to cause dyskinesia. In addition, we find that PNKD mice show evidence of aberrant endocannabinoid-dependent long-term depression in the indirect pathway, which may be a cellular substrate for the firing changes seen *in vivo*. In support of these synaptic changes being relevant for the generation of involuntary movements, we find that blocking endocannabinoid receptors *in vivo* can prevent dyskinetic attacks. These findings suggest that an imbalance in striatal direct and indirect pathways is both necessary and sufficient to produce dyskinesias in mice.

Title: Activity of basal ganglia output neurons in Parkinsonian mice

Authors: *C. J. LOBB, D. JAEGER
Biol., Emory Univ., Atlanta, GA

Abstract: Changes in the firing rate and pattern of basal ganglia output neurons are hypothesized to underlie motor deficits in Parkinson's disease. To test this hypothesis, we performed behavioral and electrophysiological experiments on two groups of mice: saline-treated (control) and unilaterally treated 6-OHDA (Parkinsonian) mice. Both injections were done in the medial forebrain bundle. Injection of 6-OHDA in mice caused a profound depletion of striatal dopamine along with a loss of nigrostriatal dopaminergic neurons. 6-OHDA-treated mice had robust behavioral deficits showing reduced locomotion and increased rotations in the cylinder and arena tests. In one set of electrophysiological experiments, we acutely recorded the activity of substantia nigra pars reticulata (SNpr), the major output nucleus of the basal ganglia, from the above control and Parkinsonian mice under urethane anesthesia. SNpr neurons recorded from anesthetized 6-OHDA-treated mice displayed a strong ~1 Hz oscillatory firing pattern in contrast to control mice which fired spikes in a regular firing pattern. The mean firing rate was also

significantly reduced in 6-OHDA-treated mice (control inter-spike interval (ISI): 41±6 ms, n = 3; 6-OHDA ISI: 288±56 ms, n = 15). Analysis of spiking of SNpr neurons from 6-OHDA-treated mice with local field potentials recorded in cortex revealed that SNpr neurons fired in phase with cortical slow-wave activity. Experiments were also performed in chronic experiments in the awake state. To do this, a headplate was attached to the skull with dental acrylic and a craniotomy made leaving the dura intact. Head-fixed mice were trained on a simple behavioral paradigm (a 10% sucrose reward was given at a fixed interval of 60 s with each reward preceded by a cue light). SNpr recordings were made from these awake, head-fixed mice during the holding period between rewards. Results from these experiments are currently under investigation and will be included in the final poster.

Title: Dopamine reinforcement signals modify the direction of spike timing dependent synaptic plasticity in the striatum

Authors: *S. D. FISHER[1], Y. F. ZHANG[1], M. J. BLACK[1], W. C. ABRAHAM[2], J. N. J. REYNOLDS[1]
[1]Anat., [2]Psychology, Univ. of Otago, Dunedin, New Zealand

Abstract: Plasticity of cortical synapses onto spiny projection neurons in the striatum is thought to critically underlie the formation of sensorimotor associations between actions and outcomes. Previously we have shown that potentiation of cortical motor signals is most effective when they are followed by a temporal conjunction of depolarization and dopamine. A potential source of this conjunction is the superior colliculus (SC), due to its pathways to the striatum via thalamic nuclei and substantia nigra pars compacta (SNc). Moreover, these pathways can be engaged by light stimuli that have been potentiated in the SC through pairings with a primary reinforcer. In recent years the precise timing between pre and postsynaptic activity, termed spike timing-dependent plasticity (STDP), has been proposed as a generic mechanism to modify synaptic

weights. However, during reinforcement learning, STDP is unlikely to be the sole determinant of the direction of plasticity. Reinforcement of an action can occur seconds later, much longer than the millisecond timing relevant to STDP. We therefore hypothesized that, *in vivo*, corticostriatal plasticity is determined not only by STDP but also by behaviorally relevant reinforcement signals. To investigate this hypothesis, we made intracellular recordings from spiny projection neurons in urethane-anesthetized rats. In STDP experiments, presynaptic cortical activity both preceded ('pre-post') and followed ('post-pre') postsynaptic spiny neuron activity by 5-10 ms, during 60 pairings at 0.1 Hz. The STDP condition was paired with a sensory input (light flash) one second later, and a dopamine signal (SNc electrical stimulation) a second after that, to secondarily reinforce the light flash. Under these conditions, pre-post STDP pairings potentiated cortically-induced post-synaptic potentials (+13% EPSP slope at 20 min, $p < 0.05$) whereas post-pre STDP pairings resulted in robust depression (-28% EPSP slope at 20 min, $p < 0.05$). This is in sharp contrast with the findings from *in vitro* experiments where post-pre potentiation is often found. Furthermore, pre-post STDP without sensory and dopamine signals resulted in depression (-7% EPSP slope at 20 min, $p < 0.05$), suggesting that the presence of salient sensory reinforcement signals modifies the direction of STDP. The finding of pre-post potentiation in the striatum aligns with traditional Hebbian views of plasticity, and emphasizes the need to investigate this phenomenon *in vivo* where neuromodulator levels are physiological. These results demonstrate that the synaptic weighting of cortical inputs to spiny neurons can be enhanced through pairing with a salient sensory stimulus.

Title: A putative vglut1-positive cortico-pallidal glutamatergic projection: Differential organization between the internal and external globus pallidus

Authors: *Y. SMITH, A. MATHAI, J.-F. PARE, R. C. MOOT
Yerkes Res. Ctr., Udall Ctr. Excel. For Parkinson's Dis. and Dept. of Neurol., Atlanta, GA

Abstract: It has long been known that both the internal and external pallidal segments (ie GPi and GPe) receive massive glutamatergic innervation from vesicular glutamate transporter 2 (vGluT2)-positive neurons in the subthalamic nucleus (STN). In this study, we present further evidence for the existence of a vesicular glutamate transporter 1 (vGluT1)-positive input to the monkey and human globus pallidus. Because the main source of vGluT1 terminals in the forebrain is the cerebral cortex, our data suggest the existence of a putative “cortico-pallidal” glutamatergic system in primates. Although both GPe and GPi contain vGluT1-positive terminals, their overall pattern of distribution is strikingly different between the two pallidal segments. While they are evenly distributed throughout the whole extent of GPe, they are confined to the peripallidal and medialmost “limbic” regions of GPi, a pattern of distribution similar to that of pallidohabenular neurons in monkeys. In contrast, the core of GPi is almost entirely devoid of vGluT1 terminals in normal monkeys and humans. At the electron microscopic level, vGluT1-positive terminals in both GPe and GPi vary in size (~0.5-1.5 μm in diameter), are densely packed with round synaptic vesicles, contain occasional mitochondria and form asymmetric synapses. However, their pattern of synaptic connectivity dramatically differs between the two pallidal segtments. While almost 90% vGluT1-positive terminals in GPi target dendritic shafts of various sizes, vGluT1 terminals form synapses almost exclusively with “spine-like appendages” or small-diameter dendrites in GPe. In comparison, vGluT2-positive terminals display a very similar pattern of synaptic connectivity between GPe and GPi, i.e. in contact with dendritic shafts of various sizes in both nuclei. In conclusion, this study suggests the existence of a direct vGluT1-containing cortical projection that displays a differential degree of regional and synaptic specificity in GPe and GPi of monkeys and humans. In GPi, cortico-pallidal terminals are distributed to subserve specific relationships with limbic-related pallidohabenular neurons. In GPe, these terminals establish highly specific synaptic connections with spine-like structures and distal tips of pallidal dendrites. A cortico-pallidal connection could possibly allow for a direct route through which cortical influences could bypass the striatum and the subthalamic nucleus, to reach GPe and GPi neurons. The characterization of the exact cortical origin, and physiological significance of such a cortico-pallidal system in normal and parkinsonian states is under study.

Title: Loss of glutamatergic thalamic input (vGluT2-positive) in deep layers (layer VI) of primary motor cortex (M1) of MPTP-treated parkinsonian monkeys

Authors: *R. M. VILLALBA[1], J.-F. PARE[1], T. WICHMANN[2], Y. SMITH[2]
[1]Yerkes Resch Ctr. and Udall Ctr. of Excelence For Parkinson's Disease, Emory Un, Atlanta, GA; [2]Yerkes Res. Ctr., Udall Ctr. Excel For Parkinson's Dis. and Dept of Neurol., Emory Univ., Atlanta, GA

Abstract: The primate primary motor cortex (M1) receives a substantial innervation from the mesocortical dopamine system. Previous findings from our laboratory have shown that there is a significant loss of tyrosine hydroxylase (TH)-positive innervation of M1 (Weinkle et al., 2011, Soc. Neurosci. Abstr. 883.2) and a reduction in the spine density on cortical layer V pyramidal neurons (Smith et al., 2013, Soc. Neurosci. Abstr. 240.01) in M1 of MPTP-treated parkinsonian monkeys. Functional studies indicate that M1 corticospinal neurons decrease their firing rate and display abnormal discharge patterns in parkinsonian monkeys (Pasquereau and Turner, 2011, Cerebral Cortex 21:1362). These pathophysiologic changes in M1 pyramidal neurons are likely to be associated with remodeling of the glutamatergic innervation of M1 in the parkinsonian state. The goal of the present study was to examine whether the glutamatergic input from the thalamus, identifiable by its expression of the vesicular glutamate transporter type 2 (vGluT2), also undergoes changes in its density and ultrastructural features when monkeys are rendered parkinsonian by treatment with MPTP. Our preliminary results comparing the intensity of vGluT2 immunostaining at the light microscopy level (measured with ImageJ) in M1 in control and MPTP-treated parkinsonian monkeys showed an 80-85% decrease in the intensity of vGluT2 immunoreactivity in deep cortical layers (lower layer V/layer VI), while the intensity vGluT2 immunostaining increased by 20-25% in layers II-III. Preliminary electron microscopy results of

vGluT2-positive axo-spinous synapses in control and MPTP-treated animals in deep cortical layers in M1 have shown also different morphologies. While in control animals the postsynaptic densities (PSDs) of axo-spinous vGluT2 synapses were highly variable in shape ranging from macular to perforated with multiple active zones, the PSDs of axo-spinous synapses formed by vGluT2 terminals in parkinsonian monkeys were largely macular. Quantitative studies are in progress to characterize in more detail the ultrastructural features and pattern of synaptic connectivity of these thalamocortical synapses in control and parkinsonian monkeys. A deeper understanding of changes in the synaptology of the thalamocortical system that is associated with the development of parkinsonism will help us to better understand how cortical pathology contributes to aspects of the pathophysiology in Parkinson's disease.

Title: Effects of stimulation of the internal globus pallidus on thalamic activity patterns in parkinsonian monkeys

Authors: S. KAMMERMEIER[1,2], I. HAMADA[1], A. DEVERGNAS[1], D. PITTARD[1], Y. SMITH[3], *T. WICHMANN[3]
[1]Yerkes Natl. Primate Res. Ctr., Emory Univ., Atlanta, GA; [2]Ludwig-Maximilians-University, Munich, Germany; [3]Dept Neurol, Emory Univ. Sch. Med., ATLANTA, GA

Abstract: Stimulation of the internal globus pallidus (GPi) is one of the major functional surgical treatments used for advanced Parkinson's disease (PD). The effects of this intervention on electrical activity patterns in downstream targets of GPi output, specifically the thalamus, are not known. This series of experiments examined these effects in two Rhesus monkeys that were rendered moderately parkinsonian by treatment with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), using standard electrophysiologic recordings before and after

treatment with MPTP. In the post-MPTP state, we recorded the spiking activity of neurons in the ventral thalamus before and during electrical stimulation of the ventrolateral motor territory of GPi with macroelectrodes (bipolar 120 Hz stimulation, 0.5 mm inter-contact distance, biphasic stimuli, 100μs/phase, 200 μA). The stimulation had modest effects on the animals' parkinsonism. Our analysis of the spiking activity of neurons showed a slight reduction of firing and increased bursting (as compared to the normal state) in the basal ganglia- and cerebellar-receiving areas of the ventral thalamus. Spectral analyses revealed an increase in the 3-13 Hz range of frequencies and a reduction in the gamma-range of frequencies in the basal ganglia-receiving area of the thalamus, as well as an increase in the 1-3 Hz range in the cerebellar-receiving territory. GPi stimulation had no effects on the distribution of spikes within inter-stimulus intervals and only minimally increased firing. However, the stimulation markedly reduced oscillations in the 13-30 Hz ranges in both territories. The results confirm that oscillatory and non-oscillatory characteristics of spontaneous thalamic activity are altered in the parkinsonian state. Electrical stimulation of GPi did not entrain thalamic activity patterns, but changed oscillatory activity in the ventral thalamus towards more normal levels.

Title: Localization of Cav3.1 T-Type calcium channels in the monkey thalamus: light and electron microscopic immunocytochemistry using subtype-specific antibodies

Authors: *E. CHEN[1,2,3], J.-F. PARÉ[2,3], S. JENKINS[2,3], T. WICHMANN[2,3,4], Y. SMITH[2,3,4]
[1]Biol. Sci., [2]Yerkes Natl. Primate Res. Ctr., [3]UDALL Ctr. of Excellence for Parkinson's Dis. Res., [4]Neurol., Emory Univ., Atlanta, GA

Abstract: The motor dysfunction of Parkinson's disease (PD) results from degeneration of the nigrostriatal dopaminergic system, and the consequent functional changes of basal ganglia-thalamocortical circuits. Changes in thalamic activity, including an increase in burst discharges of thalamic neurons, are associated with the development of parkinsonism. In part, the abnormal bursting activity in PD may involve de-inactivation of T-type calcium channels (Cav3) following neuronal hyperpolarization. It is unclear whether this abnormal thalamic burst activity is the result of altered hyperpolarization from basal ganglia inputs, or changes in the localization and function of T-type calcium channels in the thalamus. As part of an effort to address the involvement of T-type calcium channels in abnormal thalamic activity, we studied the cellular, subcellular and subsynaptic localization of the Cav3.1 channel in the ventrolateral (VL) and centromedian/parafascicular (CM/Pf) thalamic nuclei, the main thalamic targets of basal ganglia outflow, in normal monkeys and in monkeys rendered moderately parkinsonian following chronic exposure to MPTP. At the light microscopic level, strong Cav3.1 neuropil immunoreactivity was found throughout the monkey thalamus, with the exception of the reticular nucleus. The intensity of immunolabeling in CM/Pf was lower than in VL. There was no obvious difference in the overall pattern and intensity of immunostaining between normal and parkinsonian monkeys. At the electron microscopic level, most Cav3.1 immunoreactivity was found in dendritic shafts of various sizes. In VL, 40-50% dendritic profiles displayed Cav3.1 immunoreactivity. At the subcellular level, aggregates of Cav3.1 immunoperoxidase and immunogold labeling were commonly found in the post-synaptic densities of putative asymmetric glutamatergic synapses, suggesting a role in excitatory transmission. Occasional pre-synaptic labeling was also encountered. There were no significant differences in the pattern of subcellular and subsynaptic localization of Cav3.1 between normal and parkinsonian monkeys. Thus, Cav3.1 is widely expressed in the basal ganglia-receiving nuclei of the thalamus in normal and MPTP-treated monkeys. Any involvement of these channels in increased thalamic bursting activities in the parkinsonian state is likely mediated by altered hyperpolarization of thalamic neurons rather than changes in the expression of Cav3.1 channels in the thalamus.

Title: Electrophysiological effects of local administration of a selective T-type calcium channel blocker on thalamic neurons

Authors: *A. DEVERGNAS[1,2], Y. MA[1,2], I. HAMADA[1,2], C. K. JONES[3,4], C. W. LINDSLEY[3,4], Y. SMITH[1,2,5], T. WICHMANN[1,2,5]

Ctr., Nashville, TN; [4]Vanderbilt Ctr. for Neurosci. Drug Discovery, Nashville, TN; [5]Dept. of Neurol., Emory Univ., Atlanta, GA

Abstract: Traditional antiparkinsonian dopamine replacement therapy is effective, but often leads to significant side effects that limit the usable dose range in many patients. There is, therefore, a need to develop non-dopaminergic approaches for the treatment of parkinsonian motor signs. One such approach is to use medications that normalize firing pattern abnormalities, specifically the known increases in burst firing, that result from nigrostriatal dopamine loss in the basal ganglia-thalamocortical circuits. In this study, we used the highly selective T-type calcium channel blocker, ML218, to test the hypothesis that some of the increased bursting in the thalamus is dependent on the activation of T-type calcium channels, we examined the effects of T-type calcium channel blockade on thalamic firing in parkinsonian monkeys. To do so, we examined the electrophysiological effects of local microinjections of ML218 on the activity of neurons in the ventral anterior and ventrolateral nucleus of the thalamus in 3 MPTP treated parkinsonian monkeys. Given the large size of thalamocortical neuronal cell bodies compared with interneurons, most of the recorded cells in our sample are likely thalamic projection neurons. The intra-thalamic injections of ML218 were done with a custom-built injectrode, consisting of a standard tungsten recording microelectrode glued to a thin silica injection tube. ML218 administration (2.5mM solution in artificial cerebrospinal fluid, 0.5µl, 0.1- 0.2µl/min) did not selectively change parameters descriptive of bursting in the thalamus (such as the proportion of spikes within bursts, the frequency of burst, or the maximal rate of firing within bursts). However, we observed prominent changes in other parameters. Thus, of 43 recorded thalamic neurons 18 (42%) showed a decrease, and 13 (30%) displayed an increase in their firing

rate. Both changes were seen within and between bursts. We also found that ML218 exposure reversed some of the MPTP treatment-induced changes in oscillatory power of thalamic firing, by decreasing oscillations in the 3-30 Hz range, and increasing the frequency above 30 Hz. These unexpectedly heterogenous effects of ML218 may be due to the fact that T type calcium channels in the monkey thalamus are widely expressed in thalamic interneurons and at pre-synaptic locations in addition to projection neurons.

Title: Optogenetic modulation of cortico-thalamic interactions in monkeys

Authors: *A. GALVAN[1], X. HU[2], Y. SMITH[1], T. WICHMANN[1]
[1]Yerkes Res. Ctr. and Dept. Neurol., [2]Yerkes Res. Ctr., Emory Univ., ATLANTA, GA

Abstract: The cerebral cortex and relay thalamic nuclei are reciprocally connected. Information transfer from cortical inputs to thalamic neurons cannot be studied with conventional electrical stimulation methods because the stimulation affects indiscriminately cortical projection neurons, interneurons, cortico-cortical connections, and (antidromically) thalamocortical fibers. In this study, we used optogenetic tools to selectively activate the terminals of projections from the primary and supplementary motor cortex (M1, SMA) to the ventrolateral (VL) motor thalamus in rhesus macaques. We compared the efficacy of two excitatory opsins, ChR2 and the red-shifted C1V1(TT), and studied the electrophysiological responses of thalamic cells elicited by optical activation of their cortical afferents. Two monkeys received recording chambers for access to motor cortices and thalamus. We injected the M1 and SMA with 30 µl of AAV5-CamKII-C1V1 (E122T/E162T)-EYFP in one hemisphere and AAV5-CamKII-hChR2 (H134R)-EYFP in the other hemisphere. After at least 6 weeks, optrodes (standard tungsten electrodes glued to 0.2 mm

OD optical fibers) were introduced into M1, SMA or the VL to light-activate opsin-expressing neurons (in cortex) or their terminals (in thalamus), while simultaneously recording the extracellular activity of neurons in the vicinity of the stimulation site. We found that 64/104 (61%) of cortical neurons and 65/165 (39%) of thalamic neurons responded to nearby optical stimulation in the C1V1 transfected hemispheres (in two monkeys). In one monkey (so far) we have recorded 64 cortical and 32 thalamic neurons in the ChR2 transfected hemisphere, and found that 20 cortical neurons (32%) and 8 thalamic neurons (25%) responded to light stimulation. For both opsins, the responses of cortical neurons to 20 ms light pulses were, in most cases, short-latency increases in firing rates. However, the responses of thalamic neurons to light stimulation of C1V1 or ChR2-expressing cortical terminals were far more variable, with many neurons showing decreases, or combinations of increases and decreases of firing. In most cases, thalamic responses were only elicited with long (500 ms) light pulses. The prolonged time to respond, and the fact that stimulation of the (excitatory) opsins lead to inhibitory effects in some thalamic neurons, suggest that at least some of the physiological effects of cortical terminals stimulation could be mediated through activation of polysynaptic circuits.

Title: Multi-digit position and force coordination during unconstrained grasping

Authors: ***A. NACERI**[1], M. O. ERNST[1], M. SANTELLO[2]
[1]Bielefeld Univ., Bielefeld, Germany; [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Small children learn to grasp objects before learning to walk or to talk. Grasping and handling objects found in daily life (e.g., cell phones, books, door handles, etc.) is one of the basic ways in which humans interact with their environment. Yet, grasping is a complicated task

when considered at the cognitive level. Grasping and manipulation tasks are highly unconstrained as an infinite number of combinations of digit positions and forces distributions can lead to stable grasps. This is due to redundancies at different levels of the sensorimotor system. In this work, we investigate this redundancy problem by examining how humans control grasping of a hand-held object using three, four and five digits in response to external perturbations. Our results revealed a similar variability in digits' initial placement when grasping with different number of digits. Moreover, the distribution of digit normal forces were modulated depending on the number of digits used, their locations, and the type of the external perturbations. Principal component analysis revealed that more than 95% of the digit force variance was accounted by the first two components. Finally, participants learned to compensate the external torque within the first perturbations within each trial during the holding phase. We propose that that the redundancy problem was addressed by the central nervous system in a similar fashion on a trial-to-trial basis in terms of digits' initial placements, but differently in terms of digits normal force distribution that was controlled online depending on the number of digits actively involved in the grasp.

Title: Haptic grasping configurations in early infancy reveal different developmental profiles for visual guidance of the reach vs. the grasp

Authors: *J. M. KARL, I. Q. WHISHAW
Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: The Dual Visuomotor Channel theory proposes that reaching consists of two movements mediated by separate but interacting visuomotor pathways that project from occipital

to parietofrontal cortex. The Reach transports and orients the hand to the target while the Grasp opens and closes the hand for target purchase. Adults use vision to integrate the Reach and the Grasp into a single prehensile act. Young infants produce discrete preReach and preGrasp movements, but it is unknown how these movements become integrated under visual control throughout development. Highspeed 3D video analysis and linear kinematics were used to examine 4 to 24 month old infants, as well as blindfolded and sighted adults, as they reached to grasp a vertical rod. Hand orientation and aperture were measured when the hand first made contact with the target to determine the extent to which vision was used to orient the Reach vs. close the Grasp prior to contact. The youngest infants resembled blindfolded adults in that they failed to orient and close the hand prior to target contact. Between 9 and 24 months, infants were able to orient the Reach prior to target contact as accurately as sighted adults, but Grasp closure took longer to develop and even 24 month old infants failed to substantially close the hand prior to target contact. Infants of all ages differed from sighted adults, who oriented, opened, and closed the hand prior to target contact. The results suggest that the Reach and the Grasp are adaptively uncoupled in early infancy to capitalize on different sensory cues - vision for the Reach and haptics for the Grasp. Due to relatively delayed development of visual guidance for the Grasp, complete integration of the two movements into a single visually guided action occurs over a prolonged time period lasting into early childhood. The results support the proposition of the Dual Visuomotor Channel theory that the Reach and the Grasp are separate movements derived from different neural origins. They extend the original theory by indicating that haptic inputs also access the Reach and Grasp pathways and that it is likely these, rather than visual inputs, that shape the initial development of separate Reach and Grasp pathways in parietofrontal cortex.

Title: Grasp force coding in F5 and AIP in a delayed grasping task

Authors: *R. W. INTVELD, H. SCHERBERGER
German Primate Ctr., Goettingen, Germany

Abstract: Studies focusing on the neural representation of hand forces have traditionally targeted the primary motor cortex (M1) due to its direct connections to the corticospinal tract. Few studies have also looked at premotor areas, where a stronger representation of movement planning is found. In this study we focused on the macaque ventral premotor cortex, also known as area F5, because of its strong relation to grasping movements, and on the anterior intraparietal area (AIP) that is directly connected to F5. AIP is highly active during the planning and execution of grasping movements, but its role in the control of grasp force is virtually unknown. We trained a macaque monkey on a delayed grasping task, in which a manipulandum (handle) was grasped with the right hand with one of two grip types, either a power grip or a precision grip. Every grip had to be held for 1 second at one out of three force levels. Both the particular grip type and the required amount of force were cued to the monkey in the beginning of each trial. We then recorded neural activity from F5 and AIP in the left hemisphere, contralateral to the moving arm, with chronically implanted floating microelectrode arrays (FMAs; MicroProbes for Life Sciences). Two 32-channel FMAs were implanted in each area (total of 128 electrodes). We found that single unit activity in F5 and AIP was strongly modulated by both grip type and grasping force. Response to grip type was similar in both areas. However, grasping force was more strongly coded in F5 than in AIP during most epochs of the task. Only during the cue presentation and the holding phase, when the monkey was actively maintaining the force level, similar proportions of AIP neurons showed force modulation as in F5. Neural modulation was also different in both areas, with F5 neurons showing more often an increase in activity with increased hand force, whereas AIP neurons were modulated to similar degree toward an increasing and decreasing force level. These preliminary results demonstrate a clear, but potentially different involvement of AIP and F5 in the planning and execution of grasp forces.

Title: The effect of electrical microstimulation of the macaque anterior intraparietal area during grasping

Authors: *R. VAN EUPEN[1], P. JANSSEN[2]
[1]Kuleuven, Leuven, Belgium; [2]Res. Group Neurophysiol., KULeuven, Leuven, Belgium

Abstract: The macaque anterior intraparietal area (AIP) is known to be crucial for object grasping. In humans, disruption of neural activity by transcranial magnetic stimulation (TMS) over parietal cortex during grip adjustment delays the grasp time, suggesting that the human homologue for AIP may be crucial for online control of grasping movements. In an effort to better localize the disruption of neural activity, we used single-cell recordings and electrical microstimulation in AIP of two macaque monkeys while the animals performed a reach-to-grasp task, in which a sudden change in the orientation of the object required an adjustment of the grip. Monkeys had to maintain stable fixation on the object for 450 ms before a light illuminated the object. After a delay period, the light switched off and an auditory go-cue instructed the animals to reach, grasp and pull the object to obtain a liquid reward. In the non-perturbation (NP) condition, the object orientation did not change during the trial. In the perturbation (P) condition, the object was rotated quickly by 90 degrees, 360 ms before the go-cue. Prior to the microstimulation experiment, we recorded single-unit activity. Almost all neurons (16/19, 84%) showed a modulation of their firing rate when object perturbation occurred. This modulation was in accordance with the neuron's orientation selectivity in 53% (7/14) of the orientation-selective neurons. In order to interfere with normal AIP activity, we electrically stimulated in 50% of both the P and NP trials (biphasic, 300 Hz, 300-500mA) in the 400 ms epoch before the go-cue, i.e. the epoch in which visual updating with the new object orientation in the object perturbation condition was possible. In both monkeys, AIP microstimulation shortened reaction times in the NP condition ($p < 0.001$). However, in the P condition, AIP microstimulation also significantly shortened reaction times ($p < 0.001$; main effect perturbation: $p = 0.67$; interaction: $p < 0.001$). In contrast, no significant effect of AIP microstimulation on the reach-to-grasp time was observed. No effect of microstimulation on reaction time or reach-to-grasp time was observed when stimulating in neighboring area LIP or in area 5 in the medial bank of the intraparietal sulcus. Thus, electrical microstimulation of AIP did not disturb reach-to-grasp movements and even shortened reaction times, irrespective of object perturbation. These results suggest that AIP microstimulation may enhance neural sensitivity in the motor system during object grasping.

Title: Calcium imaging in motor cortex of mice grasping regular or irregular ladder rungs reveals cortical control of forelimb movement parameters according to relevance

Authors: W. OMLOR[1], A.-S. WAHL[2], H. LÜTCKE[1], C. VON ACHENBACH[2], M. VAN 'T HOFF[1], H. KASPER[1], M. WIECKHORST[1], M. E. SCHWAB[2], *F. HELMCHEN[1]

Abstract: The horizontal ladder paradigm is frequently used to quantify deficits of cortically controlled skilled motor acts in rodents modeling Parkinson's disease or stroke. However, the role of the motor cortex during skilled locomotion on ladder rungs remains poorly understood at the level of neuronal networks. In transgenic mice expressing channelrhodopsin-2 in neocortical layer 5 neurons, we optogenetically mapped the motor cortex and identified a region, in which equivalent forelimb movements - involving all proximo-distal joints - were generated across animals. In the respective forelimb area of each mouse we applied calcium imaging using yellow cameleon Nano140 to record the activity of layer 2/3 neuronal networks while the head-fixed animal was moving across regularly or irregularly spaced rungs on a ladder wheel. Forelimb kinematics such as changes in shoulder, elbow, wrist and digit joints were simultaneously quantified using high-speed videography. For the regular rung pattern, the activity of neuronal subsets was correlated mainly with digit joint angles, which were encoded most precisely in the cell population. For the irregular pattern, neuronal subsets showed high correlations with digit and additionally shoulder joint angles, providing enough information to predict these kinematic parameters based on the population activity. We propose that skilled grasping under the two conditions demands cortical fine-control of digit joints while the unpredictable reaching distance on the irregular pattern requires in addition increased cortical shoulder control. Our findings demonstrate how motor cortex networks dynamically orchestrate selective movement parameters according to their relevance in the specific task and movement sequence.

Title: Grasp-specific modulation of corticospinal excitability during observation of person vs. hand actions

Authors: ***K. L. BUNDAY**[1], J. M. KILNER[1], R. N. LEMON[1], M. DAVARE[1], G. A. ORBAN[2]
[1]Univ. Col. London, London, United Kingdom; [2]Dept. of Neurosci., Univ. of Parma, Parma, Italy

Abstract: It is well established that observing actions performed by others can modulate corticospinal output. Studies have shown that this so-called 'motor resonance' can be modified by a variety of different contexts. Recently, brain imaging studies in monkeys (Nelissen et al 2005) have revealed differential activations within the ventral premotor cortex (PMv) when an individual versus only a hand is observed grasping an object. However, whether this differential processing in PMv has a distinct effect on corticospinal output remains unknown. To address this issue, we asked subjects to observe a series of videos or static images in which a whole person or merely the hand was seen reaching and grasping a peanut (precision grip) or an apple (whole hand grasp). Thus, subjects (n=18, right-handed) observed 8 conditions pseudorandomly presented in 4 blocks (20 trials/condition) in a 2x2x2 factorial design (video vs. static image; whole person vs. hand; precision grip vs. whole hand grasp). Using transcranial magnetic stimulation (TMS), we examined motor evoked potentials (MEPs) in the first dorsal interosseous (FDI) and abductor digiti minimi (ADM) at the point that the hand contacted the object. TMS intensity was adjusted to produce an MEP size of approximately 1 mV (~115% rMT) in the FDI. Within each block baseline MEPs were also collected at random during the inter-trial-interval and used to normalise each muscle. Subjects were instructed to fixate a central dot on the screen and remain with their hands relaxed throughout each block. To make sure subjects attended the stimuli, they had to report when the fixation dot was dimmed (1/8 trials). We found that

observing a video of a whole person or hand performing a precision grip significantly increased MEPs in the FDI compared to ADM. Conversely, ADM MEPs were increased compared to FDI during observation of a person or hand performing a whole hand grasps. In contrast, observing a static image of a person or hand interacting with the objects revealed no significant differences in FDI and ADM MEPs across grasp. Further analysis suggests a specific effect of observing a whole person on FDI MEPs only during precision grip. Our results indicate that observing actions performed by a whole person leads to modulation of corticospinal excitability in a grasp-specific fashion, similar to observation of actions merely performed by a hand. They are consistent with the view that multiple premotor sectors projecting to the primary motor cortex respond to action observation, one of them being a human homologue of F5c.

Title: Object-specific single neuron and population activity in rhesus macaque primary motor cortex during a reach-to-grasp task

Authors: *R. N. TIEN[1,2], S. PEREL[3,2], A. B. SCHWARTZ[1,2]
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Neurons in primate primary motor cortex (M1) display patterns of activity related to finger and hand movement during object grasping and manipulation. Previous studies have correlated M1 single unit and population activity to wrist and hand kinematics, represented by joint angles (JAs). In this study, we ask if, and how, higher-order task features, specifically information about the object being grasped, are represented in M1 neural activity. To this end, we recorded wrist and finger JAs concurrently with well-isolated single M1 neuron firing rates

(FRs) from two rhesus macaques performing a reach-to-grasp task. The subjects grasped a diverse set of objects presented at various spatial locations and orientations. We found that JA profiles were consistent over repeated reaches to the same object regardless of spatial location. This allowed us to construct a preferred joint angle (PJA) vector for each object in JA space, defined as the mean of each JA feature over all reaches to one object. These PJAs were used to construct a linear classifier that could identify the grasped object from JA values during single trials with high (>90%) accuracy. Multiple linear regression was then used to construct a PJA vector for each neuron. We found that the mean FR of each neuron was proportional to the angular distance between the neuron's PJA and the PJA of the object being grasped, suggesting that individual M1 neurons systematically prefer movements toward certain objects over others, analogous to the classical finding that M1 neurons systematically prefer movements in specific directions in three-dimensional space. We then examined the neural data as a pseudo-population by constructing object-specific preferred firing rates (PFRs) in neural space, defined as the mean FR for all neurons across all reaches to one object. Multi-dimensional scaling and cluster analysis revealed that the object-specific PJAs were clustered in a similar way to the object-specific neural PFRs, indicating that movements toward objects that were similar in terms of JAs were represented similarly in M1. Finally, we asked if M1 activity carried object-related information beyond that found in the JAs alone. First, for each neuron, object-specific PJAs were constructed using FR and JA data from reaches to only one object at a time. We found that a neuron's PJA could change significantly depending on which object was grasped. We also found that objects could still be classified using only the residual FRs after the variance due to changes in JAs was subtracted away. These findings suggest that M1 population activity could carry object-specific information beyond simply representing kinematics.

Title: The role of anterior intraparietal area in updating weight to size mapping for skilled grasp

Authors: *M. DAVARE[1], A. NURUKI[3,2]
[1]Sobell Dept., [2]Inst. of Neurol., London, United Kingdom; [3]Fac. of Engin., Kagoshima Univ., Kagoshima, Japan

Abstract: Grasping and manipulating objects require the brain to extract useful information from multiple sensory sources, in particular vision and haptics (touch). When lifting objects, fingertip forces rely on the integration of a sensorimotor memory acquired from previous visuo-haptic experience and online visual cues. However, how the cortical grasping circuit combines vision to haptics with a differential gain during planning and execution of grip-lift movements is still unknown. Since the anterior intraparietal area (AIP) is part of the cortical grasping circuit and involved in multisensory integration of visual and haptic cues, we hypothesized it is a good candidate for controlling the planning of fingertip forces by encoding a specific weighting between sensorimotor memory and online visual cues. Here we used conflicts between vision and haptics to test their relative gain in biasing force planning for the next lift. Subjects (n=12) interacted with a virtual reality environment to grasp haptic objects simulated by two Phantom robots while they received online visual feedback via a 3D screen. Object size (2 or 7 cm height) and weight (1 or 3.5 N) were varied pseudoramdomly. In 20% of trials, size and weight were incongruent (i.e. small-heavy or large-light objects). We quantified grip force rate peak (GFR) as a behavioural read-out of force planning. We also applied theta burst transcranial magnetic stimulation (cTBS) over AIP to test its causal role in combining vision to haptics for controlling force scaling. As expected, we first found that GFR was significantly higher (23% increase) for large objects compared to small ones, irrespective of the size or weight of previous objects. Interestingly, a visuo-haptic conflict in the previous trial biased the sensorimotor memory effect. GFR was significantly lower (11% decrease) when the previous object was large-light compared to small-light. Conversely, there was a significant increase in GFR (16%) when the previous object was small-heavy compared to large-heavy. Applying cTBS over AIP changed these effects of visuo-haptic conflicts on GFR scaling by altering the relative weighting between sensorimotor memory and visual cues. These results show that the cortical grasping circuit can rapidly adapt to a new mapping between weight and size and that AIP is causally involved in combining haptics with visual cues for the online control of force during skilled grasp.

Title: Laterality of grasp-related activity in macaque areas AIP and F5

Authors: *J. A. MICHAELS[1], H. SCHERBERGER[1,2]
[1]Neurobio., German Primate Ctr., Göttingen, Germany; [2]Biol., Georg-August-Universität Göttingen, Göttingen, Germany

Abstract: In primates, the anterior intra-parietal area (AIP) and area F5 of the ventral premotor cortex (PMv) play key roles for the transformation of visual target information into appropriate motor plans for object manipulation. While much research has focused on how these areas represent grasp planning and execution signals for contra-lateral movements, very little is known about grasp planning for the ipsi-lateral hand. To study this, we trained a female macaque monkey to perform a delayed grasping task, in which a handle was grasped in one of 5 distinct orientations with the contra- or ipsi-lateral hand with a power or precision grip. On any given trial, cue lights and an auditory cue indicated the appropriate grip type and the hand to be used, respectively. During the task we recorded single- and multi-unit activity simultaneously from AIP (n = 201) and F5 (n = 173) in the right hemisphere. In order to quantify the laterality of neural tuning, we compared the activity of each unit during contra- and ipsi-lateral grasps. During the instruction and movement epochs, firing rates were on average 25% higher during contra-lateral trials in both areas. However, most units were modulated by grasps of either hand, suggesting task dependency regardless of the hand used. Interestingly, grip type tuning was 1.5 times more prevalent during contra-lateral trials, suggesting a more functionally significant role. The hand used for grasping was significantly encoded during the instruction epoch in 38% of units in AIP and 56% of units in F5 (3-Way ANOVA). During movement execution this tuning increased in AIP (50%), but decreased in F5 (36%). Grip type and handle orientation tuning was present in 16% of units in AIP during instruction, while grip type tuning was present in 25% of F5 units. Grip tuning was always maximal during grasp execution. Interestingly, many units switched their preferred grip or hand during memory or movement, suggesting a flexible encoding of task parameters during grasp preparation and execution. To further elucidate the functional role of contra- and ipsi-lateral activity during grasp preparation, we calculated the functional correlation between AIP and F5 during the instruction epoch (i.e., how similarly task conditions were encoded in the neural state spaces of AIP and F5). We found that task conditions were encoded similarly in AIP and F5 during contra-lateral grasps (r-value: 0.74), but not during ipsi-lateral grasps (r-value: 0.07). Taken together, our results suggest that AIP and F5 are very active during grasp movements of either hand, but functional communication between AIP and F5 might take place primarily during contra-lateral grasping.

Title: An EMG-based state machine decoder for the detection of hand posture and grip force for reach-to-grasp tasks

Authors: *A. GAILEY, M. SANTELLO, P. ARTEMIADIS, M. ISON
Biol. and Hlth. Systems Engin., Arizona State Univ., Phoenix, AZ

Abstract: The loss of a hand can dramatically affect the ability to perform activities of daily living, hence quality of life. To date, EMG-controlled prosthetic hand systems are based on decoding electromyographic (EMG) signals from the arm to discriminate among hand postures and specific types of grasps, i.e., two-digit precision grasp, three-digit precision grasp, and the full-hand grasp. However, these systems do not discriminate hand pre-shaping prior to object contact from hand posture at contact with the object. To address this gap, we asked able-bodied subjects (n = 4) to perform a reach-to-grasp task while recording surface EMG from five electrodes placed around the circumference of the upper forearm. Subjects were instructed to pre-shape their hand, contact the object, apply a specific amount of force (which varied across trials) on a force-sensing device, lift the object, hold it for a few seconds, replace the object on the table, and release it. The state machine decoder contains three basic states: (1) resting state, (2) preparatory grasping state, and (3) object contact state. States 2 and 3 consisted of four sub-states, each denoting a different type of grasp. A multiclass machine learning classifier classified among the four different grasp types in state 2 and the resting state. Next, for a given identified grasp type, we used another machine learning classifier to discriminate the preparatory grasping state from the contact state. When contact with the object was detected, a sigmoidal fit to the sum of multiple EMG amplitudes was used offline to relate the co-contraction levels of the muscles to the total grip force on the object. We were able to distinguish among different grasp types within the preparatory grasp state, with an accuracy ranging from 92% to 97%. However, the decoder predicted the contact event to occur earlier or later than the actual contact (average: -0.64 and +0.56 s, respectively, across subjects) A similar error magnitude was found for the detection of object release (range: -0.61 to +0.22 s). For prediction of grip force across subjects, the average normalized root mean squared error was relatively small (20% for the two-digit grasp, three-digit grasp and five-digit precision grasp; 18% for the full-hand grasp). These preliminary results show that the preparatory grasping pose alone is sufficient to discriminate

among four different grasp types, and that pattern recognition techniques can reasonably detect changes in EMG signal patterns when transitioning from a preparatory grasping pose to contact with the object. Future work will explore transitions between grasp types for in-hand object manipulation.

Title: Object-directed action sequences decoded from human frontoparietal and occipitotemporal networks

Authors: ***J. P. GALLIVAN**[1], I. S. JOHNSRUDE[2], R. FLANAGAN[2]
[2]Psychology, [1]Queen's Univ., Kingston, ON, Canada

Abstract: Object manipulation tasks (e.g., drinking from a cup) typically involve sequencing together a series of distinct motor acts (e.g., reaching towards, grasping, lifting and transporting the cup) in order to accomplish some overarching action goal (e.g., quenching thirst). Although several studies in humans have investigated the neural mechanisms supporting the planning of visually guided movements directed towards objects (such as reaching or pointing), only a handful have examined how manipulatory actions--those that occur after an object has been grasped--are planned and represented in the brain. Here, using event-related functional MRI and pattern decoding methods, we investigated the neural basis of real-object manipulation using a delayed movement task in which participants first prepared and then executed different object-directed action sequences that varied either in their complexity or final action goals. Consistent with previous reports of preparatory brain activity in non-human primates, we found that activity patterns in several frontoparietal areas reliably predicted entire action sequences in advance of movement. Notably, we found that similar sequence-related information could also be decoded from pre-movement signals in object- and body-selective occipitotemporal cortex (OTC). These

findings suggest that both frontoparietal and occipitotemporal circuits are engaged in transforming object-related information into complex, goal-directed movements.

Title: Connectional heterogeneity of the macaque dorsal prefrontal area 46 (46d)

Authors: E. BORRA, M. GERBELLA, V. GIORGETTI, S. ROZZI, *G. LUPPINO
Neurosci., Univ. of Parma, Parma, Italy

Abstract: The prefrontal cortex is composed of distinct sectors differentially involved in executive functions. Recent connectional evidence showed that ventral area 46 (46v) could contribute to motor behavior through topographically organized connections with inferior parietal and ventral premotor areas involved in hand-, arm-, and eye-related sensorimotor circuits (Gerbella et al. 2013. Cereb Cortex 23:967-87). In the present study, we placed injections of neural tracers (11 injections, 4 macaques) in different parts of dorsal area 46 (46d) to examine whether and how this area could contribute to different aspects of motor control. The results showed rostrocaudal connectional gradients within area 46d. The caudalmost part of area 46d displayed connections with prefrontal (8B, 8A, 8r, 8/FEF), premotor (F7/SEF), and inferior parietal (LIP) oculomotor areas. Other connections involved the fundus of the principal sulcus, the posterior cingulate cortex, and the ventral part of medial (PGm) and superior (V6A) parietal areas. In contrast, a relatively more rostral sector of area 46d, at about 3-6 mm from the caudal tip of the principal sulcus, showed robust connections with several arm-related areas. Specifically, this prefrontal sector was densely connected to both the premotor areas F7 and F2 and the dorsal part of parietal area V6A. Weaker connections involved other arm-related premotor (F6 and F5) and parietal (PGm and PG/Opt) areas. In the prefrontal cortex, the

connections were dense with area 46v and weaker with areas 9, 8B, 8r, and 12l. In the cingulate cortex, dense connections involved area 24c and weaker areas 24a, 24b, 23a, and 23b and the posterior cingulate cortex. Finally, tracer injections placed further rostrally in area 46d showed a different connectivity pattern characterized by connections mainly with the prefrontal areas 10, 9, rostral 46v, 45A, and 12l, the orbitofrontal area 11, and the premotor area F7. Other connections involved the posterior cingulate cortex, the superior temporal area STP, and the insula. Altogether, the present data show that area 46d displays general rostrocaudal connectional gradients similar to those observed in area 46v. Specifically, the caudal part of area 46d hosts two different sectors: a caudal one connected to inferior parietal and frontal areas involved in controlling oculomotor behavior and a more rostral one connected to superior parietal and dorsal premotor areas involved in visually guided arm reaching movements. The present data suggest that area 46d contribute to the control of oculomotor behavior and of reaching-grasping movements based on visuo-spatial information and behavioral guiding rules.

Title: Similarity of representations in human dorsal- and ventral-stream brain regions during object viewing and grasping

Authors: *S. FABBRI[1,2], K. STUBBS[2], R. CUSACK[2], J. C. CULHAM[2]
[1]Donders Ctr. for Cognition, Radboud Univ., Nijmegen, Netherlands; [2]The Brain and Mind Inst., Univ. of Western Ontario, London, ON, Canada

Abstract: One influential model of the visual system has emphasized the segregation between vision-for-action in the dorsal stream (occipital to parieto-frontal cortex) vs. vision-for-perception in the ventral stream (occipital to temporal cortex). Functional magnetic resonance

imaging (fMRI) studies comparing levels of activation have shown some support for the functional segregation of the two visual streams. For example, areas in the dorsal stream (such as the anterior intraparietal sulcus, aIPS) have shown higher activation during grasping vs. reaching while areas in the ventral stream (such as the lateral occipital cortex, LOC) have not. However, newer multivoxel pattern analysis (MVPA) approaches have the potential to reveal effects beyond those manifested by activation levels alone. Here we used representational similarity analysis to explore how 6 geometrical shapes (sphere, cylinder, plate, cube, bar, and disk) presented in 3 sizes (small, medium, and large) are decoded in the human brain during different tasks. By correlating the patterns of brain activity measured with functional magnetic resonance imaging (fMRI) while 12 participants passively viewed or grasped each of the 18 objects, using a precision grip with 2 or 5 digits, or a whole hand grasp, we were able to measure the extent to which visual, motor, or both dimensions, are represented in different regions in the human brain. Cluster analysis revealed that pattern of activity in LOC shared similarities with ventral and dorsal premotor cortices (PMv, PMd), aIPS and primary motor cortex (M1). This similarity was mainly driven by sensitivity in these regions to differences between tasks. Within these regions, object properties, like shape and size, were processed during grasps to various extents. Moreover, object features were also represented in LOC and aIPS during passive viewing. These results suggest stronger similarity in visual processing between the two visual streams than previously indicated by brain activation levels alone, in line with evidence in monkeys of direct connections between the two streams.

Title: Are there interlimb differences in lower extremity stability and dexterity?

Authors: *L. LEVEY[1], A. B. SAWERS[1], M. LYLE[2], L. H. TING[1]
[1]Biomed. Engin., Emory University/Georgia Inst. of Technol., Atlanta, GA; [2]Applied Physiol., Georgia Inst. of Technol., Atlanta, GA

Abstract: Interlimb differences in upper extremity motor performance have been proposed to arise from the lateralization of motor function whereby one cortical hemisphere specializes in trajectory and direction control for dexterous arm functions (Sainburg, 2002), while the other hemisphere specializes in maintaining stable postures (Bagesteiro, 2003). Here, we sought to test whether similar interlimb differences in stability and dexterity exist in the lower extremities, and whether such interlimb differences in motor function correspond to foot preference. We tested the ability of the lower limb to maintain stability by measuring the magnitude and variation of the center of pressure (CoP) velocity during single limb standing (SLS) with eyes closed. We tested lower limb dexterity using the lower extremity dexterity (LED) test (Lyle, 2013), which examines how well the leg can dynamically interact with an unstable surface. During the LED test, subjects are positioned in an upright partially supported posture and use one leg to compress a spring prone to buckling using the highest force that can be sustained for 16 seconds. Higher force production on this task has been correlated to motor agility (Lyle, 2013). Ten unimpaired adults (25±4.0 years) performed both tests. Each leg was tested in a randomized order. Interlimb differences were identified for each test suggesting limb specialization. The magnitude ($p < 0.001$) and variation ($p < 0.05$) of the CoP velocity during SLS was found to be significantly different between legs, suggesting there is a leg specialized for maintaining stability. The magnitude ($p < 0.01$) but not the variation ($p = 0.57$) of the maximal vertical GRF during the LED test was also found to differ significantly between legs, suggesting there is a leg specialized for dexterity. However, we found no consistent pattern of specialization across individuals. Six participants performed both tests better on the same leg suggesting that one leg was specialized for both stability and dexterity, while four participants performed each test better on different legs suggesting that one leg was specialized for stability and the other was specialized for dexterity. Additionally, no relationship was identified between performance of either of the tests and Schneider's foot preference assessment (Schneider, 2010). Our results suggest that interlimb differences in the lower limb may not be governed by similar hemispheric specialization as the upper limbs. Nevertheless, tests of dexterity and stability may be effective in explaining differences in lower limb motor coordination observed in gait and balance.

Title: Correlates between motor cortical output and control of the digits during common-practiced hand dexterity tasks

Authors: *Z. A. RILEY[1], A. W. MEEK[2], J. WILLIAMS[2], N. R. ECKERT[2]
[1]Indiana University- Purdue Univ. Indianapolis, Columbus, IN; [2]Indiana University- Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Few situations in ordinary living require use of the digits to such a degree that cortical outputs are significantly modulated. Examples of this are the use of digits for braille reading in blind individuals, or playing an instrument as a professional musician. However, both of these are extreme examples where there was either damage elsewhere in the nervous system or the task required significant skill training. For unimpaired individuals the only tasks that could reach comparable daily use would be cellular phone text messaging or typing on a computer keyboard. The purpose of the present study was to examine motor cortical outputs in muscles of the hand and forearm (abductor pollicis brevis [APB], abductor digiti minimi [ADM], first dorsal interosseus [FDI], and flexor carpi radialis [FCR]) relative to text messaging and keyboard typing ability. Transcranial magnetic stimulation was used to examine cortical representations and stimulus recruitment curves for the aforementioned muscles in 10 healthy subjects (range: 20-34 yrs). This was compared with their performance of a functional texting task (FTT) and functional keyboard task (FKT). Both tasks required completing as many 45-character long phrases as possible in 2-minutes, each on a cell phone keyboard and on a standard computer keyboard. The number of correct characters yielded a performance score, and the number of correct characters / characters possible determined an accuracy score, for each task. After the texting and keyboard tasks the individuals cortical representations and recruitment curves were examined. Subjects had mean scores of 338±65, and 559±103 characters on the FTT and FKT, respectively. The scores were significantly higher in the FKT ($p \leq 0.001$). The accuracy scores were higher for the FKT as well (98.3±2.8% vs 97.5±1.3%, $p = 0.02$) A stepwise regression model including the slope of the recruitment curve, and volume, center-of-gravity (CoG), and area of the cortical representation of APB was used to determine if the individual FTT scores and accuracy could be predicted. Only the volume and CoG terms were able to predict 79.3% of the variance in the FTT score ($p = 0.004$). There were no predictors of the FTT accuracy. The same variables were included for all muscles in a model to examine predictors of FKT scores and accuracy, though none were significant predictors. The results of this study suggest that cortical outputs, specifically APB representation volume and CoG, can help predict cellular phone texting ability. The differences observed between the FTT and FKT could be due to the focused nature of texting (using only thumbs) versus the distribution of activity across all digits in keyboard typing.

Title: Facilitating supplementary motor area using near-infrared spectroscopy mediated neurofeedback improves postural stability but not hand dexterity

Authors: *H. FUJIMOTO[1,2], M. MIHARA[2], N. HATTORI[1], M. HATAKENAKA[1], H. YAGURA[1], T. KAWANO[1], H. OTOMUNE[2], I. MIYAI[1], H. MOCHIZUKI[2]
[1]Neurorehabilitation Res. Inst., Morinomiya Hosp., Osaka, Japan; [2]Dept. of Neurology, Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: Background: There is accumulating evidence that the supplementary motor area (SMA) is involved in various aspects of motor control including postural control, inter-limb coordination, and coordinating temporal sequences of actions. However, its potential as a candidate for therapeutic target promoting functional recovery after stroke remains controversial. Objective: To investigate whether the SMA facilitation affects the hand dexterity and/or postural control in cause-and-effect manner, we used near-infrared spectroscopy (NIRS) mediated neurofeedback (NF) The system aims to induce neuromodulation via voluntary control of cortical activities by real-time presentation (Mihara M et al. Stroke 2013;44:1091-8). Method: Twenty healthy right handed subjects participated in this study (M: F = 7: 13, 28.1 ± 4.6 years old). As a marker for cortical activation, we used oxygenated hemoglobin derived signal measured by using a 50-ch continuous wave NIRS system with 4 short distance channels for correcting the extra-brain contamination. NF session consisted of 16 repetitions of 5second - task and 8-16 second rest periods. Subjects were asked to control their SMA activation according to the feedback signals without specific strategic instruction. Each subject received the REAL session in which their own SMA activation was fed back and the SHAM session in which the SMA activation of other subjects was fed back, with an interval of more than one week. Before and after each NF session, postural stability and hand dexterity were assessed using cumulative

length of center of pressure (COP) displacement during standing and 9-hole PEG test score (9HPT) with non-dominant hand respectively. NF effect on the SMA activation was assessed using comparison between first 6 blocks and last 10 blocks in each NF sessions. Behavioral changes were analyzed using repeated measures ANOVA with $p<0.05$ as significant. Results: Group analysis of cortical activation revealed that the SMA activation was enhanced only in REAL condition. COP length was maintained in REAL condition whereas it slightly increased after NF in SHAM condition. On the other hand, 9HPT scores did not change after NF in both REAL and SHAM condition. There was significant interaction between group (REAL vs. SHAM) and time ($F1,38=6.2$; $P<0.05$) on COP length, but there was no significant interaction on 9HPT, suggesting that the SMA facilitation improved postural stability but not hand dexterity. Conclusion: Our findings suggest a cause-and-effect relationship between the SMA and postural control, and provided the rationale for SMA modulation as therapeutic target for balance disorder after stroke.

Title: Visual and haptic guidance to facilitate inter-manual transfer of handwriting skills

Authors: I. TAMAGNONE, *V. SANGUINETI
Dept Informatics, Bioengineering, Robotics and Systems Engin., Univ. of Genoa, Genoa, Italy

Abstract: Survivors of cerebrovascular accidents or amputation involving the dominant hand are forced to transfer their handwriting skills to their non-dominant hand. This process typically takes several months of training by occupational therapists and the overall success is highly subject-dependent. The goal of this study is to explore the mechanisms underlying the inter-manual transfer of handwriting skills and to investigate whether technological solutions can facilitate this process. In a previous study we demonstrated that robot-assisted training may accelerate inter-manual transfer. Specifically, we found that in order to facilitate learning, haptic guidance must account for the temporal aspects of the movement. Here we go one step further,

by asking whether the benefit for learning comes from haptic guidance or from temporal information, irrespective of the modality (either visual or haptic). The experimental apparatus consisted of a manipulandum with three degrees of freedom (Novint Falcon), with a customized pen-grip connected to the robot endpoint. A computer screen placed horizontally below the pen tip displayed a top view of a notepad. The robot recorded the pen tip movements that, when in contact with the screen, were continuously displayed as a red trace. We compared three different assistance modalities. In the static visual (SV) modality, subjects could see a static trace of the reference template. In the dynamic visual (DV) modality, subjects were presented with an animated version of the reference template (i.e. a moving target). In the dynamic visual + haptic (DVH) modality, subjects were provided visual guidance (as in DV) but in addition the robot generated forces toward this moving target, with a magnitude proportional to the target-pen distance. At the beginning of each trial, a letter was displayed and subjects had to reproduce it in writing. Subjects were divided into three groups (SV, DV, DVH). Training took place in one-hour sessions during three consecutive days. Before and after each training phase, subjects were tested through free-hand drawing of the same letters used in training, but without assistance. Across days, the magnitude of assistive forces was gradually reduced. An assessment procedure, inclusive of the trained letters and non-trained letters was repeated at the beginning of day 1, at the end of the third day of training and on the day after (day 4) to assess retention. Early results suggest that the final performance - learned handwriting movements - exhibits between-groups differences both spatial and temporal aspects. Specifically, temporal information seems crucial for learning.

Title: Time-of-day effects on brain activity during the imagination and execution of finger opposition movements

Authors: *L. BONZANO[1], L. ROCCATAGLIATA[1], G. L. MANCARDI[1], C. PAPAXANTHIS[3], M. BOVE[2]

[1]Dept. of Neurosci., [2]Dept. of Exptl. Med., Univ. Genoa, Genoa, Italy; [3]INSERM U1093: Cognition, Action, et Plasticité Sensorimotrice, Univ. de Bourgogne, Dijon, France

Abstract: During motor imagery a person internally simulates a movement without actually performing it. It has been shown that similar neural processes and brain areas are activated during mental and actual actions. Imagined actions are based on internal predictive models. Interestingly, motor prediction is influenced by the time of the day, and consequently by the amount of daily physical activity. In particular, the accuracy of motor prediction, assessed by calculating the temporal equivalence (isochrony) between actual and imagined actions, significantly varies according to the time of the day. Better performance (i.e., isochrony between actual and mental movements) is achieved in the afternoon than in the morning. This phenomenon can be explained by a continuous update of internal predictive models, by means of self-supervised learning, throughout the day. Here, we performed an fMRI study (n=15) at 7 a.m. and at 2 p.m. During each session, subjects had to actually and mentally perform a simple sequence of finger opposition movements (thumb-to-index, medium, ring and little) as fast as possible. Motor performance was recorded by using a magnetic-resonance-compatible engineered glove. The sequence was repeated five times and the duration of the whole task was calculated; during motor imagery, the subjects were instructed to tap the index with the thumb at the beginning and the end of the task. Actual and imagined movements were faster at 2 p.m. than 7 a.m. Motor prediction, assessed by the absolute difference (a.d.) between actual and mental movements, was better at 2 p.m. (a.d. = 1.7±1.3 s) than 7 a.m. (a.d. = 2.9±1.7 s). For actual movements, the fMRI analysis revealed that brain activity in the morning was more distributed and involved the primary motor cortex, the supplementary motor area (SMA), and the cerebellum. In the afternoon, the areas involved were similar but more localized and lateralized to the left brain and right cerebellar hemisphere, as a result of a better reorganization and optimization of circuits involved in the control of fine finger movements. For mental movements, at 7:00 a.m. we found very extensive activation of the SMA and the involvement of the left premotor areas, but the right cerebellum showed very low activity. At 2:00 p.m., the areas involved were similar to those activated in the morning but with reduced activations. Interestingly, the left parietal lobe was also recruited. Our results indicate that motor performance level and brain areas activation varied during the day. This should be taken into account when planning a rehabilitation program based on motor imagery.

Title: Role of contralateral anterior intraparietal sulcus in coordinating digit force to position for dexterous manipulation

Authors: *P. J. PARIKH[1], M. DAVARE[2], M. SANTELLO[1]
[1]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ; [2]Motor Neurosci. and Movement Disorders, Univ. Col. of London, London, United Kingdom

Abstract: During dexterous manipulation, humans have an exquisite ability to coordinate fingertip forces as a function of digit placement. However, the underlying neural mechanisms are not well understood. The anterior part of intraparietal sulcus (aIPS) is known to be involved in the control of force and hand shaping during grasping movements. Thus, aIPS is a potential candidate for controlling digit force modulation to position. We addressed this issue by inducing 'virtual lesions' of aIPS contralateral to the hand interacting with the object. Eight subjects generated torque (70 Nmm) on a virtual object rendered by two haptic devices attached to the fingertips to control the lateral motion of a cursor to intercept a falling ball. For Exp#1, visual feedback of the object was not allowed throughout the trial. Object width (large, L; small, S) was changed unexpectedly across trials, thus requiring subjects to accurately modulate digit forces based on somatosensory feedback of digit positions at contact. We hypothesized that digit force-to-position modulation without visual feedback of digit placement would require aIPS. aIPS was disrupted using single-pulse transcranial magnetic stimulation (spTMS) at (Early) or 100 ms (Late) after object contact. For Exp#2, subjects performed the same task with visual feedback of the object, but its width was changed unexpectedly at grasp onset. This required subjects to use visual feedback of the new object width to adjust grip aperture, and change the digit forces they had originally planned in order to perform the manipulation task. We hypothesized that aIPS is necessary for enabling force-to-position coordination based on visual feedback of object width. aIPS was disrupted using spTMS at grasp onset. Conditions were separated according to when the object width remained the same (LL, SS) and was different (LS, SL) across and within trials. Subjects were able to generate adequate torque on the object to achieve the task goal. For Exp#1, early vs. no TMS increased peak force rate (FR) by 2.01±1.4 N/s for the LL condition. For SS and LS conditions, early vs. no TMS delayed accurate scaling of forces by >100 ms. Late TMS did not interfere with the magnitude of peak FR nor timing of force profiles. For Exp#2, TMS at grasp onset delayed the time to achieve 10% of peak grasp velocity by 150 and 70 ms for SL and LS conditions, resp. The perturbing effects of TMS over aIPS on hand shaping also impaired FR scaling, but in a condition-dependent manner. Our findings suggest the role of aIPS in integrating somatosensory feedback of digit position for control of forces, and visual feedback information of object width for predictive control of force-to-position control.

Title: Classification of hand shapes for dexterous control of a five-fingered robot hand using neural signals in the macaque inferior temporal cortex

Authors: *R. HAYASHI[1], S. SAGA[2]
[1]Syst. Neurosci. Group, AIST, Tsukuba, Ibaraki, Japan; [2]Div. of Information Engin., Univ. of Tsukuba, Tsukuba, Japan

Abstract: Introduction: Previous researches on brain-machine interface (BMI) have demonstrated dexterous hand prosthetic control by decoding motor cortex signals associated with finger movements. These approaches are, however, not applicable for patients with paralysis resulting from the damaged motor cortex. On the other hand, considering our ability to visually imagine intended hand movements and the fact that neurons in the inferior temporal (IT) cortex are involved in the visual representation of body parts including hand, it is conceivable that neural signals in the IT cortex are also available for dexterous control of prosthetic hands. To assess the feasibility of this alternative approach, we demonstrated a prosthetic hand emulator control based on the classified hand shapes using IT neural activity. **Method:** Multi-unit activity was recorded from 190 electrodes chronically implanted in the IT cortex of a macaque monkey while the animal viewed images of three different hand-signs (rock, scissors, and paper). The recorded data was converted to the spike count with the time window of 100 ms and processed to classify which image was viewed at a time (3 hand sign images or blank screen) with linear discriminant analysis. Offline processing was used to evaluate the classification performance. The decoded output was then used to control a five-finger moveable robotic hand (Handroid,

ITK co. ltd.) with a cosmetic cover made of RTV silicone rubber fabricated by Satoh Giken co., which imitates a real human hand. **Results: C**lassification accuracies were very high as 82.0% on average (chance level performance is 25%) when all data acquired from 190 ch during one recording session was included in the analysis. Hand shape was decoded with highest accuracy (88.8%) at the latencies of 400 ms after visual stimulus onset, followed by gradual decrease in accuracy down to 64.0 % until the offset of stimulus. Data from 2 trials per image is enough to train a classifier that achieves 72.6 % correct classification on average. Analysis on data randomly sampled across different sessions shows that neural signals from more than 350 ch provide higher classification accuracy than 90 % on average. These results suggest that the dexterous control of a prosthetic hand will also be feasible if decoding the ensembles of several hundreds of neurons in the visual cortex.

Abstract: A parietal-frontal network in the primate brain is central to the sensorimotor integration for grasping. Nodes of the network include zones in anterior and posterior parietal cortex that are connected through parallel pathways to nodes in motor and premotor cortex. Our understanding of the functional dynamics of the network nodes has emerged primarily from single unit recordings, which provided invaluable insight about how neurons are tuned to stages of prehension. Nevertheless, the spatial clustering of grasp-related neurons within each network node remains unknown. We have adopted a multi-pronged strategy that involves optical imaging,

intracortical microstimulation, and single unit recording in behaving monkeys, to investigate the functional organization of the grasp network nodes. We trained a macaque monkey to reach, grasp, and lift a knob with its preferred hand. A chronic chamber implanted in the contralateral hemisphere provided access to the hand and forelimb representations in primary motor (M1), dorsal premotor (PMd), ventral premotor (PMv), and areas 1 and 2. Optical imaging maps were collected under 630 nm wavelength illumination during all stages of the grasp task and in various control conditions. A prominent activation domain (~ 2 mm^2) characterized the response pattern in M1. Intracortical microstimulation in and near the M1 domain evoked hand movements including flexion or extension of the digits, or wrist dorsiflexion. Similarly, single unit recordings from the same domain showed that neurons modulated their firing rates as the hand approached and grasped the target. Smaller domains were identified in PMd and PMv and their activation generally led the temporal pattern of the M1 domain. Three activation domains in parietal cortex were sequentially driven in a mediolateral pattern. Receptive field mapping with multi-unit recordings indicated that those domains were in rostral aspects of area 2. Moreover, the medial domain overlapped the forearm representation, whereas the lateral domains overlapped representations of the palm and digits. Our multi-pronged approach allows us to gain novel insight about the spatial organization of the grasp domains in frontal and parietal cortex and to resolve their functional dynamics.

Title: Do spatial and temporal cues interact during proprioceptive estimates of arm motion?

Authors: *H. M. WEEKS[1], A. J. BASTIAN[3,2]
[2]Neurosci., [1]Johns Hopkins Univ., Baltimore, MD; [3]Kennedy Krieger Inst., Baltimore, MD

Abstract: Humans can estimate the visual consequences of movement using proprioception (i.e. the sense of limb position and motion). Here we asked how well people could judge the timing of passive arm movements that occurred at different speeds, and thus moved different spatial extents. Healthy young controls performed a spatial-temporal psychophysical task in a KINARM robot where the arm was moved in the horizontal plane. They were first shown a dot that represented the position of the fingertip of their unseen arm. The dot disappeared and the robot passively moved the subject's hand directly to the right of its initial position at a constant velocity. During the movement, a visual dot appeared briefly, moved at the same velocity of the fingertip, and then disappeared. The subjects' task was to compare the onset of the dot to their felt fingertip and they were told that the dot might appear before their fingertip reached the dot onset location (early) or after their fingertip passed that location (late). Subjects then were asked to verbally indicate whether the dot appeared too early or too late relative to their ongoing movement. The paradigm was a two alternative forced choice task method of constant stimuli using temporal shifts of the dot including 0, ±200, ±400, ±600, and ±800 msec. We tested each subject on the task three different times with three different velocities (7, 9, and 11 cm/sec). For each velocity the temporal shifts were the same, but faster velocities produced larger spatial shifts. This allowed us to determine whether subjects could utilize additional information from different sized spatial shifts, or were solely relying on the temporal information. To analyze proprioceptive acuity, we fit a logistic function to each subject's data in the temporal shift domain. We then calculated the slope of each fit. We hypothesized that people would have better acuity (i.e. steeper slopes) when the spatial shifts were larger for the faster speeds. However, this was not the case. Acuity was no different for the temporal shifts across the different speeds, indicating that subjects did not benefit from traveling farther for a given time shift. This occurred despite the fact that the spatial extent traveled changed by a minimum of 22% for the same temporal shift. We conclude that the nervous system does not appear to benefit from clear spatial cues in augmenting this type of temporal proprioceptive task.

Title: The effect of force level on the force reproduction error changes with force direction and arm posture

Authors: *B. ONNEWEER[1], W. MUGGE[2], A. C. SCHOUTEN[1,3]
[1]Biomechanical Engin., Delft Univ. of Technol., Delft, Netherlands; [2]Fac. of Human Mmovement Sci., MOVE Res. Inst. Amsterdam, VU University Amsterdam, Netherlands; [3]MIRA Inst. for Biomed. Technol. and Tech. Med., Lab. of Biomechanical Engin., University of Twente, Enschede, Netherlands

Abstract: Golgi Tendon Organs and tactile sensors provide the central nervous system with sensory information about forces. The CNS integrates these sensory signals and the resulting force estimate can comprise systematic and random errors due to sensorimotor uncertainties. Previous studies show a force reproduction error, being the systematic error, where subjects generate too high forces when reproducing externally applied target forces [1] or self-generated target forces up to 40N [2,3] and generate too low forces when reproducing self-generated forces of 130N and up [3]. So far force perception has only been looked at in one degree of freedom and one direction, not taking into account that force perception might not behave isotropically. The goal of this study was to assess the effect of force level on the force reproduction error in different force directions and arm postures (shoulder and elbow angles) in the horizontal plane. We hypothesize that the force reproduction error will decrease with increasing force level as shown previously [3], but will differ in size for each force direction. Subjects (n=36, all right handed, 24 men) were divided into three groups and were instructed to match an onscreen target force (10N, 40N or 70N) in magnitude and direction (8 directions, 45 degree increments, in random order) with visual feedback and subsequently reproduce the same force vector without visual feedback in two arm postures. Per subject and arm orientation, ellipses were used to describe the force estimates of both reference and reproduction trials. The orientation, the direction of the principal axis, of the reproduction ellipses did not change with force level, but changed with arm posture and always pointed towards the shoulder. In the direction perpendicular to the principal axis, subjects generated too high forces for 10N and too low forces for 70N which is in accordance to results in one degree of freedom [3]. However, in the direction of the principal axis the force reproduction error increased with force level. These results show that the effect of force level on the force reproduction error depends on force direction and on arm posture. References: 1 Shergill SS; Bays PM; Frith CD; Wolpert DM. Title: Simultaneous multichannel microelectrode recording from macaque primary motor cortex and primary somatosensory cortex during an intuitive reach to grasp task

Authors: *S. N. FLESHER[1,2], A. B. SCHWARTZ[1,3], R. A. GAUNT[1,4,2]
[2]Dept. of Bioengineering, [3]Dept. of Neurobio., [4]Dept. of Physical Med. and Rehabil., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The role of somatosensory feedback in the control of movement is a fundamental question in motor control. The goal of this current study was to identify and characterize functional relationships and connections between primary somatosensory cortex (S1) and primary motor cortex (M1) by simultaneously recording from areas M1 and S1 in a behaving rhesus macaque performing an out-center reach to grasp task. Two sets of intracortical microelectrode arrays, each containing an array of 88 recording electrodes placed in area M1, and an array of 32 recording electrodes placed in area 1 of S1. The M1 arrays were placed, based on cortical landmarks, in the upper arm representation of M1 and the S1 arrays were placed in the hand and finger representation of area 1. Placement of the S1 arrays was verified by receptive field mappings. The subject then performed reaches to a target located in one of four positions in three-dimensional space, grasped the target object, maintaining contact as it was translated to a central location. The target object was attached to a presentation robot through a compliant link to enable manipulation and positioning of the object. The object was instrumented with a force sensor to measure the pressure with which it was being grasped as well as a three-axis accelerometer to provide details about how the object was being manipulated during the transport phases. The object itself incorporated the reward delivery system, which was positioned at the subject's mouth at the end of a successful trial. During all phases of the movements, neural activity was recorded from the electrode arrays in M1 and S1. All channels were spike sorted online. We sought to identify changes in S1 firing based on the state of the reach, and correlate peak firing rates to object contact and other movement characteristics of the reach and grasp. We classified the states of the reach as reach, grasp and carry, and release and return, and identified

changes in the neural activity among states. The majority of units (87.3%) from the S1 array strongly preferred the grasp and carry phase to the release and return phase. A slight preference (67.67%) was also shown for the reach phase over the release phase. The results provide insight into the role of sensory feedback during a motor task. The relationships between these cortical populations during the different phases of the task may indicate a shift in information being relayed by the sensory feedback during a motor task. This material is based upon work supported by the National Science Foundation Graduate Research Fellowship under Grant No DGE-1247842 and DARPA award number: N66001-10-C-4056.

Title: Precision of fine and gross pointing movements differs across visual conditions

Authors: *J. M. HONDZINSKI, S. A. WINGES
Kinesiology, Louisiana State Univ., BATON ROUGE, LA

Abstract: People often produce reaching and pointing movements which undershoot remembered target locations in darkness relative to an illuminated environment. This “dark phenomenon” of undershooting has been observed for straight arm and multi-joint arm movements. Because fine motor skills normally require greater precision than gross motor skills, this study was designed to determine whether the dark phenomenon also exists for a fine motor skill pointing task. Specifically, we questioned whether similar outcomes would exist for pointing movements to remembered target locations using the finger or whole upper limb. Since we recently showed that the gravitational pull cannot explain endpoint precision differences between visual conditions, we reasoned that mass differences between the finger and arm body segments would be negligible. If true, a pointing motor program would dominate the task control resulting in similarities in fine and gross precision control for each visual condition. Young adults with no reported neurological impairments produced pointing movements to real targets and remembered target locations in complete darkness (DARK) or normal room lighting

(LIGHT) from standing and side lying body orientations. Gaze was anchored on target or remembered target locations during the pointing movement. Three targets were located at a 1.5 m distance directly in front of subjects. Target levels included the shoulder, eye, and mid trunk. Subjects began with either the arm flexed up by the ear before producing ARM movements or the horizontal supported arm with finger extended at about a 45 degree angle, pointing above/past the eye level target, before producing FINGER movements. Six pointing movements were performed to each target in each in each visual condition when pointing with the ARM or FINGER in standing and side lying orientations. Movements of the shoulders, elbow, metacarpophalangeal (MCP) joint of the second digit, and the fingertip of the dominant pointing limb were recorded. Subjects often ended pointing movements in the DARK short of those in the LIGHT regardless of body part used when standing. This undershooting was observed, but less common in the side lying condition. The greater movement at the MCP joint produced greater variability, likely accounting for greater similarities between visual conditions in this condition. Conclusion: The phenomenon of undershooting remembered target locations in the dark exists for different body segments. The similar endpoint precision which exists for FINGER and ARM pointing movements suggests similar control strategies for endpoint accuracy regardless of the gross or fine motor control needed.

Title: Fine-tuned force control under consistent visual feedback of object motion

Authors: *S. TAKAMUKU, H. GOMI
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: The ability to precisely estimate the forces involved in our action is essential for dexterous motor control. Visual feedbacks during dynamic object manipulation can contribute to this estimation in two ways. First, feedback of hand position can improve our estimation of endpoint forces from muscle tensions by providing information on arm posture. Secondly,

feedback of object motion can also contribute to our estimation of endpoint forces based on inverse dynamics, the estimation of force from motion. Here, to elucidate the potential contributions of the two computational processes, we examined grip forces during moving a simulated spring-mass-damper system in a cyclic manner while providing visual feedback(s) of the position of the hand and/or the position of the mass. In addition to the visual feedback, the damping factor of the system was also varied so that the phases of the load force, relative to the hand motion, differ between conditions (i.e., two-way factorial design of visual feedback and damping factor). The interest was on how each visual feedback contributes to adjusting the grip force to the timings of the load forces. If our visual feedback is to contribute by providing information on arm posture, the feedback of the hand position would improve our grip force control. Alternatively, if the feedback is to contribute based on inverse dynamics calculation, the feedback of the object motion would contribute. Analysis of cross-correlation between the grip force and the load force revealed that visibility of object motion tends to improve the synchrony of the two forces. Meanwhile, we found no evidence to support the idea that visibility of the hand improves our grip force control in this situation. Our result was consistent with the idea that the visual feedback directly contribute to our force control based on inverse dynamics, rather than indirectly contributing based on improving our estimations of arm posture. In terms of dynamic force control, seeing the objects we control rather than our hand is likely to lead to a better performance.

Title: Predictive coding and sensory gating in autism spectrum disorders

Authors: *J. FINNEMANN, P. FLETCHER, C. TEUFEL, D. WOLPERT, J. INGRAM, K. PLAISTED-GRANT
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Background: Motor deficits are reported for as much as 80% of ASD cases (Green, 2009) and yet their aetiology and relationship with the core symptoms of autism remains unexplored. Since motor difficulties correlate with scales of autism severity (Hilton et al., 2011)

and predict daily life skills (Kopp et al., 2010), a better understanding of the deviant mechanisms in individuals with ASD bears direct relevance to developing intervention strategies and support. Based on the 'connectivity theory of autism' (Belmonte et al, 2004; Cherkassky et al., 2006) which states that autism is characterised by an increase in short-range connections and reduced long-range connectivity, one might speculate that differences in motor cognition will be found in those tasks that depend on the long-range connections between M1 and the premotor and parietal areas whereas functionality of short-range connections between M1 and somatosensory areas is intact. Whereas sensorimotor areas are involved in the post-predictive feedback loop, predictive processes are thought to be driven by premotor areas (Schubotz & von Cramon, 2002). Thus one might expect differences in predictive processes in individuals with ASD, which has indeed been suggested in a recent Bayesian model of autistic perception (Pellicano & Burr, 2012).
Objectives: To review and refine the ideas about predictive mechanisms of sensorimotor processing in ASD vis-à-vis the emerging models about active inference (Friston 2012, 2013) and predictive coding (Friston & Kiebel, 2009, Friston, 2009). It has been suggested that atypical perception in ASD might be the result of aberrant neuromodulatory control of the synaptic gain in specific parts of the cortical hierarchy (Friston, Lawon & Frith, 2012; Lawson et al., 2014)
Experiment: A well-established way to investigate prediction in motor processes at the behavioural level is to measure the sensory attenuation of self-generated versus externally-generated tactile input. In the experiment a lever - via a torque motor - exerts a mild pressure to the participants' index finger. The volunteers' response then varies depending on the condition: participants are asked to 'match' the pressure either by pressing on the lever with their other index finger or by adjusting a slider which controls the torque motor. The slider is a potentiometer which transduces a force gain at the ratio of 0.5N/cm. Where possible results of this experiment will be linked to measurements of somatosensory gating measured before and during movements of the individual to differentiate between central and peripheral mechanisms of SEP gating.

Title: Pantomime Grasping attenuates tactile sensitivity of the moving limb

Authors: *F. L. COLINO[1], G. BINSTED[2]
[1]Sch. of Hlth. Exercise Sci., Univ. of British Columbia Okanagan, Kelowna, BC, Canada; [2]Sch. of Hlth. & Exercise Sci., The Univ. of British Columbia, Kelowna, BC, Canada

Abstract: A multitude of events bombard our sensory systems at every moment of our lives. Thus, it is important for the sensory cortex to gate unimportant events. Tactile suppression is a well-known phenomenon defined as a reduced ability to detect tactile events on the skin before and during movement. Previous experiments (e.g., Chapman et al., 1987; Milne et al., 1988; Williams et al., 1998) found detection rates decrease prior to and during finger movement but most experiments examined tactile gating in simple motor tasks, such as index finger abduction. But, there is no reasonable expectation to utilize sensory feedback in finger abduction. Hence, many studies examined tactile gating in various visuo-motor tasks such as pointing (Buckingham et al., 2010), juggling (Juravle & Spence, 2011), grasping (Colino et al., 2014; Juravle et al., 2011), and during normal gait (Duysens et al., 1995; Morita et al., 1998; Staines et al., 1998). The present study examined how tactile detection changes in response to task demands. Participants performed two tasks in two separate experimental sessions: a "reach-to-grasp" session and a "pantomime reach" session. Nine human participants used their right hand to reach and grasp a cylinder in both sessions. Session order was counterbalanced across participants. Tactors were attached to the index finger and the forearm of both arms and vibrated at various epochs relative to a "go" tone. Vibrations could occur at 0 ms relative to imperative cue up to 360 ms post-cue in 60-ms intervals. Only one tactor was randomly activated in any given trial and at one interval relative to the imperative cue. Vibration time was renormalized trial-by-trial relative to reaction time. When participants performed reach-to-grasp targets, tactile acuity decreased at the right forearm before movement onset (Colino et al., 2014) but no suppression was observed at the right index finger or at the left limb. However, when participants performed pantomimed grasping, similar pattern was observed except at the right index finger. Sensitivity decreased at the right index finger suggesting that task demands modify sensory-motor circuitry (see Fink et al., 2014). These results indicate that the task affects gating dynamics in a temporally- and contextually-dependent manner and implies that feedforward motor planning processes can modify sensory signals.

Title: The effect of effector movement on body- and gaze-centered spatial coding of proprioceptive-tactile reaching

Authors: *S. MUELLER, K. FIEHLER
Exptl. Psychology, Justus-Liebig Univ. Giessen, Giessen, Germany

Abstract: There is converging evidence that the reach target and the hand are represented in multiple spatial reference frames at the same time, and that the influence of each reference frame on reaching depends on the current sensory context (Pouget et al., 2002). In a previous study we showed that effector movement between target presentation and response led to a shift from gaze-independent to gaze-dependent spatial coding of somatosensory targets (Mueller & Fiehler, 2013, 2014). However, which reference frame was used when it was not a gaze-dependent one remained unspecified. In the present experiment we investigated whether proprioceptive-tactile reach targets are represented in a body- and/or a gaze-centered reference frame, and whether the contribution of body- and gaze-centered reference frames varies with the presence of an effector movement before the reach. Participants were asked to reach to an unseen finger of their left hand which was indicated by a mechanical touch (the proprioceptive-tactile target). Reaches were performed with the right hand in total darkness and with the head fixed. In order to test for body- and gaze-dependent coding of reach targets, we varied (i) the starting location of the reaching hand, (ii) the target location, and (iii) gaze direction. Effector movement was manipulated in 2 separate blocks that differed in whether the left hand was kept stationary at the target location throughout the trial (stationary condition) or actively moved to the target location, received a touch and was moved back before the reach (moved condition). We compared horizontal reach errors of trials that were similar in gaze coordinates but different in body coordinates and vice versa using a correlation approach. Under the assumption that two movements that are represented in the same reference frame also produce similar errors, significant correlations indicate the use of the respective reference frame (body- or gaze-centered). With regard to gaze-dependent coding we only obtained significant correlations in the moved condition but not in the stationary condition, which is in line with our previous results. Interestingly, we found significant correlations in body coordinates in both conditions (stationary

and moved), indicating a predominant use of a body-centered reference frame in the stationary condition and the use of both body- and gaze-centered reference frames when the target hand was moved before the reach. Our results suggest that gaze-centered coding of somatosensory reach targets depends on the presence of an effector movement, while body-centered coding is immanent.

Title: Haptic guidance needs to be intuitive not just informative to improve human motor accuracy

Authors: *W. MUGGE, I. A. KULING, E. BRENNER, J. B. J. SMEETS
Fac. of Human Movement Sci., VU Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Humans make both systematic and random errors when reproducing learned movements. Haptic guidance can improve human motor performance through assistive forces that provide additional information about the desired movement. Forces that guide the operator to the target feel intuitive and provide information about the direction and distance to the target (through force scaling). Our study examined whether haptic guidance needs to be intuitive to be useful, or whether it is the additional information about the target's position with respect to the hand that improves the operator's performance in a position reproduction task. We applied force fields that scaled the force exerted to the subject's arm linearly with the distance to the target, exerting no force at the target position. Non-guiding force fields do not affect position accuracy[1], so we hypothesized that without time constraints subjects would reproduce a prior position equally accurately with 90 degrees (Perpendicular) or 180 degrees (Opposing) rotated guidance as with guidance directed towards the target (Assisting), because the guidance forces provide the same information to the subjects. Ten subjects (30.8 (SD 9.3) years, 6 male and 4 female, all right handed) made a series of reaches to visible targets with a haptic device (PHANToM Premium 3.0/6DoF). The reaches were performed in pairs of trials towards the same target, first

with and then without visual feedback about their hand position. The end-point accuracy (systematic error) and precision (random error) in the blind trials were assessed in four conditions (blocked design): no, assisting, opposing and perpendicular guidance. Both the accuracy and precision were significantly better with assistive guidance than in all other conditions. With opposing and perpendicular guidance, subjects took significantly longer to complete a reach and their performance did not differ from performance without haptic guidance. This study shows that haptic guidance only improved position reproduction when using it was intuitive. Subjects ignored the same information when presented non-intuitively, even in this static case without time constraints. References 1. Kuling IA; Brenner E; Smeets JBJ. Title: The effects of aging on proprioceptively guided reaching movements in three dimensional space

Authors: *T. I. GONZALES[1], T. S. SCHAAP[2], T. J. W. JANSSEN[3], S. H. BROWN[1]
[1]Univ. of Michigan, Ann Arbor, MI; [2]VU Univ., Amsterdam, Netherlands; [3]Amsterdam Rehabil. Res. Inst., Reade, Netherlands

Abstract: Aging is associated with impaired upper limb proprioceptive acuity, as reflected by decreased position matching accuracy with increasing task complexity and movement extent. Studies have shown that older adults have greater difficulty reproducing limb position when interhemispheric transfer of proprioceptive feedback is required (Adamo et al., 2007,2009; Herter et al., 2014) although limb asymmetries, thought to reflect non-dominant specialization for position sense (Sainburg 2002; Goble et al. 2006), persist in older populations (Adamo et al. 2007). Most studies have primarily used single joint or planar paradigms to examine age-related changes in proprioception. It is unclear whether these changes can be generalized to more complex multi-joint movements, where additional sensory feedback may affect performance. For example, King & Karduna (2013) found no differences in matching accuracy between the preferred and non-preferred arms when young adults performed a proprioceptive reaching task in

the vertical plane. Since age-related declines in cognitive function may impair the ability to integrate multiple sources of sensory feedback (Goble et al. 2009), deficits in position matching ability in older adults may persist when tasks are performed in three dimensional space. The accuracy with which young and older participants reproduced remembered reference hand positions was assessed under different experimental conditions. Participants matched reference positions located directly to the front or 45° to the side relative to the midline using the preferred and non-preferred arms. Either the same (i.e. ipsilateral matching) or the opposite (i.e. contralateral matching) arm was used to reproduced the reference position. No significant differences in matching accuracy were found between young and older participants when matching ipsilaterally. When matching contralaterally, accuracy was significantly worse in older participants for reference positions located to the side, which may reflect age-related changes in the perception of peripersonal space (Ghafouri & Lestienne 2000). In contrast to previous studies, accuracy did not differ between the preferred and non-preferred arms in either group. These results extend previous findings demonstrating age-related impairments in proprioceptively guided arm movements when interhemispheric transfer is required. Additional sensory feedback when reaching in three dimensional space may attenuate differences in limb asymmetries found in previous position matching studies.

Title: Precision of arm position sense strongly depends on arm configuration

Authors: *K. OH[1,2], B. I. PRILUTSKY[1,2]
[1]Applied Physiol., [2]Ctr. for Human Movement Studies, Georgia Inst. of Technol., Atlanta, GA

Abstract: Arm position sense is not uniform across the arm workspace. Several studies have shown that precision (random error) of reproducing a target hand position is significantly lower when the hand is away from the body than when it is closer to the body; similarly, precision of

reproducing target hand positions in the left-right direction is lower than that in the forward-backward direction (van Beers et al 1998; Wilson et al. 2010). The non-uniformity of hand position sense precision is poorly understood. It is generally agreed that the muscle spindles are a major contributor to arm position sense, and their signals encode joint angles. We hypothesized, based on known geometric properties of a two-segment kinematic chain, that less precise hand position sense observed in locations away from the body may be caused by relatively smaller changes in the joint angles for the same hand displacement. To test this hypothesis, we conducted a geometric analysis of a two-segment kinematic chain representing the human arm for the hand horizontal workspace. The analysis involved derivation of the Jacobian for the arm model, and the associated norm, condition number, eigenvalues and eigenvectors to investigate the error amplification of hand position due to small errors in joint angles. The analysis revealed the theoretical distribution of hand position error amplification in the horizontal workspace. To test the theoretical predictions for the hand position sense precision, 7 healthy subjects performed two arm position matching tasks without visual feedback using a bimanual robot Kinarm (BKIN, Canada). In the first task, Kinarm repeatedly moved the dominant right hand in 4 positions in the horizontal workspace in random order, and the subject was instructed to match joint angles of the left arm to the joint angles of the right arm. In the second task, the subjects were instructed to match the left hand movement distance and direction from the initial hand position to those of the right hand. The experimental precision distribution at each target location was described by a best-fit ellipse and compared with the theoretical predictions. The results demonstrated close similarity in terms of the area and orientation of the precision distribution between the experiments and theoretical prediction. The theoretical and experimental precision level was lower in the left-right direction than in the forward-backward direction, in agreement with previous studies (van Beers et al 1998; Wilson et al. 2010). We concluded that the arm configuration contributes substantially to the precision of arm position sense across the arm horizontal workspace.

Title: Identification of functional muscle synergies for the control of gravitational loads during reaching movements

Authors: *E. V. OLESH[1], W. J. TALKINGTON[2], V. GRITSENKO[2]
[1]Erienne V Olesh, Morgantown, WV; [2]Human Performance, Physical Therapy Div., West Virginia Unversity, Morgantown, WV

Abstract: Forces produced during multi-segmental limb motion constitute a challenging set of parameters that must be controlled by the central nervous system. However, the modalities of neural control signals that reflect the controlled parameters and produce muscle contractions are a matter of active debate. We have addressed this issue by investigating the role that gravitational and motion-related joint torques may play in the formation of muscle synergies for movements of the arm. We recruited healthy subjects to perform reaching tasks in a center-out paradigm. These reaching tasks originated from either a medial (center of the trunk) or lateral (side of the body) starting position. The hand movements were either in a vertical or horizontal planes. Both limbs were tested. Using a virtual reality system (Oculus Rift and Vizard, WorldViz Systems), a total of fourteen targets were arranged around each starting location in a circular pattern. Subjects were instructed to start at one of the four initial positions (two for each limb) and move as quickly and as accurately as possible to the target of interest, which was indicated by a color change. Each trial was completed when the subject returned to the initial starting position. Fifteen movements to each target were completed in a randomized order. Electromyography data was recorded from twelve muscles of each arm using Motion Lab systems. In addition, kinematic data was collected using the Impulse motion capture system (Phasespace). Data were then processed using custom scripts written in Matlab (MathWorks). Motion capture data were used to calculate joint angles for shoulder, elbow, and wrist. These angular kinematics were then used to calculate joint torques, which were subdivided into gravitational and motion-related components. We then applied a decomposition analysis to examine the relationship between joint torque components and muscle activity profiles. We have shown that joint torque components can be used to decompose muscle activity profiles for individual movements. This suggests that separate functional muscle synergies may exist for the production of voluntary motion and for the compensation for loads due to gravity.

Title: Haptic fMRI: Mapping neural activation during planning and reaching for unconstrained three degree-of-freedom tasks

Authors: *S. MENON, M. YU, H. GANTI, K. BOAHEN, O. KHATIB
Stanford Univ., Stanford, CA

Abstract: Recent advances in combining haptic interfaces, robots that are designed to monitor and perturb human motion, with high resolution functional magnetic resonance imaging (Haptic fMRI) have enabled non-invasive experiments that study spatial reaches, visually guided trajectory tracking, and object manipulation in virtual worlds [1]. Here, we use Haptic fMRI to demonstrate that unconstrained three degree-of-freedom motions can elicit heterogeneous neural activation at the millimeter spatial scale. The activation is task specific and spans motor, somatosensory, and pre-motor cortex; the former two exhibit motion-related activation and the latter also exhibits planning related activation (Fig. 1). In contrast with classical limb-mapping experiments [2,3], where different joints elicit correlated neural activation in individual voxels, our fMRI time-series measurements differ dramatically across brain regions and tasks. Such activation time-series are not well explained by generalized linear models with canonical haemodynamic response functions. To compensate, we used an impulse response model to factorize the time-series for each voxel into task-specific components, which helped capture neural activation heterogeneity. Plotting the impulse response model predictions on an inflated brain helped localize motor planning to a sub-section of pre-motor cortex (see Fig. 1, inflated brains; c.s, central sulcus). The primary motor and somatosensory cortices, in contrast, exhibit a reduction in signal during planning and, with some parts of pre-motor cortex, a wide-spread increase during reaching. The lack of time-series correlations at a millimeter spatial scale indicates that our experiment is unaffected by common fMRI artifacts like head motion or magnetic field drift, which induce low spatial-frequency correlations across brain regions. 1. Title: Using single pulse microstimulation to assess excitability of cortical microcircuits

Authors: *D. S. SOTEROPOULOS
Inst. Neurosci, Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Intracortical microstimulation has been (and still is) one of the mainstay techniques used in movement neuroscience for assessing motor cortical function and connectivity in animal models. Single pulse intracortical microstimulation (sICMS) is well suited to assess cortical connectivity as it often elicits responses in other nearby cortical neurones and the short (<2ms typically) artefact duration means that short latency responses can be reliably measured (using a Peri-Stimulus Time Histogram - PSTH). Whilst these responses are used to characterise how cortical sites interconnect, this technique has not been used to assess connectivity changes during behaviour. Changes in response probability during behaviour may provide a measure of cortical excitability but there are a number of factors that need to be accounted for. An important factor is the non-stationary spiking rate during behaviour - changes in background activity are likely to affect the impact of the cortical stimulus on spiking probability even if there is no underlying change. The feasibility of this approach was tested on motor cortical data collected from an awake behaving monkey during microstimulation. We first examined whether we could model the early excitatory response of cortical neurones often seen in response to sICMS. A non-leaky "integrate and fire" neurone model of the cortical cell was created, that matched the interval spike statistics and time varying spiking rate of the real neurone. A simulated excitatory post-synaptic (EPSP) response was then added to the input of the simulated neurone at regular intervals - this corresponded to the "sICMS". The size of this EPSP was adjusted so that the response in the simulated PSTH matched that in the real PSTH. This allowed us to test what the expected changes in response size would be at different background rates, assuming a constant EPSP amplitude. This was applied to cortical neurones responding at short latency to callosal stimulation or to cortical neurones responding to microstimulation of an adjacent microelectrode. For the callosally responding cells (n=3), the changes in response probability with background firing rate of the real cells was well matched by our simulations, as expected given that axonal tract stimulation should produce an invariant post-synaptic response. For cortical neurones responding to sICMS (n=3) this was not the case, particularly for higher firing rates (which typically corresponded to movement epochs). This discrepancy may correspond to changes in cortical excitability during movement.

Title: Spatial bias, the superior colliculus and prism adaptation

Authors: *A. CHAUDHARI[1,2], A. BARRETT[1,2]
[1]New Jersey Med. Sch., Newark, NJ; [2]Kessler Fndn., West Orange, NJ

Abstract: Objective: To demonstrate that externally modifying superior colliculus activity may lead to observable changes in spatial bias. Background: Sprague 1966 first described an experiment where ablation of the contralesional superior colliculus (SC) led to improvements on spatial tasks in cats with induced parietal neglect. Since then, studies have shown that: (1) isolated deactivation of the SC may result in asymmetric spatial behavior, and (2) right visuoparietal damage may reduce input and activity in the ipsilesional SC. We hypothesized that stimulating the right SC may alter spatial performance bias. We also compared this effect with prism adaptation. Methods: A.A. is a 29-year-old woman who presented with spatial bias and extinction following a right midbrain/collicular hemorrhage. On Visit 1, A.A. underwent a computerized line-bisection task with and without SC stimulation with dual rotating checkerboards and right hemi-patching. For comparison, on Visit 2, A.A. underwent the task before and after one prism adaptation training session (PAT; Goedert et al., 2013). Results: A significant change in line bisection error was observed with both SC stimulation [baseline mean=-2.1±6.53mm, stimulation mean=+2.2±5.36mm; $p<0.01$] and PAT [pre-prism mean=-3.0±5.07mm, post-prism mean=-0.7±5.42mm; $p<0.05$]. However, both SC stimulation and PAT shifted Aiming, motor-intentional errors rightward. This rightward shift tended to be higher in far space (SC $p<0.05$; PAT $p=0.07$). Discussion: Superior colliculus activation and PAT may alter spatial bias via related mechanisms. In our participant, who had right SC damage, left SC activation may have resulted from visual stimulation. We observed reduction in leftward Aiming bias, which may have especially affected far space. Further research investigating SC stimulation and its long-term effects may results in novel or more effective treatments for disorders such as spatial neglect.

Figure 1: fMRI scan of the participant in coronal (A) and sagittal (B) sections. Voxels in green exhibited significant differences in activity with and without SC stimulation. Cross hairs are placed at the approximate location of the superior colliculus, though the structure is difficult to distinguish because of the hemorrhage.

Title: Object grasp by the ipsilateral and contralateral hands evokes similar responses from posterior parietal cortex (PPC) neurons

Authors: *E. P. GARDNER[1], J. CHEN[1], J. L. BAKER[2]
[1]Dept Physiology/Neuroscience, New York Univ. Sch. Med., NEW YORK, NY; [2]Brain Mind Inst., Weill Cornell Med. Col., NEW YORK, NY

Abstract: The contralateral hemisphere has traditionally been implicated in sensorimotor control of each hand. However, we previously observed PPC responses to actions of either hand during natural grasping. To compare cortical representation of the hands during skilled prehension, we trained macaques to perform a reach-to-grasp instructed delay task, and recorded neural responses bilaterally in PPC. The protocols assess responses evoked by the left and right hands performing the same grasp task, and quantify firing rates when both hands act together. Five objects (represented as white icons on a monitor screen) were tested per session: two near each hand, and one at the midline. Icons of the rewarded object(s) were colored red after both hands were placed on the start keys; the animal maintained this posture during an 800-ms delay until the cue color changed to green. The animal was trained to reach, grasp and pull the object(s),

hold it for >800 ms, and then relax the grasp. The hand closest to the object was typically used to perform the task. Neural activity was recorded simultaneously from arrays of 32 implanted microelectrodes placed at symmetric locations in the PPC hand area of both hemispheres. Firing rates were compared during 8 planning and execution stages. Common patterns of activity occurred when the animal used the left, right, or both hands. Responses in the superior parietal lobule (SPL) to reach, grasp and pull by either hand were similar in time course, but were generally higher in rate to the contralateral hand. IPL neurons encoded the time course of hand actions, regardless of which hand was used to accomplish task goals. Firing rates during the delay period, when hand use was presumably planned, were lower than during action stages (reaching, hand shaping, grasping and pulling). Bimanual trials, when both hands performed the same actions in tandem, evoked prolonged spike trains that form a composite of responses to each hand alone. Bimanual spike trains reflected the timing of hand actions in single knob trials, and the trial duration was lengthened when both hands acted together. Hand preferences--percentage of trials in which each hand was used to grasp objects at the midline--are reflected in the left-right grasp sequence of bimanual trials, with the preferred hand leading the less preferred one. Bimanual coding may thereby play an instructive role in motor equivalence and skill learning when each hand performs the same movements.

Title: Cognitive motor interference regarding upper extremity function among stroke patients

Authors: *J.-H. SHIN[1], S.-D. EUN[1], S. JEONG[1], S. LEE[1], J. LEE[1], S. KIM[2], J. LEE[3], H. CHOI[1]
[1]Rehabil., Natl. Rehabil. Ctr., Seoul, Korea, Republic of; [2]Hanyang Univ., Seoul, Korea, Republic of; [3]Seoul Natl. Univ. Bundang Hosp., Seongnam, Korea, Republic of

Abstract: Background: Cognitive deficit after stroke is such a common symptoms that that cognitive aspects should be regarded as an important issue in the stroke patients with motor impairments. The concept of "cognitive motor interference" has been arisen to explain the situation, where cognition and motor interferes each other. We sought to characterize the cognitive motor interference during reaching in stroke patients and normal controls and to identify the relationship between motor and cognitive performance. Methods: A total of 16 stroke patients and 12 normal control subjects were enrolled. They completed midline reaching with five different kinds of cognitive tasks (COWAT categorized test, serial 7 subtractions, auditory clock, and judgment of line orientation test), or without task. The reaching performance was measured with the help of motion analysis system (VICON, Oxford, UK) using plug-in upper limb model market set. Generalized estimation equations was applied for statistical analysis using SPSS 18.0 Results: 1) Stroke versus control During reaching using affected or non-dominant hand, forward peak velocity showed significant difference between cognitive tasks and groups (stroke, normal control), and backward peak velocity showed interaction (cognitive task x group) and significant difference between groups. During reaching using unaffected or dominant hand, forward peak velocity showed significant difference between groups, and backward peak velocity showed significant between cognitive tasks. 2) Affected versus unaffected hemisphere During reaching using affected hand, there was no difference between affected hemispheres and cognitive tasks in terms of forward and backward peak velocity. During reaching using unaffected hand, forward peak velocity differs according to the cognitive task, but not affected hemisphere. 3) Mild versus moderate motor impairment During reaching using affected hand, forward peak velocity was different according to the cognitive tasks and backward peak velocity was different according to the motor impairment severity. During reaching using unaffected hand, there was no difference between different cognitive tasks and motor impairment severity. Conclusion: These findings demonstrate the cognitive motor interference in upper extremity performance among stroke and normal control, which is more evident with stroke patients. The interference depends on the cognitive task, and it was definite according to the motor impairment level. Thus we hypothesize the cognitive motor interference is derived from combination of motor and cognition capacity.

Title: Abnormal muscle patterns underlie poor upper limb control during reaching in children with dystonia

Authors: *M. BERTUCCO[1], C. NGUYEN[1], T. D. SANGER[2]
[1]Biomed. Engin., [2]Biomed. Engineering, Child Neurology, Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstract: Childhood dystonia has been defined as a movement disorder in which involuntary muscle contractions cause twisting and repetitive movements, abnormal postures, or both. Abnormal upper extremity movements are a disabling and poorly understood symptom of this disorder. Kinematic studies have shown increased random movement variability of multiple joints during reaching that may be the external consequence of the inability to suppress unwanted components of movement due to basal ganglia dysfunction. Little is known about the pattern of muscle activity that leads to abnormal postures in children with dystonia during multijoint goal-directed movements. Therefore, the aim of this study was to describe the spatio-temporal characteristics of muscle activity that underlie impaired movement execution during multjoint reaching in childhood dystonia. Twenty-one children with primary and secondary dystonia (D) and age-matched healthy control children (C) were recruited in the study. The subjects were seated and used the index finger to reach a target (width 3 cm) distanced approximately 90% of the arm's reach length from the body as fast and accurately as possible. Kinematic data were recorded using a magnetic tracking device with eight sensors attached at the bony landmarks of the principal upper limb joints. The electrical activity of eight upper limb muscles was recorded using surface electromyography (EMG). We found significantly longer movement times (on average C = 0.680 and D=1.056 s; $p< 0.01$) and less accurate performance, computed as the endpoint variability at the target, (on average C = 0.46 and D=2.11 cm2; $p< 0.01$) in children with dystonia. Additionally, children with dystonia showed a larger variability (measured as standard deviation) both at distal (hand, C = 4.1 and D=6.1 cm; $p< 0.01$) and proximal joints (shoulder, C = 1.3 and D=1.9, $p< 0.01$). Principal Component Analysis on the kinematic data, computed on the three-dimensional joint trajectory, showed a lower signal-to-noise ratio in group D with respect to group C. The EMG analysis showed an abnormal tri-phasic muscle pattern throughout the movement in group D. Although both groups showed similar magnitudes of co-contraction either at the shoulder and elbow joints, group D displayed a different time-varying co-contraction with a distinctive ramp pattern while approaching the target. The results suggest that abnormal spatio-temporal activation of agonist-antagonist muscles contribute to the

abnormal postures in childhood dystonia, and lead to jerky and imprecise trajectories during reaching.

Title: Advanced techniques for the computational modeling of human movement

Authors: ***G. G. GAMBLE**, M. YAZDANI, R. HECHT-NIELSEN
UCSD, San Diego, CA

Abstract: Computational modeling has been a successful tool in describing many aspects and characteristics of human movements. While such models typically have a sound theoretical and mathematical foundation, their interpretations and neuronal implementations in the human motor system are not clear. We propose several techniques that enable an analysis of computational models that elucidate the neural implementation and behavior of the underlying motor system. We offer methods which can transform existing, purely mathematical models into models that represent anatomy and physiology more directly, thus rendering these models easier to interpret in terms of the motor system. For example, we show how to convert most optimal control models of movement from utilizing continuous control signals to instead utilizing sparse control signals. Even though sparse signals are discontinuous, the movements that result are continuous and smooth. Such sparse control signals have a clear neuronal interpretation as a sequence of spikes. These control signals are qualitatively simpler than their non-sparse counterparts, yet yield comparable if not better results when applied towards modeling human movements. We demonstrate this by quantitatively comparing this technique to human reaching movements. In addition, we discuss new ways to visually analyze data of human movement as compared to computational model output. Other related techniques will also be discussed.

Title: Bayesian filtering of surface electromyography as a human-computer interface

Authors: *A. FEINMAN, M. BERTUCCO, N. H. BHANPURI, T. D. SANGER
USC, Los Angeles, CA

Abstract: Surface electromyography (sEMG) has shown tremendous promise as a non-invasive human-computer interface (HCI) for patients with motor system impairments, such as amputation or dystonia. In previous work, our group has shown that controlling the sEMG signal (i.e., myocontrol) through the implementation of non-linear Bayesian filtering algorithms for sEMG. opens the possibility of using sEMG to control devices without complex post-processing algorithms. In this study, we used sEMG with Bayesian filtering for real-time control of a robotic arm. Four subjects were given control of two degrees of freedom (vertical and lateral endpoint position). Control of the robot was examined using a paradigm similar to the original Fitts' Law experiment (Fitts 1954). In each trial, a pair of bars was presented to the subject, and they were asked to tap the robot endpoint back and forth between the two bars as quickly as possible without missing. Subjects generated isometric contractions of the FCU and biceps by grasping a rod fixed to their chair, with FCU controlling lateral position and biceps controlling vertical position. When the subject was at rest, the robot endpoint rested in one of the bars. Subjects had to control their contractions and relaxations to tap between the bars. The two bars were identical in shape in each trial, but the width of the bars and/or the distance between the bars varied across trials to generate six indices of difficulty in the range of 1-4 bits. The forward movement of successful forward-and-back movements was analyzed. Movement times of the forward movement for successful trials ranged from 0.6-0.9 seconds across the set of IDs. The index of performance across these 4 subjects with little practice was 9.1 bits/s, as compared to 10.3 bits/s as reported during use of a computer mouse (Card, English, and Burr 1978). This data shows that Bayesian filtering of sEMG has the capacity to serve directly as an HCI for simple movement tasks. Control of more complex systems, such as myoelectric prosthetics, may be improved through use of this method. Furthermore, examining how healthy and impaired individuals learn to use myoelectric devices may provide an insightful comparison to how both healthy and diseased sensorimotor systems control bodily limbs.

Title: Using non-negative matrix factorization as a filter to improve usability of myocontrol

Authors: ***C. NGUYEN**[1], M. BERTUCCO[1], D. J. BERGER[2], A. D'AVELLA[2], T. D. SANGER[1]
[1]USC, Los Angeles, CA; [2]Santa Lucia Fndn., Rome, Italy

Abstract: For children with dystonia, prosthetic devices can provide mobility, manipulation, and functional communication. However, the goals of prosthetic control in children with impairments need to be different from those in adults. Children need flexible interfaces whose motions are not described in advance, so they can develop their own movements and explore varying and unpredictable goals. We use electromyographic control ("myocontrol") to accomplish this. Surface EMG is a non-invasive way to capture EMG, but the high level of noise makes it difficult to use in real-world applications. Furthermore, it has proven difficult for even healthy adults to learn myocontrol with multiple degrees of freedom. These issues may be addressed with Bayesian non-linear filtering of EMG and dimensionality reduction from the high-dimensional muscle space. We have developed a Fitts' Law paradigm to assess the information transmission during myocontrol. Previously, we showed that myocontrol in healthy young adults using single muscle control with Bayesian-filtered EMG has a performance level comparable to that of force control. In this study, we tested whether muscle synergies affect the feasibility of myocontrol in young healthy adults, children with dystonia and age-matched controls by comparing 3 different myocontrol conditions: (1) single muscle control, (2) all muscle control, (3) synergy control. Subjects moved a cursor in two-dimensions in an isometric point-to-point reaching task using myocontrol. In single muscle control, one muscle corresponded to one dimension of movement. For our task, the flexor carpi ulnaris moved the cursor horizontally and the biceps moved it vertically. For all muscle control, EMG from 8 muscles was mapped to the 2-dimensional plane using multiple regression with the torque direction. For synergy control,

synergies were identified using non-negative matrix factorization. Fitts' Law was used to calculate the average index of performance (IP) for each synergy in the analogous 1-D task. The 3 synergies with the highest IPs were then used to control the cursor in the 2-D task. The speed-accuracy tradeoff across the 3 different myocontrol conditions was similar in controls, however, performance improved for children with dystonia. Results suggest that dimensionality reduction may act as an additional, personalized filter in noisy EMG. This work will also improve our understanding of the existence of synergies in dystonia and direct future research in rehabilitation.

Title: An empirical validation of the cost of effort during arm-reaching

Authors: *A. A. AHMED
Integrative Physiol., Univ. Colorado, BOULDER, CO

Abstract: An optimization approach has proven particularly successful in developing theoretical models of movement control. The underlying theory is that the brain optimizes movement over the following cost function that includes a cost for error and a cost for effort, representing the intuitive idea that one generally seeks to move in the most accurate and most efficient manner possible. Models implementing such cost functions have done an impressive job explaining behavioral observations at multiple levels of analysis and in multiple tasks. However, there is an increasing amount of experimental observations that deviate from optimality. This highlights a fundamental assumption that limits this approach's explanatory power. The difficulty of directly measuring movement effort costs forces one to make a priori assumptions about how the

movement effort costs are represented. Models that penalize effort as a function of squared force, squared torque, square rate of toque development have all been able to predict human motor behavior, without any experimental validation of the actual effort cost. Here we measure effort costs directly in the form of metabolic rate, via expired gas analysis, in a variety of reaching tasks, to determine the function that most appropriately represents effort costs during human reaching movements. Subjects made planar reaching movements while grasping the handle of a robotic arm. They reached at a number of different speeds, to different distances, at prescribed curvatures, and against different resistances. During all reaching movements we measured metabolic rate via expired gas analysis. We developed a two-link arm model and simulated the reaching movements in the experiments. For each movement, we calculated effort costs that have been historically successful in predicting reaching trajectories or metabolic cost in locomotion: mechanical work, torque squared, rate of torque development squared, and more. We also calculated the sum of absolute force, as it has been hypothesized that effort should track linear force. Model-calculated efforts costs were compared to experimentally measured effort costs to determine the best representation of effort cost during reaching movements. Preliminary results show that a linear cost on force and mechanical work did a poor job of predicting movement trajectories, compared to torque-squared. Thus far, these findings provide empirical support for the quadratic effort term commonly implemented in optimal control models of arm-reaching.

Title: The two learning systems in motor control: reward vs. sensory prediction errors

Authors: *P. VASWANI[1], R. SHADMEHR[2]
[1]Dept. of Neurosci., [2]Dept. of Biomed. Engin., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The difference between the expected and actual consequences of action, called sensory prediction error (SPE), is a critical signal for motor learning. However, many studies

have demonstrated that reward can influence behavior. Typically, these two goals are congruous; actions that minimize SPE also maximize reward. However, the neural bases of learning from these two signals are separate. When faced with conflicting signals, how does the brain select behavior? We asked subjects to make reaching movements and, using two viscous force fields or visuomotor rotations, presented subjects with two sensory consequences (cursors) for each action. If subjects can learn actions that maximize reward, they should learn the mapping of actions to one consequence and ignore the large errors in the other. Instead, subjects chose actions that minimized SPE across trials, forsaking reward. We found that even when subjects were taught a rewarding solution, when presented with both perturbations unpredictably, they chose actions that minimized SPE but did not maximize reward. Next, we presented subjects with both sensory consequences in a single trial. In this case, there was no SPE, but both perturbations were present. Subjects did not adapt to the mean perturbation, and instead selected a rewarding solution. To verify that the reward (points) in our task was affecting behavior, we presented subjects with both perturbations simultaneously, but consistently rewarded only one of the consequences. We observe that subjects always selected the rewarding solution. Therefore, when faced with no SPEs, actions maximized reward. However, when faced with SPEs, actions appeared blind to reward. Finally, we asked if a strong reward signal could overcome the hegemony of learning from SPE. We provided subjects with a mild SPE by coloring one of the two cursors, unpredictably. When both cursors were rewarded, i.e. in the presence of a strong reward cue, subjects' behavior was biased by the SPE, but they were able to maintain behavior that resulted in task success. However, when we reduced the frequency of the reward, in the presence of the mild SPE, subjects no longer maintained a solution that received reward, and instead reduced the SPE. Sensory prediction error provides a strong learning signal to the motor system that dominates behavior, even when it results in a reduction in reward. In the absence of an SPE, the motor system can maximize reward. Only when SPE is mild and a strong reward signal is provided do we observe a balance between the two systems. Otherwise, sensory prediction error dominates motor learning.

Title: Does task engagement level affect how we move?

Authors: *Y.-A. CHEN, Y.-C. CHUNG, B. KIM, C. WINSTEIN
Div. of Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstract: High subjective engagement level is consistently found when motor tasks are performed under virtual or augmented reality conditions. In previous work, attentional demand was greater during a reach task to a virtual target compared to a real target. More importantly, engagement level was generally higher in the more difficult virtual compared to the easier real target condition. This study investigated the impact of engagement level on movement strategy by comparing reach kinematics for those with low- or high-engagement ratings during virtual target (VT) and real target (RT) conditions. Using a within-subject design, 15 participants (59-88 yrs old) performed reach movements to targets arranged in a circular 8-target pattern; there were 48 reaches per condition and each from standing and stepping. A Kinect™ camera positioned in front captured each reach; position data were resampled at 12Hz. Movement onset/offset was defined as the first time at which the tangential velocity of the wrist virtual marker was above/below 1 cm/s. Kinematic variables included movement time (MT), time to peak velocity (TTPV), and time after peak velocity (TAPV). Participants' self-assessed engagement to each condition was acquired using a 5-level Likert scale for a single item administered after reaching. Participants were categorized into low-, neutral- and high- engagement (E) groups based on scale scores. Reaches from standing to VT for participants with high-E showed longer MT than those with low-E; the longer MT was attributed to longer TAPV. Interestingly, MT for reaches from stepping to VT were independent of engagement. However, in spite of similar MT, the high-E group demonstrated shorter TTPV and longer TAPV than the low-E group. For easier reaches to RT, there was no evidence that engagement level modulated any kinematic measure. These findings provide indirect evidence that engagement level may impact movement strategy, but only for relatively difficult tasks. Reaches to RT were relatively easy (from open-ended post-interview); RT reaches exhibited a symmetric velocity profile suggestive of a default strategy regardless of engagement level. In contrast, during more challenging VT reaches, a high-E level was associated with slower movements and a prolonged homing-in phase. We speculate that high-E may harness more attentional resources toward goal achievement. These preliminary group level findings suggest an interaction between engagement level and task difficulty on movement strategy. Further analysis of individual-subject variability within engagement level groups is needed to confirm or refute the group level analysis.

Title: Characterization of visuomotor behavior in patients with schizophrenia under a 3D-depth inversion illusion

Authors: *J. NGUYEN, S. M. SILVERSTEIN, T. V. PAPATHOMAS, E. B. TORRES
Rutgers Univ., New Brunswick, NJ

Abstract: Evidence has shown that patients with schizophrenia (SZ) are less susceptible to experiencing depth-inversion illusions (DIIs) (Keane et al., 2013; Dima et al., 2009; Koethe et al., 2006; Schneider et al., 2002). DIIs produce illusory motion and perceived depth reversal of scenes or objects in which physically concave angles are perceived as convex and vice versa (Papathomas, 2007). It has been hypothesized that the observed reduction in sensitivity to DIIs may be due to reduced ability to apply stored knowledge to visual perceptual processes. How this anomaly translates to sensory motor processes and kinesthetic sensing is largely unexplored in SZ. We examine the signatures of motor output variability of continuous reach-to-grasp motions in a number of patients with SZ in relation to typically developing controls. They are asked to reach for an embedded target on a 3D-DII. Specifically, we study motions with different levels of intent: the goal-directed reach deliberately aimed at the target, and the transitional, non-instructed retraction of the arm as subjects bring their hand to rest. The signal-to-noise patterns embedded in the motor output variability of these continuous motions are a form of kinesthetic re-afference. From trial to trial, their modulation and central control depend on the continuous returning afferent stream, which those motions themselves cause. In typical controls, their stochastic signatures discriminate between the different levels of intent, but these patterns are disrupted in clinical populations, including autism and Parkinson's disease (Torres et al., 2013; Yanovich, et al., 2013). Since little is known about sensory-motor integration and kinesthetic re-afference sensing in SZ, especially in the transitional movement domain, we here aim to characterize any perturbations that may arise in addition to visual perceptual impairments. Two 3D stimuli were used: (1) a proper-perspective in which perspective-painted cues are congruent

with the bottom-up signals of binocular disparity and motion parallax, and (2) a reverse-perspective, in which the painted cues competed with bottom-up signals, eliciting bistable percepts of: (a) veridical depth and (b) illusory reverse-depth percept in which concave parts are perceived as convex and vice versa. The control subjects viewed the stimuli and grabbed at planar disk targets while we recorded their movements. Their signatures of motor output variability could automatically discriminate levels of intent and illusory state. We discuss signatures of motor output variability for the SZ patients in relation to the control subjects.

Title: Identifying MI/PMv neural ensemble states associated with motor errors using spike train similarity analysis

Authors: *T. C. WHALEN[1], C. E. VARGAS-IRWIN[2,3], J. P. DONOGHUE[5,2,4,3]

Abstract: Neural encoding of movement-related variables is frequently examined within the context of instructed delay tasks. Analysis typically focuses on trials where the subject correctly interprets the instructions, choosing an action previously associated with a specific cue. Here, we compare neural activity patterns associated with correct and incorrect action selection: in addition to decoding what action was ultimately executed, we use neural activity patterns to identify trials in which the instructional cue was not correctly interpreted. We trained three male rhesus macaques to perform a reach-and-grasp task in which a cue for one of two grips is given followed by a go cue. Data was recorded from motor cortex (M1) and ventral premotor cortex (PMv) using chronically implanted microelectrode arrays. Single unit activity was sorted using an automated density-based algorithm (Vargas-Irwin and Donoghue 2007). We projected spiking activity during the delay between grip and go cues into a spike train similarity space (SSIMS) to evaluate the relationship between spiking patterns. The SSIMS algorithm produces a low-dimensional representation of neural activity where the distance between points quantitatively represents the similarity between recorded ensemble states. We find that correctly executed trials produce a consistent progression of ensemble states that clearly separate clusters associated with specific grip strategies. Error trials diverge from this set of trajectories, traversing ensemble states which are not normally encountered in correctly executed trials, despite identical actions being performed. Error trajectories diverge from normal trajectories at various times, including errors occurring during cue encoding as well as grip selection. Using SSIMS models, we successfully differentiate between correct and error trials for a given action with accuracy significantly higher than chance. We find no significant differences between classification accuracy in M1 and PMv, and find that small ensembles of approximately ten neurons are generally sufficient for classification. These findings suggest the existence of a neural signature of errors present in cortical motor areas. Early detection of these possible error states may contribute to designing more accurate neural decoding algorithms for use in brain computer interfaces.

Title: Inverse vs forward dynamics analysis of join control during arm movements

Authors: *N. DOUNSKAIA, W. WANG
Arizona State Univ., Phoenix, AZ

Abstract: During multi-joint movements, the limb segments mechanically affect each other, and therefore, the joints cannot be controlled independently. How the brain organizes control of multi-joint movements has been extensively studied. Inverse dynamics models have been used with this purpose for longer than 40 years. They allow the assessment of the contribution of active and passive torques to net torque (NT) at each joint. More recently, the induced acceleration analysis (IAA) developed with the use of forward dynamics models has started to gain popularity. The IAA allows estimation of contribution of active and passive torques to joint accelerations. However, the IAA is more complex because it requires the usage of both the inverse and forward model. In addition, interpretation of passive factors that contribute to joint accelerations is not straightforward. We compared the inverse dynamics analysis and the IAA by applying them to 3D arm movements performed during a free-stroke drawing task. The task requires the production of series of strokes from the center to the perimeter of a horizontal circle while selecting stroke directions in a random order. In our previous studies, subjects performed the free-stroke drawing task while keeping the arm in the horizontal plane. An anisotropic distribution of strokes revealed directional preferences. The inverse dynamics analyses demonstrated that the preferred directions were characterized by a specific control pattern of the shoulder and elbow during which one joint was rotated actively, by muscle torque (MT) and the other joint was rotated predominantly passively, by interaction torque (IT). In the present study, gravitation torque (GT) affected joint motions in addition to IT and MT. The inverse dynamics model was used to compute two characteristics, a contribution of passive torque (PT=IT+GT) to NT and impulses of MT, IT and GT. The IAA was used to compute the contribution to joint acceleration of MT, GT, and other passive torques that depended on joint velocity as well as on MT and GT applied to the other joints. All three analyses revealed the same pattern of joint control in both the preferred and non-preferred directions. The interpretation of the passive mechanical factors influencing joint motions was more straightforward when the inverse dynamics analyses were used. We conclude that, if a general pattern of joint control needs to be assessed, inverse dynamics analyses are adequate, and may be preferable due to simplicity and straightforward interpretation of inter-segmental dynamics effects. However, the IAA may be advantageous for precise assessment of the contribution of various factors to joint accelerations.

Title: Influence of gravity on direction preferences of arm movements

Authors: *W. WANG[1], N. DOUNSKAIA[2]
[1]Kinesiology Program, Arizona State Univ., TEMPE, AZ; [2]Kinesiology Program, Arizona State Univ., Tempe, AZ

Abstract: We previously demonstrated directional preferences during horizontal arm movements with the use of a free-stroke drawing task. Subjects produced strokes with the fingertip from the center to the perimeter of a horizontal circle, selecting movement directions in a random order. An anisotropic distribution of strokes revealed preferred directions. They were characterized with a specific joint coordination pattern that included active control by muscle torque (MT) of either the shoulder or elbow (the leading joint) and passive motion, due to interaction torque (IT), of the other (trailing) joint. The wrist was voluntarily fixed in all directions. Here, we investigated the influence of gravitational torque (GT) on the directional preferences. Again, the free-stroke drawing task was used but the circle was orientated in two vertical planes, frontal and sagittal. Also, the arm's joints were allowed to rotate in 3D space. Frequency of stroke production across directions and torques at the three joints were computed. Preferred directions were apparent in both conditions. In all preferred directions, at least one joint, either the shoulder or elbow, was accelerated largely by passive torque (PT=IT + GT). In each condition, there was one preferred direction in which GT also played a dominant role in accelerating the other joint. The wrist was predominantly fixed in all directions. The results supported the previous finding that there is a preference to passively rotate one of the two joints of the shoulder-elbow linkage (the trailing joint). In contrast to horizontal arm movements during which passive motion of this joint was produced by IT generated by motion of the leading joint, both IT and GT contributed to the trailing joint motion production during the non-horizontal movements. In addition, gravity was often exploited to substitute for MT in the production of motion of the leading joint (the joint that generated IT used to rotate the trailing joint). However, the possibility to rotate the leading joint by GT did not make these directions more preferred than those in which the leading joint rotated actively. This finding does not support the minimization of muscle energy expenditure as a primary factor that determines the anisotropic preferences of arm movements. Rather, the revealed directional preferences point to the use of the internal model of inter-segmental dynamics during movement planning for selection of movement directions in which neural control that provides coordination of joint motions during movement execution is simplified by using predominantly passive motion of at least one joint.

Title: Electrocorticographic decoding of high-level action goals following verbal instruction

Authors: *G. HOTSON[1], G. MILSAP[2], D. P. MCMULLEN[3], B. A. WESTER[5], W. S. ANDERSON[3], J. W. KRAKAUER[4], N. E. CRONE[4], N. V. THAKOR[2]

Abstract: Brain-machine interfaces have recently made great strides in allowing subjects to reach out and grasp objects. However, this is only the first step in enabling users to accomplish more complex action sequences. Brain-machine interfaces under direct neural control currently lack the speed and precision to perform complex action sequences to accomplish meaningful activities of daily living. Decoding high-level action goals would therefore be of great benefit, as this would allow for a semi-autonomous brain-machine interface to assume low-level control of the effector to perform the necessary action sequence. Here we show that a high-level representation of goal intention can be found in the high gamma signal of electrocorticography following verbal instruction cues. Subjects were first instructed with one of two high-level goals ("look" or "drink"), then instructed how to accomplish the goal ("arm" or "waist"), and finally they were given a "go" cue. Upon hearing the "go" cue, the subject inspected the water level of a measuring cup or drank from it with a straw. Either task could be performed by either bending at the waist or picking the cup up with their arm, depending on which cue they received. We found that the high gamma activity preceding the go signal was significantly modulated by the initial high-level goal cue ($p<0.05$, Tukey's test with Bonferroni correction for multiple comparisons

across time points). This activation was located in electrodes over the left posterior middle temporal gyrus, an area which has previously been implicated in decoding word semantics (particularly when manipulable tools are involved). An accuracy of 80% was achieved when classifying between the two high level goals when "waist" was the second cue. This classification was done during the time period immediately preceding the "go" cue through linear discriminant analysis with leave-one-out cross-validation. These results suggest that a user's high-level action goal can be decoded from electrocorticography, and can potentially be used to help operate a semi-autonomous brain-machine interface.

Title: Eye-hand coordination: Evidences for interaction at the level of motor planning

Authors: *A. GOPAL P A[1], S. JANA[2], A. MURTHY[2]
[1]Natl. Brain Res. Ctr., Bangalore, India; [2]Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: Eye-hand coordination appears to be a ubiquitous element underlying many of our skilled behaviors. It is still unclear how eye and hand systems, which are functionally and anatomically separate, are coupled to produce coordinated eye and hand movements when a task demands it. Though it is generally accepted that coordinated movements are generated by the interaction between these two separate systems, the computational architecture underlying such interaction remains unclear. While McPeek and colleagues have shown that eye and hand systems appear to index a common target selection stage, the possibility of interactions occurring between eye and hand effectors during motor planning, is not known. With this particular aim, we recorded the eye and hand movements of human subjects performing fast and slow hand

movements to a peripherally appearing target after a variable fixation time. No explicit instruction was given concerning the eye movements. The velocity instructions were given 1000 ms before the appearance of the target so that the subjects could prepare for the upcoming movement. This negated the confound that the reaction time of the subjects maybe influenced by the added decision making stage regarding the velocity to be employed for the current trial. Since visual and the positional attributes of the target were identical, differences across velocity conditions could be attributed to interactions during motor planning independent of target selection. The comparison between the trials of fast and slow conditions revealed that eye movements, though not explicitly instructed, were affected by the conditions. Eye movements had higher peak velocities when accompanied by a fast hand movement. The correlation between the eye and hand peak velocity, though low, was significant, and was sensitive to the hand velocity. We also observed a trial to trial variation in the amplitude of the eye and hand, which we attributed to inaccuracy at the level of target selection. However, even after the effect of amplitudes was regressed out, we observed a low but significant correlation between peak velocities of the eye and hand, which we attribute to interactions occurring during movement planning.

Title: Impedance-based communication for human-robot interaction

Authors: ***K. MOJTAHEDI**[1], B. WHITSELL[2], P. ARTEMIADIS[2], M. SANTELLO[1]
[1]Sch. of Biol. and Hlth. Systems Engineering,, Arizona State Univ., Tempe, AZ; [2]Mechanical and Aerospace Engineering,School for Engin. of Matter, Transport and Energy, Arizona State Univ., TEMPE, AZ

Abstract: The improvement of human-robot interaction is an active area of investigation. Enabling humans and robots to cooperate in attaining common goals has important implications

for a wide variety of activities, including recreation, military applications, and approaches aimed at rehabilitation of sensorimotor function using exoskeletons. Physical interaction between humans and robots has been mainly characterized by the notion of mechanical impedance. However, the extent to which limb impedance can be used to physically convey information about high-level goals, e.g. the preferred direction of motion, remains to be investigated. The present study was designed to quantify human-human physical interactions where one agent ("follower") was instructed to infer the intended direction of motion of another agent ("leader"). The strategy used by human agents, consisting of the "follower" probing the upper limb impedance of the "leader", was then studied during interactions between a human and a robot agent. We found that human subjects could infer the intended direction of the other human agent with a level of accuracy (48.8% on average for all directions) above chance level (16.6%, 1 out of 6 possible directions). We interpreted these findings as evidence for arm impedance being used as a means of communicating preferred directions among cooperating agents. To test this hypothesis, we conducted experiments involving a human subject and a robot arm using the same human-human collaboration. Both roles (leader, follower) were given to both agents (human, robot) in two separate experiments. The results showed that control of the leader's impedance was a critical factor in conveying the preferred direction to the follower. Specifically, when subjects were asked to infer the intended movement direction of a robot, or vice versa (68% and 51% of level of accuracy on average for all directions, respectively), an impedance-based strategy similar to that used during human-human interactions could account for the high percentage of accurate inferences of direction of the planned arm movement. The present findings support the notion of impedance as a viable means of communication between biological and non-biological agents and its future potential for being utilized to communicate high-level goals during cooperative actions.

Title: Independent control of stabilizing reflexes and triggered reactions in the human arm

Authors: *H. LEE[1,2], E. PERREAULT[1,2,3]
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Dept. of Biomed. Engin., Northwestern Univ., Evanston, IL; [3]Dept. of Physical Med. and Rehabil., Northwestern Univ., Chicago, IL

Abstract: The long-latency stretch reflex is a motor response to external perturbations of posture within a time window slower than short-latency reflex but prior to the onset of voluntary activity, and plays important roles at the interface of reflexive (rapid and automatic) and volitional (slow and adaptable) control. Previous studies demonstrated two distinct components of the long-latency stretch reflex: stabilizing reflexes opposing the perturbations and triggered reactions releasing pre-planned motor actions. Each of these two distinct functions has been extensively investigated separately, and there is growing consensus that multiple convergent neural pathways contribute to them. However, it is not known how these neural pathways are integrated when both postural stability and prepared motor action are relevant. Our hypothesis was that the stabilizing and triggered components of the long-latency stretch reflex can be modulated independently during arm reaching movements. This hypothesis was evaluated by assessing reflex modulation in mechanical environments that destabilize arm posture in a controlled fashion, independently from the planned movements. Our results demonstrate significant environmental specific modulation (stabilizing reflex) and target dependent modulation (triggered reaction) of the long-latency stretch reflex, and no interaction between them within individual muscles during the transition from posture to movement. These results support independent control of two different components of the long-latency stretch reflex and strengthen the growing consensus of multiple convergent pathways contributing to it: corticospinal pathways for stabilizing reflexes and brainstem pathways for triggered reactions.

Title: The role of the cortex in the control of arm stability

Authors: *D. B. SNYDER, S. A. BEARDSLEY, B. D. SCHMIT
Marquette Univ., Milwaukee, WI

Abstract: Arm control has been studied behaviorally for many years. While there is a good understanding of the systems level processes that mediate arm control and stabilization, the neural mechanisms, particularly those involved in arm stability remain unclear. In the work presented here, we use electroencephalography (EEG) and electromyography (EMG) together with goal directed stabilization tasks to examine what extent co-contraction and intermittent voluntary corrections contribute to stabilization and to understand how brain areas interact over time to stabilize the arm. Ten college aged subjects performed a series of 2D reach and hold tasks using a passive arm support system (recording limb position) to control a cursor projected onto a horizontal display. Each task condition consisted of a point to point movement to a target followed by a 4 second stabilization period. In the Stability condition, the subjects' arm was perturbed during the stabilization period. In the Voluntary condition, subjects were instructed to mimic the perturbation paths from the Stability condition upon reaching the target. In the Co-contraction condition, subjects were asked to co-contract (10 - 20 %) during the stabilization period. In the Point to Point condition, subjects were asked to stabilize at the target with no perturbations applied. EEG data was recorded using a 64 channel electrode system, filtered from 0.1 to 100 Hz, amplified and processed using independent component analysis to remove artifacts. EMG data was recorded from the flexor carpi radialis, extensor carpi ulnaris, biceps, lateral head of the triceps, and the anterior and posterior deltoid, filtered from 10 to 350 Hz, amplified by 1000, root mean squared (100 ms window) and normalized. MATLAB was used for all data analysis. Spectrograms and time courses in individual power bands were computed for the EEG data to examine the time course of cortex activity. The spectrograms for each of the four conditions all show a higher power in the rest period before movement compared to the stabilization period in the Beta band (13 - 26 Hz), which is consistent with the phenomenon known as event related desynchronization (ERD). The ERD occurred within 500 ms of the movement cue, during the point to point movement and was sustained throughout the entire stabilization period for all four conditions. Analysis of the individual power bands showed an enhanced ERD during the stabilization period for the Co-contraction and Voluntary conditions versus the Stability condition versus the Point to Point condition. These results suggest Beta band power may be associated with error processing due to the varying amount of error in each condition.

Title: Graded neural selectivity in sensorimotor cortex reflects reward-independent preferences during rule-based reach goal selection in monkey

Authors: *L. SURIYA-ARUNROJ[1], A. GAIL[1,2]
[1]Sensorimotor Group, German Primate Ctr., Göttingen, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Göttingen, Germany

Abstract: Neurons in dorsal premotor cortex (PMd) and parietal reach region (PRR) can simultaneously encode two alternative motor goals when monkeys have equal preference to choose either goal. This is true even if goals are selected based on two competing spatial transformation rules, i.e. without a spatial target stimulus marking the potential motor goal locations. (Klaes et al, 2011). Here, we test if graded preferences for such rule-based reach goals are reflected in graded spatial selectivity of individual neurons during decision making, and if preference encoding occurs independent of reward expectancy. A rhesus monkey had to determine the correct reach goal from two instructive cues. A pre-cue consisted of two differently colored triangles which appeared at one of the four cardinal directions from the center (e.g. top) and which pointed to two opposite directions (e.g. left and right). The pre-cue indicated, first, the two possible goals in a given trial, located at 90^o clockwise (CW) and 90^o counterclockwise (CCW) relative to its own position (rule). Second, the triangle sizes could differ and represented the probability with which the rule corresponding to each triangle would be instructed later. After a delay, a spatially neutral color cue was presented. In instructed trials the cue was equal-colored to one of the pre-cue triangles and indicated the valid rule. In interspersed free-choice trials the color was neutral and both potential goals were randomly rewarded with equal amount and probability. Preliminary results show that the pre-cue successfully induced a reward-independent graded preference in the monkey: The response alternative which was more likely to be instructed at the end of the trial according to the size of the pre-cue, was chosen more often and faster even in free-choice trials when there was no objective advantage from freely selecting this alternative. The spatial selectivity of individual PMd and PRR neurons during motor planning was modulated in accordance with the degree of later choice bias, i.e. showed weak spatial selectivity in balanced trials and increasingly stronger selectivity with increasing bias of the animal. We conclude that in a rule-based motor goal

selection task, the probability with which a rule is instructed induces a reward-independent subjective preference in free-choice behavior. The degree of behavioral preference is reflected in the degree of spatial selectivity of individual neurons in PRR and PMd corroborating the relevance of both areas in rule-based motor goal selection. Title: Vestibular contribution to arm movement planning

Authors: *J. GAVEAU[1], D. J. DICKMAN[1], S. D. NEWLANDS[2], C. PAPAXANTHIS[3], D. E. ANGELAKI[1]
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Otolaryngology, Univ. of Rochester Med. Ctr., Rochester, NY; [3]INSERM U1093, Univ. of Burgundy, Dijon, France

Abstract: Multiple studies have demonstrated the brain's ability to build internal representations of environmental and musculoskeletal dynamics, allowing efficient planning of limb movements. We have recently reported that both humans and monkeys optimally utilize the gravitational force when reaching in the vertical plane. Furthermore, vestibular signals are thought to allow the macaque brain to compute an internal model of the gravity force (Angelaki et al. 1999, 2004). The present study aimed at probing the potential role of vestibular signals in planning arm movements in macaques. Using a virtual reality system, three macaques were trained to perform single degree of freedom reaching movements between sets of two targets. The task consisted of shoulder flex/extension or shoulder ab/adduction (20 degrees amplitude). Kinematic and electromyographic (fine wire intra-muscular electrodes) signals were recorded from the right arm. After extensive training, two monkeys underwent a bilateral labyrinthectomy (ablation of the vestibular organs) and daily recordings were performed starting 24h post-surgery. Before surgery, we observed directional asymmetries on the kinematics of arm movements performed in the vertical plane but not in the horizontal plane (as previously reported). Precisely, the time to peak acceleration was shorter and the acceleration peak was larger for upward than for

downward movements. These asymmetries result from specific patterns of muscle activations that (along with theoretical simulations) demonstrate the optimal integration of the gravitational force into the planning processes of reaching movements. After surgery, we observed specific modifications of movement kinematics in the vertical plane but not in the horizontal plane. First, spatial errors that differed between upward (undershoot) and downward (overshoot) movements were observed early after surgery (first 3 sessions). Second, the above-mentioned directional asymmetry disappeared or even slightly reversed; i.e. the time to peak acceleration being longer and the peak acceleration being smaller for upward than for downward movements. This effect lasted for about ten days and slowly vanished such that vertical movements progressively returned to normal (after 20 days). Overall, our results unveil the contribution of vestibular signals to the planning of reaching movements: monkeys behaved as if the gravity force was absent immediately after labyrinthectomy. Furthermore, these results suggest that remaining sensory cues (visual, somatosensory) allowed the monkeys to progressively re-optimize the planning of vertical arm movements after labyrinthectomy.

Title: Stochastic motor control as probabilistic inference in spiking neural networks with noise

Authors: ***D. KAPPEL**[1], D. PECEVSKI[1], A. WHITFORD[2], S. CHASE[3], W. MAASS[1]
[1]Inst. for Theoretical Computer Sci., Graz Univ. of Technol., Graz, Austria; [2]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA; [3]Ctr. for the Neural Basis of Cognition and Biomed. Engin., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: The organizational principles of motor control in biological organisms are still largely unknown. Several recent publications, based on behavioral data and abstract models, have

proposed that probabilistic inference provides a suitable theoretical framework for understanding salient aspects of biological motor control [1,2]. Bayesian inference is a special case of such probabilistic inference (where one focuses on the role of priors and applications of Bayes' theorem). While these approaches reproduce many features of actual movements, it has been difficult to relate these abstract models to the biological substrate of neural computation and motor control in the central nervous system, i.e., to networks of spiking neurons. Therefore it has not been possible to test the validity of these models against neural recordings. Here we propose a model that implements stochastic motor control by solving a probabilistic inference problem with networks of spiking neurons. Our approach is based on recent work that has shown that the stochastic dynamics of networks of spiking neurons can approximate probabilistic inference through sampling [3]. This finding provides a solution to an important subclass of probabilistic inference problems and allows us to solve behaviorally relevant motor control task directly with spiking neurons, even with biologically realistic substantial amounts of noise. Furthermore, the architecture of our network allows the control problem to be inverted to predict the outcomes of motor acts. We demonstrate the viability of our model in a simulation of a standard arm reaching task, and show that the model readily reproduces a number of experimental results. Specifically, (1) we show that the network is able to compensate for perturbations applied during task execution, (2) we find that the strategies exploited by the model for corrective movements are similar to those exploited by behaving monkeys, and (3) we show that the experimentally observed trial-to-trial variability of our model neurons mimics recordings from motor cortex. This trial-to-trial variability enables the network to exploit redundancies in the task representation in order to explore alternative solutions. Our work thus provides a missing link between theoretical models of motor control and their biological implementation. **References:** [1] Botvinick M, Toussaint M (2012) Planning as inference. Title: Sport fencing as a model system for studying complex, highly trained reaching movements

Authors: A. N. MICHAELSEN, *C. L. CLELAND
Biol., James Madison Univ., Harrisonburg, VA

Abstract: Neural strategies and mechanisms underlying reaching movements have received intense study in both animals and humans. In most previous multi-joint reaching experiments, subjects were instructed to move their arm to a specific target. Similarly, in fencing the goal of the fencer is to move the arm to move the tip of blade to a specific target - the opponent's body. In foil fencing, the tip must not only hit the target but also compress in its axial direction by 500g. Although most fencing actions involve direct extension of the arm/blade toward the target, the "flick", an advanced action, requires the fencer to rapidly decelerate the blade base to produce curvature that is difficult for the opponent to parry. The flick requires precise kinematic amplitude and timing to control both the resulting location and axial pressure. The specific aim of this study was two-fold: first, to determine the kinematic strategy employed by high level fencers; second, to determine if the flick is a useful model system to study complex, multi-joint movement requiring precise trajectory control. Fencers were instructed to stand "en garde" and then flick at a simplified model of the top of the shoulder (horizontal plate), a common target of the flick. Scoring success was determined by a standard scoring box. Movement was recorded with a high speed camera (650 fps) positioned perpendicular to the plane of movement. Markers were placed on the tip and base of the blade to determine its location and orientation. Markers on the arm allowed measurement of shoulder, elbow, wrist and "finger" joint angles. The results revealed that two kinematic factors - horizontal distance of the hand from the target at impact and the peak rotational finger velocity, had the greatest effect on scoring. Interestingly, hand height at impact, commonly singled out by coaches, was not significant. Several aspects of the flick suggest it may be a useful model system 1) the movement requires precise control, presumably of joint trajectories, to achieve success. The success rate of nationally ranked fencers was about 50%. 2) The flick movement is confined to a plane, simplifying video recording. 3) The fencing community can provide highly trained fencers that have taken years to learn the flick.

Title: Competing costs determine the dynamical structure of inter-trial variability in a shuffleboard task

Authors: *J. P. CUSUMANO[1], J. M. MAHONEY[1], J. B. DINGWELL[2]
[1]Dept. of Engin. Sci. & Mechanics, Penn State Univ., University Park, PA; [2]Dept. of Kinesiology and Hlth. Educ., Univ. of Texas at Austin, Austin, TX

Abstract: The statistical variability universally observed in repeated trials of goal-directed tasks is a fundamental characteristic of the human perception-action system. In response to fluctuations that arise from intrinsic multiscale physiological noise, performers make adjustments in each trial in an attempt to perfectly execute a movement task. We describe a model-based data analysis approach that views motor variability as arising dynamically from this process of inter-trial error correction. Our approach combines simple stochastic optimal control models with the concept of goal equivalent manifolds (GEMs). The GEM arises from task redundancy, and contains all possible body states resulting in perfect task execution (i.e. zero goal-level error): it is defined using a minimal body-level state variable that determines the outcome of an individual trial. Using this approach, we analyze inter-trial fluctuations observed in experiments with two versions of a virtual shuffleboard task, for which the 2D body state is given by the position and velocity of the shuffleboard puck at release. We show that the structure of observed variability arises from a regulation process that seeks to minimize interacting costs that include, but are not limited to, goal-level error correction. The goal of each task is to release a puck with initial position and velocity so that it stops on a target line. In the first version, the coefficient of friction along the virtual court is constant. The second version includes a patch of virtual "ice" (with zero friction) after the target line: this penalizes overshooting the target. We analyze both tasks using the dynamical GEM framework to characterize the local geometric stability of repeated trials. Then, an optimal inter-trial controller with error, bias, and ergonomic terms is defined, and its weight parameters are estimated from the experimental data. We find the local stability properties are not distinguishable between the two versions. We also show that an optimal controller minimizing only error at the target does not capture the empirically-observed behavior, but a controller with competing bias and ergonomic costs can replicate both the dynamic and steady-state behaviors. Thus, while goal-level error is a dominant cost minimized by the human perception-action system during goal-directed movements, it is not the only one. In particular, our work suggests that relatively small additional costs, such as those stemming from ergonomic, physiological, and/or psychological factors, must be considered in combination with

error minimization in order to completely characterize experimentally-observed motor variability.

Title: Co-optimization of multiple competing action plans

Authors: *K. BARTON[1], J. P. GALLIVAN[1], C. S. CHAPMAN[2], D. M. WOLPERT[3], J. R. FLANAGAN[1]
[1]Queen's Univ., Kingston, ON, Canada; [2]Univ. of Alberta, Edmonton, AB, Canada; [3]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: We often encounter situations in which there are multiple objects that can be acted upon. Several influential cognitive theories propose that in such situations, we represent multiple potential actions plans in parallel prior to one of the plans being executed. A commonly held, but as yet untested, assumption is that such action plans are independent from one another. Here we show that competing potential actions not only interact, but are in fact co-optimized. Participants viewed two potential rectangular targets of varying orientations and, when one of the targets was cued, were required to rapidly place the rectangular tip of a hand-held tool on the cued target. Some target orientations uniquely required either supination or pronation of the wrist to align the tool with the target, whereas other "ambiguous" target orientations equally afforded either pronation or supination. We found that on trials in which an ambiguous target was cued, participants were more likely to supinate or pronate the wrist when the competing potential target necessitated supination or pronation, respectively. Moreover, choosing the compatible orientation resulted in a reaction time advantage. Our results demonstrate that individuals

integrate task-relevant features across multiple objects so as to co-optimize plans to act on these objects.

Title: Inactivation of Parietal Reach Region (PRR) affects reach but not saccade choices in spatial decisions

Authors: *V. N. CHRISTOPOULOS[1], I. KAGAN[2,1], R. CHO[1], R. A. ANDERSEN[1]
[1]Div. of Biol., Caltech, Pasadena, CA; [2]German Primate Ctr., Goettingen, Germany

Abstract: A growing body of neurophysiological studies challenges a long-held theory that views decision-making as a distinct cognitive process from the neural systems for perception and action. Recent findings suggest that many action decisions emerge through a continuous competition between populations of neurons within the same brain regions that plan and guide action execution. The main line of evidence is the existence of decision-related neural activity in brain regions that are involved in sensorimotor processing. However, it could be argued that the activity is not "genuinely motor", but instead is related to spatial attention or visual salience. One approach to establish whether particular regions are involved in the decision process is to temporarily perturb these regions and observe the effects on decision making. We studied whether PRR inactivation causes deficits on attention and/or on decision-making. We reversibly inactivated part of PRR by locally injecting the GABA-A agonist muscimol, while a monkey performed memory-guided reach or saccade movements either to a single target (instructed trials) or selected between two targets presented simultaneously in both hemifields (free-choice trials). Reaches were performed by means of a 2-D joystick positioned between the legs of the animal sitting in an upright position. In the reach trials, the animal used the arm contralateral to

the inactivated hemisphere. Additionally, the animal was required to keep eye fixation on a central point during the reaching sessions. The results showed that the animal exhibited a spatial decision bias towards the ipsilesional targets after PRR inactivation in the free-choice trials, but only for reaching. On the contrary, the inactivation did not affect the saccadic choices. We also found no significant effects on the reaching/saccadic movements to single targets presented in either hemifield. These results cannot be accounted for as deficits in spatial attention, since the "lesion" had an impact only on the reaching and not on the saccade choices. Rather, the results support PRR being causally involved in decision-making for selecting between reach actions. These findings provide a new conceptual advance in understanding neglect-like disorders as a deficit of the decision-making process rather than sensory attention. Additionally, we developed a biologically plausible computational framework that explains how PRR inactivation affects reaching but not saccade choices.

Title: Effects of age and fear cognitions on motor behavior in a step and reach task with varying support surface conditions

Authors: K. MCFADDEN[1], L. RUSSELL[1], L. HONG[2], M. NAKAZAWA[2], *J. S. THOMAS[3]
[1]PT, [2]Biomed. Sci., Ohio Univ., Athens, OH; [3]Ohio Univ., ATHENS, OH

Abstract: The purpose of this study was to determine the effects of age and fear of falling on movement time and joint excursions used to complete a step and reach task under varying surface conditions. Specifically, the coefficient of friction was systematically reduced via the application of a commercial cooking spray (i.e., PAM) on the linoleum support surface on which participants were standing barefoot. Twenty-one healthy male and female participants (11 ages 19-24, 10 ages 55-62) were instructed to step and reach with their right hand to a high or low target in the mid-sagittal plane. Participants reached three times to each target as fast as possible.

Targets were located such that the subject could reach them, in theory, with a forward step equal to ½ of their hip height, elbow extended with the shoulder flexed to 90 degrees, and trunk flexed to 15 degrees (high target) or 60 degrees (low target). Floor conditions for this study varied as follows 1) No Pam (NP); 2) Pam sprayed under just the left/plant foot (PP); 3) Pam under just the right/land foot (PL); and 4) Pam under both feet (PB). Prior to each change in surface condition, participants rated their concern of slipping or falling during the task using a 10 cm visual analog scale (VAS) where zero indicated "no concern," and 10 indicated "extremely concerned." Participants wore a safety harness that allowed free movement, but prevented an impending fall by resisting rapid accelerations of the participant's body toward the floor. Whole body kinematics were recorded using a 7-camera Vicon MX-13 System and peak-to-peak 3D joint excursions were determined using custom software. Fear of falling as assessed by the VAS increased from 1.19 cm (± 2.0) for NP condition to 6.9 cm (± 2.9) for PB condition ($p<0.05$). However, there were no age-related differences in these assessments. Three-way mixed-model ANOVAs revealed that movement time increased on average from 687.0 ms (± 47.0) to 869.2 ms (± 49.3) when the support surface was made more slippery ($p<0.05$). There was a trend for older subjects to have a MT about 134 ms greater than younger subjects ($p=0.065$). Older subjects used less lumbar flexion compared to younger subjects ($p<0.05$) and there was a surface condition by age interaction ($p<0.05$) showing that older subjects used increased lumbar rotation across surface conditions. The results show that varying surface conditions increased fear; in parallel, older participants altered movement strategy by decreasing lumbar flexion and increasing lumbar rotation. Further research is needed to assess the influences of fear cognitions on changes in motor planning in older cohorts.

Title: Are there shared resources for motor planning?

Authors: *L. OOSTWOUD WIJDENES[1], R. B. IVRY[2], P. M. BAYS[1,2]
[1]Sobell Dept. of Motor Neurosci. and Movement Disorders, UCL Inst. of Neurol., London, United Kingdom; [2]Dept. of Psychology, Univ. of California, Berkeley, CA

Abstract: Different characteristics of human perception and memory can be described successfully with a resource model. In particular, resource models describe the decrease in precision with which individual items can be represented if the total number of items increases. Neurophysiological data suggests that the representations of items and movements towards these items are closely related. Therefore, we examined if a resource model could also describe the precision with which movement plans are represented. If this is the case, the precision of individual movements plans should decrease if the number of movement plans increases. In the first experiment, we examined if preparing one movement resulted in less movement planning variability than preparing two movements. Participants made speeded reaching movements with their left or right hand towards visual targets, in response to a go-signal. To manipulate the number of movement plans, we used a delayed response cueing procedure that allowed the participant to limit planning to a single hand or required that they plan potential movements with both hands. In the early cue condition, the required reach hand was cued at the same time as the target appeared, 1200 ms before the imperative. In the late cue condition, the hand cue was specified at the same time as the imperative, 1200 ms after target onset. We expected that with the early cue, participants would prepare a movement only with the instructed hand, while with the late cue, participants would prepare two movements to the target, one with each hand. Variability in initial movement direction was higher in the two-plan condition than the one-plan condition, demonstrating a cost associated with planning multiple movements, consistent with a limited resource. To test if the effect is due to an increase in movement planning variability, or due to a more general preparedness of the hand in the early cue condition, we varied the timing of the target presentation in two more experiments. In the early target condition the target was cued 1200 ms before the go-signal and in the late target condition the target was cued at the same time as the go-signal. In experiment 2 the hand was always cued early (1200 ms before the imperative), and in the experiment 3 the hand was always cued late (at the imperative). The results showed that initial movement variability was only decreased if the movement trajectory was fully specified. We conclude that movement planning variability increases if the number of plans increases, consistent with a limited resource model. Our results indicate that alternative movements cannot be planned independently even when they involve different limbs.

Title: The neural correlates of dissociating the spatial directions of eye and arm movements

Authors: *D. J. GORBET, L. E. SERGIO
Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Typical visually-guided arm movements involve first making a saccade to an intended target location and then a reach toward the direction of our gaze (i.e. “standard” visuomotor mapping). However, many increasingly common tasks require us to move our eyes in one direction while reaching in a different direction (i.e. “non-standard” visuomotor mappings, such as using a computer mouse). Yet most of what we know about the neural activity underlying coordinated eye-hand movements comes from examination of tasks where either the eyes or the hand are held in a fixed position as the other effector is moved. In a previous behavioural study, we demonstrated that spatially dissociating the directions of eye and arm movement results in changes to the kinematic properties of both effectors, even when participants are equally proficient at both tasks. This result suggests that the neural control of standard and non-standard visuomotor mappings differ (Gorbet & Sergio, 2009). These putative differences in brain activity are relevant not only for our fundamental understanding of visuomotor control but also have potential clinical implications for diagnostic and rehabilitative approaches. In the study presented here, we used fMRI to compare the neural correlates of standard eye-hand mapping where both effectors moved to the same cued target location and a non-standard mapping where the eyes moved to the cued target location but the hand moved 180 degrees in the opposite direction. An instructed-delay event-related imaging paradigm was used to facilitate examination of preparatory-related brain activity prior to motor onset. Female participants were used exclusively to avoid potentially confounding sex-related differences in brain activity associated with visually-guided reaching (see Gorbet and Staines, 2011). Whole brain comparisons of the two conditions reveal significantly greater preparatory brain activity associated with the non-standard task in the dorsal premotor, posterior parietal, and dorsolateral prefrontal cortical regions. Multivoxel pattern analyses within independently localized task-related regions suggest that regions of the prefrontal cortex are integral to the ability to spatially dissociate the directions of eye and arm movements. These regions correspond with our groups previous neurophysiological and clinical findings. Taken together these data characterize a network of regions crucial to the decoupling of a movement from its guiding sensory information. Title: Parietal activation during vergence eye movements: Implications for attentional control of reaching behavior

Authors: *C. W. TYLER, L. T. LIKOVA, S. C. NICHOLAS
Smith-Kettlewell Brain Imaging Ctr., Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Introduction. No mechanism for the control of near-far direction of vergence has been reported, although the frontal eye field (FEF) regions of cortex have been associated with both lateral (saccadic) and depth (vergence) eye movement control. We used event-related fMRI to dissociate convergent (nearwards) from divergent (farwards) eye movement activation throughout the human cortex. Methods. Auditory (verbal) signals triggered convergent and divergent eye movement in an event-related paradigm with eyes closed while recording whole-brain fMRI BOLD activation on a 3T Siemens scanner. Results. Significant vergence direction specificity was seen in the region of the precentral gyri (Brodmann 6) often designated as the human homolog of the FEF, with the nearward movement eliciting much stronger activation than the farward movement (including a separate island of activation in the most inferior part of area 6, PMVr, which was only activated for nearward movement). In parietal cortex, there was see-saw modulation between the superior parietal lobule (nearward) and the angular gyrus (farward). These are brain regions involved in reaching behavior and the spatial awareness of the body, respectively. Despite the absence of visual input, there was also differential activation in anterior hMT+ (human MST), which encodes motion vector fields. There was no activation in the retrosplenial cortex, and area often associated with perceived self-motion in depth. Conclusion. Vergence eye movements in the dark activate the parietal regions involved in reaching behavior, suggesting that this activation may be related not just to the arm movements per se but also to the eye movements associated with the reaching behavior, or even to the attentional control of changes in spatial distance involved in both tasks. In general, spatiomotor tasks are accompanied by eye movements for visual guidance and feedback, unless specifically controlled for. Eye movements themselves involve both visual and attentional guidance, and spatial representation

of target location and movement. All these factors need to be taken into account in interpreting cortical activation in complex motor tasks, which needs to be broken down into its component elements before the brain networks involved can be properly understood.

Title: Anticipation modulates sound representation and behavioral performance

Authors: *I. CARCEA[1], M. N. INSANALLY[1], R. C. FROEMKE[2]
[1]Skirball Inst., NYU Med. Ctr., New York, NY; [2]Mol. Neurobio. Program, New York Univ. Sch. of Med., New York, NY

Abstract: Anticipation represents a form of attention directed towards an upcoming stimulus in order to facilitate its processing. This type of attentional control significantly increases arousal and contributes to states of high engagement during behavioral tasks, likely by preparing dedicated brain regions for sensory processing and motor execution. Frontal cortical areas contribute to attention-dependent modulation of stimulus representations in sensory cortices, and to performance on sensorimotor tasks. We identified a circuit mechanisms that orchestrates neuronal activity across distinct brain structures and across defined temporal domains during attentional states. Here, we used two variants of an auditory-based operant conditioning go-no go task in rats to examine how anticipatory recruitment of attentional resources dynamically impacts behavioral performance and sound representation in the auditory cortex. In one task variant the trials were randomly initiated, whereas in the other variant the animal initiated the trials. The latter self-initiated task variant included a defined anticipatory period preceding stimulus onset. Rats performed significantly better on self-initiated trials (random initiation d'=1.4±0.9, self-initiation d'= 2.3±1.1). This improvement in performance negatively correlated with the duration of the anticipatory period. Using single unit recordings in behaving rats, we found that

anticipation bi-directionally modulates sound evoked-firing rates in the auditory cortex, while conserving mean evoked activity at the population level. Self initiation also increased the reliability of sound-evoked neuronal spiking in the auditory cortex. To investigate if adjustments in baseline activity contribute to the above neuronal dynamics, we analyzed pre-stimulus firing in the auditory cortex and in a reciprocally connected frontal area, the medial agranular frontal cortex (maFC). We found a progressive and significant suppression of activity in both these regions during the anticipatory period. In maFC, the amount of spontaneous firing rate suppression was the best predictor of behavioral performance. We are now examining how activity, both measured and optogentically controlled, relates to frontal and auditory cortical neural dynamics. Together, our findings contribute new insights into the circuit mechanisms of attention by advancing the knowledge on the interaction between frontal and sensory cortices during behavioral engagement.

Abstract: Point-and-click control of a computer could restore independence and communication for people who are unable to move or speak. Our ongoing BrainGate pilot clinical trial has previously reported accurate real-time decoding of motor intent in people with tetraplegia. We have previously demonstrated target acquisition times of 5-8s in a standardized task, and continue to pursue faster and more reliable control to create a practical assistive technology. Here, we report methods that have yielded a substantial improvement in speed (2-3s acquisition times) while maintaining the same target acquisition rate. Furthermore, they reduce the need for supervised recalibration tasks with explicitly defined targets, which take time away from practical BCI use. One challenge for point-and-click control using an intracortical BCI is nonstationarity in the recorded neural signals. Without recalibration, this can cause neural control to degrade over the course of minutes or hours. Continuously- and recursively-computed normalization of firing rate means and variances, particularly during periods of rest (between "blocks"), improves control by increasing the stationarity of neural features extracted from nonstationary recordings. In an online comparison of cursor control with a fixed Kalman filter, adaptive normalization outperformed fixed normalization by a difference of 1.7s per target acquisition (35.7% improvement, $p<0.001$). Importantly, this method stabilizes extracted signals even in periods of rest, during which calibration data cannot be collected. This suggests that underlying neural information about movement intent recorded from intracortical arrays may be more stable than previously reported once we account for drift in mean and variance. When combined with unsupervised recalibration of the Kalman filter during practical BCI use (see Jarosiewicz, et al, SFN 2014), these and other adaptive approaches may allow for long-term use of a BCI without the need for disruptive supervised calibration tasks. Related work by Nuyujukian, et al, and Pandarinath, et al, SFN 2014, discusses progress towards high-performance communication using point-and-click typing.

Abstract: The BrainGate pilot clinical trials represent an important, ongoing collaborative effort to translate fundamental neuroscience and neuroengineering into a powerful assistive device for people with tetraplegia due to cervical spinal cord injury, stroke, muscular dystrophy, or motor neuron diseases including amyotrophic lateral sclerosis. There are four actively enrolling clinical trial sites: Massachusetts General Hospital (coordinating center), Providence VA Medical

Center, Stanford Medical Center, and Case Western Reserve University. Researchers from those institutions, as well as at Brown University, also play a central role in the analysis of neural data, the creation of novel decoding algorithms, and the integration of the volitionally controlled neural signals. There have been nine participants enrolled thus far, with more than 6000 intracortical array implant days across those participants. Since January 2013, two active participants have been engaged in research sessions at Brown/MGH/PVAMC and Stanford. Of note, all BrainGate research sessions occur primarily in the research participant's place of residence. This ensures that the investigational BrainGate system is being developed and tested in the environment where such an assistive device must function for its future users. Through April 2014, there have been 123 research sessions run at Stanford University and 71 sessions run at Brown/MGH/PVAMC with the current two participants, both of whom have ALS. Sessions begin with a 20-30 minute setup period and usually last 2-4 hours, depending on the energy level, engagement, and daily schedules of the participants. Sessions involving neural cursor control typically consist of 10-20 blocks of data collection with 20-200 trials in each block (approximately 2-10 minutes). Clinical Neurotechnology Research Assistants (CNRAs) at both sites conduct sessions with a consistent style of interaction and "participant first" priority while enabling multiple scientific and engineering questions to be posed. The simultaneous enrollment of these two participants creates new opportunities and challenges in terms of both validating and deploying research sessions. The ability to test scientific hypotheses simultaneously with multiple participants has proven useful, allowing us to quickly iterate the development of advanced decoding methods for communication and multi-dimensional control of external devices.

Sch., Boston, MA

Abstract: Brain-computer interfaces (BCIs) promise to restore communication and independence for people with severe motor disabilities by translating decoded neural activity directly into control of a computer. However, nonstationarities in recorded brain activity can degrade the quality of neural decoding over time, and periodically interrupting ongoing use of the BCI to perform decoder recalibration tasks would be time-consuming and impractical. Previously, we showed that typing performance in a neurally-controlled communication interface can be maintained without disruptive recalibration routines by mapping neural activity to movement intentions that are inferred retrospectively based on the user's subsequent selections. In two individuals with tetraplegia using a neurally-controlled point-and-click communication interface, typing speed using an "unsupervised" decoder (calibrated using data acquired during neurally-controlled free typing) was equivalent to typing speed using a "supervised" decoder (calibrated using a task with pre-defined targets). The current study extends this finding to several more sessions with two additional participants, and demonstrates for the first time that these methods can keep the BCI calibrated over long periods of practical, self-paced BCI use without the intervention of a technician. Technical innovations that made this possible include automated calibration routines running in parallel with decoding software, adaptive

normalization of extracted neural features, click decoder recalibration in parallel with directional decoder calibration, residual bias suppression, and other innovations (see Sarma et al. and Simeral et al., SFN 2014, for details). By introducing the potential to maintain decoder performance during extended use of unsupervised point-and-click assistive applications, this unsupervised calibration approach advances the potential clinical utility and independent use of BCIs by individuals with severe motor disability.

Title: Integrating advances in signal processing and decoding into intracortical BCIs for people with tetraplegia

Authors: *J. D. SIMERAL[1,2,3,6], A. A. SARMA[2,1,3], B. JAROSIEWICZ[4,1], D. BACHER[2,3], M. L. HOMER[5,3], B. SORICE[6], J. SAAB[2,3], J. P. DONOGHUE[1,4,2,3], L. R. HOCHBERG[1,2,6,7,3]

Abstract: A broad range of research aims to contribute methods for translating recorded cortical signals into commands for assistive devices. In the BrainGate trial, research activities performed at each participant's place of residence provide the unique opportunity and practical motivation to develop and evaluate neural signal processing and decoding techniques that enable real-time neural control of assistive devices and communication software. To date, technical complexity and the nature of ongoing research have demanded the active engagement of trained technicians during use of this intracortical brain-computer interface in the home environment (see Blabe et al.). Here we list recent advancements in neural signal processing and neural decoding approaches and the ongoing integration of these into a neuroprosthetic system that could one day enable reliable long-term in-home BCI use without technical oversight. We decode motor intent from combinations of spiking activity (spikes) and local field potentials (LFPs) recorded from one or more microelectrode arrays implanted in motor cortex of individuals with severe motor disability. Because isolating spikes manually or through any of numerous automated "sorting" methods is time consuming and impractical for independent use, we have instead used threshold crossing counts after non-causally filtering for spike band frequencies, which has been shown to improve the extraction of information about movement intent from spike band activity (Masse et al., in review). We have also extracted motor intent-related information from the power in various frequency bands identified in the literature for decades as having information pertaining to movement intention (particularly in able bodied monkeys). However, we find that in practice the optimal bands for information extraction vary substantially between individuals and even across days. Therefore, we have developed and evaluated a data-driven method for improved selection of LFP bands to use for real-time decoding. We also describe innovations in neural decoding within the Kalman filter regime, such as automatic unsupervised decoder re-calibration during practical BCI use (see Jarosiewicz et al., SFN 2014) and continuous re-normalization of extracted neural signals during both use and non-use (see Sarma et al., SFN 2014), and evaluate the efficacy of non-parametric decoding methods in achieving neural control. Additionally, we report progress towards a wireless, mobile, embedded platform for safe and convenient neural signal processing and decoding.

Abstract: Motor cortex (MC) plays a central role in the generation of voluntary movement, yet increasing experimental evidence has shown that it is not simply a circuit dedicated exclusively to generating motor outputs. MC is engaged during action observation as well as execution, suggesting a cognitive role related to abstract representations of movement. However, the extent to which MC dynamics change depending on the task context, such as the cognitive involvement of the subject, remains largely unknown. Here, we apply a novel relational decoding and visualization technique to study how single cell and ensemble activity changes across three cognitive conditions in human motor cortex. Relational decoding uses similarity measurements describe the relationship between multiple data samples. Spike train similarity space (SSIMS) analysis builds upon this framework by combining spike train metrics with dimensionality reduction techniques, producing similarity measures between neural activity patterns that can be

easily quantified and visualized. This approach does not require an explicit parameterization of neural data with respect to external variables, minimizing assumptions about putative neural encoding schemes. People with long-standing tetraplegia who have implanted multielectrode arrays as part of the BrainGate pilot clinical trial viewed an animation of an arm making point-to-point movements to four evenly spaced targets from the first person perspective. Participants were instructed to watch, imagine, or attempt the viewed action. Our results show that the context change between Watch, Imagine, and Attempt conditions is differentially encoded by neural activity at a level comparable to movement direction. Direction-related information is evident across all conditions distributed over a substrate of overlapping neuronal populations. Direction selective neurons typically alter their firing properties across conditions, incorporating information about both cognitive set and movement direction. Our findings demonstrate that MC circuits encode information in a flexible, context dependent manner, building upon a perceptual base, and suggest that cortically-driven neuroprosthetic systems will need to incorporate mental engagement states in addition to those directly related to movement parameters.

Title: State space modeling of local field potentials in motor cortex during observed, imagined, and attempted arm movement in humans with tetraplegia

Authors: D. L. MENZER[1,2,3], J. M. FELDMAN[2,3], E. OAKLEY[5], L. R. HOCHBERG[1,3,5,6,3], J. P. DONOGHUE[1,2,4,3]

[1]Ctr. for Neurorestoration and Neurotechnology, Rehab. R & D, Dept. of VA Med. Ctr., Providence, RI; [2]Dept. of Neurosci., [3]Inst. for Brain Sci., [4]Sch. of Engin., Brown Univ., Providence, RI; [5]Neurol., Massachusetts Gen. Hosp., Boston, MA; [6]Neurol., Harvard Med. Sch., Boston, MA

Abstract: Neural activity in primary motor cortex (M1) can be used as a command signal for neural interfaces for people with tetraplegia (Hochberg et al., 2006; 2012). Spiking and local field potentials (LFPs) in M1 are modulated by attempted movement (Shaikhouni, 2010) and cognitive state (Feldman et al., 2011; Menzer et al., 2012), and can be decoded to provide information on these variables. This study presents a novel method of analyzing LFPs in a state space framework. The method uses spectral power difference and dimensionality reduction to compare the LFPs recorded on different experimental trials. We compare the difference in power on all pairings of trials of LFP recorded during the experiment separately for the 1-5, 15-30, 100-150, and 150-200 Hz frequency bands. Next, dimensionality reduction is used to represent the data in a 3D state space that allows for clustering analysis. We use this novel LFP State Space (LFPSS) approach to analyze the relationship between cognitive state and modulation of M1 LFPs during observed, imagined, and attempted arm movement (Watch, Imagine, Attempt; WIA task). In this task, participants view the identical computer-generated animation showing an arm performing center-out reach movements. LFPs were recorded from multielectrode arrays implanted in M1 of three people with tetraplegia enrolled in the pilot clinical trial of the BrainGate (IDE) Neural Interface System. We recorded 96 LFP channels simultaneously in 3 sessions with two participants, and 2 sessions in the other. Analog LFP data were filtered (0.3-7,500 Hz) and digitized to 30,000 samples/s. LFPs were then low-pass filtered (1-200 Hz) and downsampled to 1,000 samples/s. As reported previously (Menzer et al., 2012), LFP power was elevated in the 1-10 Hz and 60-200 Hz bands during arm movement compared to premovement. LFP power was also suppressed in the 10-40 Hz during movement vs. premovement. These power modulations were strongest during Attempt and weakest during Watch. The novel LFPSS procedure separates these data by cognitive strategy, especially during arm movement observation. This effect is strongest in the gamma frequency ranges > 100 Hz. This novel method is also used to evaluate the timecourse of changes in the relation between LFPs and cognitive state during the trials. These relationships between LFP modulation and cognitive state underscore the potential utility of M1 LFPs as a control signal for neural interfaces.

Title: Classifying movement types during an instructed delay task from motor cortex recordings in an individual with paralysis

Authors: *J. SAAB[1,2], J. A. PERGE[1,4,2], T. MILEKOVIC[3,2], J. D. SIMERAL[4,1,5,2], B. SORICE[5], J. P. DONOGHUE[4,3,1,2], L. R. HOCHBERG[4,1,5,6,2]

Abstract: Intracortical Brain-Computer Interfaces (iBCIs), including the investigational BrainGate Neural Interface System, are being developed to assist individuals with neurological injury or disease. Commonly, iBCIs record signals from motor cortical areas, decode continuous movements or classify movement types, and then send the resulting control signals to an assistive device. Decoders and classifiers are built on neural activity recorded while movements are attempted or imagined. In this study, we investigate the information available in neural activity occurring during the preparation of movement. We recorded activity within the arm area of motor cortex using two silicon multi-electrode arrays placed in participant T7, a 58-year-old man with amyotrophic lateral sclerosis. He performed an instructed delay task consisting of a

random sequence of four movement types: (i) elbow flexion, (ii) elbow extension, (iii) thumb flexion, and (iv) thumb extension. The delay period was of variable length so as to minimize the predictability of cues. We then applied an offline multi-class linear discriminant analysis to classify movement types using multiunit spiking activity prior to cue presentation, during the delay period, and during task execution (i.e. intended movement). As expected, prior to cue presentation, classification accuracy remained below chance-level (27% correctly classified movements). Accuracies then increased to above chance-level during the delay period (66%) and task execution (91%). These results indicate that movement goals can be predicted prior to task execution in the motor cortex of an individual with tetraplegia. As has been shown in non-human primate studies, using these predictions to weight real-time kinematic decoder outputs can reduce decoding errors and improve BCI control.

Abstract: An important potential application for Brain Computer Interfaces (BCIs) is the control of computer cursors and keyboards for the restoration of communication. This report, combined with a paired report (Nuyujukian et al., SfN 2014), describes the development and application of one such BCI for use by a participant with amyotrophic lateral sclerosis (ALS), as part of the BrainGate2 FDA Pilot clinical trial. Our participant was achieved typing rates between 4.4-6 words per minute (22-30 net correct selections per minute), representing, to our knowledge, the highest reported communication rates of any human BCI. Participant T6 is a 51 yr old woman with declining motor function due to slowly-progressive ALS. She was implanted with a 96-channel electrode array (Blackrock Microsystems) in the hand area of dominant motor cortex. The data presented here were collected more than 13 months post-implantation. Spiking activity and high-frequency local field potential power (150-450Hz) were extracted for use as control signals. The ReFIT Kalman Filter (Nuyujukian et al., SfN 2014, Gilja*, Nuyujukian*, et al., Nat Neuro 2012) was used for continuous 2-dimensional cursor control. To achieve full "point-and-click" control of the computer interface, we added, in parallel, an algorithm for detecting transitions between movement and click-states: the Hidden Markov Model (HMM; Nuyujukian et al., SfN 2012). The participant generated a volitional click signal by attempting to squeeze her non-dominant hand (ipsilateral to the implanted array). This caused a suppression of neural firing, which could be detected as an intention to click. At each time step, the HMM estimated the state likelihoods based on a multivariate Gaussian model of the neural data, the previous likelihoods, and the prior probability of state transitions. Performance of the combined point-and-click interface was measured using two tasks - a grid task, in which the participant acquired randomly presented targets on a 6x6 square grid, and a keyboard task, in which the participant typed phrases using a QWERTY-keyboard layout without, using word completion or error correction. In the grid task, the participant was acquired targets with less than 10% false click rate and a bitrate between 2.2-3 bits per second. In the keyboard task, the participant was able select characters at speeds between 22-30 net correct selections per minute (4.4-6 wpm). These results demonstrate the successful translation of high-performance BCI methods for continuous control and discrete selection. This promising point-and-click interface could serve as a practical method to restore communication for persons with severe paralysis.

Abstract: One important potential application of brain computer interfaces (BCIs) is the restoration of communication for people with paralysis. Here, along with a paired report (Pandarinath, et. al., SfN 2014), we describe the development and application of an intracortical BCI decoder in the BrainGate2 FDA pilot clinical trial (NCT00912041). On a free-paced task using a traditional qwerty keyboard layout, our participant achieved typing rates of 4.4-6 words per minute (22-30 net correct selections per minute), representing, to our knowledge, the highest reported communication rates of any human BCI. Participant T6 is a 51 year old woman with declining motor function due to slowly-progressive ALS who was implanted with a 96-channel electrode array (Blackrock Microsystems) in the hand area of her dominant motor cortex in Dec 2012. Data presented here were collected from ongoing research sessions 13 months post implantation. Both spiking activity as well as high-frequency local field potential power (100-450Hz) were extracted for use as inputs to the neural decoder. Initial kinematic training data was collected using a data glove (Fifth Dim. Tech.) that mapped index finger flexion to the X dimension and thumb flexion to Y. A neural decoder was then generated from this behavioral training data. The decoder used for cursor control was the ReFIT Kalman Filter (Gilja*, Nuyujukian*, et. al., Nature Neuroscience 2012), which was previously shown to be faster and easier to use for this participant (Gilja, et. al., SfN 2013). Continuous cursor performance was evaluated with a center-out task and a random target Fitts task. On an 8 target center out acquisition task with 12cm target distance, 3cm diameter targets, and a 500ms hold time; T6 typically achieved success rates exceeding 95% and average aquire times under 1.5 sec. On a random target Fitts task with a 500ms hold time, where target distance and diameter would vary from trial to trial, T6 was able to consistently achieve a Fitts bitrate exceeding 1 bit/sec. In a typical experimental session, which would last two to four hours and span thousands of trials, participant T6 continued to move her fingers slightly during neural control blocks as she did during finger training blocks. As a control, she was asked to limit her finger movements and place her hands flat on a table while controlling the cursor, yielding comparable levels of control under this paradigm as well. These findings confirm that the ReFIT-KF algorithm successfully translates to a human participant from the healthy, intact, animal models in which it was originally developed and reported. These results may help make BCIs more suitable for the restoration of communication.

Title: Brain-machine interface performance is mediated by an internal model of decoder velocity gain

Authors: *S. D. STAVISKY[1], J. C. KAO[2], S. I. RYU[6,2], K. V. SHENOY[1,2,3,4,5]
[1]Neurosciences Program, [2]Electrical Engin., [3]Bioengineering, [4]Neurosciences Inst., [5]Neurobio., Stanford Univ., Stanford, CA; [6]Dept. of Neurosurg., Palo Alto Med. Fndn., Palo Alto, CA

Abstract: Imagine moving a computer cursor to select an icon. If you use your own laptop, then you know how fast the cursor will move in response to your trackpad input; this allows you to select the icon quickly and precisely. If you instead reach for an unfamiliar laptop with a higher cursor velocity gain, you will move the cursor too quickly and overshoot the icon. Conversely, if the velocity gain is less than you expect, you will move the cursor too slowly. This example illustrates the control theory-inspired view that the motor system learns an internal model to predict the resulting sensory consequences when a physical plant (e.g. the arm) is driven by its motor commands. There is considerable evidence of internal model use when the motor system moves the body, but the field is just beginning to ask whether similar computational strategies are used to control a brain-machine interface (BMI) (Golub et al., 2012). Whereas that study manipulated the mapping between neural activity and cursor movement direction, we instead changed the BMI's velocity gain and observed how a subject's performance depends on whether they are given the opportunity to learn this gain. Two macaques were implanted with 96-channel arrays in both primary motor and dorsal premotor cortex. They first performed a 2D point-to-point cursor task with their hand. We used these data to train a velocity Kalman filter that decoded multiunit spikes to move the cursor. We varied the decoder by scaling its output velocity by 0.5 ("slow"), 1 ("normal"), or 2 ("fast") while the monkey performed the task. During the blocked condition (BC) a given decoder gain was presented for prolonged use.

During the interleaved condition (IC), one of the three gains was randomly chosen for each trial with no overt cue as to which gain was being used. We predicted that performance using each gain would be better during BC than IC trials in a manner akin to the example of using a familiar versus a frequently changing laptop cursor. We found performance differences between IC and BC trials indicative of the monkeys having a better internal model of the velocity gain during BC than IC BMI use. Times to target were 9% (12%) faster on BC compared to IC trials for monkey R (J) using the slow decoder, and 22% (17%) faster when using the fast decoder. Mean cursor speeds in the first 300 ms of fast decoder trials were 9% (11%) faster in IC than BC trials, leading to 74% (88%) further target overshoot distance. Conversely, the monkeys drove the slow decoder 9% (13%) slower in IC compared to BC trials. These results suggest that BMIs can be a platform for investigating internal model use in the motor system, and that adept BMI performance may be mediated by learning the properties of the BMI.

Title: A robust and high-performance brain-machine interface using a nonlinear recurrent neural network trained with years of neural data

Authors: *J. C. KAO[1], S. D. STAVISKY[2], D. SUSSILLO[1], S. I. RYU[5,1], K. V. SHENOY[1,3,4,2]
[1]Electrical Engin., [2]Neurosciences Program, [3]Bioengineering, [4]Neurobio., Stanford Univ., Stanford, CA; [5]Dept. of Neurosurg., Palo Alto Med. Fndn., Palo Alto, CA

Abstract: Clinically viable brain-machine interfaces (BMIs) must not only perform well, but should also be robust to across-days and within-day changes in the neural data. Linear techniques, including state-of-the-art Kalman filter-based decoders (e.g., Gilja et al., 2012) are not well-suited for dealing with non-stationary data because their modeling assumptions result in underfitting. Thus, although neural recordings from the previous months to years may be available, these decoder architectures do not adequately make use of the richness and variance of these datasets. Our goal was to overcome this by using nonlinear techniques (e.g., Sussillo et al., 2012). We present a novel nonlinear architecture for BMI use that is constructed to improve robustness: the multiplicative recurrent neural network (MRNN, Sutskever et al., 2011). The nonlinearities in the MRNN enable improved robustness by (1) leveraging multi-year training datasets and (2) training with explicitly perturbed neural data. We report both performance and robustness results superior to the current state-of-the-art. We implanted one monkey with 96-electrode arrays in both primary motor and dorsal premotor cortex and collected neural data across two years of reaching experiments. We trained the MRNN using a merged training set comprising approximately 120 datasets (60,000 trials) collected from 08/31/2012 until the day prior to experimentation in 03/2014. To train the decoder to be robust to unexpected neural changes, we perturbed the neural training data by randomly increasing or decreasing spike counts. We first evaluated if the MRNN could outperform an existing state-of-the-art BMI decoder, the FIT-KF (Fan et al., 2014), which was trained with data collected on the day of experimentation. The MRNN acquired targets faster than the FIT-KF (5.7% more targets per minute (tpm), $p < 0.05$). We next evaluated the robustness of the MRNN and FIT-KF to an unexpected loss of channels. The MRNN sustained better performance than the FIT-KF in the face of channel loss (52.1% more tpm across conditions, $p < 0.05$). Finally, we evaluated the robustness of the MRNN and FIT-KF to a natural sampling of neural non-stationarities. Both decoders were trained without access to the last four months of data and were then evaluated day after day, sampling naturally occurring neural differences between distant training days and the evaluation day. The MRNN substantially outperformed the FIT-KF (105% more tpm, $p < 0.05$). These results demonstrate that a nonlinear decoder that leverages a diversity of training data can substantially increase the robustness and performance of a BMI.

Title: A brain-controlled spinal interface (BCSI) for reanimation of paralyzed limbs after spinal cord injury

Authors: *A. IEVINS[1,2,3,4], M. SUNSHINE[1], A. BOSMA-MOODY[1,4], R. CARLSON[1,4], C. MORITZ[1,2,3,4]
[1]Rehabil. Med., [2]Physiol. & Biophysics, [3]Program in Neurobio. & Behavior, [4]NSF ERC for Sensorimotor Neural Engin., Univ. of Washington, Seattle, WA

Abstract: Brain and spinal cord injuries often lead to severe motor impairments that limit individuals' daily activities and independence. Incomplete injury to the cervical spinal cord is the most common spinal cord injury diagnosis, and restoration of hand and arm function is the highest treatment priority for individuals with cervical spinal cord injuries. Recent advances in brain-machine interface and microstimulation technologies provide opportunities for the development of new devices that could restore motor function after central nervous system injury. We are developing a closed-loop brain-controlled interface that records movement intention from the brain and delivers task-specific real-time stimulation to the spinal cord using state-of-the-art neural recording and intraspinal microstimulation technologies. The primary goal of this Brain-Controlled Spinal Interface (BCSI) is to re-animate and restore function to the paralyzed hand and arm. We have tested early versions of this BCSI in a rat model of cervical spinal cord contusion injury. Animals' forelimb function was analyzed using standard behavioral assessments, and various aspects of forelimb function were quantified during alternating sessions with the BCSI engaged and deactivated to distinguish the immediate effects of the BCSI from those attributable to gradual rehabilitation. Our results indicate that BCSI operation enables improved forelimb function after spinal cord injury; for example, BCSI operation enabled a 5-fold increase in peak lever deflection and a 75% decrease in number of attempts preceding a successful lever press when compared with trials in which the BCSI was deactivated. These results support the potential utility of a BCSI in restoring function to the paralyzed hand and arm after spinal cord injury.

Title: Novel electrocorticographic brain-computer interface framework for dexterous robotic control

Authors: ***D. SARMA**[1,2], J. WU[2], V. KUMAR[3], J. G. OJEMANN[4], R. P. N. RAO[3]
[2]Bioengineering, [3]Computer Sci. and Engin., [4]Neurosurg., [1]Univ. of Washington, Seattle, WA

Abstract: An implanted chronic brain-computer interface (BCI) could improve the quality-of-life for individuals with severe neuromuscular deficits by providing a system to enact intuitive, volitional control of assistive devices. Electrocorticography (ECoG)-based control systems for dexterous upper-body robotic prostheses have shown promise to fulfill this role. However, current methods for analyzing and modeling electrocorticographic (ECoG) data are still relatively limited. Moreover, Brain-computer interfaces (BCIs) based on ECoG data still rely primarily on linearly translating power in single high-frequency bands (70-200Hz) to the movement of a cursor. To be effective in the long term, a BCI system for hand prosthetics must be developed such that it can replicate natural human control by taking advantage of motor primitives as represented in ECoG data. Ideally, these BCIs must be able to exploit the brain's natural abilities, including its remarkable plasticity, to accomplish fine manipulation tasks. Here we demonstrate preliminary techniques for dimensionality reduction of ECoG motor and sensory field potential recordings into synergistic motor primitives and present a framework to control a highly dexterous and adaptable robotic hand. Utilizing ECoG data recorded at different resolutions we are able to test a variety of strategies for robotic control as well as better understand the neural dynamics of innate human hand control. Leveraging recordings from 10 subjects, implanted with clinical (10mm spacing), medium (5mm spacing), and high-resolution (3mm spacing) platinum subdural ECoG grids (implanted as per separate epileptic clinical considerations), suggests the presence of synergistic movements of individual digit joints during coordinated grasping further establishing this type of dimensionality reduction as a robust set of

targets for control of the robotic systems. Through this system, we hope to significantly advance our understanding of the computational basis of human manipulation capabilities and enhance the utility of ECOG for hand prosthetics.

Title: Volitional modulation of optically recorded calcium signals during neuroprosthetic learning

Authors: *K. CLANCY[1], A. KORALEK[1], R. COSTA[2], D. FELDMAN[1], J. CARMENA[1]
[1]UC Berkeley, Berkeley, CA; [2]Champalimaud, Lisbon, Portugal

Abstract: Brain-machine interfaces (BMIs) have recently emerged not only as a promising treatment for paralyzed patients, but also as a powerful technique for investigating neuronal network dynamics during learning. While past work BMIs has demonstrated striking network reorganization with cell-specificity during learning, the majority of BMI research to date has been performed with chronically implanted microwire arrays, which offer limited spatial resolution for monitoring network reorganization during learning. We operantly trained mice to modulate spike-related calcium signals in individual neurons recorded with two-photon imaging through a chronic cranial window. Mice successfully controlled an auditory cursor to earn reward using neural activity in both motor and somatosensory cortices, exhibiting performance improvements across- and within-sessions. The learned modulations were sensitive to reward contingency, suggesting that they are goal-directed rather than habitual. Learning was accompanied by changes in the network correlation structure and sparsening of task-relevant activity modulations on fine spatial scales (tens of microns). Mice could control a single neuron to drive task behavior. Together, these results demonstrate spatially precise network alterations during learning and introduce a powerful new paradigm for dissecting the local network mechanisms of neuroprosthetic control.

Title: Decoding dexterous finger movements from peripheral neural signals using machine learning algorithms

Authors: *C. BARTON[1], S. PADMANABAN[1], T. DAVIS[2], H. A. C. WARK[3], D. T. HUTCHINSON[4], B. GREGER[1]
[1]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ; [2]Neurosurg., [3]Bioengineering, [4]Orthopaedics, Univ. of Utah, Salt Lake City, UT

Abstract: Peripheral nerve implant based motor prostheses have the potential to provide dexterous control of individual digits to the user. Intrafascicular microelectrode arrays were implanted in the median and ulnar nerve of two human subjects who had undergone trans-radial amputations. Neural signals from the microelectrode arrays were recorded when subjects performed instructed volitional phantom finger movements, e.g. as guided by a virtual robotic hand. Discrete (individual finger movement) and continuous (movement trajectories) components of neural signals are required for robust control of a neural prosthesis. We achieve this by employing a Multiclass Support Vector Classification for identifying individual finger movements with 12 DOF on one day of data. Neuronal firing rates during the time of movements were extracted as input to the SVM. The classification accuracy for all 12 degrees of freedom was 76.8%, while an example finger, i.e. little finger flexion, abduction and extension, the classification accuracy was 91.76%. Additionally, the movement trajectories for the little finger were decoded using Support Vector Regression with a mean squared error of 14.83%. We also demonstrate an experimental design for a peripheral nerve implant of a microelectrode array in a healthy nonhuman primate. Neural signals will be recorded from an intrafascicular Utah slanted electrode array during a finger movement task performed with a mechatronic manipulandum which continuously records both position and force for the thumb, index and middle fingers. These movement parameters will be estimated from the neural signals, while the data recorded from the manipulandum provide a control. A chronic implantation in a nonhuman primate will allow for investigation of the long-term reliability of neural control signals from the peripheral system while allowing for greater control of experimental parameters than is possible with sub-chronic human implantations. A chronic peripheral implantation will allow for future work comparing the efficacy of linear, e.g. Kalman filter, and nonlinear, e.g. SVM & SVR, decoding algorithms when applied to both continuous force and position parameters. The application of nonlinear Machine Learning algorithms to peripheral neural signals may enable improved dexterous control of motor prostheses.

Abstract: Background Severely disabled people, especially patients suffering from amyotrophic lateral sclerosis (ALS) have great difficulty in daily movements and communication. Brain-machine interfaces (BMI) enable such disabled people to control machines and to communicate with others through the direct use of brain signals. In this study, we investigated neural decoding and prosthetic hand control using electrocorticograms in a completely paralyzed ALS person. Methods The patient was completely paralyzed except for slight eye and mouth movements. We implanted a patient-specific 96-channel grid electrode fitting to the sensorimotor cortices for three weeks. Four types of hand and arm imagery movements were decoded using a support vector machine algorithm, and prosthetic hand control was performed using a real-time, continuous decoding and control algorithm. Safety and efficacy including classification accuracy of upper arm movements and performance of prosthetic hand control (grasping and releasing a soft ball) were evaluated. Results Subdural hematoma was found and surgical evacuation was performed 5 days after electrode placement, but there were no neurological deficits later than 10 days after the implantation. High gamma band activities and cortical potentials were clearly induced by imaginary hand movements in the hand knob in the precentral gyrus. Classification accuracy of hand and arm movements was 77.7% (50% by chance). Regarding prosthetic control, averaged required times were 7 s for grasping a ball and 2 s for releasing it. Conclusion This is the first report that demonstrated that a completely paralyzed ALS patient was able to control a prosthetic hand in a real time.

Abstract: The goal of CLINATEC® Brain Computer Interface Project is to improve tetraplegic subjects' quality of life by allowing them to interact with their environment through the control of effectors with multiple degrees of freedom after training. Thanks to a long-term wireless 64-channel ECoG recording implant WIMAGINE® (Wireless Implantable Multi-channel Acquisition system for Generic Interface with NEurons) and an innovative signal processing, the subject should be able to control a 4-limb exoskeleton EMY (Enhancing MobilitY). The ECoG signals from the subject's brain will be recorded and wirelessly transmitted to a base station by the WIMAGINE® implant. This implant is composed of an array of 64 biocompatible electrodes, a hermetic titanium case which houses electronic boards, biocompatible antennas for wireless transmission of the data, and a remote power supply. Qualification tests are in progress to demonstrate compliance to the European Directives for Active Implantable Medical Devices. Innovative ECoG signal decoding algorithms will allow self-paced control of the exoskeleton by decoding the subject's brain activity. The neuronal signal processing approach is based on a tensor data analysis. It allows simultaneous treatment of the signal in several domains,

(frequency, temporal, and spatial). Before applying the BCI platform to patients, a set of preclinical experiments are carried out on male Macaque Rhesus. Ethical approval was obtained from ComEth in accordance with the European Communities Council Directive of 1986 (86/609/EEC) for care of laboratory animals. As the WIMAGINE® implant (designed to be implanted in patient's skull) is too large for implantation in primate's skull, a silicone-platinum cortical electrode array was epidurally implanted over the motor cortex and connected to the recording electrodes of the implant WIMAGINE® by means of a transcutaneous connector and a specially designed test assembly. The primate was trained to reach an exposed target using the right hand. The hand movements were recorded by an optical motion capture system Vicon (Motion Systems, Oxford, UK). During the calibration stage, the primate's ECoG data were correlated with the hand position data to identify a prediction model. This model was applied to the ECoG data on the second stage to generate control commands for the arm prosthesis. High performance decoding of the continuous three-dimensional hand trajectory from epidural ECoG signals of the primate's brain allows reproducing the arm movement by the exoskeleton arm (EMY) in real time.

Title: Spike-by-spike control using an adaptive optimal feedback-controlled point process decoder improves BMI performance

Authors: *M. M. SHANECHI[1,2], A. ORSBORN[2], H. MOORMAN[2], S. GOWDA[2], J. M. CARMENA[2]
[1]ECE, Cornell Univ., Ithaca, NY; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: Closed-loop decoder adaptation (CLDA) methods fit the decoder parameters during closed-loop BMI operation based on the neural activity and inferred user velocity intention. Combining Kalman filters (KF) with CLDA has resulted in the high-performance ReFIT-KF decoder (Gilja et al. 2012). Here we demonstrate proficient, robust, and generalizable spike-by-spike BMI control enabled by a novel CLDA algorithm, termed an adaptive optimal feedback-controlled (OFC) point process filter (PPF). In addition to providing a different mathematical encoding model, PPF allows users to issue neural commands and receive feedback of the consequence of such commands at a much faster rate (every 5ms) than the KF (typically every 50-100ms). Moreover, it allows the decoder parameters to be updated on a fast spike-by-spike time-scale compared with the currently used time-scale of minutes. In addition to using the point process model, adaptive OFC-PPF models the brain in closed-loop BMI operation as an infinite-horizon optimal feedback-controller (Shanechi et al. 2012) to infer velocity intention during adaptation, in contrast to current intention estimation methods. We recorded multi-unit activity from the primary motor cortex of two rhesus macaques over tens of online BMI sessions. We investigated the advantages of adaptive OFC-PPF both during CLDA and at steady-state. During CLDA, we found that spike-by-spike adaptation resulted in faster convergence in decoder parameters compared with current batch-based techniques, and was robust to initialization. Moreover, the OFC intention estimation resulted in a PPF with higher performance compared with a PPF obtained using current intention estimation techniques. We then compared the steady-state performance of adaptive OFC-PPF with that of a KF that was trained using SmoothBatch CLDA (Orsborn et al. 2012) and the CursorGoal method (Gilja et al. 2012). In both monkeys, OFC-PPF outperformed the trained KF in a self-paced center-out movement task with 8 targets. This improvement generalized to a multi-curvature obstacle avoidance task. To understand the fundamental reasons behind this improvement, we designed novel experiments to dissociate the effects of the three components that are different in a PPF compared with KF. These are the mathematical encoding model, the increased control rate, and the increased feedback rate. Our experiments showed that each of these three components improved BMI performance in both monkeys. Hence our results identify fundamental factors that facilitate the brain's ability to achieve proficient BMI control.

Title: Reconstruction of hand trajectories from MEG recording for BCI application

Authors: *T. AKSENOVA, N. ARIZUMI, M. C. SCHAEFFER, C. PÖSCHL, T. COSTECALDE, E. LABYT, N. TARRIN, C. MESTAIS, A.-L. BENABID
CLINATEC, CEA-LETI MINATEC, Grenoble, France

Abstract: The goal of the Brain Computer Interface project at CLINATEC®, CEA, Grenoble is to allow a tetraplegic subject to control external effectors, such as a 4-limb exoskeleton EMY (Perrot, et al., 2013) using ElectroCorticoGram (ECoG) recording through WIMAGINE® implants (Charvet, et al., 2013). Within the framework of the project the multi-way decoding algorithm (Eliseyev & Aksenova, 2013) was developed and tested in preclinical experiments for upper limb real movement trajectory reconstruction from ECoG recordings of nonhuman primates. In the present work, to ensure future clinical applications, algorithms were tested in humans, in MEG experiments for real and virtual (imagined) movements. The performance of real and virtual movement trajectory reconstruction was studied. During the experiments, predefined movements were performed after a visual stimulus at randomized time moments. Trajectories of predefined movements were registered with the same operators outside the MEG session using VICON movement tracking system and accelerometer. During MEG session two types of movements (reach-down-back and reach-left-back) were mixed in both cases of real and virtual tasks. In case of real movements, trajectory information was registered with a MEG compatible accelerometer in parallel to neuronal activity. For performance validation recordings were split in training and test sets. Training recordings were used for decoding model calibration. MEG and VICON recordings were synchronized according to accelerometer in case of real movements. In case of virtual movements they were synchronized (fixed and restricted variation in starting point and duration) in a way to obtain the best decoding performance. Restricted set of MEG sensors located in the neighborhood of motor region was specified by experts. Preliminary results (2 operators, 2 and 1 session respectively) of reconstruction: the correlation coefficients between real/virtual and predicted trajectory are respectively CC = 0.68 (CCx = 0.67, CCy =

0.61, CCz = 0.75), and CC = 0.52 (CCx = 0.50, CCy = 0.46, CCz = 0.61). The most informative frequency bands were 6-12Hz and 60-80Hz for real and virtual movements. Perrot, Y., et al. (2013). Title: Thresholding the discriminant output improves the reliability of communication using visual P300 speller brain-computer interface (BCI) for physically disabled persons

Authors: *K. MORI[1], Y. MATSUMOTO[2], T. M. RUTKOWSKI[2]
[1]Dept Rehabil. Sensory Functions, Natl. Rehab Ctr. Persons W/Disab, Tokorozawa, Saitama, Japan; [2]Life Sci. Ctr. of TARA, Univ. of Tsukuba, Tsukuba, Japan

Abstract: Brain-computer interface (BCI) enables the most severely disabled persons even to express their thoughts. Visual P300-based BCI decodes user's attention to a particular letter in a matrix from visually evoked potentials. The accuracy of 70% or better in decoding the users' intended letters is commonly considered good enough. However, the message with 30% errors in the spelling often becomes ambiguous to interpret. In most BCI systems that utilize P300 responses, the stimulus that scores highest with a given discrimination method automatically becomes the output of the decoder. Although there are studies using a dictionary and grammar to counter the errors, the process may add another layer of ambiguity, which could hinder a human reader from inferring an intended message correctly. In this study, another approach was tested

whether inhibiting the decoder output from statistically low-reliable trials may increase the overall accuracy of the output characters and aid communication. [METHODS] Patients who were on mechanical ventilation due to amyotrophic lateral sclerosis (ALS), as well as neurologically normal subjects participated in the study. 8 to 15 channels of EEG data were collected with a V-Amp (Brainproducts, Germany). The subjects were instructed to mentally count the number of flashes of an indicated character in a matrix. A modified P300 Speller of BCI2000 (Wadsworth Center, Albany, NY) was used in repeated offline simulation analyses with different thresholding for the same EEG data sets. The scores of the discriminator output were standardized and thresholded, and the inferred characters were produced only when the scores were higher than the threshold. This study has been approved by the internal research ethics committees of the respective affiliated institutions of the authors. [RESULTS] With a proper value of the threshold, almost all wrong inferences were eliminated from the output if the accuracy of the unthresholded inferences was relatively good. However, it did not improve the accuracy if the unthresholded performance was less than 70%. [CONCLUSIONS] A method to improve the accuracy of visual P300 speller BCI with output thresholding is proposed. The improvement observed here suggests that the performance of BCI may not be uniformly stochastic for the subjects with a relatively good overall BCI speller performance. By detecting and rejecting the output of low reliability trials, the overall BCI speller could be made more reliable, which should help improve the communication with the people in the locked-in state.

Title: Evaluation of fractal dimension estimation of eeg signals for features extraction in motor imagery based bci

Authors: *J. MONTALVO
CINVESTAV Del IPN, Distrito Federal, Mexico

Abstract: A Brain Computer Interface (BCI) is a tool that enables a direct communication between a brain and a computer; it provides a non-muscular channel for sending commands or messages to the external world. The BCI translates brain activity into computer commands using

preprocessing, feature extraction and classification methods. Feature extraction is an important step because it has the effect to improve on the classification accuracy and speed. Features extraction is the process of simplifying the representation of the data by reducing its dimensionality; get in its relevant characteristics. The fractal dimension is a statistical measure that shows the complexity of an object, signal or quantity, which is self-similar over some region of space or time interval. The brain signals are self-similar and we can consider them fractal pieces to obtain their features with some method like Higuchi, DFA, Katz and Hurst exponent algorithm. There are several of fractal dimension estimation methods, but some are not applicable to all types of data that have fractal proprieties. The objective of this work is using the fractal dimension to evaluate the features extraction in motor imagery for detect sensorimotor rhythms (mu 8-12hz and beta 18-26hz) marked by right and left hand motor imagery with the fractal dimension. Based on motor imagery is possible to detect this activity with only three main channels C3,C4 and Cz using the 10-20 international system for EEG. The classification method was performed by Neural Networks with good results. The algorithms were tested with the signals of two persons (each person with different session). The sessions were recorded in a EEG with 14 channels but for this work only 3 channels were used C3,C4 and Cz. The sampling rate was 256Hz and the protocol settings were based on model proposed by Pfurtscheller for the discrimination of two mental states. The task of the patient was to imagine and execute movements of the right and left hands depending on a visual guide displayed in the screen of a computer; in the entire task, the patient was kept with open eyes. In this work, it was observed that the faster algorithms Hurst Exponent go and the slower the Higuchi algorithm is, and about the accuracy the best method is the Katz algorithm and the worst is the Hurst exponent. With the Katz method good accuracy was obtained with only two electrodes (C3 and C4); and it was faster than the Higuchi algorithm that it had the second best accuracy This project was supported in part by CONACYT

Title: Plasticity following skilled learning and the implications for BCI performance

Authors: *N. MRACHACZ-KERSTING[1], N. JIANG[2], K. DREMSTRUP[1], D. FARINA[2]
[1]SMI, Sensory-Motor Interaction, Aalborg Univ., Aalborg, Denmark; [2]Georg-August Univ., Goettingen, Germany

Abstract: During use of a brain computer interface (BCI) the user is trained to fit into the performance of the BCI governed by a classifier or a detector. However, any design of a BCI must address the fact that the brain is undergoing continuous adaptation through learning (Sanes & Donoghue, 2000) and hence consider the principles related to how the brain acquires, improves and maintains its natural function. Here we investigated if a commonly used signal extracted from the electroencephalogram, (EEG) the movement related cortical potential (MRCP) is affected by motor learning. Eight healthy, volunteers (25-43 years) with no history of neurological conditions participated. Ten monopolar EEG channels (FP1, Fz, FC1, FC2, C3, Cz, C4, CP1, CP2 & Pz) were recorded (sampling frequency of 256 Hz). The learning task comprised a six randomized figures each sketching a different series of combinations of ankle movements. Subjects were instructed to these as displayed on a computer screen by controlling the activation level of their tibialis anterior (TA) muscle. A single training run lasted for 4 min followed by a 2 min rest period. A total of eight training runs (32 min of training) were completed. The signals were band pass-filtered (0.05-10 Hz, 2nd order Butterworth filter) and data divided into epochs of 4 s (from 2 s before to 2 s after the onset of EMG in the TA). The main time of interest for the MRCP was prior to the peak negativity as this is where the movement is conventionally detected for device control. The average EEG signal from -2 to -1 s prior to task onset and its associated SD were extracted from the EEG data. Results showed that during motor learning, the variability of the EEG activity within 1-2 s prior to movement onset (the SD within the time window), increased significantly while the averaged MRCP amplitude showed no difference. Results demonstrate that the trial to trial variability of the MRCP in the time prior to the peak negative phase was significantly greater during the learning of a motor task. This has important implications in the design of any MRCP-based BCI for online detection of movement. Online detecting relies on threshold values for the period prior to movement onset, thus the findings here suggest that BCI performance will decline with skill acquisition unless the algorithm is adapted to the new level of activity.

Title: The need to be me: Influence of participant specific instructions on mu-based BCI performance

Authors: M. SCHLUSSEL[1], A. BATTISON[1], T. FULLER[2], V. L. CORBIT[3], Y.-C. YU[2], *L. A. GABEL[1]
[1]Psychology & Program in Neurosci., [2]Electrical & computer Engin., Lafayette Col., Easton, PA; [3]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Brain-computer interface (BCI) technology is a growing field, becoming an increasingly viable aid for individuals who have lost normal neural motor output. The mu rhythm, a sensorimotor rhythm that is suppressed when one imagines motor activity, has been particularly utilized in BCIs because of its potential for diverse applications. While many novel implementations of mu BCIs have been developed, little work has been conducted investigating how to improve the neural signal coming from participants. Previous research from our laboratory suggested that specific instructions for imagined movement and relaxation improve overall strength of mu rhythms (Corbit et al., 2013). Improved mu power was hypothesized to improve performance on a mu-based BCI device. However it is important that sustained control over mu power, rather than maximum strength of mu rhythm is attained in order to successfully operate a BCI device. The current study aimed to improve participants' mu BCI performance by giving them participant specific instructions for imagine motor behavior for improved control over sustained mu power. Based on previous research from our lab participants were able to successfully produce mu rhythms in response to imagined motor or relaxing behavior in a single trial. Building upon these methods participants were provided with instructions (non-specific, specific, or participant specific instructions on how to imagine motor behavior) and the ability to control the strength of the mu rhythm was analyzed. The BCI system algorithm calculated a bilateral mu power value from two electrodes positioned over the left and right sensorimotor cortices and compared to a participant's baseline value to determine if the power increased or decreased; this difference corresponded to feedback shown on a computer screen. Preliminary evidence suggested there is a significant difference in control over mu power based on the type of instructions provided to the participant. These data may suggest that the success of an individual using a mu-based BCI device may depend on the type of instructions provided. Decreasing training time, increasing BCI literacy, and enhancing control over mu-based BCI devices will make this type of BCI device more accessible to individuals with impaired motor behavior.

Title: EEG change through long term brain-computer interface training in focal hand dystonia

Authors: ***Y. HASHIMOTO**[1], T. OTA[2], M. MUKAINO[3], J. USHIBA[4]
[1]Dept. of Electrical and Electronic Engin., Kitami Inst. of Technol., Hokkaido, Japan; [2]Asahikawa Med. Univ. Hosp., Hokkaido, Japan; [3]Fujita Hlth. Univ., Aichi, Japan; [4]Keio Univ., Kanagawa, Japan

Abstract: An electroencephalogram (EEG)-based brain-machine interface or brain-computer interface (BCI) has originally succeeded to control robotic arm and home electronics by extracting features in EEG, and thus has expected to be a tool to compensate lost motor functions in patients with amyotrophic lateral sclerosis or spinal cord injury. Recently, some research groups succeeded in showing another possible use of BCI, that is, as a tool to promote neural plasticity causing functional recovery from stroke. The number of clinical applications of such BCI-based neurorehabilitation is expected to increase in the near future. Focal dystonia is a disorder of movement characterized by involuntary, sustained muscle contractions, frequently causing twisting and repetitive movements or abnormal postures of a body part. Writer's cramp (WC) is an example of task-specific focal hand dystonia. WC was once believed to be a purely psychological problem, but more recently is understood to be due to more specific neural dysfunction, including that of the basal ganglia. The current study employed a BCI paradigm to provide visual feedback of ongoing EEG features that represents the exaggerated excitability of the sensorimotor cortex during hand movement, and assessed neurological and behavioral changes through 30-day use in a WC patient as a clinical pilot study. Each recording day, a participant was requested to perform the following: (1) tonic contraction of the right extensor muscle (tonic motor task) for 60 s; (2) right hand extension with rhythmic auditory cue for 40

times, one every 2.5 s (repetitive motor task) for 40 times; and (3) write Japanese characters with a pen and digital pen tablet(writing task). The patient completed biweekly one-hour training for over 30 times without any adverse effects (for totally over a year). In first 10 times of training, significant decrease of the beta frequency component (26-34 Hz) during handwriting was confirmed, and was associated with clear hand wringing improvement. In last 10 times of training, the hand did not show comparatively large hand writing change, but the average of pen pressure was significantly decreased ($P<0.01$) by the training. Our results suggest that there is another application of therapeutic BCI for patients with exaggerated cortical activity associated with involuntary muscle contractions, such as a dystonia patient, using visual feedback of abnormal EEG activity.

Title: Identifying hand poses using common spatial patterns in human electrocorticographic signals

Authors: ***C. KAPELLER**[1], C. SCHNEIDER[2], K. KAMADA[3], H. OGAWA[3], N. KUNII[4], R. ORTNER[1], C. GUGER[1]
[1]Guger Technologies OG, Schiedlberg, Austria; [2]g.tec Guger Technologies OG, Schiedlberg, Austria; [3]Dept. for Neurosurgery, Asahikawa Med. Univ., Asahikawa, Japan; [4]Dept. for Neurosurgery, The Univ. of Tokyo, Tokyo, Japan

Abstract: Decoding brain activity of corresponding high-level tasks may lead to an independent and intuitively controlled Brain-Computer Interface (BCI). Most of today's BCI research focuses on analyzing the electroencephalogram (EEG) which provides only limited spatial and temporal resolution. Derived electrocorticographic (ECoG) signals allow the investigation of spatially highly focused task-related activation within the high-gamma frequency band, making the

discrimination of individual finger movements or complex grasping tasks possible. Common spatial patterns (CSP) are commonly used for BCI systems and provide a powerful tool for feature optimization and dimensionality reduction. This work focused on the discrimination of (i) three complex hand movements, as well as (ii) hand movement and idle state. Two subjects S1 and S2 performed single ‘open’, ‘peace’ and ‘fist’ hand poses in multiple trials. Signals in the high-gamma frequency range between 100 and 500 Hz were spatially filtered based on a CSP algorithm for (i) and (ii). Additionally, a manual feature selection approach was tested for (i). A multi-class linear discriminant analysis (LDA) showed for (i) an error rate of 13.89 % / 7.22 % and 18.42 % / 1.17 % for S1 and S2 using manually / CSP selected features (see Fig. 1), where for (ii) a two class LDA lead to a classification error of 13.39 % and 2.33 % for S1 and S2, respectively. Such a BCI system can be used to control a virtual or physical avatar just by brain activity and the study showed successfully that hand hand-poses can already be decoded to be transferred to avatar movements in real-time.

Title: Real-time artificial hand posture control by using electrocorticographic signals from human sensorimotor cortex

Authors: *S. ZHANG[1,2], D. WANG[1,2], Y. LI[1,2], Q. ZHANG[1,2], J. ZHU[1,3], X. ZHENG[1,2]
[1]Qiushi Acad. for Adv. Stud., Zhejiang Univ., Zhejiang, China; [2]Dept. of BME, Zhejiang Univ., Hangzhou, China; [3]Neurosurg, 2nd Affil Hops, Zhejiang Univ., Hangzhou, China

Abstract: Brain-machine interfaces (BMIs) build a direct communication pathway between brain and external devices, which provide a hope for restoring lost motor function for the disabled. Electrocorticographic (ECoG) signal from sensorimotor cortex has successfully been used in classification of hand grasp types or arm movement directions and in prediction of hand trajectories and muscle activities because it is less invasive than microelectrode and can offer higher spatial resolutions than EEG. However, investigations on real-time robotic prosthesis control using ECoG are lacking, despite its potential in practical neuroprosthesis and neurorehabilitation technology. In this study, we recorded ECoG signals from subdural macro-electrodes covering sensorimotor cortices of two patients who were undergoing inpatient monitoring for diagnosis and treatment of intractable epilepsy. Participants performed three hand postures following visual cues: Rock-Paper-Scissors. Movement instruction alternated with rest where the participant was explicitly instructed to rest hand for a random time. The three hand postures with an additional resting state were classified asynchronously using a fuzzy k-nearest neighbor model, and an artificial hand was controlled online using a shared control strategy. The results showed that the high gamma power (70-120 Hz) of ECoG signals from 8 and 13 of electrodes was responsive to hand movement in two participants respectively. The offline classification performance of ECoG for three hand postures was as high as 97.1% on the average. In the online demonstrations, the instantaneous status of hand postures could be extracted from ECoG signals recording from only 5 macro-electrodes and successfully to control the artificial hand with averaged accuracy of 76% and 85.1% respectively. Our pilot studies demonstrated that ECoG signals from human sensorimotor cortex could be used to decode information about hand postures and be interpreted as real-time control commands for artificial hand, suggesting its potential application in practical BMIs.

Title: Arm prosthetic control through electromyographic recognition of leg gestures

Authors: ***K. R. LYONS**, S. S. JOSHI
Mechanical and Aerospace Engin., UC Davis, Davis, CA

Abstract: Use of surface electromyography (sEMG) has shown promise as a method of controlling prosthetic devices, but current control paradigms may suffer from at least one of two main problems: non-intuitive input and invasiveness. A typical approach to the problem is to recognize gestures by recording EMG signals from multiple muscle sites near the amputation and analyzing these signals with a classification algorithm to detect a discrete user intention (e.g. close hand, rotate wrist, etc.). Here, we introduce the idea of recording EMG from the lower leg as the control input to a prosthetic arm. The user performs gestures with the lower leg or foot which map relatively intuitively to forearm or hand movements, requiring essentially no training. A completely noninvasive system for recording, processing, and transmitting commands from the leg to a prosthetic arm could be reduced to a sleeve design with embedded electronics. Although the musculature of the lower leg is somewhat different from that of the forearm on which most EMG-based gesture recognition research is performed, we show that many leg and foot gestures, which have directly analogous arm and hand movements, can be recognized with pattern recognition techniques.

Title: Altered spatial representation of event related desynchronization during finger and shoulder motor imagery

Authors: *K. HASEGAWA[1], T. ONO[3], M. LIU[2], S. KASUGA[4], J. USHIBA[4]
[1]Grad. Sch. of Sci. and Technol., Keio Univ., Kanagawa, Japan; [2]Dept. of Rehabil. Med., Keio Univ., Tokyo, Japan; [3]Saiseikai Kanagawa-ken Hosp., Kanagawa, Japan; [4]Dept. of Biosci. and Informatics, Keio University, Fac. of Sci. and Technol., Kanagawa, Japan

Abstract: Scalp electroencephalogram (EEG) based Brain-Computer Interface (BCI), can facilitate motor learning by explicit representation of motor-related cortical activity, and has been proposed as a rehabilitative measure for stroke hemiplegia. BCI rehabilitation systems often use event-related desynchronization (ERD) of the 8-13 Hz component in the parietotemporal EEG, which is known as a cortical sensorimotor excitability marker, but a little is known about its somatotopical characteristics observed during distal and proximal muscle contractions in the upper extremity. Functional anatomy has revealed that proximal muscles tend to be innervated bilateral corticospinal paths rather than distal muscles, thus ERD may be distributed bi-hemispherically. In this study, we assessed spatial distribution of ERD with various types of upper limb movement and imagery. 128 channels of scalp EEGs were recorded from three healthy individuals. The monitor was placed in front of the participants to give a task cue of Rest (4s) - Ready (2s) - Task (5s). During the task period, the participants were asked to image either finger pinching or shoulder elevation movement in a random order. Noted here that visual feedback of the amplitude of ERD derived from different hemispheres was given for each. The tasks required were thus as follows; right finger pinching imagery with ipsilateral ERD feedback, right finger pinching imagery with contralateral ERD feedback, right shoulder elevation imagery with ipsilateral ERD feedback, and right shoulder elevation imagery with contralateral ERD feedback. As results, contralateral ERD during right finger pinching imagery was found regardless of contralateral or ipsilateral side of feedback. On the other hand, bilateral ERD during right shoulder elevation imagery was found. Larger ERD was seen in the hemisphere at which feedback signal was derived. These results implies that motor imagery with distal muscles recruited contralateral sensorimotor cortex dominantly, whereas motor imagery with proximal muscles recruited bilateral hemispheres. From these findings, we expected that feedback with the ipsilateral ERD to the imaged hand may lead activation of the ipsilateral cortex, and would contribute to establish a pathway-dependent neurorehabilitation for stroke in future.

Title: Proprioceptive feedback modulates motor cortical activity during the control of an intracortical microelectrode brain-machine interface

Authors: *D. M. RAGER[1,2], J. E. DOWNEY[4], J. L. COLLINGER[4,5,6], D. J. WEBER[4,5], M. L. BONINGER[5,6], V. VENTURA[2,3], R. A. GAUNT[4,5]

Abstract: Loss of proprioception is known to severely impair motor control. Previous research by Ghez et al. demonstrated that people lacking proprioceptive input show significant deficits in reaching tasks performed without visual guidance. People with proprioceptive loss are also known to be unable to walk without visually attending to their legs. However, the neural mechanisms by which proprioception aids in the planning and execution of visually guided movements are not well understood. In this study, we explore the neural and behavioral impact of providing proprioceptive feedback to a subject using a prosthetic arm controlled by an intracortical microelectrode brain-machine interface (BMI). A single subject with tetraplegia and intact sensation was implanted with two 96-channel microelectrode arrays in primary motor cortex (M1). The subject made both visually-guided and blinded reaching movements with the BMI-controlled prosthesis with and without proprioceptive feedback, which was provided by moving the subject's limb in coordination with the prosthetic arm. The subject was specifically instructed to move the prosthetic arm back and forth across two lines in the horizontal plane as many times as possible during each one minute trial. Poor task performance in the no feedback condition was associated with a decrease in the mean firing rate of recorded M1 units and an increase in inter-channel spiking correlations as compared to any other feedback condition. Task performance was dependent on the paradigm used to train the BMI decoder; performance degraded significantly when proprioceptive feedback was added to a decoder trained using visual feedback only. This behavioral result was accompanied by significant changes in the preferred

velocity-tuning direction of the majority of recorded M1 units. Paradoxically, proprioceptive feedback resulted in better task performance than no feedback, but the mean path length per line-crossing and variance of movement in the non-task-relevant dimension were significantly smaller in the visual feedback/visual-trained-BMI condition than in the visual+proprioceptive feedback/visual+proprioceptive-trained-BMI condition. Performance differences between the visual and visual+proprioceptive feedback conditions were marked by different patterns of neural population activity, characterized by inter-channel spiking correlations. These findings suggest that neural tuning and dynamics change dramatically under various visual and proprioceptive feedback conditions, and that existing BMI decoding algorithms may not be suited to interpret the neural code resulting from proprioceptive inputs to M1.

Title: Brain-Machine interface using human parietal cortex: Control of prosthetic devices from anterior intraparietal area and Brodmann's area 5

Authors: *S. KELLIS[1], C. KLAES[2], T. AFLALO[2], B. LEE[3,2], Y. SHI[2], K. PEJSA[2], K. SHANFIELD[5], S. HAYES-JACKSON[5], M. AISEN[5,4], C. HECK[4], C. LIU[3,6,2], R. A. ANDERSEN[2]

Abstract: The posterior parietal cortex (PPC) processes sensory inputs, develops motor plans, and projects outputs to motor and pre-motor areas. In both human and nonhuman primate work,

subregions of parietal cortex have been implicated specifically in planning reach movements (parietal reach region and Brodmann's area 5) and grasping (anterior intraparietal area, AIP). Neuronal activity, recorded from PPC of non-human primates, shows coding of different movement types, e.g. specificity for reach movements of the contralateral and ipsilateral limb and grasp postures of the hands. Moreover, PPC represents both kinematic trajectories as well as goals for reach movements. Local field potentials recorded from PPC manifest with stronger power than in other areas of cortex, and encode information about movement planning. These high-level, cognitive encodings of movements suggest that PPC would be an ideal target for a neural prosthetic to assist paralyzed patients. Based on these findings, we initiated a clinical trial to evaluate a brain-machine interface using signals recorded from the PPC of a tetraplegic human subject. To secure representation of both grasp and reach, we implanted Utah electrode arrays in the presumed anterior intraparietal area (AIP) and Brodmann's area 5 (BA5). The implantation sites were selected based on functional magnetic resonance imaging of the subject when he imagined reaching or grasping. In the first year after implantation, there have been no device-related adverse events in the course of our study, and neural signal recordings have been very stable. We have found strong evidence for the important qualities of PPC that motivated our study, including encoding for multiple effectors, goal and trajectory decoding, representation and online control of grasp, and the utility of local field potentials. The participant has demonstrated brain control of a physical robotic limb and virtual reality scenarios that include control of virtual limbs and 3D computer cursors. To our knowledge this is the first motor prosthetic demonstrated in a human with an implant outside motor or premotor cortex. The results demonstrate that the PPC is an excellent target for signals for prosthetic control. The high-level, cognitive nature of the signals provide for versatile and intuitive control of external assistive devices.

Title: Potential of neural-network based modeling of bladder pressure from sacral dorsal root ganglia recordings

Authors: *S. S. RAJAGOPALAN[1], S. E. ROSS[2], T. M. BRUNS[2]
[1]Univ. of Michigan, Bloomfield Hills, MI; [2]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Automatic evacuation of the bladder in patients who have lost the ability can be achieved with medical devices that stimulate nerves to control the bladder. These devices, however, are typically unaware of the bladder state and are inefficient. Neural signals measured from sacral dorsal root ganglia (DRG) show significant correlation with bladder pressure and have high signal to noise ratio when compared to peripheral nerve locations. It is thus possible to estimate bladder pressure through the measurement of these neural signals. Previous research has shown the potential of data fitting techniques (using least squares), assuming a static relationship between the neural response and bladder pressure. Such techniques require offline pruning and sorting of channels and are inefficient in modeling dynamic systems. An alternative approach is offline system identification through artificial neural networks (ANN). The model can then be used for implementation in real-time neuroprosthetic bladder control. A catheter was inserted into the bladder to measure the pressure, while microelectrode arrays were inserted in sacral DRG of alpha-chloralose anesthetized cats. The measured pressure was filtered using a 4 Hz low-pass Butterworth filter, and used as target data during the model identification. Ninety neural recording channels from S1 and S2 DRG were used to calculate firing rates which were then used as inputs to the ANN. It was observed that a non-linear, auto-regressive moving average ANN provided the best input-output response. The ANN was first trained using "open-loop training" to obtain initial parameter guesses. In this method modeling errors at each time step are not propagated to the next prediction step as the measured pressure value is used instead. Next, "closed-loop training," which exclusively feeds back model estimated pressure at each step to predict the next output, was then applied thereby propagating modeling errors at every step. The trained network was then implemented in Simulink towards real-time bladder pressure estimation. Neural networks, trained separately using partial data from a given dataset, were able to model the same dataset with high accuracy (mean-squared error (mse) < 2 cmH2O), but did not fit other datasets at all. However concurrent training, using multiple data sets yielding promising results (mse < 10 cmH2O) across multiple datasets. Further refinement is necessary before implementation of a real-time ANN in a bladder neuroprosthesis.

Title: Targeting sacral dorsal root ganglia for concurrent monitoring and control of bladder function via electrical stimulation

Authors: *S. E. ROSS, J. T. BENTLEY, T. M. BRUNS
Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Current strategies for bladder control using electrical stimulation typically do not incorporate feedback on bladder state, requiring continuous stimulation. We are developing a closed-loop strategy that targets sacral dorsal root ganglia (DRG), which contain the cell bodies of sensory afferent fibers innervating the lower urinary tract. These fibers include the pelvic and pudendal nerves, which carry information about the state of the bladder and the pelvic region. These DRG may provide an ideal interface location for a neuroprosthetic device for bladder control, as we can both monitor bladder state and stimulate sensory pathways that drive spinal circuits for bladder control. Recent work has shown that stimulation near 30 Hz in sacral DRG can elicit reflex bladder contractions and 5 Hz stimulation can lead to bladder relaxation. Penetrating microelectrode arrays of lengths 1.0 mm or 0.5 mm were inserted in S1 and S2 DRG in alpha-chloralose anesthetized male cats. Neural activity and bladder pressure (via a supra-pubic bladder line or urethral catheter) were recorded at different bladder volumes. Stimulation (200 microsecond pulsewidth, 7.5 - 37.5 microamperes, and 1 - 33 Hz) was delivered on individual and multiple electrode channels at different bladder states. We observed DRG stimulation-driven bladder excitation of up to 40 cmH20 and bladder relaxation of more than 30 cmH20. During these trials, we also monitored at least 9 neural recording channels that correlated to bladder pressure, each of which tracked the pressure during stimulation. This concurrent stimulation and bladder state monitoring demonstrates the potential for a closed-loop DRG neuroprosthesis for bladder control.

Title: A novel interface for visualizing and controlling stimulation on high-channel-count electrode arrays

Authors: *A. M. WILDER, M. A. FRANKEL, S. D. HIATT, E. L. BARCIKOWSKI, K. S. GUILLORY
Ripple, SALT LAKE CTY, UT

Abstract: The past two decades have seen tremendous advances in the use of high-channel-count electrode array technologies for electrophysiology research. Such arrays have spurred the development of a new generation of data acquisition instruments to amplify and sample hundreds of signals at very high rates. Accompanying software development efforts have produced a wealth of applications for visualizing and analyzing large numbers of signals in parallel—both off-line and in real-time. More recent electrophysiology instrumentation efforts have produced hardware devices capable of delivering distinct electrical stimulation patterns on hundreds of electrode channels concurrently. To realize the full potential of these high-channel-count stimulation platforms, new software programs and a host of new visualization and control paradigms are needed. We have developed a graphical interface for generating, arranging and executing stimulation patterns concurrently on hundreds of electrodes. The interface is based on the metaphor of music scoring and draws inspiration from a variety of graphical interfaces in the consumer electronics industry—specifically multi-track audio editing applications. The interface presents the user with a list of all stimulation channels provided by the hardware. The interface also presents a simple, form-based interface through which the user can, for each channel, design one or more stimulation patterns. Finally, the interface provides a graphical, timeline-like representation of a stimulation "score" to which the user can add and arrange any stimulation patterns he/she has defined. Individual patterns can be used multiple times in a single score, and they can be selected and modified as needed in between executions of the score. The time-base of the score visualization can be adjusted to allow the user to inspect details of a specific pattern or access an overview. The user can also scroll the visualization window in time to access various periods of the score. The software provides other useful options such as allowing the user to play a score an arbitrary number of times in a row (i.e. loop mode), and saving the score for use at a latter time. Though this software application represents a tiny fraction of the range of possible high-channel-count stimulation control paradigms, it is the first to tackle this difficult task.

Title: The development and validation of a high channel count simultaneous stimulation and recording system

Authors: *E. L. BARCIKOWSKI[1], S. D. HIATT[1], D. M. PAGE[2], S. M. WENDELKEN[2], G. A. CLARK[2], K. S. GUILLORY[1]
[1]Ripple, Salt Lake City, UT; [2]Dept. of Bioengineering, Univ. of Utah, Salt Lake City, UT

Abstract: Emerging fields in the study of neural motor systems and neural engineering are beginning to require both large electrode counts and the ability to record neural signals simultaneously from stimulation electrodes. Additionally, stimulation across a large number of electrodes needs to be performed concurrently and independently between channels. In order to record immediately after a stimulation pulse, recording amplifiers require a mechanism to settle quickly to remove stimulation artifacts. Current commercially available stimulation systems do not allow simultaneous recording and do not accommodate large numbers of channels or use only a few multiplexed channels for stimulation that do not allow the channels to be truly independent. We have developed a stimulation/recording front end to address these issues. Each front end can provides up to 32 channels of independently controlled stimulation and recording, and each front end is connected to our data acquisition system that can connect to 16 front ends, allowing for a total of 512 channels of simultaneous stimulation and recording. The recording amplifiers include a fast settle capability that allows for neural recordings free of stimulation artifacts 1 ms after a stimulation pulse. These amplifiers have high impedance (250 MΩ) and low noise (2.1 μV). The stimulation/recording front end is small, fitting on a 2”x1.3” circuit board that weighs 5.2 g, so it may be placed very close to an electrode site. On the bench top, this system was tested using a Utah Electrode Array (UEA) in saline. A 1 kHz signal was injected into the saline while producing stimulation in the UEA with a series of biphasic pulses of varying amplitudes and duration. The 1 kHz signal was recorded both with and without stimulation showing that the fast settle capability completely recovers the signal 1 ms after stimulation. *In vivo* validation was completed in neural tissue, recording from a UEA implanted in cat sciatic nerve. Action potentials were recorded from afferent sensory activity while the paw was moved at the ankle joint. Stimulation pulses were delivered on the UEA at 30 to 100 Hz across a range

of pulse amplitudes and durations while producing action potentials. The stimulation/recording front end fast settle allowed for successful recordings of action potentials 1 ms after stimulation.

Title: Changes in response properties in motor cortex neurons during brain-machine interface control

Authors: C. LIBEDINSKY[1], R. SO[2], Z. XU[2], C. GUAN[2], *S.-C. YEN[3,4]
[1]Singapore Inst. for Clin. Sci., Singapore, Singapore; [2]Inst. for Infocomm Res., Singapore, Singapore; [3]Natl. Univ. Singapore, Singapore, Singapore; [4]Singapore Inst. for Neurotechnology, Singapore, Singapore

Abstract: Background: Over 60,000 people each year suffer from spinal cord injuries that paralyze all four of their limbs. Many of these patients indicate that the ability to control a wheelchair using brain-machine interface (BMI) would be among their top priorities. For this reason, considerable effort has been devoted to the development of BMI systems that would enable self-motion. Multi-electrode arrays chronically implanted in primary motor cortex can be used to collect activity from multiple neurons simultaneously. Since single neuron signals have a high bandwidth, decoded information from these signals can be used to control machines with several degrees of freedom. Methods: Two monkeys were trained to move a robotic platform towards a target positioned in different locations of a room using a joystick. After training, both animals were implanted with multi-electrode arrays in the hand/arm area of primary motor. Their arms were then restrained, the joystick removed, and they were trained to control the robotic platform using single unit activity recorded from the implanted electrodes. Brain signals were used to determine movement initiation and direction in real-time and in a free-running mode. Results: Single neuron analysis of response profiles during BMI control revealed the existence of three distinct populations of cells: (1) Motor-BMI neurons, which maintained their selectivity

profiles consistent with that found during joystick control, (2) Motor-only neurons, which lost the selectivity present during joystick control, and (3) BMI-only neurons, which acquired selectivity that was not present during joystick control. Discussion: Activity of Motor-BMI neurons appears to reflect intended movement direction, while activity of motor-only neurons seems to be related to actual arm-movements. On the other hand, activity of BMI-only neurons may reflect the learning process that the monkeys undergo to control the platform using BMI.

Engin., [5]Dept. of Speech, Language & Hearing Sci., Boston Univ., Boston, MA; [6]The Picower Inst. for Learning and Memory & Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Brain-computer interfaces (BCIs) aim to provide a means of communication to the severely paralyzed by recognizing changes in brain signals and translating (decoding) them into commands for operating computers and other devices. Despite recent improvements, BCIs are prone to errors, and most of them still rely on knowledge of the "ground truth" to improve their performance, which is not feasible for actual clinical applications. In this project we characterize error-related signatures in local field potentials (LFPs), and assess their potential for automatic performance monitoring (decoder error detection), binary-choice selection, and unsupervised adaptive decoding. We recorded from three 32-channel Utah arrays implanted in the supplementary eye field (SEF), frontal eye field (FEF), and dorsolateral prefrontal cortex (PFC) of two macaque monkeys performing a brain-controlled 6-choice delayed saccade task. During online brain-computer interaction, intended saccades were decoded from delay-period multi-unit

activity, and feedback was given to the subjects via discrete cursor movement and reward (contingent on the classifier decoding the correct location but independent of any overt movement). Offline analysis of correctly and incorrectly decoded trials showed a characteristic time domain LFP waveform for trials with decoder errors (error-related potentials, or ErrPs), which were similar within each array, but different across them. ErrP amplitude was modulated by the distance between the true target and the decoded one -the closer the decoded target to the true location, the smaller its amplitude. Finally, offline automatic decoder error detection was carried out using post-feedback ErrPs and a linear classifier. Errors were correctly detected on 97% of trials on average for monkey 1, and 96% of trials for monkey 2. Our results suggest high levels of accuracy for decoder error detection that could be useful as a BCI control signal or as a supervisory signal for adaptive decoding, and in the long term for more reliable BCIs.

Title: Smooth degradation of behavior with ICMS electrode silencing

Authors: *M. C. DADARLAT, P. SABES
BioEngineering, Univ. of California, San Francisco, San Francisco, CA

Abstract: Smooth and effortless control of neural prosthetic devices will require somatosensory feedback, in particular proprioception_the sense of the body's position in space. We have previously shown that multi-channel intracortical microstimulation (ICMS) can provide the real-time feedback needed for non-human primates to perform a reaching task. Specifically, we used patterned stimulation across eight electrodes to encode the distance and direction from the monkey's current hand position to that trial's reach target. The ICMS pulse rates of the eight electrodes followed a cosine tuning in direction, with equally spaced "preferred directions," and

a mean rate that scaled with distance. Monkeys were able to perform reaches guided by ICMS alone and, if both vision and ICMS inputs were present, would integrate the artificial sensory input with natural vision to form a minimum-variance estimate of position. These results established that ICMS can be used to provide artificial sensory information. Nevertheless, the monkey's strategy in interpreting the ICMS signal is not known. The ICMS encoding scheme creates redundancy across electrodes: in principle the animal could determine the instantaneous distance and direction from just two of the eight stimulating electrodes. In order to determine how the animals make use of this redundant information, we selectively "silence" sets electrodes (zero their stimulation amplitude) during a given trial. Behavioral sessions consisted of interspersed paired vision and ICMS trials and ICMS-only trials. For ICMS-only trials, we silenced either zero, two, four, or six of the eight stimulating electrodes. We found that behavioral performance (as measured by percent correct trials, total number of movement sub-segments, and total movement time) degraded smoothly with the number of silenced electrodes. In particular, the monkey showed difficulty completing reaches to the parts of space represented by the silenced electrodes, but not elsewhere. Furthermore, attempted reaches in these directions proved noisier, as measured by the variance in errors of initial reach angles.

Title: Decoding hand gestures using high-density ECoG in somatosensory cortex

Authors: *M. P. BRANCO[1], Z. V. FREUDENBURG[1], M. G. BLEICHNER[2], M. J. VANSTEENSEL[1], E. J. AARNOUTSE[1], N. F. RAMSEY[1]
[1]Dept. of Neurol. and Neurosurg., UMC Utrecht Brain Ctr. Rudolf Magnus, Utrecht, Netherlands; [2]Dept. of Psychology, Univerisity of Oldenburg, Oldenburg, Germany

Abstract: Brain-Computer Interfacing (BCI) is an emergent technology, which enables paralyzed patients to restore or replace motor function. One of the chief challenges is to increase the number of translational degrees-of-freedom. Electrocorticography (ECoG), which has very good spatial and temporal signal resolution, opens the possibility of distinguishing between complex and fine movements based on sensory-motor cortical activity, which could provide a

new multi-channel communication device for locked-in patients. Bleichner showed that four hand gestures could be anatomically distinguished with 74-97% accuracy for two subjects [1]. The anatomic (spatial) classification was based on the different patterns across channels produced by the mean gamma (70-125 Hz) power of the gestures. One of the questions is whether decoding can best performed from primary motor cortex M1 or from somatosensory cortex. In paralyzed patients, the execution of the movement is compromised, leaving motor imagery or attempted movements as the only decodable cognitive activity. It is not clear whether motor imagery activates primary motor cortex: Hermes ea [2] showed with fMRI that in healthy volunteers motor imagery failed to activate M1, but did activate somatosensory areas. This was further supported by ECoG where imagined movement failed to generate activity in M1. Thus, motor imagery might be better decoded from somatosensory cortex. Here we test whether from sign language gestures can be decoded from somatosensory cortex. We investigate the decodability of four gestures using high-density ECoG grids (3 mm center-to-center electrode spacing) covering the somatosensory cortex near the hand region. We employed decoding algorithms to classify the gestures using spatial and temporal information, limited to the power in the 70-125 Hz range and to electrodes on the somatosensory cortex. Results are reported for five epilepsy patients. Hand gestures were decoded with a mean classification rate of > 77 %, corroborating the proposition that spatio-temporal patterns of somatosensory activity may be an additional hallmark for specific gestures. Classification was significantly above chance level (mean 24%, determined by method validation with random values) and was validated using a leave-one-out cross-validation by means of Pearson correlation. The results suggest that somatosensory cortex may be a good candidate for motor imagery-based BCI. Furthermore, this work encourages the use of high-density ECoG grids as a robust and reliable BCI platform for fine movement decoding. [1] - Bleichner, M. G. (2014) Thesis. Title: Stochastic facilitation of prosthetic derived sensory stimulation in primates

Authors: *J. C. TANNER[1], C. K. OVERSTREET[2], S. I. HELMS TILLERY[1]
[1]SBHSE, Arizona State Univ., Tempe, AZ; [2]Nanovision Biosci., San Diego, CA

Abstract: Providing natural and practical sensory feedback in neuroprosthetics is a top priority in brain computer interfaces. This experiment seeks to provide tactile information from a prosthetic's environmental interactions and create repeatable, discriminable, and meaningful sensations via intracortical microstimulation (ICMS). In particular, we aim to provide robust tactile cues, such as the direction of slip. For our studies, we used a prosthetic fingertip known as the BioTac. To approximate environmental actions, the device uses impedance across electrodes embedded in a deformable skin filled with fluid; as pressure is applied to the fingertip, the skin deforms and the impedance adjusts accordingly. We derived ICMS stimulation trains by performing scanning motions in eight directions with the device (0o to 315o on 45o intervals) and choosing three impedance electrodes which modulated across those directions. Using the distinct patterns of these chosen electrodes, multichannel stimulation of somatosensory cortex was delivered to a NHP that had been trained on a two alternative forced choice discrimination task with pairs of visual, auditory, or ICMS stimuli. Trials were blocked by stimulus mode and randomized between same and different pairs of stimuli. Results from stimulation sessions (n=65 days) indicate that using this method of stimulation, and animal could achieve ~60% correct pattern discrimination, between stimuli separated by 90o. In order to increase the discrimination ability of the NHP, we introduced stochastic facilitation (SF, the introduction of a secondary noise signal) to the ICMS trials. SF can increase a system's response to small amplitude signals. We delivered randomized SF congruently with our derived patterns and saw marked improvement. Preliminary SF stimulation sessions (n=4 days) using a 10% SF elicits an increase in NHP's discrimination accuracy by ~20%. In order to better analyze the benefit we need to continue recording stimulation data, determine the ideal SF distribution, and refine the generation of BioTac derived stimulation patterns.

Title: Discrimination of electrical stimulation to primary somatosensory cortex

Authors: *S.-S. KIM, T. CALLIER, G. TABOT, F. TENORE, S. BENSMAIA
Univ. of Chicago, Chicago, IL

Abstract: One way to restore the sense of touch in upper-limb neuroprostheses is to electrically stimulate primary somatosensory cortex (S1) in the hopes of eliciting meaningful percepts. Our lab has been developing algorithms to convert patterns of sensor activation on the prosthesis into appropriate patterns of electrical stimulation of S1. In the present study, we probed the discriminability of electrical pulse trains and compared it to that of mechanical indentations of the skin. Specifically, we presented monkeys with pairs of stimuli (electrical or mechanical) that differed in amplitude and had them judge which of the two stimuli was stronger. On each trial, a standard stimulus, whose amplitude was constant across the experimental block, was compared to a comparison stimulus, whose amplitude varied from trial to trial. We could then characterize the relationship between the discriminability of the stimulus pairs - electrical or mechanical - as a function of the difference in amplitude between the standard and the comparison. From these functions, we could estimate amplitude discrimination thresholds for both mechanical and electrical stimuli. We could then investigate the degree to which the amplitude discrimination thresholds for electrical stimuli depend on other stimulation parameters, such as frequency. We found that the discriminability of electrical stimuli that differ in amplitude is relatively independent of other stimulation parameters and that, perceptually, electrical stimuli seem to scale linearly with amplitude while mechanical stimuli scale logarithmically.

Title: Developing dry-electrode, minimal preparation BCI for the everyday user

Authors: *S. M. GORDON, B. KELLIHAN
DCS Corp., Alexandria, VA

Abstract: Brain-Computer Interface (BCI) technologies represent a major advance in human-computer interaction (HCI). Whereas traditional BCI systems have focused on providing assistance to populations with physical or neurological disorders, emerging systems are being developed for healthy populations for applications such as monitoring cognitive fatigue and measuring both alertness and drowsiness levels. Furthermore, BCI is finding interest within the gaming industry as a potential new form of gamer interaction. Given the potential application and utility of such technology, modern BCI systems are poised to join the ranks of other popular, consumable, wearable electronic devices. Prior to mass distribution for the general public, however, BCI systems must be developed to 1) utilize dry electrode technologies, thus eliminating the need for messy gels that can potentially dry-out causing poor signal quality, 2) be easily donned/doffed, 3) have minimal-to-no calibration time, and 4) work for a large portion of the population. Here we describe our efforts and initial results in building such a BCI system. Starting from a Mindo 32S dry-electrode EEG system we were able to construct a 2-channel BCI system that was integrated within a comfortable softcap design. The system can be donned in less than one minute. Our first sample application was category selection using well-established evoked potential components, such as the P300. Using an unsupervised learning approach that focused on identifying outliers, initial results indicated that for over 70% of the subjects tested, we were able to achieve correct classification without a priori training. While it, of course, remains to be shown that other BCI approaches can be mapped to such dry-electrode technology and made to work with zero-training, we believe our system is an important step in demonstrating that BCI can be transitioned from the laboratory to the everyday user.

Engin., [2]Mark Wainwright Analytical Ctr., Univ. of New South Wales, Sydney, Australia; [3]Sch. of Med., Univ. of Western Sydney, Sydney, Australia; [4]Australian Sch. of Advanced Med., Macquarie Univ. Hosp., Sydney, Australia; [5]Save Sight Institute, Univ. of Sydney, NSW, Australia, Univ. of Sydney, Sydney, Australia

Abstract: Microelectrode arrays surgically implanted sub-scleral into the suprachoroidal space are being developed to electrically interface with neighboring nervous tissue of the retina to treat visual impairments. To simultaneously assess implanted arrays and their surrounding tissue, we implemented a contrast-enhanced microCT X-ray method to image enucleated ovine eyes which had previously been surgically implanted with arrays. Our method was developed to assess three important characteristics of the intact, post-implant eye: (1) 3D location of device components with respect to eye features, (2) physical damage to device interconnects and electrodes due to surgical techniques used, and (3) underlying pathology of tissue surrounding implanted device components. Our method involves collecting and fixing the eye with the implant remaining inside, treating with an X-ray contrast solution, imaging with a microCT system, and analyzing the collected data. Results demonstrated 3D imaging of both the metallic components (electrodes and interconnecting tracks, Fig.1c) and the contrast-enhanced soft tissue of the sheep eyes (single plane shown in Fig.1a; cross-section of 3D rendering shown in Fig.1b) using microCT imaging. Results of this work have informed the spatial design of the microfabricated array as well as the surgical procedure used to implant the device. Future applications of this method may inform the assessment of other metal implants in tissue, such as cardiac pacemakers and stents, deep-brain stimulation electrodes, and other implanted devices, especially ferromagnetic implants not compatible with microMRI imaging.

Title: Microbiota regulates microRNA expression in the hippocampus in a sex dependent manner

Authors: *G. MOLONEY[1], O. O' LEARY[1], L. DESBONNET[1], F. SHANAHAN[2], T. G. DINAN[3], G. CLARKE[3], J. F. CRYAN[1]
[1]Anat. and Neurosci., [2]Dept. of Med., [3]Psychiatry, Univ. Col. Cork, Cork, Ireland

Abstract: Accumulating evidence highlights that the gut microbiota communicates with the CNS to influence brain function and behaviour. Understanding how the gut microbiota achieves this influence is a new frontier of neuroscience. The use of germ-free (GF) animals has been pivotal in progressing research in this area. Studies in GF mice have described changes in gene expression, particularly in the hippocampus and we have previously shown that many of the molecular consequences of growing up germ-free in the CNS are more evident in males. MicroRNAs (miRNAs) are small, non-coding RNAs that are critical to cellular function and regulation of gene expression. However, the possibility that miRNAs in the brain might be under the influence of the gut microbiota and involved in the regulation of gene expression and associated downstream behaviours remains unexplored. The aim of this study was to assess the impact of an absent microbiota on the expression of miRNAs in the hippocampus of GF, and conventionally-colonised (CC) animals. Moreover, we sought to determine if any changes could be rescued by colonisation of the GF animals post-weaning (GFC) by removing mice from the GF unit after weaning and housed in the standard facility with faecal matter from their conventionally colonised counterparts to promote the development of the gut microbiota. Animals were euthanized and the brain removed, the hippocampus dissected and stored at −80 °C. RNA was extracted from hippocampi using the miRVana isolation kit and RNA quality was assessed. Microarray was performed as previously described, with the level of significance

set at $p<0.05$ and a fold change of 1.3. miRNAs were selected for follow up using qRT-PCR based on differences in expression between groups based on gender and colonization status. 16 miRNAs showed gender and microbiota specific alterations. There was a significant effect of gender and colonisation status on levels of miR294-5p with a significant increase in this microRNA in male GF mice compared with male CC mice. This alteration was reversed following colonisation and a significant decrease in miR294-5p was noted between GF and GFC mice. We show that the microbiota modulates expression of miR294-5p in the hippocampus of mice and that these alterations can be rescued following the introduction of a gut microbiota post weaning. These findings confirm our hypothesis that the gut microbiota can recruit microRNAs to potentially influence gene-expression at the level of the CNS and that this capacity is amenable to microbiota manipulation later in life. Further analysis of miR294-5p and its mRNA targets may reveal important molecular pathways for brain-gut microbiome signalling.

Title: Microbiome impacts vasopressin immunoreactivity in juvenile Swiss-Webster mice

Authors: ***N. V. PETERS**[1], M. J. PAUL[3], B. CHASSAING[2], A. GEWIRTZ[2], G. DE VRIES[1]
[1]Neurosci. Inst., [2]Ctr. for Inflammation, Immunity and Infection, Georgia State Univ., Atlanta, GA; [3]Psychology, Univ. at Buffalo, SUNY, Buffalo, NY

Abstract: The microbiome is the collection of microorganisms that inhabit our bodies, including the gut, and plays a role in multiple biological processes. The gut microbiome is thought to influence the brain and behavior through the gut-brain axis, and has been implicated in the control of anxiety behavior, social behavior and immune function. Furthermore, the microbiome may affect the development of neurodevelopmental disorders such as autism spectrum disorders, which are characterized by deficits in social behavior and are frequently associated with gastrointestinal disorders. These conditions present themselves in juveniles. The neuropeptide vasopressin has also been shown to modulate anxiety, social, and sickness behaviors. We hypothesized that the microbiome impacts anxiety and social behaviors, in part, by affecting

vasopressin signaling. To test whether the microbiome can influence the expression of vasopressin in the juvenile brain, we compared levels of vasopressin immunoreactivity in three-week-old male and female Swiss-Webster mice that lack microbiota (germ-free; GF) with conventionally colonized (CC) mice. Preliminary analysis indicates that GF mice have higher vasopressin fiber densities in projection areas of the suprachiasmatic nucleus, including the subparaventricular zone of the hypothalamus and the paraventricular nucleus of the thalamus. This suggests altered output of the circadian system, perhaps affecting behavioral and/or physiological rhythmicity of GF animals. As vasopressin projections of the SCN also affect the HPA axis these changes may contribute to altered HPA function in germ-free mice.

Title: Toll-like receptor 2 and sex differences in SCN vasopressin expression

Authors: *C. FIELDS[1], A. KIM[1], J.-D. LI[2], G. DEVRIES[1]
[1]Neurosci. Inst., [2]Ctr. for Inflammation, Immunity & Infection, Georgia State Univ., Atlanta, GA

Abstract: Toll-like receptors are key players in the innate and adaptive immune system in vertebrates. These receptors register the presence of molecular patterns that signal the presence of infectious agents or aberrant physiological processes, and their activation leads to an immune response. By and large, their role in normal brain development and physiology remains elusive. In our facilities, TLR2-/- mice show high levels of anxious behavior (unpublished observations). We therefore investigated whether TLR2-/- mice display aberrant levels of vasopressin, a neuropeptide implicated in anxiety-related behaviors as well as in innate immune responses. Sections from brains of wildtype (WT) and TRL2-/- male and female mice were processed immunohistochemically for the presence of vasopressin. Vasopressin-immunoreactivity was

measured using gray-level thresholding in hypothalamic nuclei and hypothalamic and extrahypothalamic vasopressin projection areas. Expectedly, projection areas from the bed nucleus of the stria terminalis (BNST) showed an expected large sex difference in fiber density (males > females) but no overall effects of genotype, however the ventral septal area shows an interaction effect trending towards an elimination of the male-biased sex difference in vasopressin immunoreactivity. Unexpectedly, mice displayed an overall sex difference in vasopressin immunoreactivity in the suprachiasmatic nucleus (SCN; females > males). In addition, TLR2-/- mice displayed a higher density of vasopressin immunoreactivity in the SCN compared with their WT counterparts. In SCN projection areas, females showed greater levels of vasopressin immunoreactivity than did males. However, within the dorsomedial nucleus of the hypothalamus, TLR2-/- mice showed less vasopressin immunoreactivity than did WT, while in the paraventricular nucleus of the thalamus there was a trend towards a decrease in the female-biased sex difference in vasopressin immunoreactivity in TLR2-/- mice. No sex or genotype effects were observed in anti-vasopressin staining for the PVN or SON. Interestingly, vasopressin is one of most pronounced neuropeptide outputs of the SCN, and its expression shows a distinct circadian rhythm, which may underlie circadian rhythms in the immune system. SCN vasopressin production has also been linked to HPA activity; however, it is unknown whether TLR2 signaling affects those rhythms or the HPA axis. To our knowledge, this is the first study to show a sex difference in SCN vasopressin immunoreactivity in mice.

Title: Early expression of Osteopontin impacts Central Nervous System pathogenesis by controlling the Caspase-1-dependent Inflammasome and apoptosis during early West Nile virus infection

Authors: *M. MARCONDES[1], N. BORTELL[2], B. CONTI[2], H. FOX[3]
[1]The Scripps Res. Inst., La Jolla, CA; [2]THE SCRIPPS RESEARCH INSTITUTE, La Jolla, CA; [3]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Osteopontin (OPN) upregulation is common to several Central Nervous System (CNS) inflammatory pathogeneses, and participates in the migration, survival, and activation of inflammatory cells. However, the mechanisms by which OPN modulates inflammatory pathways and neuropathogenesis are not clear. To understand the role of OPN in CNS viral infections, we used a mouse model of West Nile Virus (WNV) infection, where OPN levels in the brain increase significantly from day 3 post infection (pi). WNV infection in animals lacking OPN (OPN KO) increased mortality (94%) compared to C57Bl/6 wild-type (WT) mice (50%), in correlation with higher CNS viral load on day 3 pi, higher levels of type I/II IFNs and iNOS. The analysis of IFN-responsive innate immune genes on day 5 pi revealed increase of the Caspase 1-inflammasome components in OPN Kos compared to WT mice, which correlated with significantly higher levels of circulating mature IL1b. We also found that Caspase 8 was highly induced in the brains of infected WT, but not in KO mice. In In animals lacking OPN there was an increased expression of Caspase 3 and higher apoptosis in the brain tissue, compared to WTs. Together, these results indicate that OPN expression, particularly at early time points, provides protection against the spread of viral infections in the CNS by negatively controlling the type I IFN-induced, Caspase 1-dependent inflammasome, while promoting an alternative, Caspase 8-associated pathway for controlling the virus as well as by preventing the apoptosis of infected cells during CNS viral infections such as WNV.

Title: Prostaglandins as central mediators of neuro-immune pathways

Authors: *P. REVATHIKUMAR[1], N. AGALAVE[2], E. LE MAÎTRE[1], C. I. SVENSSON[2], P.-J. JAKOBSSON[1], M. KOROTKOVA[1], J. LAMPA[1]
[1]Dept. of Med., [2]Dept. of Physiol. & Pharmacol., Karolinska Institutet, Stockholm, Sweden

Abstract: BACKGROUND Activation of cholinergic anti-inflammatory pathway (CAP) by vagus nerve stimulation (VNS) is known to regulate inflammatory conditions. However, the exact central mechanisms still remain unclear. We have recently shown that, prostaglandin (PG) E_2 inducing enzyme microsomal PGE synthase-1 (mPGES-1) is essential for CAP function (Le Maître, ARD 2012). Here, we intended to study the role of central PG system in neuro-immune regulation and the CAP. **MATERIALS & METHODS** Central PG-blockade: Male C57BL/6 mice (n=8) received lipopolysaccharide (LPS) (1.25 mg/kg; i.p) +/- diclofenac (10 µg) intrathecally and LPS + diclofenac i.p (5 µg). After 6 h, mice were sacrificed and cytokine content of KC-GRO, TNF and IL-10 in the brain and spleen was measured using a Mesoscale multiplex assay. Brain PG-inducing enzymes: Male C57BL/6 mice (n=7) were injected with LPS (2 mg/kg; i.p). After VN isolation, it was either electrically stimulated for 5 minutes (VNS) or left unstimulated (SHAM). After 6 h, mice were sacrificed and brains were collected. Expression of the rate limiting enzymes COX 1/2 and mPGES-1 was quantified by immunohistochemistry. *c-FOS* mRNA level was analyzed by *in situ* hybridization in Hippocampus (Hi), Hypothalamus (Hy), Periaqueductal gray (PAG), Cingulate cortex (CC) and Dorsal raphe nuclei (DRN). **RESULTS** Intrathecal PG blockade had no effect on KC-GRO or TNF production in the brain, but strongly suppressed the corresponding levels of KC-GRO in the spleen (317.53±31(LPS) vs. 82.07±24 (LPS + Diclofenac i.t), $p<0.05$), and also displayed a tendency to suppress splenic TNF cytokine content. Diclofenac i.p. did not affect KC-GRO nor TNF content in spleen, but up regulated these cytokines in brain, in line with previous data (Sacco et al, 1998). IL-10 was unaffected in both brain and spleen. After VNS, there was a significant up regulation of c-FOS expression in vagus related areas such as Hi (75.3±5.7 (SHAM) vs. 105.0±1.7 (VNS); $p<0.001$) and Hy (73.8±9.4 vs. 102.2±6.7; $p<0.05$). Moreover, the same areas displayed a VNS-induced increase in mPGES-1 protein, (Hi 0.60±0.09 vs 0.69±0.12; Hy 0.87±0.19 vs. 1.66±0.28 $p<0.05$). On the contrary, VNS did not affect induced COX1/2 expression. **CONCLUSION** Together with our previous data, these results suggest a key role for the brain PG system in neuro-immune communication between the brain and spleen. An involvement of PGE_2 in CAP activation is further suggested by the CAP-induced up regulation of mPGES-1 in vagus-related brain areas. Since COX1/2 was not affected in this context, mPGES-1 may constitute a future target in the development of pharmacological interventions for regulation of CAP-mediated immune suppression.

Title: IL-1beta sensitizes its own response in hippocampal neurons

Authors: *G. A. PRIETO, E. D. SMITH, M. NGUYEN, L. TONG, C. W. COTMAN
Inst. for Memory Impairments and Neurolog. Disorders, Irvine, CA

Abstract: Acute systemic inflammation can impair learning and memory, particularly in aging. Similarly, chronic brain inflammation contributes to cognitive decline in neurodegenerative diseases. These findings suggest that the aged brain may develop an increased sensitivity to inflammatory factors, thus rendering neurons vulnerable to immune challenges. BDNF plays an essential role in learning and memory. Previously we found that BDNF signaling is suppressed by acute IL-1beta in neurons. We hypothesized that chronic IL-1beta may sensitize its own on response and thereby contribute to age-related cognitive decline. We treated rat hippocampal neuronal cultures with IL-1beta for different times (1, 3, 6, 12 and 24 h) and evaluated the expression of IL-1 receptor-1 (IL-1R1), IL-1 receptor accessory protein (AcP) and AcPb, a neuron-specific AcP splice-variant involved in neuroprotection. IL-1beta increased the expression of IL-1R1 and AcP, but not of AcPb, thus affecting AcP/AcPb ratio. Concentration-response studies confirmed that IL-1beta upregulates AcP and IL-1R1 expression. Paralleling the increased expression of IL-1R1 and AcP, we found a boosted IL-beta response in neurons pre-treated with this cytokine. Specifically, we found an enhanced IL-1beta potency for the suppression of brain-derived neurotrophic factor (BDNF) signaling, as measured by Akt/mTOR phosphorylation. Sensitized IL-1beta response for inhibition of BDNF signaling was found to be dependent on both IL-1R1 and AcP, as demonstrated by experiments using the IL-1 receptor antagonist (IL-1ra) and knock down AcP using shRNA. Finally, the Toll/IL1 receptor (TIR) domain mimetic AS-1, a low-molecular weight and cell-permeable compound, confirmed that sensitized IL-1beta response depends on IL-1R1-AcP. Our data support the idea that inflammatory environments contribute to neuron dysfunction by IL-1beta-induced suppression of BDNF signaling, and this can be prevented by a TIR mimetic.

Title: Serotonin 2A receptors modified taurine transport in lymphocytes of rat treated with fluoxetine

Authors: *M. G. COLMENARES, L. LIMA
Inst. Venezolano De Investigaciones Científicas, Caracas, Venezuela, Bolivarian Republic of

Abstract: Serotonin (5-HT) is a monoamine implicated in the regulation of many physiological and pathological systemic events. Fluoxetine, a selective 5-HT reuptake inhibitor and antidepressant, modulates immune cell functions, such as mitogen-induced lymphocyte proliferation and natural killer cell cytolytic activity. The aim of this work was to determine the role of 5-HT2A receptors on lymphocyte taurine transport after treatment with fluoxetine. Male Sprague-Dawley rats were given fluoxetine, 10 mg/kg ip, or vehicle for 1 week. [3H]Taurine was explored *ex vivo* in the presence of the agonists of 5-HT2A receptors, (±)-2,5-dimethoxy-4-iodoamphetamine hydrochloride (DOI), 0.001, 0,01 and 1 μM. The antagonist ketanserin, 0.01, 0.1, 1 and 10 μM was also given. Capacity of transport (Vmax) increased in mononuclear cells of rats treated for 1 week with fluoxetine. Affinity (Kt) was significantly different at 1 week of treatment. In concordance with previous results, fluoxetine treatment affected Vmax of taurine transport, new evidences support that DOI significantly inhibited the elevation of taurine transport produced by fluoxetine treatment. Ketanserine, by itself, did not affect taurine transport. These results indicate that fluoxetine could play an important role in the regulation of taurine transport by allowing an autocrine effect of 5-HT trough 5-HT2A receptors in lymphocytes, and further encourage exploring other 5-HT receptors and their functional consequences during antidepressant treatment.

Title: Anti-inflammatory effect of remifentanil in the mouse brain after systemic lipopolysaccharide administration

Authors: *S. MAEDA[1], R. OHNISHI[2], Y. TOMOYASU[2], H. HIGUCHI[1], T. MIYAWAKI[2]
[1]Dept Dent. Anesthesiol., Okayama Univ. Hosp., Okayama, Japan; [2]Dept. of Dent. Anesthesiol. and Special Care Dent., Okayama Univ. Grad. Sch. of Medicine, Dent. and Pharmaceut. Sci., Okayama, Japan

Abstract: Inflammation, caused by infection, injury, surgery and autoimmune disease, is arranged by a lot of factors, including psychological condition. During the course of the inflammation, fatigue, high fever and pain are brought, and occasionally it can be a cause of death. Thus, a controlling inflammatory reaction is not only for an earlier recovery or an alleviating suffering, but also for a saving life. Opioids, which are often used against a surgical invasion under general anesthesia as well as a cancer pain, affect immune reaction, but a detail mechanism and a clinical significance remain unclear. Remifentanil is an intravenous opioid for general anesthesia, and can be used for induction and maintenance in most of all general anesthesia because it is metabolized quickly by non-specific esterase, context-sensitive half-life is short and is hardly affected by liver and kidney function. A purpose of our study is to clarify the anti-inflammatory mechanism of opioids, and in this study, we evaluated the effect of remifentanil against acute general inflammation induced by LPS in the brain as well as peripheral organs. We used acute general inflammation model generated by intraperitoneal injection of LPS into mouse. Remifentanil was continuously administered through osmotic pump implanted subcutaneously. Under deep anesthesia, liver and brain were removed. From the samples, total RNA was purified and cDNA was synthesized. Using the cDNA, level of inflammatory cytokine mRNA was evaluated with real-time PCR. Interleukin 6 mRNA levels in both the brain and liver were raised by LPS injection, and those were inhibited by continuous infusion of remifentanil in mouse. Especially, IL-6 reaction to LPS was totally inhibited by remifentanil in the hypothalamus while that in liver was significant but ambiguous. Pharmacological effect of remifentanil is mediated with opioid receptors, and a direct inhibition of inflammatory cytokine on immune cells has been suggested recently. On the other hand, main

targets of opioids, including remifentanil, are opioid receptors in the central nervous system, and clinical effect of remifentanil is suppression of reaction to invasion. In addition, the hypothalamus is the center of stress reaction. Thus, a suppression of IL-6 reaction in the hypothalamus by remifentanil is likely due to the inhibition of reaction to invasion, at least in part.

Title: Tumor necrosis factor induces specific neurograms in the sensory vagus nerve

Authors: *S. S. CHAVAN, S. ROBBIATI, B. E. STEINBERG, H. SILVERMAN, T. TSAAVA, P. T. HUERTA, K. J. TRACEY

Abstract: Peripheral neural networks project real-time information to the central nervous system about the body's physiological status through the afferent fibers of the vagus nerve. As a part of this network, peripheral neural circuits also continually monitor and sense the *immunological* status of host, and relay that information to the brain stem and hypothalamus that in turn activates an effector neural response. Here we have mapped the peripheral neural activity that occurred in response to tumor necrosis factor (TNF) by recording from the cervical vagus nerve of adult mice. Following 10 min of baseline recording, in which vagus showed baseline spike frequency of 7.6 ± 1.6 Hz, animals received intraperitoneal administration of cytokine. TNF induced dose and time dependent increases in vagus nerve activity with an activation peak at ~3 min and a response rate of 35.9 ± 5.2 Hz. Administration of trypsin-digested TNF failed to induce significant increases in the vagus nerve activity. Using TNF receptor knockout animals, we confirmed that TNF induced signals are mediated in TNF-receptor specific manner. Together, these studies demonstrate that TNF induces a ligand-specific, receptor-mediated, dose-dependent enhancement in the peripheral vagus neurograms. The identification of TNF-specific neural signatures provides mechanistic insight into the immunological sensory neural code. Supported by grant from DARPA (W911NF-09-1-0125) to KJT.

Title: Characterization of LRRK2-linked signaling pathways in human lymphoblast

Authors: ***T. LI**[1], L. KONG[2], J. THOMAS[2], A. SAWA[3], W. SMITH[2]
[1]Univ. of Maryland, Baltimore, MD; [2]Univ. of Maryland, Pharm. Sch., Baltimore, MD; [3]Johns Hopkins Schizophrenia Ctr., Baltimore, MD

Abstract: Mutations in the leucine-rich repeat kinase-2 (LRRK2) gene cause autosomal-dominant Parkinson's disease (PD) and contribute to sporadic PD. Common genetic variation in LRRK2 modifies susceptibility to immunological disorders including Crohn's disease and leprosy. Previous studies have reported that LRRK2 is expressed in B lymphocytes and macrophages, suggesting a role for LRRK2 in immunological functions. In this study, we characterized the LRRK2 protein expression and phosphorylation using human lymphoblasts. Lipopolysaccharide (LPS), a preinflammatory agent, treated human lymphoblasts resulted in increases of LRRK2 expression and kinase activities in a time dependent manner. Moreover, increase of LRRK2 protein expression by LPS appeared to be associated with activation of Toll-like receptor 4(TLR4) signaling. Treatment with LRRK2 kinase inhibitor, LRRK2-in-1, reduced LPS-induced TNF-α secretion. These results suggested that LRRK2 is actively involved in preinflammatory responses in human lymphoblasts.

Title: Chronic thoracic spinal cord injury impairs peripheral T-cell immunity by inducing T-cell exhaustion

Authors: ***J. ZHA**[1], A. SMITH[2], S. ANDREANSKY[2,3], V. BRACCHI-RICARD[1], J. R. BETHEA[4]
[1]Miami Project to Cure Paralysis, Dept. of Neurosurg., [2]Dept. of Microbiology and Immunol., [3]Dept. of Pediatrics and Med., Univ. of Miami Miller Sch. of Med., Miami, FL; [4]Dept. of Biol., Drexel Univ., Philadelphia, PA

Abstract: Chronic spinal cord injury (SCI) induces immune depression in patients, which contributes to their higher risk of developing infections and poorer prognosis. Using a well-established influenza virus mouse model, we demonstrated that chronic SCI mice have deficits in viral clearance following influenza infection, with a reduction in the number of virus-specific $CD8^+$ T-cells, suggesting the peripheral T-cell immunity is affected by chronic SCI. To study the chronic effects of SCI on the peripheral T-cell immunity, we used a severe contusion SCI mouse model at thoracic level 9 and investigated the peripheral T-cells under pathogen-free condition. We found that chronic SCI down-regulated both $CD4^+$ and $CD8^+$ T-cell cytokine production, but did not affect the T-cell proliferative capability. The observed $CD8^+$ T-cell dysfunction correlated with increased expression of programmed cell death 1 (PD-1) exhaustion marker on these cells. Blocking PD-1 signaling *in vitro* restored the CD8+ T-cell functional defect. In addition, we showed that chronic SCI mice had higher levels of splenic norepinephrine (NE), which contributed to the T-cell exhaustion phenotype, as T-cells show higher PD-1 expression and dysfunction in cytokine production following sustained exposure to NE *in vitro*. Taken together, these results indicate that alteration of sympathetic acitivity following chronic SCI induces T-cell exhaustion, which in turn impairs T-cell function and contributes to immune depression. T-cell exhaustion pathway should be considered as a new therapeutic target for the treatment of chronic SCI-induced immune depression.

Title: Neuronal input modulates antigen flow through peripheral lymph nodes

Authors: *W. HANES[1], P. S. OLOFSSON[1], T. TSAAVA[1], Y. A. LEVINE[2], S. S. CHAVAN[1], K. J. TRACEY[1]
[1]The Feinstein Inst. For Med. Res., Manhasset, NY; [2]SetPoint Med. Corp., Valencia, CA

Abstract: The lymphatic system serves an important role in immunity. Extracellular fluid drains into the lymph vessels in tissues and is subsequently filtered through lymph nodes, where immune responses to foreign antigens are initiated. This initial exposure to an antigen, by infection or vaccination, is a critical step in developing protection against subsequent infection. A better understanding of these early steps in the initial host response could inform improvements in vaccination strategies. Antigen injected into a mouse hind foot dorsum flows first through the popliteal lymph node, then to the sciatic lymph node, before continuing up into the major thoracic lymphatic vessels. Interestingly, in mice immunized to Keyhole-Limpet Hemocyanin (KLH), flow of IrDye-labeled KLH was restricted through the popliteal and sciatic lymph nodes. Examination of KLH concentration one hour after administration in the hind foot, revealed a significant decrease in sciatic and popliteal KLH levels in immunized mice compared to naïve animals. Because neurons have recently been described to respond directly to bacterial infection, and because lymph nodes are innervated with motor and sensory neurons, we reasoned that neurons may regulate antigen flow in peripheral lymph nodes. Blocking of neuronal activation with bupivacaine at the popliteal and sciatic lymph nodes in immunized animals resulted in restoration of antigen flow, with an increase in popliteal antigen. Conversely, direct activation of neuronal signals at the popliteal lymph nodes of naïve animals using monopolar electrical stimulation resulted in significant decrease of antigen trafficking compared to sham stimulated controls. Skin samples taken from the injection site of immunized animals showed colocalization of PGP9.5-expressiong neurons and antigen signal, suggesting a direct activation of sensory neurons by antigen. Taken together, these studies reveal that neuronal input plays a significant role in regulation of hind limb lymph node antigen trafficking.

Title: Circadian time of infection affects the progression and outcome of vesicular stomatitis virus-induced encephalitis

Authors: *K. GAGNIDZE[1], I. KARATSOREOS[3], P. D'AGOSTINO[1], Z. MASHEEB[1], K. BULLOCH[1,2]
[1]Neuroimmunology and Inflammation Program, Lab. of Neuroendocrinology, [2]Lab. of Mol. Immunol., Rockefeller Univ., New York, NY; [3]Dept. of Integrative Physiol. and Neurosci., Col. of Vet. Medicine, Washington State Univ., Pullman, WA

Abstract: Circadian rhythms are recurring patterns of behavioral, endocrine and physiological parameters that exhibit periodicities of approximately 24 hours. Furthermore, many immune parameters exhibit circadian rhythmicity. For example, immunoreactions such as rate of phagocytosis, lymphocyte proliferation, antigen presentation as well as levels of serum cytokine and cytokine receptors have been shown to display significant circadian variations. Likewise the immune responses to various pathogens also display striking circadian dependency. Intranasal (i.n.) infection with vesicular stomatitis virus (VSV) in mice is characterized by the development of viral-induced encephalitis. Based on the expression of CD45, CD11b and CD11c, we have recently described three distinct cell populations that accumulate in the olfactory bulbs (OB) of VSV-infected mice. Further phenotypic and functional analysis revealed a heterogeneous group of immune cells with complex immunological functions within each of these cell populations. Thus, VSV-induced encephalitis mouse model provides an excellent system to study proinflammatory responses within the brain. In the present study we used this model to evaluate the effect of circadian rhythms on the pathogenesis of the viral-induced encephalitis. Two groups of mice were maintained on the opposite 12h:12h light-dark cycle and were subjected to i.n. VSV infection at either (i) onset of light (rest) cycle (designated as zeitgeber time 0, ZT0); or (ii) onset of dark (active) cycle (designated as zeitgeber time 12, ZT12). The health and survival of animals were monitored daily for two weeks. We found that the disease progression was significantly slower in mice infected at ZT12 compared to mice infected at ZT0. Accordingly, the survival rate of mice in ZT12 group was significantly higher, indicating that animals infected at the onset of active cycle were more resistant to viral-induced encephalitis. In addition,

increased survival rate of ZT12 mice was accompanied by a significantly larger proportion of CD45+/CD11b+/CD11c+ cells, which we have shown to be peripherally derived monocytic dendritic cells (DCs) with antigen-presenting capability. These data indicate that the local cellular response to VSV immune challenge is under circadian (or at least diurnal) regulation. Thus, further studies are warranted to identify antiviral response genes as well as the lineage and migration pattern of CD11c+ DCs that are under the control of circadian clock. These studies will provide new mechanistic insight into the development and resolution of neuroinflammatory pathologies.

Title: Electrophysiological properties of thalamic relay cells are prone to neuro-immune modulation by Interleukin-1β, interleukin-6 and tumor necrosis factor-α

Authors: *V. N. SAMIOS, T. INOUE
Waseda, Tokyo, Japan

Abstract: The reciprocal communication between brain and body has long called attention of human civilization, especially regarding health and disease paradigms. Inflammatory processes seem to play a key role in that relation, so that currently it is possible to find a growing body of evidence reporting actions of major pro-inflammatory cytokines, such as interleukin-1β (IL-1β), interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α) in the brain. Considering that pro-inflammatory cytokines may affect information processing in neurons through cellular and molecular actions, experiments were conducted in order to investigate such actions. For that purpose, relay neurons in the thalamic dorsal lateral geniculate nucleus in mouse brain slices were exposed to IL-1β, IL-6 and TNF-α and studied with the patch-clamp technique. IL-1β promoted hyperpolarization of the resting membrane potential (Vrest), decrease of input resistance (Rin), decrease of Ih rectification and decrease in action potential (AP) threshold. IL-6

promoted decrease of Rin and increased latency of low threshold calcium spike (LTS) burst. TNF-α promoted decrease in the count of APs and prolonged inter-spike intervals in LTS bursts. Computer simulations provided candidates for ionic conductance affected by those cytokines, suggesting that IL-1β may cause an increase in the membrane potassium leak conductance and a decrease in the Ih current. The results here presented demonstrate, for the first time, that IL-1β, IL-6 and TNF-α have modulatory effects over electrophysiological properties of thalamic neurons. These effects may have clinical relevance when considering inflammatory conditions, either central or systemic.

Title: Mechanism of Natural Killer cytotoxicity against peripheral sensory neurons *in vitro*

Authors: *A. J. DAVIES, J. CHOI, M. LEE, S. OH
Dept. of Physiol., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Natural Killer (NK) cells are circulating lymphocytes that display innate cytotoxicity against transformed tumor and virus-infected target cells, however very little is known about the interactions between NK cells and the nervous system. Dorsal root ganglion (DRG) neurons cultured from embryonic (E15) mice were more susceptible to lysis by syngenic IL-2 primed NK cells than DRG neurons cultured from adult mice. We show that cytotoxicity against embryonic DRG neurons is functionally dependent on the activating NK cell receptor NKG2D and that the ligand RAE1 is expressed over 10-fold higher in embryonic DRG neurons compared to adult by real time PCR. IL-2 primed NK cells spontaneously produced IFN-y and the cytotoxic factor granzyme B. We found that co-culture of NK cells with either embryonic or adult DRG neurons potentiated levels of granzyme B in the culture supernatant as detected by ELISA while levels of IFN-y were reduced, suggesting a switch to a cytotoxic phenotype. Using live confocal Ca2+-

imaging we show that embryonic DRG lysis is preceded by a rapid, synchronous intracellular Ca2+ response. We also observe that adult DRG neurites are minimally susceptible to Ca2+-dependent degeneration by IL-2 primed NK cells. In conclusion, expression changes of natural killer ligands may drive NK cell cytotoxicity against peripheral sensory neuron targets.

Title: PACAP receptor expression of hematopoietic stem/progenitor cells in mouse bone marrow with special reference to sympathetic innervation

Authors: Z. XU[1], *S. TANAKA[2], H. OHTAKI[1], J. WATANABE[1], Y. HIRAIZUMI[3], S. NUMAZAWA[2], S. SHIODA[1]
[1]Dept. of Anatomy, Showa Univ. Sch. of Med., Tokyo, Japan; [2]Dept. of Pharmacol., Toxicol. & Therapeut.,, Showa Univ. Sch. of Pharm., Tokyo, Japan; [3]Dept. of Orthopaedic Surgery, Showa Univ. Sch. of Med., Tokyo, Japan

Abstract: Functional linkage between nervous system and immune system is essential for maintaining homeostasis. In this crosstalk, the pathway via hypothalamic-pituitary-adrenal (HPA) axis has received more attention than the direct innervation of the immune organs. Pituitary adenylate cyclase-activating polypeptide (PACAP) has been thought as a neurotransmitter and immune-regulator, but its role in immune organs is poorly understood. Therefore, the purpose of this study is to investigate the role of PACAP in the crosstalk between nervous system and central immune organ, bone marrow (BM). The sympathetic nerve fibers were detected in the BM by frozen sections with tyrosine Hydroxylase and neurofilament 200 antibodies, wrapped with GFAP positive Shwann cells. Gene expressions of three PACAP receptors (PAC1R, VPAC1R and VPAC2R) were recognized in the BM by RT-PCR, but few expressed of these ligand PACAP. Then, PAC1R was multiple-immunostained with

hematopoietic cell markers in BM smear sections. Strong expression of PAC1R was detected in larger size and light chromatin condensation cells which were co-expressed with hematopoietic stem/progenitor cell markers (CD34, CD117 and Sca-1). PAC1R-like immunoreactions were also merged with Gr-1 and F4/80, which were myeloid markers. These results suggest that innervation of sympathetic nerve to the mouse BM where PAC1R is expressed on hematopoietic stem/progenitor cells and myeloid lineages. The source of PACAP in the BM, neuronal or humoral, and its regulatory role in hematopoiesis are studied at present.

Title: Mechanisms by which estradiol (E2) suppress neuronal cox-2 gene expression

Authors: *W. STACEY[1], R. M. UHT[1,2]
[1]Univ. of North Texas Hlth. Sci. Ctr., FORT WORTH, TX; [2]Inst. for Aging and Alzheimer's Research, Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Mechanisms by which estradiol (E2) suppress neuronal *cox-2* expression Winfred N Stacey[1] Rosalie M Uht[1, 2] [1]Department of Pharmacology and Neuroscience, University of North Texas Health Science Center, Fort Worth, TX 76107, USA [2]Institute for Aging and Alzheimer's Research, University of North Texas Health Science Center, 3500 Camp Bowie Blvd, Fort Worth, TX 76107, USA ABSTRACT Data from culture and animal models indicate that 17β-estradiol (E2) deprivation increases susceptibility to neurodegenerative and neuropsychiatric diseases. E2 plays a key role in attenuating inflammatory response in the brain by suppressing expression of pro-inflammatory genes; however, the mechanisms by which E2 suppress neuronal pro-inflammatory genes are not well established. The pro-inflammatory cyclooxygenase-2 gene (*cox-2)* is selectively expressed in neuronal populations of the amygdala, hippocampus and cortex (Yamagata, 1993; Kaufmann, 1996). Although E2 downregulates *cox-2* expression in the periphery, E2 effects on neuronal *cox-2* expression remain uncharacterized. To characterize the

effect of E2 on *cox 2* in neuronal system, we used the AR-5 rat neuronal cell line (Mulchahey, 1999). This immortalized line is derived from the amygdala. We first determined that the cell line constitutively expresses COX-2 protein by Western blots and immunocytochemistry, and mRNA and hnRNA by RT-qPCR. Twenty-four hours of E2 exposure reduces neuronal COX-2 mRNA and hnRNA levels. To assess whether the E2 effect was mediated by ER-alpha (ER-α) and/or ER-beta (ER-β) we treated the cells with E2, Diarylpropionitril (DPN), and propyl-pyrazole-triol (PPT). E2 and DPN treatment led to suppression of COX-2 mRNA and hnRNA after 24hrs. In distinction, PPT had no effect. Collectively, the data indicate that E2 suppresses neuronal *cox-2* expression through ER-β. Keywords: E2, *cox-2*, Neuroinflammation Funding: This work was supported by National Institutes of Health Grant R01-MH082900 (to R.M.U.)

Title: Multiple intracellular antigen specific T cells enhance chronic but not acute inflammation in EAE

Authors: *A. RAYASAM[1], B. D. S. CLARKSON[2], M. G. HARRIS[2], A. RITTER[2], L. STEINMETZ[2], J. KARMAN[3], M. SANDOR[2], Z. FABRY[2]
[1]Univ. of Wisconsin - Madison, Madison, WI; [2]Pathology, Univ. of Wisconsin-Madison, Madison, WI; [3]Genzyme Corp., Cambridge, MA

Abstract: Multiple sclerosis (MS) is a chronic demyelinating disease involving abnormal immune-mediated processes directed towards the central nervous system (CNS). MS is partly driven by myelin-specific autoreactive T cells that infiltrate the CNS. Whether the contribution of antigen specific T cells is more dominant in the acute or chronic phases of EAE is still not understood. In order to address this issue, we generated transgenic mice using the

oligodendrocyte specific promoter 2',3'-Cyclic-nucleotide 3'-phosphodiesterase (CNPase) to localize an EGFP-tagged fusion protein containing ovalbumin (OVA) antigenic peptides in oligodendrocytes (CNP-OP mice). Using this model, we tested whether anti-OVA peptide-specific sentinel OT-I (CD8+) and OT-II (CD4+) T cells contribute to disease progression in the early or late phases of experimental autoimmune encephalomyelitis (EAE), a mouse model of MS. Previously, we reported that intracellular oligodendrocyte antigens are sampled by antigen specific T cells in the deep cervical lymph nodes under homeostatic conditions. However, activated OT-I and OT-II T cells are unable to access the CNS in the absence of CNS inflammation. These results imply that under steady state conditions, the efferent CNS immune response is restricted, but the afferent immune system is intact despite the lack of conventional lymphatics. During neuroinflammatory conditions such as those that arise in EAE, OT-I and OT-II OVA specific T cells infiltrate the CNS, but the contribution of these cells to disease progression is not known. Here we report that adoptively transferred OVA257-264 peptide specific, MHC class I-restricted OT-I T cells and OVA323-339 peptide specific, MHC class II-restricted OT-II T cells did not exacerbate the acute phase (day 12-15) of EAE. However, adoptively transferred OT-I and OT-II T cells significantly enhanced EAE clinical scores in the chronic phase (Day 25-30). Furthermore, these symptoms correlated with antigen specific T cell accumulation in the brain and spinal cord implicating that the presence of OVA antigenic peptides within oligodendrocytes provides a milieu favorable for OT-I and OT-II T cell maintenance that likely contributes to a toxic environment resulting in augmented demyelination, axonal degradation and cell death. Together these results indicate that autoreactive T cells directed toward intracellular brain antigens exacerbate EAE symptoms and suggest that therapies targeted towards brain antigen specific T cells deserve more attention for treating MS.

Title: Reovirus-mediated induction of ADAR1 (p150) only minimally alters RNA editing patterns

Authors: *J. L. HOOD[1], M. V. MORABITO[7], C. R. MARTINEZ, III[2], J. A. GILBERT[3], E. A. FERRICK[4], G. D. AYERS[5], J. D. CHAPPELL[6], T. S. DERMODY[6], R. B. EMESON[3]
[1]Ctr. for Mol. Neurosci., Vanderbilt Univ., NASHVILLE, TN; [2]Pathology, Microbiology and Immunol., [3]Pharmacol., [4]Mol. Physiol. and Biophysics, [5]Ctr. for Quantitative Sci., [6]Pediatrics, Vanderbilt Univ., Nashville, TN; [7]Pediatrics, Columbia Univ., New York, NY

Abstract: Transcripts encoding ADAR1, a double-stranded, RNA-specific adenosine deaminase involved in the adenosine-to-inosine (A-to-I) editing of mammalian RNAs, can be alternatively spliced to produce an interferon-inducible protein isoform (p150) which has been shown to be up-regulated in both cell culture and *in vivo* model systems in response to pathogen or interferon stimulation. In contrast to other tissues, p150 is expressed at extremely low levels in the brain and it is unclear what role, if any, this isoform may play in the innate immune response of the central nervous system (CNS) or whether the extent of editing for RNA substrates critical for CNS function is affected by its induction. To investigate the expression of ADAR1 isoforms in response to viral infection and subsequent alterations in A-to-I editing profiles for endogenous ADAR targets, we have employed a neurotropic strain of reovirus to infect neonatal C57BL/6J mice and quantify A-to-I editing in discrete brain regions using a multiplexed, high-throughput sequencing strategy. We analyzed established editing sites known to impact protein/cellular function including transcripts encoding the serotonin-2C receptor (5-HT_{2C}R), multiple ionotropic glutamate receptor subunits, the gamma-aminobutyric acid receptor (GABA-A) subunit alpha-3, and the Kv1.1 voltage-gated potassium channel, as well as recently identified editing substrates CYFIP2, BLCAP and FLNA. While intracranial injection of reovirus resulted in a widespread increase in the expression of ADAR1 (p150) in multiple brain regions and peripheral organs, significant changes in site-specific A-to-I conversion were quite limited, suggesting that steady-state levels of p150 expression are not a primary determinant for modulating the extent of editing for numerous ADAR targets *in vivo*. We present a detailed quantitative analysis of ADAR1 p150 induction in concordance with the editing profiles of 12 editing sites in frontal cortex, hippocampus, and cerebellum, both in control and reovirus-infected animals. This study represents, to our knowledge, the first demonstration of ADAR1 p150 induction in the brain and the lack of altered editing in response to this induction is an unexpected finding.

Title: Characterization of hematopoietically-derived macrophages to the central nervous system in mixed chimeric mice

Authors: *T. D. WILLIAMS, M. W. DEFAZIO, Z. W. HEROUX, J. M. KURTZ
Biol., Emmanuel Col., BOSTON, MA

Abstract: Migration of macrophages into the central nervous system (CNS) during a non-inflammatory state is an area of research with the potential for significant clinical implications. We have established a mixed hematopoietic chimerism mouse model that utilizes donor green fluorescent protein (GFP) bone marrow cells and allows for the study of peripheral monocyte engraftment into the CNS parenchyma. Chimerism of blood and brain tissue was assessed by flow cytometry at various weeks post bone marrow transplantation (BMT). CNS macrophages were initially identified as $CD45^{mid}/CD11b^{+}$ cells. Expression of immune markers MHC class II and Ly6C was measured on both donor GFP^{+} and recipient GFP^{-} cell populations. To assess CNS macrophage and microglia morphology, Iba-1 and GFP expression was visualized using immunofluorescence microscopy (IF). At 12 weeks post-BMT, results demonstrated 43.2 ± 8.2% of hematopoietically-derived infiltrating macrophages expressed MHC class II and 38.5 ± 13.4% expressed Ly6C, whereas non-donor derived brain macrophages showed no Ly6C expression and 2.1 ± 0.2% expressed MHC class II. In the donor blood monocyte population 0.9 ± .1% of the cells expressed MHC class II and 63.3 ± 14.9% expressed Ly6C. Additionally, IF imaging showed $Iba\text{-}1^{+}/GFP^{+}$ cells closely resembled the morphology of resident microglia. These data suggest bone marrow-derived macrophages infiltrate the CNS in a non-disease state, change their phenotype, and adopt a microglial morphology.

Title: Expression of peptidoglycan sensing molecules during postnatal brain development and their regulation by the commensal gut microbiota

Authors: *T. B. ARENTSEN[1], T. FEMENIA CANTO[1], S. GKOTZIS[1], K. UDEKWU[1], H. FORSSBERG[2], R. DIAZ HEIJTZ[1]

Abstract: Pattern-recognition receptors (PRRs) play a key role in the innate immune responses by recognizing conserved microbial molecules derived from a diverse variety of microbial pathogens. However, these motifs are not exclusive to pathogens and are abundantly produced by the indigenous gut microbiota. Recent studies in germ-free (GF) mice have demonstrated that soluble peptidoglycan released by non-pathogenic bacteria can translocate into circulation and mediate remote systemic priming of immune cells. These novel findings raise the possibility that a similar mechanism may be operating within the brain. To this end, we investigated the expression of PRRs that selectively detect peptidoglycan molecules and the levels of peptidoglycan during mouse postnatal brain development (i.e., postnatal days 1, 3, 5, 7, 14, 21 and 56) as well as the influence of gut microbiota on their expression. Gene expression analysis of peptidoglycan recognition proteins (i.e., Pglyrp1-4) and nucleotide-binding oligomerization domain-containing protein (Nod)-like receptors (i.e., nod1 and nod2) showed significant expression changes during postnatal development. Interestingly, some PRRs (Pglyrp2-4) are highly expressed only during the first few days of life, indicating that a sensitive period exists, in which microbial colonization of the gut can influence brain development. Next we determined whether peptidoglycans could be detected during postnatal brain development. Peptidoglycan molecules were detected in the mouse brain and the results revealed an age-dependent increase in peptidoglycan levels during postnatal development. Perturbation of the intestinal microbiota (e.g., by using GF mice and antibiotic treatment during perinatal life) resulted in reduced brain-specific expression of some PRRs during early postnatal life. Our results indicate that microbiota-derived peptidoglycan molecules may affect brain development through activation of PRRs within the brain.

Title: Deficiency of Angiotensin II type 2 Receptors (AT2) results in increased brain damage whereas activation of AT2 does not affect lesion growth after experimental traumatic brain injury in mice

Authors: *S. CORONEL CASTELLO[1,2], E.-V. SCHAIBLE[1], A. GARCIA BARDON[1], A. S. SEBASTIANI[1], M. K. E. SCHAEFER *[1,2], K. ENGELHARD[1,2], S. C. THAL[1,2], R. TIMARU-KAST[1]
[1]Dept. of Anesthesiol., Univ. Med. Ctr. of Johannes Gutenberg Univ., Mainz, Germany; [2]Focus Program Translational Neurosci., Univ. Med. Ctr. of the Johannes Gutenberg Univ., Mainz, Germany

Abstract: Introduction: Recent studies demonstrated reduced brain damage by Angiotensin II receptor type 1 (AT1) inhibition after experimental traumatic brain injury (TBI) [1]. Alongside direct blockade of AT1 mediated vasoconstriction and inflammation, reduced brain injury may be due to increased activation of Angiotensin II receptor type 2 (AT2) that is upregulated after TBI [1]. The activation of AT2 with its antiinflammatory and regenerative properties may contribute to the protective potential of AT1 inhibitors [2,3]. Aim of the present study was to investigate the role of AT2 in murine TBI.
Methods: Study A: AT2 deficient (AT2-/y) mice and their wild type (WT) littermates were subjected to controlled cortical impact (CCI). Study B: 30 minutes after CCI and then daily the selective AT2 agonist compound 21 in low (LD 0.03 mg/kg), high dose (HD 0.1 mg/kg) or vehicle solution (VEH) was applied in C57B6 mice. In both studies neurological outcome was assessed using Neurological Severity Score (NSS). In study A contusion volume was determined 1 and 5 days, in study B 5 days after CCI in Nissl stained sections. Statistics: Wilcoxon Mann Whitney rank sum test.

Results: In both studies NSS showed no difference between groups within the first 5 days after CCI. There was no volumetric difference of brain damage 1 day after CCI in AT2-/y (40.5±4.2mm³) and WT (39.2±7.7mm³). However, contusion volume in AT2-/y was increased 5 days after CCI compared to WT (18.4±2.8 vs. 13.2±3.8mm³; $p<0.05$). Contusion volumes of LD, HD and VEH showed no differences (12.7±2.5, 12.3±3.0 and 13.8±2.4 mm³).
Discussion: While AT1 inhibition leads to reduced neurological deficit and brain damage 24 hours after TBI [1] AT2 deficient mice show no difference to WT at this time point. This suggests that AT2 has minor influence in the early phase after TBI. However, increased brain damage in AT2 deficient mice after 5 days indicates that AT2 is beneficial. Gene expression of AT2 is low in healthy adult animals. It is increased after TBI [1] and, moreover, by AT1 inhibition [4]. In previous studies it was postulated that AT2 is a protective factor in cerebral insults [2,3]. However, in contrast to AT1 inhibition selective AT2 activation did not affect secondary brain damage expansion within 5 days after TBI. The present results indicate therefore, that the neuroprotective effect of AT1 inhibition is not due to increased AT2 activity in the first 24 hours. Additive protective effects of AT2 activation with simultaneous AT1 inhibition at later time points require further investigations.

Title: IL-27 and IL-35 as gene therapy of neuroinflammation

Authors: *G. CASELLA[1], A. FINARDI[2], J. MELDOLESI *[2], R. FURLAN[2]
[1]Inst. Scientifico San Raffaele, Italy; [2]Inst. Scientifico San Raffaele, Milano, Italy

Abstract: Interleukin 27 and 35 belong to IL-12 cytokine family, which also includes, IL-12, IL-23. Even if all cytokines, belonging to this family, present a structural homology, they mediate different functions. In particular, IL-12 and IL-23 are mostly pro-inflammatory cytokines, with, respectively, key roles in the development of TH1 and TH17 cells, which represent the crucial effector cells in multiple sclerosis (MS) and its animal model experimental autoimmune encephalomyelitis (EAE). IL- 27 and IL-35 are mainly immunomodulatory cytokines and principally act on immune cell-mediated response. Current literature supports IL-27 as an immunoregulatory cytokine that modulates TH1 and TH17 cells response; IL-35 is a potent inhibitory cytokine produced by thymus derived natural regulatory T cells (nTreg) that suppresses T cells proliferation by inducing cell-cycle arrest in G1 phase without inducing apoptosis.We propose here to investigate the role of IL-27 and IL-35, through their expression by third generation lentiviral vectors in form of a single polypeptide chain containing the two subunits bound by an appropriate linker. We administered their into C57Bl/6 mice affected by chronic EAE, using the ependimal route as injection method to transfer the vector in the central nervous system (CNS). Both these cytokines, *in vitro*, demonstrate an anti-inflammatory activity: IL-35 modulates TNF-α release from stimulated CD4+ T cells in a dose dependent way, while IL-27 modulates CD4+ T cells proliferation. Nevertheless, *in vivo* present different effects: IL-35 shows slight modulation of EAE clinical score, unlike IL-27 that shows a significant modulation. Molecular analysis of IL-35 show no modulation of both pro- and anti-inflammatory genes, with the exception of M2 microglia phenotype markers Arg1 and Ym1. Unlike of IL-35, IL-27 gene therapy shows a interesting modulation of principal pro-inflammatory gene, such as iNOS, IL-23, T-bet and up-regolation of the anti-inflammatory genes: YM1, Arg1 and chemokine CCl22. The same results are obtained from the CD11b+ cells analysis from the brain tissue of the EAE mice. Pathological analysis show a significant decrease of perivascular infiltrates, which may represent a decrease in the number of postcapillary venules that are permissive to inflammatory cells diapedesis. This may suggest an effect of IL-35 gene therapy on vessel's structure. We are concluding our experiments using IL-27 and IL-35 gene therapy in EAE model and we believe that these cytokine can contribute an improvement to EAE pathogenesis, in different ways, and it's better to study their capacity to induce on M1/M2 phenotype on macrophages and microglia.

Title: Regional and phenotypic differences in hematogenous cells repopulating the brain after irradiation or chemotherapy-based myeloablative approaches for bone marrow transplantation

Authors: *Y. SUGIYAMA, G. FARACO, C. IADECOLA, J. ANRATHER
Feil Family Brain and Mind Res. Institute, Wei, New York, NY

Abstract: Bone marrow (BM) transplant is a widely used method to study the trafficking of immune cells into the central nervous system. However, the use of irradiation to induce myeloablation has been questioned because of the associated blood brain barrier alterations and induction of pro-inflammatory cytokines. Therefore, myeloablation using the alkylating agent busulfan has been proposed as an alternative (PLoS One, 8:e58544, 2013). However, the impact of different myeloablative modalities on the regional distribution and the phenotype of blood-derived cells has not been clearly established. To address this issue, we transplanted GFP+ BM into lethally irradiated (9.5Gy 18 hours before BM transplant) or busulfan-treated (30μg/g, i.p., 3,5,7days before BM transplant) C57Bl/6 mice (n=3/group), and examined GFP+ cells 14 weeks later in brain sections by confocal microscopy. GFP+ chimerism was >90% and comparable in blood neutrophils and monocytes of mice treated with irradiation or busulfan ($p>0.05$), while GFP+ chimerism in lymphocytes was lower in busulfan treated (71%) than irradiated mice (84%; $p<0.05$). In both groups, GFP+ cells were observed in the nucleus tractus solitarius (NTS), area postrema (AP), and subfornical organ, in the somatosensory cortex. However, the number of GFP+ cells repopulating the paraventricular nucleus (PVN) was higher in busulfan-treated (3025±399) than in irradiated mice (936±254/mm3; $p<0.05$; mean±SE). GFP+ cells repopulating the brain could be phenotypically divided in two major subpopulations: (a) elongated cells, closely associated with blood vessels and expressing the perivascular macrophage marker CD206 and (b) stellate cells with dendritic ramifications resembling microglia, not associated with blood vessels and expressing the microglia/macrophage markers Iba1 and cyclooxygenase-1. The number of elongated cells did not differ between irradiation- or busulfan-treated mice. However, the number of stellate cells was larger ($p<0.05$) after busulfan treatment than irradiation in PVN (irradiation 685±285; busulfan 2554±390/mm3), NTS (irradiation 644±478; busulfan 2187±261/mm3), and cortex (irradiation 7.7±1.3; busulfan 97.7±3.2/mm3). The data suggest that busulfan does not uniformly alter the brain repopulation of BM derived cells,

compared with irradiation. In PVN, NTS, and cortex, busulfan increases GFP+ stellate cells with the phenotypic characteristics of microglia. These marked regional differences in the number and phenotype of the repopulating cells need to be considered when using busulfan-based myeloablative approaches for BM transplantation.

Title: Role of Interferon gamma (IFN-γ) in protecting SH-SY5Y cells against cisplatin-induced toxicity

Authors: C. ANDREWS[1], A. HENDERSON[1], M. R. VASKO[2], *G. D. GRIFFIN[1]
[1]Dept. of Biol., Tuskegee Univ., Tuskegee, AL; [2]Pharmacol. and Toxicology, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: A serious health risk of the chemotherapeutic agent cisplatin is peripheral neuropathy. This peripheral neuropathy is caused by neurotoxicity induced by cisplatin. To find agents that would alleviate the neuropathy produced by cisplatin, this work tested the hypothesis that cytokine interferon gamma (IFN-γ) decreased cisplatin-induced cellular toxicity. IFN-γ is a cytokine that displays both antitumor and anti-inflammatory activities. Given these roles, we tested the hypothesis IFN-γ protects neural-like cells from cisplatin-induced toxicity. SH-SY5Y cells (neuroblastoma cells) were treated with cisplatin (1, 3, and 5 ng/mL) for 24 hours. Trypan blue and MTT cell viability assays were used to measure the percentage of cells surviving cisplatin treatment. All the data were analyzed using Graphpad Prism 6. An ANOVA with the post-hoc Tukey's test was used to determine the statistical significance ($p<0.05$), if warranted. The trypan blue assay demonstrated that cisplatin (5 ng/mL) reduced cell viability by 60 % within 24 hours. Next, the MTT assay data showed that pretreatment of IFN-γ (1 ng/mL)

prompted an increase in viable cells in the presence of cisplatin ($p<0.05$). Lastly, Annexin V/Propidium Iodide labeling via flow cytometry showed that IFN-γ protects the SH-SY5Y cells from cisplatin-induced toxicity. This analysis revealed that IFN-γ (1 ng/mL but not 3, 5, and 10 ng/mL) caused a decrease of 55% in cells double-labeled with Annexin V and PI (compared to cells administered captopril alone). Altogether, these results indicate that IFN-γ reduces cisplatin-induced neuronal damage in a concentration-dependent manner. These data point to the cytokine IFN-γ as a therapeutic target to ameliorate peripheral neuropathy induced by chemotherapeutic agents such as cisplatin.

Title: Neuronal activity in the mouse brain during acute endotoxemia

Authors: *T. TSAAVA, B. E. STEINBERG, S. S. CHAVAN, K. J. TRACEY
The Feinstein Inst. For Med. Res., Manhasset, NY

Abstract: The central nervous system maintains body homeostasis and regulates organ physiology. When environmental challenges disrupt this equilibrium, the brain senses the perturbation and coordinates a neurophysiological response to regain homeostasis. Selective regions of brain are activated in response to specific challenges such as pain, tissue injury and inflammation seen during bacterial infection. The current study was designed to identify specific deep brain regions that are activated in response to systemic inflammation. We used lipopolysaccharide (LPS)-induced endotoxemia as a model for systemic inflammation, and immediate early gene *c-fos* expression as a neuronal activation marker to identify the deep brain structures activated by bacterial infection. Adult male BALB/C mice were habituated by daily handling to reduce background c-Fos expression prior to LPS challenge. Following habituation, animals received intraperitoneal administration of LPS (2 mg/kg), and brain c-Fos expression was analyzed after 90 min by immunohistochemistry. c-Fos immunoreactive cells were observed in nuclear groups of hypothalamus, medulla and pons. These findings demonstrate that short-term systemic inflammation results in activation of deep brain regions responsible for

modulating physiological responses during illness. The future work will generate a detailed map of the specific brain nuclei acutely activated by LPS and compare it to the activation of other infectious agents, such as viruses.

Title: Functions of E prostanoid receptors in post-stroke inflammation

Authors: *P. B. LARKIN, Q. WANG, J. MENZIES, X. LIANG, R. JUELSGAARD, L. LIN, K. ANDREASSON
Dept. of Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA

Abstract: Stroke is the fourth most prevalent cause of death in the US and is a leading cause of disability. However, current treatment options are limited and do not help the majority of patients, primarily because these treatments target only the early pathological events that cause the initial stroke damage. To avoid this limitation, next generation therapeutics should target pathological events that exacerbate the initial injury or improve recovery after stroke. Specifically, inflammation occurs immediately after stroke and immune system activation can persist for several days or even weeks after stroke. Inhibiting inflammation by inhibiting cyclooxygenase (COX) enzymes improves stroke outcomes in animal models, even when COX inhibitors are given many hours after the stroke began. However, COX inhibition is not a viable therapeutic strategy in humans because of unacceptable side effects. Instead, we investigated the immunomodulatory E prostanoid (EP) receptors that are downstream mediators of the COX enzymatic cascade that are unlikely to contribute to the side effects of COX inhibition. The four members of the EP receptor family govern multiple distinct immunomodulatory functions in a variety of relevant cell types including neurons, endothelial cells and glial cells. Based on the role of inflammation in stroke and the function of these EP receptors in the immune system, we hypothesized that 1) the EP2 receptor mediates harmful immunomodulation and 2) the EP4

receptor mediates beneficial immunomodulation during post-stroke inflammation. We tested our hypotheses by using novel genetic and pharmacological tools to modulate either EP2 or EP4 signaling. Our genetic experiments employed conditional knockout mice that lack EP receptor expression in either neurons, endothelial cells or myeloid cells (including microglia). In contrast, pharmacological experiments that employed EP receptor agonists and antagonists allowed us to determine the effects of EP receptor inhibition in multiple cell types at both early and late time points. Our results are largely consistent with opposing roles for these two EP receptors and suggest that EP receptor mediated immunomodulation may be a viable therapeutic target in stroke.

Title: Effect of endogenous neurotoxin salsolinol and nm-salsolinol on alpha-synucein aggregation in neuroblastoma sh-sy5y cells -a step forward to uncover the mechanism of parkinson's disease

Authors: *H. QING, F. WANG
Beijing Inst. Technol., Beijing, China

Abstract: Alpha-synuclein(α-syn) aggregation and its expansion in the central nervous system is one significant pathological feature in Parkinson's disease(PD). This progression process comes with a specific inflamed tissue environment. Little is known about the role of neuroinflammation and the adaptive immune system in aggregation of α-syn in PD brain. This study is designed to elucidate the effects of two endogenous neurotoxins i.e. 1-methyl-4-phenyl-1,2,3,4-tetrahydroisoquinoline (Salsolinol, Sal) and 1(R),2(N)-dimethyl-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline (N-methyl-(R)-salsolinol , NMSal) on aggregation of α-syn in wild type EGFP -SH-SY5Y(EGFP) cells, stable wild type α-syn overexpressed α-syn -EGFP-SH-SY5Y (α-syn-WT) cells and stable missense mutation A53T-α-syn-EGFP SH-SY5Y(α-syn-A53T) cells. Here, it is found that Sal and NMSal induced aggregation of α-syn in α-syn-WT and α-syn-A53T cells but not in EGFP cells in 24 hours. Meanwhile, Sal and NMSal induced α-syn

aggregation in EGFP cells when it was co-cultured with glioblastoma multiforme cell line U87 and human T-cell leukemia Jurkat cells for 24 hours but α-syn could not accumulated in EGFP cells when it was co-cultured with U87 cells. Aggregated α-syn did not cause apoptosis but induced autophagy with increased LC3 expression level in cells, furthermore, autophagy initiator rapamycin could deduce aggregation of α-syn in EGFP, α-syn-WT and α-syn-A53T cells. Results confirmed that Sal and NMSal could induce aggregation of stable over expressed wild type and mutant α-syn in SH cells, while peripheral lymphocyte Jurkat cells could accelerate the speed and progress of aggregation of endogenous α-syn in SH cells which treated by Sal and NMSal, and aggregated α-syn could induce autophagy with increased LC3 expression level.

Title: Acute hypoxia increases proinflammatory cytokines in brain areas involved in autonomic regulation

Authors: *A. T. TAKAKURA[1], T. M. SILVA[2], R. C. SILVA[3], L. J. CHAAR[2], V. R. ANTUNES[2], N. O. CAMARA[3], T. S. MOREIRA[2]
[1]Dept of Pharmacology, Inst. of Biomed. Science, Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Physiol. and Biophysics, [3]Immunol., Inst. of Biomed. Science, Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Prolonged and continuous exposure of mammals to a low oxygen environment (chronic hypoxia) elicits remarkable morphological and physiological adjustments. These include altered gene expression, increased peripheral chemosensitivity, enhanced respiratory drive and sympathoexcitation. The current study examines the hypothesis that acute hypoxia initiates an immune response elicited by an increased expression of inflammatory cytokines.

Male Wistar rats were subjected to acute hypoxia (AH: 8% O2, balanced with N2) or normoxic (21% O2) for 3 hours. AH increased the proinflammatory cytokine IL-6 in the heart (41 ± 29 vs. normoxia: 0.04 ± 0.02), lung (25 ± 9 vs normoxia: 3.3 ± 1), kidney (1.2 ± 0.2 vs normoxia: 0.04 ± 0.02) as well in brain areas such as the rostral ventrolateral medulla (RVLM) (2.0 ± 0.4 vs normoxia: 0.9 ± 0.2) and paraventriuclar nucleus of the hypothalamus (PVN) (2.1 ± 0.3 vs normoxia: 1.0 ± 0.04). AH also increased hypoxia-inducible factor - HIF-1α within the RVLM (1.43 ± 0.2 vs normoxia 0.75 ± 0.03). No changes were observed in IL-1 β and TNF values. Taking together these results suggest that immune system may be involved in the response to chemoreceptors activation during AH

Title: Behavioral aspects of the LPS-induced sickness during lactation

Authors: *A. F. NASCIMENTO, SR[1], L. FREITAS FELICIO[1], M. BERNARDI[2], G. ALVES[1]
[1]FMVZ - USP, Sao Paulo, Brazil; [2]Paulista Univ., Sao Paulo, Brazil

Abstract: Maternal behavior (MB) in mammals has specific characteristics. The time period just after parturition is particularly sensitive to physiological changes that can modulate the expression of this important behavior. Behavioral changes observed in sick animals, are considered as sick behavior (SB). Exposure to LPS, an endotoxin derived from the wall of a gran negative bacteria, during pregnancy might cause mental diseases. In order to investigate, a possible relationship between MB and SB, animals were treated with LPS. For the study of MB and MB aggressive, 40 rats were divided in 4 groups, 2 control and 2 experimental groups. The experimental group received 100µg/kg LPS by ip, and control group the vehicle of endotoxin, after 48 hours of LPS administration the observations of SB began. For choice these days, 20 virgin and 20 lactating rats were divided in 4 groups, 2 control and 2 experimental. They received ip 100µg/kg. Body weight, water and feed consumption, and body temperature were

measured for 120h. Females in the control group were observed in the same way, but they were treated with vehicle of LPS. The results showed that: 1) In 48 hours after the treat with LPS, virgin and lactating rats showed temperature increase, loss of body weight, increase in water consumption and a decrease in consumption food, 2) In 48 hours after the treat with LPS, lactating rats showed reduced latency to rescue the first pup to the nest. In the offspring of mothers treated with LPS it was found that: 3) There were changes the vocalization pattern of pups on the 5th day of lactation from mothers exposed to LPS in 3th day of lactation; 4) Altered the Burst and phagocytosis on lactation 21th day of lactation. It is concluded that exposure of rats to LPS promoted changes in the in the interaction between mother and pups.

Title: Unique interweaved microtubule scaffold mediates osmosensory transduction via physical interaction with TRPV1

Authors: *M. PRAGER-KHOUTORSKY[1], A. KHOUTORSKY[2], C. W. BOURQUE[1]
[1]Ctr. for Res. in Neurosci., [2]Dept. of Biochem., McGill Univ., Montreal, QC, Canada

Abstract: The electrical activity of mammalian osmosensory neurons (ONs) is increased by plasma hypertonicity to command thirst, antidiuretic hormone release and increased sympathetic tone during dehydration. Osmosensory transduction is a mechanical process whereby decreases in cell volume cause the activation of transient receptor potential vanilloid type-1 (TRPV1) channels to induce depolarization and increase spiking activity in ONs. However it is not known how cell shrinking is mechanically coupled to channel activation. Using super-resolution imaging we found that ONs are endowed with a uniquely interweaved scaffold of microtubules throughout their somata. Microtubules physically interact with the C-terminus of TRPV1 at the

cell surface and provide a pushing force that drives channels activation during shrinking. Moreover, we found that changes in the density of these interactions can bi-directionally modulate osmosensory gain. Microtubules are thus an essential component of the vital neuronal mechanotransduction apparatus that allows the brain to monitor and correct body hydration.

Title: Effect of suprachiasmatic nucleus stimulation on organum vasculosum of the lamina terminalis neurons in rat hypothalamic slices

Authors: ***C. GIZOWSKI**, C. W. BOURQUE
Res. Inst. of the MUHC, Montreal, QC, Canada

Abstract: Increases in extracellular fluid (ECF) osmolality stimulate thirst by depolarizing and promoting action potential firing by osmosensitive neurons of the organum vasculosum of the lamina terminalis (OVLT). Although thirst is suppressed during sleep, this state is associated with a rise in ECF osmolality as water intake is suppressed, and body water is lost through evaporation and production of urine. The mechanism by which thirst is suppressed during sleep is unknown. In nocturnal rodents, neurons in the suprachiasmatic nucleus (SCN) are electrically silent during the dark (wake) phase and their electrical activity increases during the light (sleep) phase. Since the SCN is the master clock and thirst is suppressed during sleep, we hypothesize that SCN clock neurons inhibit OVLT neurons during sleep. To investigate this possibility we obtained whole-cell current clamp recordings from OVLT neurons in horizontal slices of adult rat hypothalamus. Low frequency electrical stimulation of the SCN (20-80 μA; 0.5 ms; 0.5 Hz) evoked a mixed fast synaptic response consisting of overlapping excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs). EPSPs were reversibly blocked by 3 mM kynurenic acid, whereas IPSPs were blocked by 10 μM bicuculline, indicating that they were respectively mediated by glutamate and GABA ionotropic receptors. In most cells the IPSP appeared to dominate the EPSP since a net hyperpolarization was observed after stimulation. We next

investigated the functional impact of stimulating the SCN at 10 Hz, a frequency corresponding to the firing rate of SCN neurons during sleep. In the absence of antagonists, repetitive stimulation for 30 s caused a reversible hyperpolarization associated with a pronounced inhibition of spontaneous firing by the OVLT neuron. This effect was accompanied by temporal summation of IPSPs and was reversibly blocked by bicuculline (10 μM), indicating the involvement of GABA-A receptors. Interestingly, the acute inhibitory effect observed during repetitive stimulation was commonly followed by a long lasting depolarization and increase in firing. Bath application of kynurenic acid and bicuculline together did not prevent this effect. However, application of the selective vasopressin V1a receptor antagonist SR 49059 (10 μM) significantly reduced the excitatory response of OVLT neurons caused by repetitive stimulation of the SCN. Although the acute inhibitory effect of GABA-A receptors observed during repetitive stimulation is consistent with our hypothesis that the SCN inhibits OVLT neurons during sleep, the functional significance of the V1a receptor mediated depolarization remains to be determined.

Title: Central effect of IL-1β on sodium appetite: Participation of specific brain areas

Authors: *J. B. FREGONEZE[1], D. R. CERQUEIRA[1], A. I. R. NASCIMENTO[2], A. L. MOITEIRO[1], E. S. ARAÚJO[1], M. A. C. ALELUIA[1], H. S. FERREIRA[3]
[1]Physiol. Dept., Federal Univ. of Bahia, Salvador, Brazil; [2]Biol. Sci., State Univ. of Southwest Bahia, Jequié, BA, Brazil; [3]State Univ. of Bahia, Salvador, BA, Brazil

Abstract: Some data appoint to the reciprocal communication between the brain and immune system and interleukin-1β (IL-1β) seems to be the mediators of this communication. IL- 1β may modulate homeostatic functions including fever, feeding, drinking and cardiovascular control. Previously we observed that intracerebroventricular injections of IL-1β inhibit salt intake in sodium-depleted rats. In the present study we investigate the effect of IL-1β injections into the median preoptic nucleus (MnPO), the subfornical organ (SFO), the central amygdala (CeA) and

the medial amygdala (MeA), brain structures that are part of the central network regulating sodium appetite. Male Wistar rats (240-260g) rats were anesthetized with ketamine/xylazine (80/7 mg/kg) for guide cannula implant in the MnPO, SFO, CeA or MeA. Five days after the surgery sodium-depleted rats received injections of IL-1β (1.6 ng/0.2 µl) into the MnPO (n=10), the SFO (n=8), the CeA (n=7), or the MeA (n=6). The control groups received isotonic saline injections the same areas (SFO n=8; MnPO n=10; CeA n=9; or MeA n= 8). The data were submitted to one-way ANOVA followed by the post-test Student-Newman-Keuls test ($p<0.05$). The results shows that, in all brain areas studied, injections of IL-1β inhibit sodium appetite in sodium-depleted rats. The volume of hypertonic saline intake at 120 min after injection of IL- 1β into MnPO, SFO, CeA and MeA was 0.46 ± 0.2 ml, 3.95 ± 0.4 ml, 0.75 ± 1.4 ml and 1.71 ± 0.7 ml respectively. The amount of saline intake in the control groups was 6.62 ± 0.2 ml (MnPO), 6.6 ± 0.1 ml (SFO), 6.7 ± 0.1 ml (CeA) and 6.02 ± 0.1ml (MeA). Comparing the results of the different areas studied, the antinatriorexigenic effect induced by IL-1β injections into SFO was less prominent than the effects observed the other areas. The results suggest that SFO, MnPO, CeA and MeA are important brain sites for IL-1β actions modulating sodium appetite.

Title: Impact of activity pattern on presynaptic inhibition of excitatory neurotransmission via somato-dendritic release in rat supraoptic nucleus neurons

Authors: *A. GAGNON[1], M. WALSH[2], T. OKUDA[1], K. Y. CHOE[1], C. ZAELZER[1], C. W. BOURQUE[1]

Abstract: Magnocellular neurosecretory cells (MNCs) in the supraoptic nucleus can secrete peptides (oxytocin and vasopressin; OT, VP) from their axon terminals in the neurohypophysis, as well as from their soma and dendrites. Previous studies have shown that the firing rate and pattern of action potential (AP) discharge of MNCs can modulate neurosecretion from axon terminals. However it is unclear if patterning can also affect exocytosis from the somato-dendritic compartment. Here we investigated if spike clustering, a firing activity characterized by the occurrence of bursts of action potentials lasting between 0.3-2 seconds, can facilitate somato-dendritic release relative to a tonic firing activity when using the same number of action potentials (100 APs). We stimulated the organum vasculosum lamina terminalis during whole cell patch clamp recordings from MNCs in angled horizontal slices of rat hypothalamus to elicit evoked excitatory postsynaptic current (EPSC) in these cells. We found a significant difference between these two types of firing activity (clustering compared to tonic) on the depression of the evoked EPSC with a greater inhibition for clustering activity ($p<.05$) for both eGFP VP and RFP OT-identified cells. To determine if this activity-dependent inhibition act on a presynaptic locus, we analyzed paired pulse ratio (PPR) that showed a reduction of PPR following different train of stimuli elicited in MNCs. These preliminary results suggest that clustering and tonic activity differentially modulate the strength of presynaptic inhibition of glutamatergic neurotransmission.

Title: Involvement of angiotensinergic mechanisms on sodium intake induced by central cholinergic activation

Authors: *C. F. RONCARI, R. B. DAVID, P. M. DE PAULA, D. S. A. COLOMBARI, L. A. DE LUCA JR., E. COLOMBARI, J. V. MENANI
Dept Physiol. and Pathol., UNESP, Araraquara, Brazil

Abstract: Central facilitatory and inhibitory mechanisms are involved in the control of water and salt intake. Important inhibitory mechanisms for the control of water and sodium intake are present in the lateral parabrachial nucleus (LPBN). Intracerebroventricular (icv) injection of carbachol (cholinergic agonist) that usually induces thirst also induces NaCl intake if the inhibitory mechanisms are deactivated with injections of moxonidine (α2-adrenoceptor/imidazoline agonist) into the LPBN. In the present study, we investigated the involvement of central angiotensinergic mechanisms on water and NaCl intake in rats treated with carbachol icv combined with moxonidine into the LPBN. Male Holtzman rats (3 months old, n = 10) weighing 290-310 g with guide-cannulas implanted into the lateral ventricle and bilaterally into the LPBN were used. Moxonidine or vehicle was injected into the LPBN and atropine (muscarinic cholinergic antagonist), losartan (AT1 angiotensinergic antagonist) or saline was injected into the lateral ventricle (LV). Fifteen minutes later, carbachol was injected into the LV. Water and 0.3 M NaCl intake was recorded for 2 h starting immediately after carbachol injection. The experimental procedure was approved by Ethics Committee in Animal Use (CEUA) from the School of Dentistry - UNESP (CEUA-FOAr 01/2011). Moxonidine (0.5 nmol/0.2 µl) injected into the LPBN increased water (11.1 ± 3.6 ml/2 h, vs. vehicle: 5.0 ± 1.2 ml/2 h) and 0.3 M NaCl intake (16.6 ± 5.8 ml/2 h, vs. vehicle: 1.0 ± 0.2 ml/2 h) in rats treated with icv carbachol (4 nmol/1.0 µl). The pretreatment with icv injection of atropine (20 nmol/1.0 µl) or losartan (100 µg/1.0 µl) abolished water (0.9 ± 0.6 ml/2 h and 1.2 ± 0.6 ml/2 h, respectively) and reduced 0.3 M NaCl intake (2.4 ± 1.3 ml/2 h and 4.0 ± 2.0 ml/2 h, respectively) in rats treated with icv carbachol combined with moxonidine into the LPBN. The results suggest the involvement of central angiotensinergic mechanisms on water and NaCl intake induced by central cholinergic activation combined with the blockade of LPBN inhibitory mechanisms.

Title: Acetaldehyde induces thirst sensation through the renin-angiotensin system in rat

Authors: I. UJIHARA, S. HITOMI, K. ONO, Y. KAKINOKI, *K. INENAGA
Kyushu Dent. Univ., Kitakyushu, Japan

Abstract: In hangover, people frequently experience heavy thirst as well as headache, nausea, vomiting and dizziness. It has been thought that the latter symptoms are elicited by acetaldehyde (ACD), a metabolite of ethanol (EtOH) while thirst sensation is elicited by EtOH-induced urination. ACD has never been considered to be a thirst inducing factor in hangover. Studies have reported that ACD causes suppression of blood pressure and stretch receptors in afferent arterioles of the kidney are stimulated by the pressure drop, and then renin is secreted from the juxtaglomerular cells of the kidney. We hypothesized that ACD is a factor inducing thirst sensation in hangover. Male Wistar rats were used in the present study. Intraperitoneal injection of EtOH significantly increased water intake. Coadministration of the aldehyde dehydrogenase inhibitor cyanamide with EtOH increased both water and salt intakes further and earlier. ACD with cyanamide more rapidly elicited water and salt intakes. The elicited water and salt intakes were suppressed by intraperitoneal and intracerebroventricular injections of angiotensin receptor AT1 antagonist candesartan. Plasma renin activity was increased after ACD while plasma osmolality and Na^+ concentration were not changed. Urination was less found in the early stage even in the administration of ACD. When rats were allowed to drink water and salt solution, urine volume was increased only after drinking, suggesting that urination is not a main trigger for initiation of drinking behavior induced by ACD. Immunohistochemical study showed that ACD increased the number of c-Fos immunopositive neurons in the brain regions of thirst center. The increased number of immunopositive cells was suppressed by candesartan. Taken together, thirst sensation by ACD may be mediated through the renin-angiotensin system and induced by activation of the thirst center of rat brain. The present study suggests that ACD causes heavy thirst sensation in hangover.

Title: Effects of the salt loading during prenatal and postnatal period on the gene expression of the adulthood offspring

Authors: *M. SANTOS DA SILVA[1], F. LUCIO DE OLIVEIRA[1], C. HINDMARCH[3], J. RODRIGUES PLAÇA[4], L. LEICO KAGOHARA ELIAS[1], W. ARAÚJO DA SILVA JUNIOR[2], D. MURPHY[3], J. ANTUNES-RODRIGUES[1]

Abstract: Several epidemiological and experimental studies demonstrated that pregnant rats, when exposed to adverse environments, permanently program the physiology and metabolism of their fetuses. Recently, several studies demonstrated that insults during ontogenic period program the profile of the genes expression in adult animals. We investigated genes expression profile of male rats from mothers (M) drinking 0.9% NaCl (MS) compared to mothers drinking water (MW) during the pregnancy-lactation period. After lactation, offspring (O) were divided into two groups, water (OW) or 0.9% NaCl (OS), until 60 days old. Thus, groups were Mother Water and Offspring Water (MW-OW), Mother Water and Offspring Saline (MW-OS), Mother Saline and Offspring Water (MS-OW) and Mother Saline and Offspring Saline (MS-OS). The transcriptome profile in the paraventricular (PVN) and supraoptic nucleus (SON) was performed using the RNA sequencing technology. The transcripts were aligned to Rattus novergicus rn5 UCSC reference genome sequence by TopHat program. Next, the alignment results were processed using Cufflinks for gene and transcript quantification at the Galaxy environment. The expression value of each transcript was calculated by FPKM. Differentially expressed genes were found by Cuffdiff program and screened out by each transcript expression in MW-OS, MS-OW and MS-OS groups compared to control group (MW-OW). Meanwhile, paired t-tests were performed to assess the difference significance. Transcripts with an value of log2 (foldchange) >= 1, log2 (foldchange) <= -1 and q-value <= 0.05 were considered differentially expressed. We identified 542 differentially expressed genes in the PVN and 171 differentially expressed genes in the SON between treatment and control groups. Among this genes, 49 were up-regulated in the MW-OS, 18 in the MS-OW and 32 in the MS-OS. Moreover, 25 down-regulated genes were found in the MW-OS, 26 in the MS-OW and 21 in the MS-OS at the SON comparison to MW-OW group. For PVN were identified 115 up-regulated genes in the MW-OS, 116 in the MS-OW and 143 in the MS-OS. Moreover, 17 genes were down-regulated in the MW-OS, 56 in the MS-OW and 95 in the MS-OS in the SON comparison to MW-OW group. These data suggest that a

high-sodium diet during pregnancy and lactation can be used as an animal model for further experiments and can provide valuable information of how changes in genes expression profile can generate diseases in adulthood by modifying the regulation of several systems as the neuroendocrine and hydroeletrolitic systems.

Title: Synergy of angiotensin II and deoxycorticosterone acetate during sodium depletion-induced salt appetite in old rats

Authors: *R. L. THUNHORST[1,2], S. CLAYTON[1], T. BELTZ[1], B. XUE[1,2], A. K. JOHNSON[1,2,3,4]
[1]Dept Psychology, [2]The Cardiovasc. Ctr., [3]Hlth. and Human Physiol., [4]Pharmacol., Univ. of Iowa, Iowa City, IA

Abstract: Old Brown Norway rats are notably deficient in expressing salt appetite after periods of sodium depletion. We hypothesize this is due to insufficient secretion of renin--with consequent diminished levels of circulating angiotensin II (Ang II)--and of the mineralocorticoid, aldosterone, in response to sodium deficit. Therefore, we tested if systemic delivery of Ang II and/or the synthetic mineralocorticoid, DOCA, will re-establish salt appetite in old (29 - 30 mo) rats. Rats were depleted of sodium by injections of the diuretic/natriuretic, furosemide. Some received DOCA (0.5 mg/kg bw, sc) after the diuresis. All had access only to sodium-deficient diet and water for 20 hrs. The next day, rats were infused for 3 hrs either with isotonic saline (10 µl/min) or Ang II (30 ng/min, iv) and provided access to water and hypertonic saline solution (0.3 M NaCl) for drinking. Intakes were recorded hourly. Depleted rats infused with isotonic

saline drank little saline solution, especially in the first hr of fluid access (i.e., 0.3 ± 0.2 ml). Depleted rats that also received sc DOCA or iv Ang II also drank trivial amounts of saline solution at this time (0.2 ± 0.2 ml and 0.2 ± 0.1 ml, respectively). However, depleted rats that received both sc DOCA and iv Ang II drank substantially more saline than the other groups (3.2 ± 0.7 ml). The amount of saline consumed by sodium-depleted rats receiving both sc DOCA and iv Ang II is the most ever observed by old Brown Norway rats in response to challenge. Non-depleted, control rats receiving either sc DOCA or iv Ang II separately drank little saline solution (0.1 ± 0.1 ml and 0.6 ± 0.3 ml, respectively). We conclude that old rats fail to express salt appetite after sodium depletion primarily because they fail to generate sufficient endogenous hormonal signal.

Title: Activation of GABAA receptors in the lateral parabrachial nucleus induces ingestion of sodium bicarbonate in rats

Authors: *J. C. CALLERA[1], R. B. DAVID[2], C. A. F. ANDRADE[2], L. A. DE LUCA JR[2], J. V. MENANI[2]
[1]Sao Paulo State Univ., Aracatuba, Brazil; [2]Physiol. and Pathology, Sao Paulo State Univ., Araraquara, Brazil

Abstract: We previously demonstrated that bilateral injection of muscimol, GABAA receptor agonist, into the lateral parabrachial nucleus (LPBN) induce strong ingestion of 0.3 M NaCl and water in rats (Callera et al., Neuroscience, 134, 725-735, 2005). In the present study we investigated if muscimol injections into the LPBN would induce the ingestion of other mineral solution like sodium bicarbonate (NaHCO3) in normohydrated rats or in cell-dehydrated rats. Male adult Wistar rats with bilateral stainless steel guide-cannulas implanted in the LPBN were used. Distilled water and 0.3 M NaHCO3 intake was measured in two-bottle tests at every 30 min during 210 min, starting 15 min after bilateral injections of muscimol or saline into the LPBN in normohydrated rats or in rats treated with intragastric load of 2 M NaCl (IG 2 M NaCl,

2 ml/rat). In normohydrated rats, bilateral injections of muscimol (0.5 nmol/0.2 µl, n=5) into the LPBN induced 0.3 M NaHCO3 intake (22.3 ± 9.3, vs. saline: 0.2 ± 0.2 ml/210 min) and a slight ingestion of water (4.4 ± 2.5, vs. saline: 0.2 ± 0.1 ml/210 min). Bilateral injections of muscimol into the LPBN in rats treated with IG 2 M NaCl also induced strong 0.3 M NaHCO3 intake (45.1 ± 9.0, vs. saline: 0.8 ± 0.3 ml/210 min), without changing water intake. These data show that muscimol injections into the LPBN also induce strong 0.3 M NaHCO3 intake in normohydrated or in hyperosmotic cell-dehydrated rats, suggesting that GABAA receptors activation in this area induces the ingestion of different mineral solutions containing sodium. Title: Effect o central administration of carvacrol on sodium appetite and blood pressure in spontaneously hypertensive rats

Authors: *A. S. BATISTA[1], C. F. PERRONE[1], J. M. ANDRADE[1], F. B. CARVALHO[1], H. S. FERREIRA[2], J. B. FREGONEZE[1]

Abstract: Carvacrol is a monterpene constituent of essential oil of oregano (*Origanum dictamus L.*). Some studies have shown analgesic, antioxidant, anxiolytic effects of carvacrol. Also, it has been observed a hypotensive and bradycardic effect after intravenous injection of carvacrol in normotensive, anesthetized rats. Preliminaries data from our Lab show that intravenous injection of carvacrol present a hypotensive and bradycardic action. In the present study it was investigated the effects of carvacrol injections into lateral ventricle on the blood pressure and sodium appetite in spontaneously hypertensive rats (SHR). Male SHR (13-16 weeks) received a guide cannula implant in the lateral ventricule (VL) and a catheter was inserted into the carotid

artery to record mean arterial pressure (MAP) and heat rate (HR) 24 h before the experiments. Sodium depletion was achieved by subcutaneous injection of furosemide (20mg/kg) and low sodium diet 24h before the experiments. The results show that 60 mim after carvacrol injections into LV did not change the blood pressure in SHR (ΔMAP: 4.9 ± 3.2 mmHg) when compared to control group, vehicle-treated (corn oil) (ΔMAP: -6.0 ± 0.9 mmHg). Conversely, the salt appetite in sodium depleted SHR was inhibited by carvacrol injections into LV (39 ± 0.8 ml) when compared to control group, vehicle-treated (7.7 ± 0.3 ml). The data suggest that carvacrol do not influence the central control of blood pressure in SHR. However carvacrol presents an effective antinatriorexigenic action. **Keywords**: CARVACROL, SODIUM APPETITE, SPONTANEOUSLY HYPERTENSIVE RATS **Financial Support:** CNPq 475252/2011-0

Title: Involvement of serotonergic receptors in the NTS on water intake induced by cellular dehydration

Authors: *R. A. TOMEO, J. MENANI, P. DE PAULA
São Paulo State Univ., Araraquara, Brazil

Abstract: The nucleus of the solitary tract (NTS), the primary site of peripheral osmoreceptor and cardiovascular afferences, is suggested to receive important inhibitory signals involved in the control of water and sodium intake. It is not clear yet which are the neurotransmitters that mediate these signals in the NTS. Central serotonergic mechanisms are involved in the control of sodium and water intake and immunohistochemical studies have shown that serotonergic receptors are present in the NTS. Therefore, in the present study, we investigated the effects of DOI (a serotonergic receptor agonist) or methysergide (a serotonergic receptor antagonist)

injected into the NTS on water and 0.3 M NaCl intake in intracellular dehydrated rats. Male Holtzman rats (290-310 g, n=13-19) with bilateral stainless steel cannulas implanted into the NTS were used. Cellular dehydration was induced by an intragastric load of 2 M NaCl (2 ml/rat) administered 60 minutes before bilateral injections of DOI (2.5 μg/100 nl), methysergide (2 μg/100 nl) or vehicle into the commissural NTS. DOI injected into the NTS of hyperosmotic rats decreased water intake (6.4 ± 1.5 ml/2 h, vs. vehicle: 9.1 ± 1.2 ml/2 h, $p<0.05$), without changing 0.3 M NaCl intake (0.3 ± 0.1 ml/2 h, vs. vehicle: 0.7 ± 0.3 ml/2 h). However, bilateral injections of methysergide into NTS did not change water intake (9.6 ± 1.3 ml/2 h, vs. vehicle: 9.0 ± 1.3 ml/2 h, $p<0.05$) or 0.3 M NaCl intake (0.9 ± 0.5 ml/2 h, vs. vehicle: 0.3 ± 0.2 ml/2 h). The present results suggest that serotonin in the NTS may activate inhibitory mechanisms that participate in the control of water intake induced by cellular dehydration.

Title: Feeding but not drinking from optogenetic stimulation of an LH to VTA pathway

Authors: *E. GIGANTE, R. A. WISE
NIH-NIDA, Baltimore, MD

Abstract: Feeding and drinking can each be induced by electrical stimulation of the medial forebrain bundle at the level of the lateral hypothalamus. Two questions remain unresolved. First, is the stimulation effective because it activates the cells of the bed nucleus or because it activates fibers of passage? Second, do the two behaviors result from activation of a common mechanism or of similar but independent mechanisms that happen to be close to one another? We have found that optogenetic activation of ventral tegmental area fibers originating from cells of the lateral hypothalamus can induce feeding in sated animals. Here we determined whether activation of the same fibers would induce drinking. We established expression of the light-sensitive cation channel ChR2 in lateral hypothalamic cells by microinjection of a viral vector (AAV-CaMKII-ChR2eYFP). We activated the fibers from these neurons by projection of a

473nm laser beam through a fiber optics probe localized to the ventral tegmental area. We administered 1-min trains of 5msec pulses at 20Hz to sated rats in a small cage with either food or water available. As previously reported, the stimulation induced feeding with short latency, and continued for as long as the optical stimulation continued, and the feeding stopped as soon as the stimulation terminated. Similar stimulation failed to induce drinking in the same animals under the same circumstances. These data confirm the previous finding that activation of projections from the cells of the lateral hypothalamic bed nucleus make a likely contribution to the feeding response to electrical stimulation of the medial forebrain bundle, but fail to confirm that the same cells contribute to the drinking response to the same electrical stimulation.

Title: The ventral tegmental area: Wide-field and confocal imaging of hypothalamic peptidergic afferents and their putative synaptic appositions

Authors: *E. M. WALKER[1], B. DE HARO[1], R. H. THOMPSON[2], A. M. KHAN[1]
[1]Biol. Sci., Univ. of Texas El Paso, El Paso, TX; [2]Biol. Sci., USC, Los Angeles, CA

Abstract: Functional relationships between the hypothalamus and the ventral tegmental area (VTA) have been studied intensively, but the circuitry mediating the interaction remains unclear. This is largely due to a diverse chemoarchitecture coupled with a poorly differentiated cytoarchitecture, making comprehensive studies difficult. To better understand the organization of the VTA and its chemical transmitters we used epifluorescence to systematically image the VTA and surrounding region in combination with *camera lucida* drawings of adjacent Nissl

sections to precisely delimit the cytoarchitecture of the region. Parallel series of sections were collected and immunolabeled for tyrosine hydroxylase-immunoreactive (TH-ir) perikarya and fibers, and hypocretin/orexin (H/O)-ir and melanin concentrating hormone (MCH)-ir fibers individually and in all possible combinations with multiple fluorescence labels. The distribution of each transmitter was mapped onto the Nissl and then summarized on a series of standard atlas templates from Swanson (‘04). Images were also screened for potential transmitter interactions then reimaged as a series of optical slices using confocal microscopy and rendered in 3-D for analysis of putative synaptic contacts. Initial analysis has focused on a region in the lateral part of the rostral VTA with extremely dense TH-ir that progressively diminishes at more caudal levels. Notably, H/O-ir and MCH-ir fibers showed a similar distribution. The vast majority of H/O-ir and MCH-ir fibers formed appositions on intermixed but distinct populations of TH-ir cell bodies and neuronal processes, with H/O-ir contacts being more prevalent. These results suggest that both the H/O and MCH axonal projections to the VTA preferentially target TH neurons, but may contribute to different circuits because they interact with distinct populations of TH neurons. Although the H/O inputs onto TH somata far outnumber MCH inputs, the majority of the MCH axons are terminating on some other neuronal cell type. While GABAergic neurons are the most likely candidate, this remains to be shown directly. These results provide a framework for understanding the anatomical basis of communication between hypothalamic and midbrain networks controlling complex behaviors.

Title: Close associations of α-MSH-immunoreactive fibers with traced vagal afferents, and catecholaminergic neurons in the rat hindbrain: high-resolution immunofluorescence studies

Authors: *S. D. CHENAUSKY[1], C. A. CAMPOS[2], R. C. RITTER[2], A. M. KHAN[1]

Abstract: Evidence suggests that the neuropeptide alpha melanocyte-stimulating hormone (αMSH) may control food intake by acting on hindbrain neural substrates, including a possible direct interaction with vagal afferents terminating in the nucleus of the solitary tract. To explore a possible anatomic basis for this interaction, we undertook studies examining the relations between αMSH-immunoreactive (-ir) fibers, biotinylated dextran amine (BDA)-traced vagal afferent endings, and dopamine-beta-hydroxylase (DβH)-ir catecholaminergic neurons in the hindbrain. We used multi-label fluorescence, wide-field imaging and confocal microscopy to examine the distribution of αMSH-ir, DβH-ir, and BDA-labeled vagal afferents. Wide-field images indicate that αMSH-ir fibers course throughout the nucleus of the solitary tract (NTS) and portions of the dorsal motor nucleus (DMX). Analyses of high-resolution optical sections show that the αMSH-ir fibers form appositions with BDA+ vagal afferents. In addition, other αMSH-ir fibers make contacts with neurons in the dorsal vagal motor nucleus and with DβH-ir cell bodies and neuronal processes. The data indicate that αMSH-ir fibers and endings are well positioned to influence distinct dorsal hindbrain targets known to participate in control food intake. We are now undertaking to map the terminations of the traced vagal afferents onto standard reference atlas plates of the region. Collectively, our data provide an anatomic basis for melanocortinergic modulation of hindbrain vagal afferent function and homeostatic control.

Title: Binge eating behavior induced by corn oil modifies preference for different corn oil concentrations

Authors: *W. ZEPEDA-RUIZ, C. RAMOS-LAZZARI, V. CHAVEZ-RODRIGUEZ, D. VELAZQUEZ-MARTINEZ
Dept. de Psicofisiologia, Univ. Nacional Autonoma De Mexico, Mexico, Mexico

Abstract: Binge is an eating disorder characterized by overconsumption of palatable food in brief periods of time; animal models allow us study some characteristics of this disorder. Most studies used Limited Access to induce binge; in this program subjects had two hours of access to sucrose for only three days per week under non-food deprived conditions. Binge eating had been induced with sucrose or shortening vegetable, but it has been reported differences in the consumption that depend on the presentation (solid or liquid) of fat. The objective of this work was to evaluate if liquid fat in the form of corn oil (30%, corn oil Mazola™ diluted with mineral oil) was useful to induce binge and if this binge can change the preference for different corn oil concentrations. Twenty-four male Wistar rats were divided in two groups: a) Control group; that have 24 hours seven days a week with access to corn oil (30%), b) Experimental group with access to corn oil (30%) on Tuesday, Thursday and Saturday 2 hours per day. In both groups food and water were freely available 24 hours seven days a week. In the first part of experiment we tested the most preferred concentration with a two bottle choice test, the concentrations evaluated were (7.5%, 30% and 60%) then we induced binge for five weeks and finally, a second two bottle choice test was carried out to evaluate if binge induced changes in the preference for different concentrations. Binge only was clearly induced in 8 subjects (Binge prone) while the four remaining subjects showed a modest increase in oil consumption (Binge resistant). There were significant differences between groups in the intake of standard food, but only in the first days of the experiment, and no differences in body weight between groups were found. Binge only decreased the preference for the lowest concentration (7.5%). Our results show that binge can be induced with corn oil; however it is important to consider that Wistar rats population is heterogeneous and that there are binge-resistant subjects. The decrease of the preference in the lowest concentration, but not in the highest, suggests that binge induced changes in the subjective value of the corn oil. However, to confirm that the lowest concentration becomes devaluated in its palatability more experiments are necessary.

Title: Lesions of hindbrain catecholaminergic projections to nucleus accumbens, bed nucleus of the stria terminalis, lateral parabrachial nucleus or locus coeruleus do not impair glucoprivic feeding

Authors: T. T. DINH, N. HUSTON, *S. RITTER
Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: We have shown previously that injection of the retrogradely transported immunotoxin, anti-dopamine beta-hydroxylase (DBH) saporin (DSAP), into the paraventricular nucleus of the hypothalamus (PVH) or arcuate nucleus, abolishes feeding in response to central or systemic glucoprivation. Since DSAP injection destroys DBH-expressing neurons with projections to the injection site, these results strongly implicate hindbrain catecholamine neurons as major mediators of glucoprivic feeding. In order to further define the essential circuitry underlying glucoprivic feeding, we injected DSAP into these additional sites: locus coeruleus (LC), accumbens shell (AcbSh), ventrolatersal bed nucleus of the stria terminalis (vlBNST) and lateral parabrachial nucleus (LPBN). These sites are innervated by hindbrain catecholamine neurons and some sites receive collateral innervation from PVH-projecting catecholamine neurons. Appropriate placement and volume for DSAP administration was determined by co-labeling of DBH-ir neurons with retrograde tracer injected into target sites. Lesions were confirmed by postmortem evaluation of DSAP injection site and by hindbrain catecholamine cell and terminal loss. We found that the feeding response to systemic glucoprivation was not significantly or permanently impaired by injection of DSAP into any of these sites. Based on our results to date, we tentatively conclude that direct projections from hindbrain catecholamine neurons to the LC, AcbSh, vlBNST and LPBN are not required for glucoprivic feeding. The hypothalamus appears to be the major recipient of direct innervation from catecholamine neurons required for glucoprivic feeding

Title: Hypoglycemia reduces c-Fos expression in the ventromedial hypothalamic nucleus

Authors: *N. FOSTER, S. AZAM, A. G. WATTS
USC, Los Angeles, CA

Abstract: A wealth of evidence indicates that the ventromedial nucleus of the hypothalamus (VMH) is critically involved in sensing cerebral glucose availability and organizing hormonal counterregulatory responses to hypoglycemia. Yet numerous studies have failed to detect hypoglycemia-associated changes in c-Fos expression in the VMH. We postulated that a high resolution analysis of c-Fos across the entire VMH may be more revealing. Male Wistar rats were injected ip with human insulin or normal saline. Blood glucose was sampled from the tail 0, 30, and 90 minutes later, followed immediately by anesthesia and perfusion. A 1-in-6 tissue series from each brain underwent immunofluorescence staining for c-Fos and NeuN for cytoarchitectonics. c-Fos-labeled neurons were tallied in each part of the VMH (anterior, dorsomedial, central, ventrolateral). We found significantly less c-Fos in the dorsomedial and central parts of hypoglycemic rats compared to euglycemic controls, with no differences in the anterior and ventrolateral parts. In these same animals we also assessed c-Fos in the medial parvicellular (neuroendocrine) part of the paraventricular hypothalamic nucleus (PVH). Here, hypoglycemia significantly increased c-Fos, which is consonant with our previous work examining PVH responses to hypoglycemia. The dorsal VMH appears to be closely associated with metabolic control as it possesses glucosensitive neurons and receptors for several metabolic hormones. Our results therefore suggest that a suppression of neuronal activity in this area may be a significant factor in the how the VMH contributes to the endocrine, autonomic, and behavioral responses to hypoglycemia.

Title: Central glucoprivation increases sympathetic drive to liver and some but not all white adipose tissue depots

Authors: *L. A. SZYMANSKI[1], J. EHLEN[2], T. J. BARTNESS[1]
[1]Biol., Georgia State Univ., Atlanta, GA; [2]Dept. of Neurobio., Morehouse Sch. of Med., Atlanta, GA

Abstract: Energetic challenges have differential effects on sympathetic drive, as measured by norepinephrine turnover (NETO), to brown and white adipose tissue depots in Siberian hamsters. Peripheral treatment with the glucoprivic agent 2-deoxy-D-glucose (2DG) increases sympathetic drive to inguinal (IWAT) and retroperitoneal (RWAT) white adipose tissue, but not epididymal (EWAT) white adipose tissue or interscapular brown adipose tissue (IBAT). Tract tracing studies in our lab have identified neural pathways from the paraventricular hypothalamus to white and brown adipose tissue via hindbrain areas that have been implicated in the control of glucoprivic feeding and hyperglycemia in other rodents. It is likely that in hamsters these hindbrain neurons modulate the increases in sympathetic drive to WAT after peripheral glucoprivic treatment. The current experiments test the hypothesis that glucose-sensing neurons in the hindbrain modulate sympathetic drive to adipose tissue. Adult, male Siberian hamsters were fitted with a cannula into the 4th ventricle (4V) in order to deliver the glucoprivic agent 5-thio-D-glucose (5TG) directly to the hindbrain. NETO was measured in IBAT, IWAT, EWAT, mesenteric white adipose tissue (MWAT), RWAT, and liver of animals treated with an acute 4V injection of either saline or 50 nmoles of 5TG. This dose of 5TG reliably induces the characteristic hyperglycemic response to acute central glucoprivation within 1 h of treatment. Another group of animals received the same dose of 5TG and changes in plasma concentrations of glycerol and free fatty acids, which provide another measure of increased fuel availability via lipolysis, were measured. Hamsters treated with 5TG showed significantly greater NETO in the liver, RWAT, MWAT, and EWAT compared to saline-treated hamsters. 5TG treatment did not induce greater NETO in IBAT or IWAT compared to saline-treated hamsters. This pattern of sympathetic activation differs from that seen in hamsters treated with 2DG or food-deprived hamsters, suggesting that changes in sympathetic output induced by decreased fuel availability are stimulus-specific. Plasma concentrations of glycerol increased significantly 4 h after central 5TG treatment, but there was not a significant increase in plasma concentrations of free fatty acids. The increases in plasma glycerol as well as the increases in NETO indicate that central glucoprivation is sufficient to increase sympathetic drive to adipose tissue. It is therefore likely that the hindbrain neurons

that have been identified as part of the pathway modulating sympathetic output to adipose tissue are glucose sensitive.

Title: Multifaceted effects of brain-derived neurotrophic factor on arcuate neurons

Authors: ***G.-Y. LIAO**[1], K. BOUYER[2], A. KAMITAKAHARA[2], C.-H. WANG[2], N. SAHIBZADA[3], R. B. SIMERLY[2], B. XU[1]

Abstract: Brain-derived neurotrophic factor (BDNF) plays a critical role in energy homeostasis, in addition to neuronal survival, differentiation, and synaptic plasticity. The *Bdnf* gene produces two populations of transcripts with either a short or a long 3′ untranslated region (3′ UTR). We previously reported that the long 3′ UTR *Bdnf* mRNA was localized to dendrites for local translation and that $Bdnf^{klox/klox}$ mice lacking long 3′ UTR *Bdnf* mRNA developed severe hyperphagic obesity. To investigate whether the obese phenotype of $Bdnf^{klox/klox}$ mice is associated with alterations in arcuate neurons, we first examined the expression of TrkB, the receptor for BDNF, in the arcuate nucleus (ARC). We found that ~15% TrkB ARC neurons were colocalized with POMC neurons and another 15% TrkB ARC neurons colocalized with AgRP neurons. TrkB signaling in these neurons does not appear to impact cell number as we detected normal numbers of POMC neurons and AgRP neurons in $Bdnf^{klox/klox}$ mice. However, DiI labeling did reveal a drastic reduction in the projection of ARC neurons to the PVH in $Bdnf^{klox/klox}$ mice on postnatal day 12. In addition, fewer POMC axonal projections were found in the dorsomedial hypothalamic nucleus (DMH) in adult $Bdnf^{klox/klox}$ mice. This observation suggests that BDNF regulates axonal growth of TrkB-expressing ARC neurons, particularly in POMC populations projecting to the DMH and PVH. We employed immunohistochemistry and patch

recordings to examine the impact of BDNF deficiency on synapses onto POMC and AgRP neurons. We found that excitatory inputs onto POMC neurons were increased in *Bdnf*$^{klox/klox}$ mice, likely due to a compensatory response to the markedly hyperphagic phenotype displayed by the mutant mice. Interestingly, AgRP neurons in *Bdnf*$^{klox/klox}$ mice had normal number of inhibitory synapses on cell bodies; however, both frequency and amplitude of miniature IPSCs in these neurons were significantly reduced. This observation indicates that inhibitory inputs onto dendrites of AgRP neurons are impaired in *Bdnf*$^{klox/klox}$ mice. We propose that BDNF inhibits food intake in part by promoting development of TrkB-expressing ARC neurons and by enhancing inhibitory synaptic inputs onto AgRP neurons.

Title: Diet-induced obesity alters the gut-brain communication and results in microglia activation in the hindbrain feeding centers

Authors: *K. CZAJA[1], A. C. VAUGHN[1], C. FLETCHER[1], L. A. BALLSMIDER[1], P. M. DI LORENZO[2]
[1]Washington State Univ., PULLMAN, WA; [2]Binghamton Univ., Binghamton, NY

Abstract: Because obesity itself is considered to be a state of chronic inflammation, we evaluated whether diet-induced obesity (DIO) alters gut-brain communication and results in microglia activation in the hindbrain feeding centers. Gastrointestinal signals that inform the brain of the quantity and quality of food being consumed during ongoing meals are important controllers of food intake. These signals contribute to the process of satiation, which results in meal termination. The nucleus of the solitary tract (NTS) in the caudal brain stem is the site at which the vagal sensory afferent fibers transmit gastrointestinal (GI) satiation signals and make their central synapses. GI-projecting motor neurons are located at the dorsal motor nucleus of the vagus (DMV). We used male Sprague Dawley rats (~ 470g body weight). Control rats were fed

Teklad F6 Rodent diet (3.1 kcal/g; 6.4% fat; RD) for the entire experiment. DIO rats received Teklad F6 Rodent diet for two weeks and then where switched to the Open Source D12492 diet (5.24 kcal/g; 34.9% fat; HFD) for four weeks. Body weight and food intake were monitored three times a week. Body fat composition was determined by a dual-energy X-ray Absorptiometry (DEXA) scan before introducing the high fat diet and four weeks later. At the end of the study the rats were transcardially perfused with 4% parafolmaldehyde. Hindbrains and nodose ganglia were collected, sectioned and stained using standard immunofluorescence methods. Primary antibody against Isolectin 4 was used to label vagal afferents. Microglia activation was determined by quantifying changes in the density of fluorescent staining with a primary antibody against the ionizing calcium adapter binding molecule 1 (Iba1). Results of the study showed a significant increase in the caloric intake and body weight in DIO rats compared to control rats. DEXA scan results revealed almost double the body fat percent in DIO rats compared to control rats (14.5% vs. 7.5% respectively). Immunofluorescent results showed a significant decrease in the density of vagal afferents in the NTS and DMV and an increase in microglia activation in the NTS. In conclusion, our results show that HFD induces obesity in male Sprague Dawley rats, triggers withdrawal of vagal afferents from the hindbrain feeding centers and results in microglia activation in the NTS. Similar alterations in the gut-brain communication after subdiaphragmatic damage to the vagus nerve, previously reported by our laboratory, suggest that HFD and/or DIO may trigger degenerative changes in vagal sensory neurons innervating the gut. However, further studies are needed to test this hypothesis.

Title: Suppressed Fos induction within the central nucleus of the amygdala corresponds with inhibited feeding in the presence of a fear-cue in male and female rats

Authors: *C. J. REPPUCCI, G. D. PETROVICH
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Our research examines environmental influences on feeding, and the brain substrates that mediate their competition with physiological drives. Here, we used a model of fear-cue induced inhibition of feeding in rats. In this preparation a tone that predicts footshocks is a fear-cue that halts feeding in hungry subjects. The first aim of the current study was to replicate the prior finding that this cessation of feeding extinguishes rapidly in males, but persists in females across repeated tests. The second aim was to extend prior lesion evidence that the central nucleus of the amygdala (CEA) is critical in this behavior, by assessing its recruitment across tests using Fos induction. Adult male and female rats were trained in alternating appetitive and aversive sessions conducted in two distinct contexts (A and B). During appetitive sessions in Context A, food-deprived rats consumed food pellets. During aversive sessions in Context B, half of rats (Experimental) received a total of four footshocks (1.0mA, 1sec) each signaled by a 60sec tone (75db, 2khz), while the other half (Control) received the same number of tones, but no shocks. Following training, food-deprived rats were tested for consumption in Context A. During each test rats received four presentations of the tone (fear-cue); no footshocks were delivered. Two additional control groups underwent an identical training regimen, except they did not have access to food during appetitive sessions or testing (No-Food Control, No-Food Experimental). Rats in the Control groups consumed substantial amounts of food during each test. Male and female rats in the Experimental groups, however, significantly inhibited food intake compared to the corresponding Control group during Test 1. Replicating prior findings, the females, but not males, in the Experimental groups also inhibited intake on Tests 2 and 3. Rats were sacrificed 90min after their final test (subsets of rats sacrificed after the 1st, 2nd, or 3rd test), and brain tissue was immunohistochemically stained to detect Fos. We found that during Test 1, rats in the Experimental groups had significantly less Fos induction in CEA than rats in the Control groups, while during Tests 2 and 3 males had significantly greater Fos induction than females. There was no difference in Fos induction between the two No-Food groups, and these groups showed lower Fos induction than all other groups. Fos induction in CEA significantly correlated with the amount of food rats consumed at test, irrespective of sex, group, or test day. Current results, combined with the prior lesion work, suggest that an active suppression of CEA neurons contributes to the anorectic effects of fear on feeding.

Title: Mice exposed perinatally to the obesogenic endocrine disruptor bisphenol-A (BPA) show impaired central and behavioral leptin sensitivity in advance of diet-induced obesity: evidence for developmental programming of hypothalamic pro-opiomelanocortin (POMC) regulation

Authors: *H. A. MACKAY, Z. R. PATTERSON, A. ABIZAID
Carleton Univ., Ottawa, ON, Canada

Abstract: Bisphenol-A (BPA) is a component of polycarbonate plastic, and is commonly found in food and drink containers. BPA has been characterized as an endocrine disruptor capable of acting as a xenoestrogen in a variety of experimental models, and because it is capable of leaching out of food and drink containers, human exposure is nearly ubiquitous. Since BPA can cross the placenta and is also found in breast milk, adverse organizational effects due to early-life exposure are of particular concern. Recent evidence from our lab has demonstrated in mice that early-life exposure to environmentally relevant doses of BPA yields a phenotype characterized by a predisposition to adult obesity in female mice and metabolic disturbance in males. Given the sensitivity of the developing hypothalamus to the organizational effects of sex steroids, we hypothesized that early-life BPA exposure adversely affects the development of hypothalamic feeding circuitry in order to bring about this phenotype. To test this hypothesis, we used male and female CD-1 mice exposed pre- and post-natally to either a control diet, a diet containing BPA (appx. 13.5 μg/kg/day), or the estrogenic diethylstilbestrol (DES) as a positive control (appx. 3 μg/kg/day). Serum from pups was collected on PND2, 8, 10, 12, 16, and 21 for analysis of circulating leptin. Results from this study show that BPA and DES exposed pups have respectively delayed and blunted postnatal leptin surges - a state of affairs that points to a role for leptin in the organizational effects of early-life xenoestrogen exposure. Adult offspring from this experiment were resistant to leptin-induced suppression of food intake, body weight loss, and hypothalamic POMC upregulation. Taken together, these data suggest that BPA, a known obesogen, may exert its effects through developmental programming of the hypothalamic melanocortin circuitry.

Title: ABHD6 loss-of-function in nucleus accumbens neurons reduces food intake and prevents diet-induced obesity

Authors: *S. TOBIN[1], D. MATTHYS[2], S. ZHAO[3], S. MADIRAJU[3], T. ALQUIER[4], M. PRENTKI[3], S. FULTON[1]
[1]Nutr., [2]Neurosci., [3]Nutr. and Biochem., [4]Med. and Pathology & Cell. Biol., Montreal Diabetes Res. Ctr. and CRCHUM, Montreal, QC, Canada

Abstract: Excessive consumption of energy-rich food largely drives the development of obesity and related metabolic disorders. The nucleus accumbens (NAc), a central component of brain reward circuitry, plays a significant role in the control of feeding and food-motivated behaviour. Alpha-beta-hydrolase domain 6 (ABHD6) is an enzyme that degrades the endocannabinoid 2-arachidonoylglycerol (2-AG) in neurons and has recently been shown to regulate de novo fat synthesis within metabolic tissues and contribute to the peripheral regulation of body weight and energy metabolism. Here, we used conditional gene targeting to determine the impact of ABHD6 in NAc neurons in feeding, energy expenditure, body weight and mood. Methods: An adeno-associated virus (AAV2/1.hSyn.eGFP-Cre.WPRE) delivering Cre recombinase ("KO") or GFP ("control") under the control of the synapsin promoter was stereotaxically injected into the NAc (500nl/side; 5x109 GC) of adult ABHD6lox/lox mice (Bl6 background). Food intake and body weight were measured in mice (n=9-10/group) consuming chow or high-fat diet for 8-10 weeks. EchoMRI (n=9-10/group) and CLAMS metabolic cages were used for measures of body composition and energy expenditure, respectively CLAMS metabolic cages were used for measures of energy expenditure. Elevated-plus maze, open-field and forced swim tests were used to assess changes in anxiety- and depressive-like behaviour (n=9-10/group). Results: AAV infection was specific to neurons as assessed by GFP + NeuN immunofluorescence, and KO mice had an average 70% reduction in NAc ABHD6 mRNA relative to controls. Male KO mice on high-fat diet consumed significantly less food, were completely protected from diet-induced weight gain and had elevated locomotor activity (dark cycle) relative to controls. KO mice did not differ from controls with respect to anxiety- and depressive-like behaviour. Conclusion: Our results show that selective deletion of ABHD6 from NAc neurons prevents diet-induced hyperphagia and obesity and increases spontaneous physical activity without inducing negative emotional states, and thus identify an important role for this enzyme in NAc controls of feeding and locomotion. These findings also support the current pursuit of ABHD6 inhibitors for the treatment of obesity and type 2 diabetes.

Neurosci. Inst., Atlanta, GA

Abstract: Decades of research suggest that different mechanisms regulate meal initiation versus termination. There is extremely limited evidence regarding the mechanisms that regulate meal onset and the interval between two meals (i.e., the postprandial intermeal interval; ppIMI). The ppIMI influences meal frequency and is a major determinant of total food intake. Emerging evidence indicates that the hippocampus, which is critical for memory, also regulates energy intake. We discovered that dorsal hippocampal neurons delay meal onset during the period following a meal. Specifically, we found that temporarily inactivating dorsal hippocampal neurons after the end of a sucrose meal with unilateral infusions of the GABA-A receptor agonist muscimol decreases the ppIMI (Henderson et al, 2013; Hippocampus). Ventral hippocampal neurons may also influence meal onset because this region has been implicated in motivational, emotional and affective processes; and permanent ventral hippocampal lesions increase total intake. Additionally, ventral hippocampal neurons project to brain areas involved in eating (i.e. hypothalamus, bed nucleus of the stria terminalis, lateral septum and nucleus accumbens). To test the hypothesis that ventral hippocampal neurons also inhibit meal onset, adult male Sprague-Dawley rats (n = 8) were implanted with a unilateral cannula aimed at the left or right hippocampus (hemisphere counterbalanced). The rats were trained to consume a 32% sucrose solution at a scheduled time daily. On experimental days, the rats were given vehicle or muscimol infusions (0.5 μg/μl; 1μl; within subject design) after they had stopped consuming the sucrose solution (i.e., during the ppIMI). Latency to consume the sucrose and the number of sucrose meals were recorded for 4 hr after the infusion. The results demonstrated that ventral hippocampal muscimol infusions significantly decreased the ppIMI and increased the number of

postinfusion meals (ps < 0.05 vs. vehicle). The present findings indicate that ventral hippocampal neurons also inhibit meal onset during the ppIMI and raise the possibility that hippocampal dysfunction may contribute to the development or maintenance of diet-induced obesity. Interestingly, the effect of inactivation was significant with fewer rats in the ventral experiment than in the dorsal study, suggesting that ventral hippocampal neurons may have a stronger inhibitory influence on meal onset. To test this, we are now directly comparing the effects of dorsal versus ventral manipulations.

Title: Afferent and efferent projections of the periventricular hypothalamus: A combined anterograde and retrograde tract tracing study in the adult male rat

Authors: *B. DE HARO, A. M. KHAN
Univ. of Texas at El Paso, El Paso, TX

Abstract: The periventricular hypothalamus is an enigmatic area thought to be involved in neuroendocrine function. The PV is parcellated in the Swanson rat brain atlas into the preoptic (PVpo), anterior (PVa), interior (PVi), and posterior (PVp) parts. The circuitry of the PV with other regions of the brain has mostly been investigated through indirect means, with the PVp being the best characterized region. Currently, there is a lack of complete understanding of other PV regions. In order to investigate further the PV circuitry we injected a cocktail of anterograde and retrograde tracers into the PV. Specifically, we injected Cholera toxin subunit b (Ctb) and *Phaseolus vulgaris* leucoagglutinin (PHA-L) into the PVi. The projections were then characterized with the use of a companion Nissl series, immunohistochemical staining for the tracers, and wide-field imaging of the PV and surrounding regions. We found projections to the

PVi arising mainly from several hypothalamic nuclei. First, confirming the anterograde analysis of ventral premammillary (PMv) projections provided by Canteras *et al*., 1992 (*J. Comp. Neurol*. 324:195-212) we found robustly labeled retrogradely filled neurons confined to the PMv. Second, several additional hypothalamic regions also displayed retrogradely labeled neurons, including the arcuate nucleus, the ventromedial nucleus of the hypothalamus, dorsomedial nucleus of the hypothalamus, and lateral hypothalamic area. The axonal projections of the PVi, in turn, mainly target anterior regions of the hypothalamus. Collectively, these data suggest that the PVi might have an important role in the control of multiple homeostatic functions.

Title: Effects of the food form of apple products on satiety and brain responses in humans: An fMRI study

Authors: M. SOTO, *N. P. DARCEL, A. MARSSET-BAGLIERI, J. PIEDCOQ, D. TOMÉ, G. FROMENTIN, N. NADKARNI
Agroparistech, Paris, France

Abstract: Background: There is little evidence as to whether satiety induced by different food forms having the same caloric content differentially alters brain responses to food cues, and which brain regions are involved. **Objective:** We assessed the differences in brain activation in response to food cues between different states of hunger induced by ingestion of sweet foods of different forms (liquid, semi-liquid and solid). **Design:** Twenty-five normal-weight men (mean ± SEM age: 23.2 ± 0.4 yrs.; BMI: 22.4 ± 0.4 kg/m^2) participated in the study. Subjects arrived fasted in the morning and had to eat a breakfast consisting of one of three apple products (cross-over design): apple juice, puree or slices, each with the same caloric content. After breakfast, a fMRI session was conducted as follows: one 'liking' session consisting of viewing images (food and objects) whilst rating their appeal value, and one 'choice' session in which participants had to choose between two images of different categories (high-fat/low-fat sweet/savory). VAS questionnaires were completed during each session to assess perceived hunger and satiety. Statistical contrasts between the three different breakfasts were calculated, and data for regions

of interest were extracted. BOLD percent change in the regions that were differentially activated were correlated to VAS scores before the fMRI session and to TFEQ scores. **Results:** Consumption of the three apple products led to differences in short-term satiety, in the order slice > puree > juice. In the 'liking' session, three brain regions were more activated after consumption of apple juice vs. apple slices: the nucleus accumbens, the orbitofrontal cortex and the hypothalamus. Neural activity in the NAcc and OFC was positively correlated with hunger ratings after breakfast (and negatively with fullness ratings). In the 'choice' session, the OFC was more activated after the juice breakfast (vs. slices) when subjects chose sweet images (rather than savory) and high-fat images (rather than low-fat). The BOLD signal in the OFC measured when high-fat foods were chosen was positively correlated with hunger ratings and ratings of 'expected pleasure to eat' self-reported after breakfast. **Conclusions:** Eating apples in the form of a solid (slices) for breakfast elicited a greater satiety than consuming the same energy in the form of a liquid (juice). Differences in food form also led to different responses to food cues of limbic (NAcc and OFC) and homeostatic (hypothalamus) regions underlying food intake.

Title: The underlying neural network of proopiomelanocortin (POMC)-mediated regulation in food intake

Authors: *C. LI, M. KRASHES
NIH/NIDDK, Bethesda, MD

Abstract: Recent studies have demonstrated the functional roles of proopiomelanocortin (POMC) and agouti-related peptide (AGRP) neurons in the arcuate nucleus (ARC) of the hypothalamus. Respectively, they have been shown to promote and attenuate body weight-gain and feeding behavior. Although much attention has focused on $AGRP^{ARC}$ functions and their downstream projections, the axonal targets and mechanisms underlying $POMC^{ARC}$ stimulation-

induced satiety has yet to be elucidated. While immunohistochemistry studies show a wide range of intra- and extra-hypothalamic structures labeled by peptides released from POMC neurons, the anatomical organization, synaptic connectivity and functions of relevant downstream sites in signaling satiety remain unknown. $POMC^{ARC}$ neurons release alpha-melanocyte-releasing hormone (α-MSH), a melanocortin-4 receptor (MC4R) agonist, which acts to reduce food intake. In contrast, AGRP neurons release the neuropeptides AGRP, a MC4R inverse agonist/antagonist, neuropeptide Y (NPY) and the fast-acting neurotransmitter GABA, all of which drive feeding. These results suggest a highly orchestrated modulatory balance on appetite-controlling MC4R-expressing neurons. The MC4Rs are essential in body weight regulation as both genetic knockout mice and human mutations lead to overeating and subsequent obesity. It has been shown that the resulting drop in body weight and food intake following 24-hr optogenetic activation of $POMC^{ARC}$ soma is dependent on melanocortin signaling. Based on the above evidence, MC4R-expressing neurons are likely targets for $POMC^{ARC}$ neurons in mediating feeding, although this has never been directly tested, mainly due to the inability to reliably mark MC4R-expressing cells. In this study, using cre-dependent viral tracing, optogenetics, and chemogenetics, we determined the anatomical and cellular downstream targets of the $POMC^{ARC}$ neurons mediating satiety with a focus on those expressing MC4R. In addition, we employed electrophysiology in combination with optogenetics to investigate the functional connection between $POMC^{ARC}$ and MC4R-expressing neurons as well as measure firing activity in these downstream neurons in distinct physiological hunger states.

Title: Hypothalamic chemoarchitecture in the adult male rat: Creating canonical atlas maps for three co-visualized peptidergic neuronal populations and their fiber systems from a single brain

Authors: *C. E. WELLS, K. PENNINGTON, A. M. KHAN
Biol. Sci., The Univ. of Texas at El Paso, El Paso, TX

Abstract: While the hypothalamus is a major homeostatic control center and its functions have been extensively studied, the precise circuitry underlying many of these functions remains ambiguously delineated. Here we extend our previous studies of the rat lateral hypothalamic area (LHA) to report the distribution and interactions of α-melanocyte stimulating hormone (α-MSH), melanin-concentrating hormone (MCH), and neuronal nitric oxide synthase (nNOS) in additional locations in the adult male rat. We have identified the locations of these proteins in the rat hypothalamus using fluorescent antibody markers, and we have employed wide-field multi-fluorescent imaging to map novel immunoreactivity (-ir) patterns of their distribution onto the Swanson (2004) reference atlas of the rat brain. Our data indicate that α-MSH-ir fibers largely avoid the LHA, while nNOS-ir and MCH-ir cell bodies and fibers are dispersed throughout this region in a heterogeneous, patterned manner. In particular, there is a subpopulation of neurons expressing both nNOS-ir and MCH-ir in the dorsolateral LHA at levels 29-31 of the Swanson atlas. **Tables 1** and **2** detail additional patterns of distribution. To our knowledge, this work marks the first time that the anatomical distributions of α-MSH, MCH, and nNOS have been mapped together in the hypothalamus in detail. Further work to understand the interactions of these molecules will aid in functional studies of this region.

Table 1. Fiber Distributions

# of peptides labeled in area	Peptides	Locations (abbreviations after Swanson, 2004)
3	α-MSH, MCH, nNOS	PV, PVH, ME, ARH, PH, TU, I
2	α-MSH, MCH	TM, DMH
	MCH, nNOS	ZI, SUM
	α-MSH, nNOS	PM, SON
1	nNOS	VMH
	MCH	MM

Table 2. Potential Synaptic Interaction Zones

Interacting peptides	Locations with potential interaction zones (abbreviations after Swanson, 2004)		
α-MSH, MCH	LHA, DMH, ARH, ME, PV, PH, TU, I	PVH	TM
α-MSH, nNOS			PM, SON
MCH, nNOS		SUM

Title: Glutamatergic regulation of the lateral septum by melanin-concentrating hormone neurons

Authors: *M. J. CHEE[1], E. ARRIGONI[2], E. MARATOS-FLIER[1]
[1]Endocrinol., [2]Neurol., Beth Israel Deaconess Med. Center, HMS, Boston, MA

Abstract: Melanin-concentrating hormone (MCH) is produced exclusively by neurons in the lateral hypothalamus and zona incerta. It regulates physiological processes, such as energy homeostasis and sleep, and affective behaviors, such as anxiety and aggression. However little is known about the functional connectivity of these neurons. While MCH neurons express other neurotransmitters that can contribute to MCH actions, including GABA and glutamate, it is not certain if they express the vesicular GABA (VGAT) and glutamate transporters (VGLUT) required for uptake and release. Furthermore, MCH projections were mapped by MCH-immunoreactive fibers but its functional release sites are not known. We first determined if MCH neurons express VGAT or VGLUT2 by using double immunohistochemistry to colocalize MCH with L10-green fluorescent protein in VGATcre;L10gfp and VGLUT2cre;L10gfp mice. Almost all MCH neurons (94 ± 3%) expressed VGLUT2 but none were VGAT-positive, therefore MCH neurons may release glutamate but not GABA. We then stereotaxically injected MCHcre mice with a cre-dependent channelrhodopsin (ChR2)-mCherry adeno-associated virus to identify MCH terminals. The densest mCherry-labelled fibers were found in the lateral septum (LS). To test the MCH to LS connectivity by light-evoked GABA or glutamate, we performed whole-cell LS recordings while photostimulating (5ms, 470nm) surrounding ChR2-expressing MCH terminals. LS photostimulation evoked both GABAergic inhibitory postsynaptic currents (eIPSC) that were completely blocked by a GABAA receptor antagonist (10μM bicuculline); as well as glutamatergic excitatory postsynaptic currents (eEPSC) that were blocked by a glutamate receptor antagonist (1mM kynurenic acid). eIPSC amplitude (423 ± 174pA) was greater than eEPSCs (69 ± 22pA), but the eIPSC onset delay (6.5 ± 0.3ms) was nearly twice as long as for eEPSCs (3.3 ± 0.3ms; $p < 0.0001$). Furthermore, pretreatment with kynurenic acid abolished eIPSC generation (by 98.8 ± 0.7%) to suggest that GABA release depends on glutamatergic inputs from MCH cells. Indeed, blocking activity-dependent transmission (500nM tetrodotoxin + 1μM 4-aminopyridine) extinguished GABAergic eIPSCs but not glutamatergic eEPSCs. This indicated that there is a monosynaptic glutamate release from LS MCH terminals that then triggers robust GABA release in the LS. These findings demonstrate direct glutamate but not GABA release from MCH neurons, so glutamatergic transmission may underlie the actions of MCH neurons in the LS. While the role of LS MCH efferents is not known, the LS may mediate some MCH functions, including nutrient-regulation, anxiety and aggression.

Title: Chronic energy imbalance via hyperlipidemic diet disrupts olfactory sensory systems and odor reversal learning in mice

Authors: *K. L. FERGUSON[1], G. A. BELL[2], M. C. JOHNSON[3], N. THIEBAUD[2], D. A. FADOOL[2]

Abstract: Well-supported data show that obesity can lead to cardiovascular and cognitive declines, yet little is understood concerning obesity's impact on sensory systems. Because olfaction is linked with ingestive behavior to guide food choice, its potential dysfunction during obesity could evoke a positive feedback loop to perpetuate poor ingestive behaviors. To determine the effect of chronic energy imbalance and reveal any structural or functional changes associated with obesity, we induced long-term, diet-induced obesity by challenging mice to high-fat diets: (1) in an obesity-prone (C57BL/6J) and obesity-resistant line of mice via voltage-gated potassium channel knock out ($Kv1.3^{-/-}$), and compared this with (2) late-onset, genetic-induced obesity in mice via melanocortin receptor 4 knock out ($MC4R^{-/-}$) in which diabetes secondarily precipitates after disruption of the hypothalamic axis. Using M72*tau*LacZ and OMP*gfp* reporter backgrounds, we quantified marked loss of olfactory sensory neurons and their axonal projections after exposure to a fatty diet, with a concomitant reduction in electro-olfactogram amplitude and reduced protein expression of Golf and mouse odor receptor 28 Loss of olfactory sensory neurons and associated circuitry was linked to changes in neuronal proliferation (Ki67) and apoptotic cycles (caspase-3 and tunel labeling) as well as increased inflammatory markers,

such as Iba-1 Using a computer-controlled, liquid-based olfactometer, mice maintained on fatty diets learned reward-reinforced behaviors more slowly, had deficits in reversal learning demonstrating behavioral inflexibility, and exhibited reduced olfactory discrimination. Olfactory dysfunctions and lost circuitry persisted when obese mice were removed from their high-fat diet to regain normal body weight and fasting glucose. We conclude that a chronic energy imbalance presents long-lasting structural and functional changes in the olfactory sensory system and leads to impaired olfactory- and reward-driven behaviors.

Title: Efferent projections of the arcuate nucleus of the hypothalamus in the adult male rat: A dual retrograde tract tracing study

Authors: *A. MARTINEZ, B. E. PINALES, A. M. KHAN
Biol. Sci., Univ. of Texas At El Paso, El Paso, TX

Abstract: By monitoring systemic signals, the arcuate nucleus of the hypothalamus (ARH) acts as an active sentinel of the metabolic needs of an animal. Such signals are additionally

transduced to several other discrete brain nuclei that function as co-regulators of energy homeostasis. Many of these nuclei send reciprocal projections back to the ARH to establish complex regulatory networks that function in concert to meet the dynamic demands of energy expenditure. While ARH function has been intensively investigated, a complete understanding of connectional patterns from the ARH to larger network targets remains poorly understood. Here we report the initial results from an ongoing study using retrograde tracers to map ARH efferents to the ventral lateral bed nuclei of the stria terminals (BSTvl), the medial preoptic nucleus (MPO) and the lateral preoptic nucleus (LPO). Using stereotaxic procedures, bilateral injections of the retrograde tracers, Fluorogold (FG) and 4',6-diamidino-2-phenylindole (DAPI), were made into the BSTvl, MPO and LPO nuclei of Sprague Dawley rats. Adjacent Nissl-stained tissue series were utilized to identify the cytoarchitecture and nuclear boundaries of the ARH for tissue series used to visualize injection sites. Retrogradely backfilled ARH neurons were mapped to the Swanson rat brain atlas (2004). All cases displayed backfilled FG and DAPI cell bodies in the ARH, along with other regions. Rostral to caudal variations in the number of positively labeled ARH neurons in the medial-lateral and dorsal-ventral orientation were present among cases with different retrograde injection target sites. In some instances, both ipsilateral and contralateral projections from the ARH were visualized. While many nuclei receive projections from the ARH, this initial study closely examines the selected target sites located in rostral regions. The data from this ongoing project will provide a better understanding of the key networks the ARH communicates with to regulate energy balance.

Title: Insulin sensitizers block effects of prenatal testosterone excess in female sheep on expression of tyrosine hydroxylase, insulin and androgen receptors in the ventral tegmental area

Authors: ***C. J. STEADMAN**[1], M. N. LEHMAN[2], V. PADMANABHAN[4], L. M. COOLEN[3]
[2]Neurobio. & Anatom. Sci., [3]Physiol. & Biophysics, [1]Univ. of Mississippi Med. Ctr., Jackson,

MS; [4]Departments of Obstetrics and Gynecology, Pediatrics, and Reproductive Sci. Program, Univ. of Michigan, Ann Arbor, MI

Abstract: Female sheep exposed to excess testosterone (T) during prenatal life, display an array of endocrine deficits comparable to those observed in women with polycystic ovarian syndrome (PCOS), including functional hyperandrogenism, insulin resistance, and increased risk for developing diabetes. Previously, we demonstrated increased food reward-seeking behavior and reduced motivation for feminine sexual behavior in prenatal T-treated ewes. A neural substrate critical for such goal-directed behavior is the mesolimbic dopaminergic system. Indeed, we recently showed that prenatal T treatment increased expression of tyrosine hydroxylase (TH), the rate-limiting enzyme for dopamine, and androgen receptors in the ventral tegmental area (VTA) of the adult ewe. In the current study, we hypothesize that insulin receptor activation plays a critical role in mediating the effects of prenatal T excess on the VTA dopamine and androgen receptor systems. We utilized prenatal and postnatal interventions with insulin sensitizers Rosiglitazone and Metformin to test this hypothesis. Ewes were treated prenatally with T (twice weekly; 100 mg testosterone propionate; ~1.2 mg/kg) during days 30-90 of the 147 day gestation period (T; n=5) or vehicle (Control; C; n=7). In addition, prenatal T-treated and control females were co-treated prenatally with rosiglitazone (daily oral 8 mg/ewe; TR; n=7; and CR; n=6) or received postnatal treatments starting at 8 weeks of age with insulin sensitizers rosiglitazone (daily oral 0.11 mg/kg; T+R; n=8; and C+R; n=6) or metformin (daily oral 7.1 mg/kg; T+M; n=4; and C+M; n=5). At two years of age, all ewes were ovariectomized and administered progesterone and estradiol sequentially to mimic late follicular phase. Brains were harvested and immunohistochemistry for tyrosine hydroxylase (TH) was used to analyze VTA dopamine expression. In addition, co-expression of TH with insulin receptors (IR) was determined and expression of androgen receptors was analyzed. Prenatal T increased VTA androgen receptor and TH expression, but reduced IR expression in TH neurons. Moreover, both prenatal and postnatal insulin sensitizer treatment partially blocked or ameliorated these effects. These findings indicate that prenatal T organizes the VTA dopamine system partly via actions on insulin receptors. Moreover, the data indicate potential interactions between androgen and insulin receptors underlying effects of prenatal T.

Title: Phenotypic characterization of Urocortin 3 in the paraventricular nucleus of the hypothalamus

Authors: *C. VAN HOVER[1], C. LI[2]
[2]Pharmacol., [1]Univ. of Virginia, Charlottesville, VA

Abstract: Urocortin 3 (Ucn 3) is a member of the corticotropin releasing factor (CRF) neuropeptide family implicated in feeding, the stress response, and sympathetic outflow. Ucn 3 nerve fibers innervate the ventromedial hypothalamic nucleus (VMH), an area known for its role in satiety and sympathetic modulation. Ucn 3 neurons in the anterior parvicellular part of the paraventricular nucleus of the hypothalamus (PVHap) project prominently to the VMH. In the present study, anatomical features of the Ucn 3 cells in the PVH area were characterized to explore their functional role. Transgenic mice with Cre recombinase (cre) expressed in Ucn 3-positive cells (Ucn 3-cre) were used to visualize the distribution of Ucn 3 in the mouse brains. The expression of Ucn 3 in these mice was first verified by crossing Ucn 3-cre mice with reporter mice with mCherry fluorescence protein driven by a ROSA promoter (Ucn3-cre-mCherry). A high degree of co-localization of Ucn 3 immunoreactivity and mCherry was observed in reported Ucn 3-enriched areas including the PVHap and medial amygdala. To further characterize the Ucn 3 cells in the PVH, brain sections of Ucn3-cre-mCherry mice were labeled for CRF, vasopressin, and oxytocin (OXY) as markers to identify subregions of the PVH. Scant colocalization among Ucn 3, indicated by mCherry fluorescence, and these neurotransmitters was seen; only a very small number of Ucn 3 cells showed colocalization with OXY in the PVHap area. Ucn 3 cells thus appear to constitute a sub-population of PVH neurons located predominately in the PVHap area. To define projections of Ucn 3 cells from the PVHap, a cre-regulated anterograde tracing viral vector that expresses farnesylated GFP (GFPf) was injected into the PVHap of Ucn 3-cre mice. GFP-positive fibers and terminals were located in the medial and anterodorsal parts of the median preoptic nucleus, the perifornical area, posterolateral portion of the bed nucleus of the stria terminalis, many parts of the PVH (the PVHap, lateral magnocellular part, ventral part, and posterior part), the anterior hypothalamic nucleus, dorsomedial part of the VMH, the arcuate nucleus, and the external zone of the median eminence. In summary, we have determined that Ucn 3 shows little overlap with other well known substrates expressed in the PVH and that these Ucn 3 cells project prominently to nuclei in the hypothalamus and the median eminence. The Ucn 3 cells in the PVH connect with a number of brain areas implicated in regulating energy balance and feeding, and the Ucn 3 PVH system appears to constitute a circuit that is separate from other well known neuropeptide regulators in energy homeostasis in the PVH.

Title: Characterization of c-Fos activation following limited access to palatable food and subsequent binge eating

Authors: ***M. M. HURLEY**, J. M. RESCH, B. MAUNZE, D. A. BAKER, S. CHOI
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Binge eating disorder is defined by aberrant and unhealthy feeding patterns, driven by a state of extreme motivation. To advance our ability to distinguish between homeostatic and motivated feeding states we have developed a paradigm where male Sprague Dawley rats exhibit a binge-like behavior for limited access to a "western diet" (WD). This paradigm includes daily ad Libitum access to a nutritionally complete standard chow while simultaneously providing restricted access to a high energy WD for 30 minutes. As a result, animals consumed over half of their daily caloric intake from the WD. This design replicates several fundamental characteristics observed in binge eating disorder in humans, with the most prevalent being voluntary food restriction in exchange for brief access to WD, despite having daily ad Libitum access to standard chow. In addition to selective food restriction, the escalating quantity of WD consumption in the brief 30 min period, thereby increasing the rate of feeding, further reflects characteristics of binge eating behavior. Moreover, this behavior is highly dependent on the palatability or preference for the food provided during the "binge session," as this behavior is not observed when the WD is substituted with standard chow. Taking this into consideration, the current study will identify brain regions demonstrating changes in c-Fos expression in animals that are offered either standard chow or WD for 30 minutes in addition to their ad Libitum access to standard chow for 14 days. We anticipate that regions involved with hypothalamic-reward system interactions specific to feeding behavior will be altered by the 30 minute intake of WD compared to standard chow. Additional analysis will include co-labeling c-Fos immunoreactivity

with *in situ* hybridization detection of mRNA for feeding neuropeptides to construct a neurocircuitry underlying binge feeding behavior. In addition to utilizing limited access to WD, we will modify this behavioral paradigm to delineate and separate homeostatic feeding from motivated feeding. This will include food restriction of standard chow up to a 6 hour period then followed by 15 minutes of limited access to either standard chow or WD (restricted feeding-limited access binge paradigm). This protocol ensures the animals are homeostatically sated when they are offered limited access to palatable or standard food and allows for the examination of feeding that is driven more by motivation or preference than caloric need. Similarly, we will examine co-labeling of c-Fos and mRNA expression to identify the potential circuits involved in motivated feeding.

Abstract: Hallucinogens drugs have a long history of use in healing ceremonies, exerting their effects primarily by activating serotonin (5-HT) 2A receptors. Despite renewed interest as therapeutic tool (e.g. psychotherapy, addictions, depression) there are little systematic research about its pharmacological effects on brain changes and behavioral states. In this work we analyzed the effect of 4-AcO-DMT (O-Acetylpsilocin) on the sleep-waking cycle, anxiety and

motor control of male Wistar rats. 4-AcO-DMT was ip administered at a dose of 1, 2 and 5 mg/kg right immediately before the beginning of the sleep recording. Likewise, open arms and RotaRotd test were carried out during the dark phase of the photoperiod. Results showed that all the doses tested decreased REM sleep during the first four hours of recording and the effect remained for a total of 12h with the higher dose. Additionally, 1 mg/kg decreased the time spent in open arms; whereas 2 mg/kg interferes with the motor control. We concluded that 4-AcO-DMT modify the sleep-waking cycle by decreasing REM sleep while increasing waking facilitating anxiety and reducing motor control.

Title: Using microarray data for an improved sleep related gene ontology and identifying candidate genes for sleep QTL

Authors: S. S. JOSHI, *B. F. O'HARA
Univ. of Kentucky, Lexington, KY

Abstract: Humans spend approximately one third of their lives sleeping, but compared with other biological processes, most of the molecular and genetic aspects of sleep have not been elucidated. A nearly random gene ontology and lack of a dedicated database containing a comprehensive list of sleep related genes and their function presents a hurdle for sleep researchers. Using a two-pronged approach to solve this problem, publicly available microarray data from NCBI GEO (National Center for Biotechnology Information - Gene Expression Omnibus) database was used to develop a list of sleep related genes for traits of interest. The data was analyzed using R Bioconductor and custom Perl scripts. The genes from this list were then matched with the genes in QTL (Quantitative Trait Loci) for the trait. The genes within the QTL chromosomal region matching any in the list of sleep-related genes were considered as potential candidates for causing variations in the Quantitative trait. Here we present the results from our preliminary study conducted for sleep deprivation (SD) using this approach. Three microarray

datasets belonging to two superseries in GEO database were analyzed. The datasets were selected on the basis of similarity of experimental design. 227 candidate sleep related genes were identified by comparing data from control and sleep deprived mice. We were able to identify 4 candidate genes in Dps1 QTL, 2 in Dps2, and 9 genes in Dps3. These Dps loci are the QTL associated with delta power in slow wave sleep. The list contains Homer1 that has already been established as a molecular correlate of sleep loss, with alleles that appear responsible for Dps1. A second highlighted gene, Asrb, has also been previously reported as a candidate gene. Analysis of additional datasets from mice and *Drosophila* is underway. The advantage of this approach is that it provides more information and cross support than a simple list of sleep related candidate genes. Experimental validation of candidate genes identified using this approach will help in establishing the validity of this method. The use of microarrays and other data for improved lists of sleep related genes is not perfect, but should represent a substantial improvement over the existing list of genes returned using the query "sleep" or other similar terms in gene ontology database, and should be useful for many sleep researchers.

Abstract: Melatonin (MEL) is an import indole released from the pineal gland, and it possesses a wide variety of neurobiological actions because is consider a pleiotropic molecule, some roles

include control of seasonal reproduction, regulation of circadian rhythms, besides is an excellent antioxidant. By the other hand consequences of sleep deprivation (SD) at the molecular level are largely unexplored. Knowledge of such molecular events is essential to understand the restorative processes occurring during sleep as well as the cellular mechanisms of sleep regulation. Until now, is documented at the literature that in the hippocampus, ERK1/2 activation is regulated by sev¬eral neuromodulators, such as trophic factors, monoamines, and neuropeptides, and this can affect a broad array of cellular functions including proliferation, survival, apoptosis, motility, transcription, metabolism and differentiation. So in this work we investigate if MEL can activate this signaling pathway by MT1 and MT2 receptor or also by anti- apoptotic proteins like BCL2 and BCLX. We administrated oral melatonin at 10mg/kg for 14 days before to performance 96 hours of REM SD by the flower pot technique. Groups were: control, MEL+96 h PS, 96hrs PS and Luzindole (30mg/Kg) I.P+MEL+96 PS. MEL was administrated daily in water consumption and oral cannula administration at 18:00 p.m, luzindole (antagonist of MT1y MT2) once daily I.P at 17:30. After 96h of SD we sacrificed by decapitation and quickly we remove hippocampal tissue and stored -80°C until used. We quantify protein/RNAm by western blot(WB) technique and Real Time-PCR respectively. Our results suggest that mice treated with MEL were significant different compared with the other groups for both techniques WB and RT-PCR.

Title: The dual orexin receptor antagonist lowers rat brain histamine levels without lowering rat brain acetylcholine

Authors: *S. M. SMITH, L. YAO, A. RAMIREZ, A. GOTTER, P. TANNENBAUM, J. USLANER, C. WINROW, S. KUDUK, P. COLEMAN, J. RENGER
Merck Res. Labs., Merck & Co., Inc., WEST POINT, PA

Abstract: Orexin, promotes wakefulness via interaction with two G-protein coupled receptors, Orexin 1 and Orexin 2. Pharmacological antagonism of these two orexin receptors promotes sleep and has been clinically validated for the treatment of insomnia. DORA-12 and DORA-22, analogs of Suvorexant, are potent dual Orexin receptor antagonists (DORAs) that promote sleep across all species tested. Previous work has demonstrated that sleep-promoting doses of DORA-22, unlike currently-marketed sleep medications eszopiclone and zolpidem (Z-drugs), do not disrupt memory in a novel-object recognition paradigm in rodents (Uslaner et al., 2013). To understand the sleep-promoting effects of DORAs and Z-drugs, we used *in vivo* microdialysis to assess histamine or acetylcholine levels in the lateral hypothalamus (LH), prefrontal cortex (PFC) or hippocampus (HIP) following administration of DORA-12, DORA-22, or Z-drugs during the wake-phase when histamine and acetylcholine levels are elevated thus mimicking conditions associated with insomnia. At sleep promoting doses, DORA-22 and DORA-12 lowered the elevated histamine levels in the LH in a dose-dependent manner to the sleep phase levels. Eszopiclone had a weak and transient effect on the elevated histamine and zolpidem had no effect at the dose tested. Similarly, in the PFC, DORA-22 and DORA-12 lowered the increased histamine to levels observed during the sleep, whereas both Z-drugs only transiently lowered histamine. In hippocampus, both histamine and acetylcholine are increased during waking phase. DORA-22 did not significantly reduce the acetylcholine (ACh) levels at 3mg/kg, which is beyond the dose needed to introduce sleep (1mg/kg). In contrast, Z-drugs doses tested below sleep induction produced a significant decrease in ACh levels with similar doses showing a negative impact in rodent memory experiments (Uslaner et al., 2013). Interestingly, recent results indicate that DORA-22 attenuates caffeine induced elevation of histamine in the LH and PFC, but has no effect on the caffeine induced acetylcholine increase in the LH and PFC during the sleep phase. In contrast, Lunesta attenuated caffeine induced both histamine and acetylcholine increase. Collectively, our data provides added insights into the mechanism of action of DORAs and Z-drugs during the sleep-wake phase and further differentiates the effects of DORAs from current standards of care.

Abstract: Purpose: Zolpidem (Zolp) is a hypnotic drug prescribed to treat insomnia, in some conditions, as a long term treatment. Although the polysomnographic findings after Zolp administration have already been described, they remain controversial. Additionally, few studies have characterized the effects of Zolp on sleep pattern in animal models of sleep restriction. Thus, the aim of this study was to evaluate the effects of the repeated administration of Zolp on sleep parameters of mice submitted to total sleep deprivation (TSD). Methods: Three-month-old Swiss male mice were subjected to control condition (CTRL) or to TSD by gentle handling for 3 h per day during 10 days. Sleep-wake cycle was assessed via electrocorticographic and electromyographic records. Two pairs of electrodes were surgically implanted in the fronto-parietal medial derivation and a pair of nickel-chrome electrodes was implanted in the dorsal muscle of the neck of mice. All of the animals were recorded for 24 h before treatment to evaluate baseline sleep parameters. On the 2nd day mice were subjected to CTRL or to TSD. After sleep deprivation mice were treated with saline (Sal) or Zolp during 10 days forming the following groups: CTRL-Zolp (n=4), TSD-Sal (n=4) e TSD-Zolp (n=4). Sleep was recorded using the Somnologica software. The sleep pattern was visually and manually scored by an experienced single blinded researcher. The following sleep parameters were considered: total sleep time (TST), slow-wave sleep time (SWS), paradoxical sleep time (PS) and wake time (W). Results: The TSD protocol was able to enhance the W time and to decrease the SWS, PS and TST when compared to baseline. Zolp administration enhanced SWS in both CTRL and TSD groups. Concerning the CTRL group, Zolp increased SWS and decreased PS in the light period. Still, we found an increase in PS in the dark period, suggesting a compensatory effect. However, when comparing the 10th to the 1st day of treatment, there was a decrease in PS in the dark period. Finally, in the PST-Zolp group the compensatory enhancement in sleep parameters was observed in the light phase and persisted throughout the treatment. Importantly, opposite to which was observed in the other groups, in the PST-Zolp group we observed modification on sleep pattern during recovery when compared to baseline sleep. Conclusions: Zolp increased

SWS in both CTRL and TSD conditions. However, this effect did not persist in mice kept in the CTRL group. Sleep deprived animals seemed to tolerate the SWS (but not PS) enhancement. Importantly, sleep-deprived mice treated with Zolp did not completely recover the sleep parameters to baseline levels during rebound.

Title: Dual orexin receptor antagonists demonstrate efficacy with chronic treatment and restore REM sleep following induced insomnia in healthy animals

Authors: J. I. BRUNNER[1], *A. L. GOTTER[3], J. STEVENS[2], P. L. TANNENBAUM[2], S. V. FOX[2], S. GARSON[1], J. USLANER[2], J. J. RENGER[1], C. J. WINROW[1]

Abstract: Insomnia treatments ideally increase all sleep stages to a similar extent, and induce natural, restorative sleep. The current pharmacological standard of care which includes GABA-A modulators promote sleep by globally inhibiting CNS activity. These drugs characteristically and preferentially promote non-rapid eye movement (non-REM) sleep at the expense of reduced REM sleep. Dual orexin receptor antagonists (DORAs), representing a novel potential treatment for insomnia, block the arousal-promoting activity of orexin peptides and promote sleep proportionately in all sleep stages. Unlike that seen following GABA-A modulator administration, quantitative electroencephalography (qEEG) spectral analysis in sleep stages is not disrupted by DORAs. Insomnia treatments should also alleviate sleep debt created by deprivation according to homeostatic need for specific sleep stages of sleep. Even in the presence of increased sleep drive in REM deprived animals, treatment with Zolpidem (30 mpk, po, QD) has no immediate impact on REM sleep in comparison to control animals, and even suppressed REM at later time points. On the other hand, sleep deprived animals treated with DORA-12 (100 mpk, po, QD) exhibit a significant increase in both non-REM and REM sleep. In addition to

promoting natural sleep, sleep medication should maintain effectiveness with chronic treatment. GABA-A modulators have previously been shown to exhibit tolerance and dependence such that sleep promoting efficacy diminishes with chronic exposure. Animals treated with Zolpidem (30MPK, po, QD) exhibited desensitization over a 5 day period, with reduced or total loss of efficacy on the last day of treatment. Treatment with DORA-12 (30 mpk, po, QD) was fully efficacious throughout the same 5 day treatment window, and also had equal effectiveness in animals previously desensitized to Zolpidem (10 mpk, po, QD). Together, these results in animal models suggest that DORAs promote sleep that is similar to natural sleep, maintain effectiveness with chronic treatment, and have efficacy that is resistant to prior desensitization to GABA-A modulators.

Title: Non-steroidal anti-inflammatory drug alters c-fos expression during rebound after rapid eyes movement sleep deprivation

Authors: *K. GUZMAN VASQUEZ, D. MILLAN-ALDACO, M. PALOMERO-RIVERO, R. DRUCKER-COLIN
UNAM, Mexico DF, Mexico

Abstract: Several works have shown that total sleep deprivation (TSD) or Rapid eyes movement (REM) sleep deprivation is detrimental for animals and humans. Moreover, mechanisms sleep rebound after sleep deprivation are unknown. Our group showed that nabumetone reduces rebound after REM sleep deprivation, therefore, the goal is shown if non-steroidal anti-inflammatory drugs (Nabumetone) modifies c-fos expression in regions of brain related with sleep regulation. Male Wistar rats (250-280g) were maintained under a controlled light-dark cycle (12:12, lights on at 07:00 A.M.) with food and water ad libitum. Rats were divided in six groups and received a treatment: cage control (Vehicle or Nabumetone); deprivation control (Vehicle or Nabumetone) and REM sleep deprivation (Vehicle or Nabumetone). During deprivation rats received each 24 hours vehicle or nabumetone i.p. administration. At the end of deprivation, rats were anesthetized intraperitoneally with sodium pentobarbital and perfused transcardially with 200 ml PBS and 200 ml 4% paraformaldehyde. Then, the brains were prepared for cryostat sectioning; coronal slices were made at the hypothalamic and pons level. Immunofluorescence was developed Nabumetone administration modifies c-fos expression in the hypothalamus. Therefore, we think proinflammatory molecules are involucre in REM sleep rebound.

Title: Optogenetic stimulation of basal forebrain cholinergic neurons promotes cortical activation both directly and indirectly

Authors: J. C. ZANT[1], T. KIM[1], A. V. KALINCHUK[1], C. YANG[1], R. E. BROWN[1], J. MCNALLY[1], S. THANKACHAN[1], J. T. MCKENNA[1], R. E. STRECKER[1], R. W. MCCARLEY[1], *R. BASHEER[2]
[1]VA Boston Healthcare System-Harvard Med. Sch., West Roxbury, MA; [2]Harvard Univ./Boston VAMC, West Roxbury, MA

Abstract: The complexity of the neuronal composition in the basal forebrain (BF) has long prevented a clear understanding of the causal role of each neuronal subtype on modulating cortical activity. Cortically-projecting cholinergic and parvalbumin expressing GABAergic neurons are suggested to modulate cortical activation. To define their specific roles, we have developed a novel opto-dialysis method combining EEG/EMG recording, *in vivo* microdialysis, and optogenetics. ChAT-ChR2-EYFP-BAC (ChAT-ChR2) mice, and AAV-ChR2 transduced Parv-cre (PV) mice (for selective cholinergic and GABAergic stimulation respectively) were outfitted with EEG/EMG electrodes, and an opto-dialysis probe, aimed at the BF area. The experiment consisted of a baseline day and an experimental day, when a 10s stimulation paradigm was repeated every min for 2h, using 10ms laser pulses (473nm) at selected frequencies (8Hz for ChAT-ChR2, 40Hz for PV). To antagonize the muscarinic receptor-mediated input on BF GABAergic neurons in ChAT-ChR2 mice, atropine was administered by reverse-microdialysis during cholinergic stimulation. The 8Hz stimulation in ChAT-ChR2 mice (n=5) resulted in a 39% reduction in EEG delta power (0.5-4Hz) when compared to the pre-stimulation period; decreased NREM to wake latency by ~15s (117 trials); and increased the total amount of wakefulness by 84% (n=5). This increased wakefulness was attenuated to 28% when atropine was simultaneously perfused (n=3). 40Hz stimulation in PV mice (n=2), to excite PV expressing GABAergic neurons, increased wakefulness by 24%. These results indicate that stimulating BF cholinergic neurons may promote cortical activation both directly and indirectly mediated by activation of neighboring cortically-projecting GABAergic and/or glutamatergic neurons.

Magdeburg, Magdeburg, Germany; [4]Inst. for Synaptic Physiol., Ctr. for Mol. Neurobio., Hamburg, Germany; [5]Dept. of Pharmacol. & Therapeut., The Univ. of Melbourne, Melbourne, Australia

Abstract: Orexin neurons selectively clustered in the lateral hypothalamus project widely across the brain and have a distinct role in sleep-wake regulation. Orexin 1 & 2 receptors (Ox1R, Ox2R) are drug discovery targets for sleep disorders and several dual Ox1R/Ox2R antagonists (DORAs) have been clinically validated in primary insomnia. Advantages of DORAs over $GABA_A$ receptor targeted hypnotics may include reduced interactions with ethanol, absence of tolerance, withdrawal and addictive potential, yet the detailed effect of DORAs on sleep architecture remains to be investigated as only a few studies have examined the effects of DORAs on EEG power spectrum. We therefore compared the effects of the four DORAs SB-649868 (50 mg/kg), almorexant (50, 150 mg/kg), MK-6096 (filorexant; 50,100 mg/kg) and MK-4305 (suvorexant; 30 mg/kg) with those of zolpidem (10 mg/kg), on sleep-wake profile and EEG power spectrum in rats. Male Sprague-Dawley rats were implanted with 4 electrocorticogram electrodes positioned on the cerebellum, visual and frontal cortex (frontal electrode serving as an earth). Pizoelectric detectors were placed on the bottom of the cages to detect activity and aid in defining vigilance states. Each rat served as its own control in a 3 day experiment: dosing at the start of the dark phase with water on day 1, vehicle on day 2, and drug on day 3. EEG signals were acquired using Harmonie and analysed with Somnologica. Post-hoc correction of vigilance states using the piezoelectric signal was performed using an internal algorithm. Relative spectral power (Hanning window) was analysed in REM epochs and in selected, continuous wake and NREM epochs. All compounds reduced wake: the four DORAs had similar effects on sleep-wake, increasing total sleep and REM sleep as a proportion of total sleep, in contrast to Zolpidem which reduced REM sleep. SB-649868, almorexant (150 mg/kg), filorexant (50 mg/kg) and zolpidem increased NREM sleep, while filorexant (100 mg/kg) and suvorexant had no effect on NREM sleep despite potent REM-enhancing effects. Wake and NREM spectral ratios were

unaffected by DORAs, in contrast to zolpidem which increased ß / γ / 5Hz power, but decreased theta power during wake. During NREM, zolpidem enhanced delta, but reduced theta power and higher frequencies. Both filorexant and Suvorexant enhanced theta power within REM sleep. In summary, the DORAs investigated preferentially enhance REM sleep, suggestive of a class action of the DORAs. Further studies are needed to investigate the effects of DORAs on enhanced REM sleep theta power and its consequences, especially in human subjects, to assess translation from rodent to human sleep studies.

Abstract: *Prunella vulgaris* (PV) is widely used as an herbal medicine for cancer, inflammatory disease, or other infection. Although its long-time usage, its effects on the function of the central nervous system have not been done so much. Here, we first observed that ethanolic extracts of *Prunella vulgaris* (EEPV) had anti-anxiety and sedative effects in stressed mice. As already

known, many active components including triterpenoid (such as ursolic acid and oleanolic acid) which possess many biological activities have been isolated. Therefore, we wanted to evaluate which component of PV induces sleep extension in pentobarbital mediated sleeping model in mice. Surprisingly, in spite of their similarity in structure and other common functions like anti-inflammation, anti-cancer, and tissue protection, only ursolic acid showed enhancement of sleep duration in pentobarbital-treated mice. These activities were abolished by bicuculline, $GABA_A$ receptor antagonist treatment. To clarify this GABA-induced effect, we measured intra brain GABA level by ELISA assay. With an effective dose of ursolic acid administration, total GABA concentration is significantly increased compared to that of vehicle treatment. Taken together, the present results suggest that ursolic acid from *Prunella vulgaris* prolongs sleep duration through $GABA_A$ receptor activation and would be useful for hypnotic agent.

Title: The dual hypocretin receptor antagonist almorexant is permissive for the activation of wake-promoting systems

Authors: *G. S. PARKS[1], D. R. WARRIER[1], L. DITTRICH[1], A. J. WILK[1], M. D. SCHWARTZ[1], T. C. NEYLAN[2], S. R. MORAIRTY[1], T. S. KILDUFF[1]

Abstract: The dual hypocretin receptor (HcrtR) antagonist almorexant (ALM) has potent hypnotic actions and is thought to promote sleep by selective disfacilitation of wake-promoting systems whereas benzodiazepine receptor agonists (BzRAs) such as zolpidem (ZOL) induce sleep through general inhibition of neural activity. Consequently, HcrtR antagonists are predicted to cause less functional impairment than BzRAs. Recent behavioral studies have supported this hypothesis as ALM causes less impairment in spatial memory tasks in rats awoken from

hypnotic-induced sleep than ZOL does. Other dual HcrtR antagonists also promote sleep at doses that do not disrupt locomotor activity or cognition. In order to gain insight into the neural mechanisms underlying the differential functional impairment of these drugs, we compared the effects of ALM and ZOL on functional activation of the currently known wake-promoting systems. Sprague Dawley rats, implanted for EEG/EMG recording, were orally administered vehicle (VEH), 100mg/kg ALM, or 100mg/kg ZOL during their active phase and were either left undisturbed or kept awake (i.e., sleep-deprived; SD) for 90 min after which their brains were collected. We measured Fos coexpression with markers for wake-promoting cell groups in the basal forebrain (BF; ChAT), tuberomammillary nuclei (ADA), lateral hypothalamus (Hcrt), and dorsal raphe (DR; 5HT). In the locus coeruleus (LC), we counted singly-labelled Fos+ cells because the density of DBH staining obscured Fos immunoreactivity in double-labeled sections. Following sustained wakefulness, Fos coexpression in histamine and Hcrt neurons was higher in VEH and ALM-treated rats than in ZOL-treated rats; moreover, the level of co-expression was indistinguishable between the VEH- and ALM-treated groups. In these neuronal populations, Fos levels were consistently elevated in ALM-treated SD rats compared to undisturbed animals whereas Fos levels were unchanged by SD in ZOL-treated animals. In contrast, no significant differences were found between groups regardless of treatment in the BF and DR. Interestingly, there were no differences in Fos expression between VEH and ALM-treated animals in the LC following SD, but ZOL-treated rats exhibited elevated Fos compared to vehicle. These results indicate that, in contrast to ZOL, ALM does not inhibit activation of the histamine and Hcrt systems and is thus unlikely to prevent activation of wake-promoting systems in response to situational demands. These results may also relate to the lower levels of cognitive impairment produced by dual HcrtR antagonists compared to ZOL.

Title: Behaviorally activated localized expression of brain-derived neurotrophic factor (BDNF) in the brainstem is a molecular signature for homeostatic regulation of rapid eye movement (REM) sleep

Authors: *S. DATTA, R. SINGH
Sleep and Cognitive Neurosci., Boston Univ. Sch. Med., Boston, MA

Abstract: Multiple lines of evidence indicate that cholinergic neurons within the pedunculopontine tegmentum nucleus (PPT) are critically involved in the generation of REM sleep. However, the specific molecular mechanisms operating within PPT neurons that underlie the homeostatic regulation of REM sleep remain largely unknown. In the present study, we tested the hypothesis that BDNF levels in key regions of the REM sleep generating network are modulated by behaviorally induced REM sleep deprivation. Adult male SD rats (n = 102) were chronically implanted with sleep-wake (S-W) recording electrodes. After surgical recovery, habituation, and final baseline S-W recordings, rats were separated into 3 groups (34 rats/group), which were each further divided into 5 subgroups. Group 1 (baseline S-W [BLS]): These animals were recorded for undisturbed S-W activity for a length of time ranging between 2 and 6 hours (between 10 AM to 4 PM). After each hour, rats from one of the five subgroups (BLS-2h, BLS-3h, BLS-4h, BLS-5-h, and BLS-6h) were quickly euthanized with CO2. The brains were then rapidly chilled on dry ice for further molecular analyses. Group 2 (selective REM sleep deprivation [RSD]): The experimental protocol and five subgroups for these animals are almost identical to those of Group 1, except that for group 2 animals, from 10 AM to 1 PM, REM sleep episodes were selectively terminated at their beginning while the animals remained connected to the recording system. Group 3 (total sleep deprivation [TSD]): The experimental protocol and subgroups for these animals are almost identical to those of Group 1, except that from 10 AM to 1 PM, Group 3 animals were deprived of total sleep. The results demonstrated that: a) during the selective RSD period, the number of interventions required to prevent REM sleep, total % of time spent in non-REM sleep, and cortical EEG slow-wave activity (SWA) increased progressively; b) during the recovery S-W period, the total % of REM sleep and total number of pontine (P)-waves were significantly greater in the RSD group than in the BLS and TSD groups; c) during the selective RSD period, the levels of BDNF expression in the PPT and subcoeruleus nucleus (SubCD), but not in the medial pontine reticular formation, ventrolateral periaqueductal gray, and preoptic area, increased progressively in the RSD group; d) there was a strong positive relationship between: REM sleep pressure and SWA, REM sleep pressure and levels of BDNF in the PPT; BDNF in the PPT during RSD and rebound REM sleep. These results suggest that selective RSD-induced increased expression of BDNF in the PPT and SubCD are determinant factors in the development of the homeostatic drive for REM sleep.

Title: Water extract from Withania Somnifera (Ashwagandha) leaves (ASH-WEX) decreases sleep deprivation-induced anxiety, impairment in motor coordination, and decline in cognitive function

Authors: *R. SINGH[1,2], G. KAUR[2], S. MANCHANDA[2], T. KAUR[2], R. MISHRA[2], S. DATTA[1]
[1]Psychiatry, Boston Univ. Sch. of Med., Boston, MA; [2]Biotech., Guru Nanak Dev Univ., Amritsar, India

Abstract: Sleep restriction/deprivation (SD) leads to negative health and performance effects, including anxiety and impairment of motor coordination and cognitive functions. Most individuals in modern society experience frequent SD, yet there is no efficacious pharmacological remedy for the negative effects of SD. Herbal medicine research suggested that ASH may be effective in treating anxiety and improving cognitive function. Therefore, using a rat model, we examined whether anxiety, impaired motor skill, and decline in cognitive function could be attenuated in SD rats pretreated with ASH-WEX. Experiments were performed on 3 groups of adult Wistar rats (n = 6 rats/group). Group 1 (vehicle treated-unrestricted sleep-wake activity [V-US]): These animals received a single intra-gastric (IG) infusion of vehicle daily for 10 consecutive days; immediately after this infusion animals were allowed US. Group 2 (vehicle treated-sleep deprived [V-SD]): The experimental protocol for these animals is similar to that of Group 1, except that on day 10, immediately after IG infusion, animals were subjected to 12 hours of SD (between 8 am and 8 pm). Group 3 (ASH treated-SD [ASH-SD]): The experimental protocol for these animals is similar to that of Group 2, except that these animals received IG infusion of ASH-WEX (140mg/kg/infusion; in a volume of about 1 ml). On day 10, after 12 hours of SD or US, all rats were tested behaviorally for cognitive function (Novel Object Recognition [NOR] test), level of anxiety (Elevated Plus Maze [EPM]), and motor coordination (Rotarod task). Brains were then removed and analyzed to study the expression of stress response and plasticity markers, Heat Shock Protein 70 (HSP 70) and PSA-NCAM, in the dorsal

hippocampus. NOR test showed that ASH-SD rats showed a higher preference index for novel object compared to V-SD rats, but less than the V-US rats, indicating that the ASH treatment attenuated SD-induced decline in cognitive function. Relative to V-SD rats, the ASH-SD rats had more open arm crossings and spent more time in the open arm. Percentages of time spent in the closed arm were comparable between ASH-SD and V-US rats. These results suggest that ASH-WEX treatment normalized SD-induced anxiety. In the Rotarod task, V-SD rats showed maximum number of falls and spent minimum time on rotating rod compared to ASH-SD and V-US rats. Results showed a decrease in HSP 70 expression in V-SD rats compared to ASH-SD rats. PSA-NCAM expression was upregulated in the ASH-SD but not in the V-SD rats. These results suggest that ASH-WEX could be used as a supplement to control SD-induced anxiety and minimize SD-induced deficits in motor coordination and cognitive function.

Title: Purinergic P2 receptor-mediated excitation of basal forebrain cortically projecting cholinergic and GABAergic neurons

Authors: *C. YANG, R. W. MCCARLEY, R. BASHEER, R. E. BROWN
Psychiatry, VA Boston Healthcare Syst. and Harvard Med. Sch., Brockton, MA

Abstract: Basal forebrain (BF) cortically-projecting neurons are broadly involved in regulating cortical activation, attention and sleep. Previous studies from our group (Yang et al., 2013; Frontiers in Neurology) showed that adenosine, which accumulates in BF during prolonged wakefulness, inhibits the glutamatergic inputs onto BF cholinergic and GABAergic neurons via adenosine A1 receptors. However, the effects of its precursor, adenosine triphosphate (ATP), an important glial/neurotransmitter are unclear. *In situ*, ATP is rapidly broken down to adenosine, leading to activation of A1 receptors. However, ATP may also have fast P2-mediated effects which are obscured when applied via bath application. In order to investigate possible P2 receptor-mediated effects without contamination by adenosine effects due to ATP degradation, here we bath applied an ATP non-hydrolyzable agonist, ATP-γ-S (100 μM) and examined its effect on BF putative cortically-projecting cholinergic and GABAergic neurons with whole-cell patch clamp. ATP-γ-S strongly depolarized (by >10 mV) cholinergic and two subsets of GABAergic neurons with large and small Ih currents, in the presence of 500 nM TTX (n=5-6/group). A broad-spectrum P2X receptor antagonist, PPADS (30 μM), with relatively low affinity for P2X4 receptors, significantly decreased the responses in cholinergic neurons and small Ih GABAergic neurons to 10-20 % of control (n=5/group), but only slightly blocked the response in large Ih GABAergic neurons (by 30%, $p>0.05$, n=5). A selective P2X4 receptor antagonist, 5BDBD (30 μM), significantly decreased ~90% of the response in large Ih GABAergic neurons (n=5) and ~65% of the response in cholinergic neurons (n=5). These data suggest that ATP-γ-S excites BF cortically-projecting neurons via at least 2 subtypes of P2X receptors. Thus, ATP released from neurons and/or glia during wakefulness has both a postsynaptic excitatory effect on BF cortically-projecting neurons mediated via P2X receptors and a presynaptic inhibitory effect on glutamatergic inputs via A1 receptors. The overall effect likely depends on the kinetics of degradation/reuptake of ATP and adenosine. P2X receptors may be interesting novel targets for pharmacological agents regulating cortical activation and sleep.

Abstract: Introduction: The symptoms of narcolepsy can occur during the course of other neurological conditions (i.e. symptomatic, narcolepsy). Inherited disorders, tumors and head trauma were the three most frequent causes for symptomatic narcolepsy. Among inherited disorders, Niemann-Pick type C (NPC), Myotonic dystrophy type 1 and Prader-Willi syndrome were mainly reported. NPC is an autosomal recessive and congenital neurological disorder characterized by the accumulation of cholesterol and glycosphingolipids in the peripheral tissues and of the glycosphingolipids in the brain. NPC is associated with mutations in NPC1 and NPC2 genes. Symptoms include hepato- splenomegaly, vertical supranuclear gaze palsy, ataxia, dystonia, and dementia. Some cases frequently display narcolepsy-like symptoms, including cataplexy. Miglustat inhibits glucosylceramide synthase, an essential enzyme for the synthesis of most glycosphingolipids. Method: The subjects were 7 patients with NPC (3 male and 4 female). Patients or families gave informed consent for the lumbar puncture. We checked clinical symptoms, PSG, MRI or CT, HLA and measured orexin levels. Result: Concerning the orexin levels, 2 cases were low level, 3 cases were intermediate, 2 cases were normal. Subjects having cataplexy had low or intermediate levels. One case (6F) treated with Miglustat (glucosylceramide synthase inhibitor) was shown to reduce cataplexy and her orexin level became normal from intermediate level. Conclusion: Moderate or severe decreases in CSF orexin levels were observed in some cases with NPC with cataplexy. However, the degree of reduction was small in contrast to idiopathic narcolepsy-cataplexy.

Title: Caffeine improve memory performance and molecular plasticity during 48h of total sleep deprivation in rat

Authors: *S. SAHU[1], M. WADHWA[1], S. DEEP[2], P. SINGH[1], U. PANJWANI[1]
[1]Neurophysiol., [2]Neurobio., DIPAS, Delhi, India

Abstract: Normal sleep-wake cycle ensures the balance of synaptic potentiation and depression which called total synaptic strength. Sleep deprivation (SD) significantly impairs the basal synaptic strength. A large body of evidence suggests that chronic caffeine treatment significantly improves synaptic plasticity during stress, including SD. Here we investigated the impact of acute caffeine administration during 48h SD on short term / reference memory performance and molecular plasticity in the hippocampus. Experimental animals were sleep deprived by novel automated cage shaking stimulus based on animal activity (immobility and freezing). In five groups the rats were subjected to two behavioral paradigm, novel object recognition test and Morris Water Maze (MWM) spatial reference memory test. Hippocampal tissues were collected for qPCR, western blotting and immunohistochemical studies. SD induced a deficit in both MWM spatial navigation memory and familiar object retrieval performance. Caffeine administration during SD significantly improved both types of memory. SD significantly decreased expression of BDNF, Gria2 (AMPA), Grin2a (NMDA) and PSD-95 in terms of both mRNA and protein level. Expression of total Gria1 (AMPA), CaMK-II and CREB mRNA/protein did not alter after SD but phosphorylated Gria1 (S831), CaMK-II (T286) and CREB (S133) significantly decreased in dorsal hippocampus. Caffeine administration during SD significantly improved phosphorylation of these molecules compared to SD. Caffeine administration during SD also prevented down regulation of Gria2, Grin2a, BDNF, PSD-95, Synapsin 1 and Synaptophysin in mRNA or protein level or both. The overall results suggested that caffeine administration preserved basal synaptic strength and facilitated cognitive performance during 48h SD.

Title: Expression of MAP-K in hypothalamus and PONS on sleep deprivation and rebound in rats

Authors: *A. POOT-AKE[1], S. MIJANGOS-MORENO[1], A. MANJARREZ-MARTÍN[2], R. JIMÉNEZ-MORENO[1], E. PACHECO-PANTOJA[2], P. AQUINO-HERNÁNDEZ[2], E. MURILLO-RODRÍGUEZ[1]
[1]Lab. de Neurociencias Moleculares e Integrativas, [2]Escuela de Medicina, Univ. Anahuac Mayab, Merida, Yucatan, Mexico

Abstract: Mitogen-activated protein kinase (MAP-K) is a protein that plays a fundamental role in the memory and sleep consolidation. For instance, there is evidence showing that expression of MAP-K is higher during sleep. However, no evidence is available regarding the homeostatic changes in MAP-K after sleep deprivation and sleep rebound process. Thus, in the present experiment, male Wistar rats were sleep deprived (total sleep deprivation [TSD]) during 6h during the lights-on period. After this, rats were sacrificed by decapitation and hypothalamus (HYP) and pons (PONS) were collected for analysis of MAP-K expression using Western blot means. A second experiment consisted in rats deprived for 6 hours, and allowed them to sleep for 4h after deprivation (sleep rebound period), and then sacrificed by decapitation. HYP and PONS were collected for further MAP-K expression analysis. In the first experiment, we found out that HYP and PONS displayed a higher expression of MAP-K after 6h of TSD compared to respective control. On the second experiment, MAP-K expression as determined by Western blot means was decreased in HYP and PONS in animals that were allowed to the sleep rebound period, compared to respective control. The current results suggest that MAP-K expression displays differences if sleep deprivation is induced or if sleep rebound process is allowed. Further experiments are required to determine the homeostatic mechanism of action of MAP-K expression during sleep.

Title: Evidence that glutamatergic neurons of the supramammillary nucleus are responsible for the activation of the dentate gyrus during paradoxical (REM) sleep in the rat

Authors: *F. BILLWILLER[1], L. RENOUARD[2], O. CLÉMENT[1], P. FORT[1], P.-H. LUPPI[1]
[1]Inserm U1028-CNRS UMR5 5292, Lyon, France; [2]Dept. of Neuroscience, Sch. of Med., University of Pennsylvania, PA

Abstract: Paradoxical sleep (PS) is characterized by muscle atonia, rapid eye movements (REM) and cortical and hippocampal activation. The pathways responsible for such activation are still a matter of debate. It has been proposed that pontine PS-on neurons activate the intralaminar thalamic nuclei and the basal forebrain cholinergic neurons which in turn activate the cortex. The supramammillary nucleus (SuM) might also play a role in such activation, in particular for the hippocampus. Indeed it projects to the medial septum and the dentate gyrus (DG) and it plays a role in the genesis of hippocampal theta rhythm (Kirk and McNaughton, 1991). It has been shown that the SuM contains a large number of glutamatergic neurons projecting to the DG (Boulland et al, 2009; Soussi et al, 2010). Besides, we recently demonstrated by means of Fos labeling that the lateral part of the SuM (SuML) contains a large number of neurons specifically activated (cFos+) during PS hypersomnia (Sapin et al, 2010). Further, we showed that a SuM lesion drastically decreases the number of cFos+ granular neurons in the dorsal DG during PS hypersomnia (Renouard et al, unpublished results). In view of these data, we hypothesized that the SuML-DG pathway activated during PS is glutamatergic. To test this hypothesis, we used a combination of Fos immunostaining and *in situ* hybridization of vesicular glutamate transporter 2 (vGLUT2) mRNA in three groups of rats: control (PSC, n=4), deprived of PS for 72h (PSD, n=4) and allowed to recover during 150 min after such deprivation (PSR, n=4). In addition, we performed vGLUT2 immunohistochemistry in PSR control animals (n=4) and PSR animals with an iontophoretic injection of ibotenic acid in the SuM (n=4. In rats subjected to PS recovery, we found that 85% of the Fos-labeled neurons located in the SuML also express the vGLUT2 mRNA. In contrast, no or only a few double-labeled neurons were observed in control and PS deprived animals. In PSR animals with a SuM lesion, we found a near disappearance of the vGLUT2 labeled fibers in particular in the dorsal DG compared with controls. These results indicate that the SuML-DG pathway selectively active

during PS is glutamatergic in nature and thus responsible for the activation of a subset of DG granular cells during PS.

Title: Modulation of gamma oscillations in the pedunculopontine nucleus (PPN)

Authors: ***S. M. DONOFRIO**[1], N. KEZUNOVIC[1], J. HYDE[1], B. LUSTER[1], S. MAHAFFEY[1], E. GARCIA-RILL[1,2], F. J. URBANO[2]
[1]Dept. of Neurobio. and Developmental Sci., Univ. of Arkansas For Med. Sci., Little Rock, AR; [2]Univ. of Buenos Aires, Buenos Aires, Argentina

Abstract: Reduced gamma band activity has been reported in schizophrenic and bipolar disorder patients. In the same disorders, increased neuronal calcium sensor protein 1 (NCS-1) expression was reported in a series of postmortem studies. These disorders are also characterized by sleep dysregulation, suggesting a role for the reticular activating system (RAS). Our discovery of gamma band activity in the pedunculopontine nucleus (PPN), the cholinergic arm of the RAS, revealed that such activity was mediated by high threshold calcium channels that are regulated by NCS-1. Here, we tested the hypothesis that a) NCS-1 normally regulates gamma band oscillations subserved by these calcium channels, and b) excessive level of NCS-1, such as would be expected with over expression, would decrease gamma band activity. Whole-cell patch-clamp responses were recorded on 9-13 day old adult timed-pregnant Sprague-Dawley rat brainstem slices. Slices were recorded at 37^0C perfused with oxygenated aCSF in an immersion chamber containing the synaptic blockers gabazine ($GABA_A$ antagonist), strychnine (glycine antagonist), 6-cyano-7-nitroquinoxaline-2,3-dione (AMPA/kainate receptor antagonist), APV (NMDA receptor antagonist), mecamylamine (nicotinic receptor blocker), and tetrodotoxin (sodium channels blocker). We found, using depolarizing 2 sec current ramps, that after 20-30 min of recording, NCS-1 at 1 uM significantly increased the frequency (percent increase 641%,

ANOVA, $p<0.03$) and amplitude (percent increase 149%, ANOVA, $p<0.02$) of gamma oscillations. Mean gamma band oscillation amplitude in PPN neurons significantly increased compared to other concentrations, including 0.5, 5 and 10 uM (Kruskal-Wallis ANOVA, $p<0.01$). Furthermore, we found that very high concentrations of NCS-1 (10 uM) reduced or blocked gamma band oscillations in these cells. NCS-1 at 10 uM concentration first remained the same or increased slightly, but decreased oscillations in PPN neurons induced by 2 sec ramps as it diffused into the cell ~15 min. These findings suggest the modulation by NCS-1 of calcium channels presumably located in the dendrites of PPN neurons that mediate gamma band oscillations. Based on these results, 1 uM NCS-1 seems to be the most critical concentration for gamma oscillation modulation, whereas 10 uM would be an excessive level in keeping with significant over expression. These results suggest that NCS-1 over expression may be responsible for the decrease in gamma band activity present in schizophrenia and bipolar disorder patients.

Title: Mechanisms behind gamma band activity in the pedunculopontine nucleus (PPN)

Authors: ***B. R. LUSTER**[1], J. HYDE[1], S. DONOFRIO[1], F. J. URBANO[2], E. GARCIA-RILL[1]
[1]Univ. of Arkansas For Med. Sci., Little Rock, AR; [2]Univ. of Buenos Aires, Buenos Aires, Argentina

Abstract: The pedunculopontine nucleus (PPN) is a component of the brainstem Reticular Activating System (RAS), and is active during waking and paradoxical sleep. High frequency, especially beta/gamma band activity drives our cognitive function during waking and REM sleep, two markedly different states of awareness. Previous results show that every cell in the PPN plateaus at gamma band frequencies and this high frequency activity is mediated by high threshold, voltage-dependent N- and P/Q-type Ca^{2+} channels. However, these results do not

indicate whether some PPN cells manifest this high frequency activity through only P/Q-type Ca^{2+} channels or only N-type Ca^{2+} channels. The proposed studies were designed to determine whether some PPN cells have only N-, only P/Q-, or both N- and P/Q-type Ca^{2+} channels, and determine how many have neither one of these. Sagittal slices containing the PPN were cut at 400 μm from 9-17 day rat pups, an age at which developmental changes have shifted and plateaued. Slices were recorded and perfused with oxygenated aCSF in a perfusion chamber containing the synaptic blockers (SB): gabazine ($GABA_A$ antagonist), strychnine (glycine antagonist), 6-cyano-7-nitroquinoxaline-2,3-dione (AMPA/kainate receptor antagonist), and APV (NMDA receptor antagonist), and also Tetrodotoxin (TTX) to block sodium channels. Whole cell patch-clamp experiments (current and voltage clamp modes) were performed at body temperature (~36.5°C) using a Multiclamp 700B amplifier. Capacity transients were cancelled using computer-controlled circuitry and series resistance was compensated in all experiments (>35%, ranging from 5-16). PPN neurons were identified as to cell type (type I has LTS, type II has I_A, type III has LTS+I_A) using voltage and current clamp I-V curves. We found that all rat PPN cell types (n=50) showed gamma oscillations in the presence of SB+TTX when membrane potential was depolarized using current ramps. PPN neurons showed gamma oscillations when voltage-clamped at holding potentials above -30 mV. The N-type calcium channel blocker CgTx partially reduced gamma oscillations (decrease of 34% compared to control, $p>0.05$), while the P/Q-type blocker AgA abolished the remainder. Both ω-CgTx and ω-Aga blocked voltage-dependent calcium currents. These results suggest that all cells in the PPN have both N- and P/Q-type Ca^{2+} channels, and that voltage-dependent P/Q- and, to a lesser extent, N-type calcium channels mediate gamma oscillations in the PPN.

Title: Sleep repairs DNA double-strand breaks that normally occur during wake

Authors: *M. BELLESI, G. TONONI, C. CIRELLI
Dept. of Psychiatry, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Sleep deprivation leads to cognitive impairments in humans and, if sustained for 2-3 weeks in rodents, it is invariably fatal. It has been suggested that neural activity associated with wake, if it is not interrupted by periods of sleep, may damage brain cells through excitotoxic or oxidative mechanisms and eventually lead to cell death, but so far direct evidence for this hypothesis has been lacking. Recently, it has been shown that physiological brain activity associated with exploration of a novel environment induces DNA double-strand breaks (DSBs) in neurons of young adult wild-type mice. Of note, the number of neurons displaying DBS foci returned to baseline levels after a 24-hour recovery period, in which mice were allowed to recover in their home cages. Here we investigated whether sleep plays an active role in repairing DNA DSBs in cortical cells of mice. One well-recognized marker of DSBs is the phosphorylation of the histone protein H2A variant X at serine 139, which can be reliably identified by using antibodies against γH2A.X. Brains of adult (10 weeks old) C57Bl/6J mice was collected after 6-8h of sleep during the day (S, n=6 mice), 6h of sleep deprivation (SD, n=6 mice) by exposure to novel objects starting at light onset, 6h of recovery sleep after 6h of SD (SDRS, n=5 mice), and 6h of enforced locomotion (without exploration of novel objects) after 6h of SD (SDSD, n=4 mice). Three coronal sections of frontal cortex for each animal were stained with antibodies against γH2A.X and counter-stained with propidium iodine to identify cell nuclei. Cells containing at least one γH2A.X-positive focus in the nucleus were scored as positive. Quantitative analysis showed that SD mice displayed a higher density of DSB foci in brain cells relative to S mice (SD: 258±40.7 cells with foci/mm3, S: 190±15.4 cells with foci /mm3, p=0.003). SDRS mice showed decreased DSB foci relative to both SD and SDSD mice (SDRS: 180±43.9 cells with foci /mm3, SDSD: 280.9±63.5 cells with foci /mm3; SDRS vs SD, p=0.01; SDRS vs SDSD, p=0.026), whereas differences between S and SDRS or SD and SDSD were not significant. These results confirm that in the cerebral cortex a period of exploration during wake induces DSBs. Moreover, they demonstrate that after induction by wake exploration, the subsequent decline in DSBs requires sleep, and not simply the passage of time.

Title: Histaminergic neurons at the intersection of circadian rhythms and the sleep wake cycle

Authors: *X. YU[1], A. ZECHARIA[1], Z. ZHANG[1], Q. YANG[1], R. YUSTOS[1], P. JAGER[2], A. L. VYSSOTSKI[3], E. S. MAYWOOD[4], J. E. CHESHAM[4], S. G. BRICKLEY[1], M. H. HASTINGS[4], N. P. FRANKS[1], W. WISDEN[1]

Abstract: Circadian clocks are widely expressed in the brain, yet their functions are unknown. Here we show that one local clock regulates the expression of histidine decarboxylase (HDC), the enzyme producing the "arousal transmitter" histamine in hypothalamic neurons. The level of this enzyme varies with time of day, being highest at the start of lights off (ZT12), and is up-regulated by sleep deprivation. We disrupted this local clock by using *HDC-Cre* recombinase to delete BMAL1, the transciption factor central to circadian rhythms, selectively in histaminergic neurons, generating *HDC-Bmal1* KO mice. *Hdc* gene expression in *HDC-Bmal1* KO mice showed a disrupted 24-hour rhythm: with reduced amplitude and advanced phase peaking at ZT08, and with *hdc* transcript levels overall higher. This greatly affected natural sleep, with changes in the distribution of wakefulness and sleep during the light-dark cycle, as well as changes in the transitions between the different sleep states. In addition to this change in sleep architecture, recovery sleep following sleep deprivation was also substantially changed, with *HDC-Bmal1* KO mice having a much reduced sleep rebound. This correlated with reduced memory: after sleep deprivation *HDC-Bmal1* KO mice performed less well than controls in object recognition. In summary, we have identified a local "histaminergic clock" that regulates HDC levels, and is necessary for maintaining appropriate sleep-wake cycle architecture.

Title: Genetically mapping the sites of zolpidem-induced sleep reveals that histaminergic neurons are key targets

Authors: *D. S. UYGUN[1], A. ZECHARIA[1], Z. YE[1], X. YU[1], R. YUSTOS[1], A. ZYSSOTSKI[2], S. BRICKLEY[1], N. FRANKS[1], W. WISDEN[1]
[1]Life Sci., Imperial Col. London, London, United Kingdom; [2]Univ. of Zurich, Zurich, Switzerland

Abstract: Zolpidem, a positive allosteric modulator of the GABAA receptor, is a popular drug for treating insomnia, and works at α1βγ2, α2βγ2 and α3βγ2 type receptors. It is not known, however, if zolpidem enhances IPSCs in selective neuronal types to induce sleep, or if it just induces a general inhibition throughout the CNS, which then non-specifically produces sleep. A phenylalanine at position 77 of the mature γ2 subunit forms part of the zolpidem binding site. Mutation of F77 to isoleucine (γ2I77) abolishes zolpidem's actions. We are interested in which brain regions confer zolpidem's ability to sedate. To investigate this, we introduced γ2F77 subunits to specific brain regions of γ2I77 mice. First, a Cre-dependent γ2F77 transgene was expressed in the histaminergic hypothalamic area of γ2I77lox mice, enabling γ2F77 subunit expression exclusively in histaminergic neurons. Second, we genetically swapped γ2F77 subunits in the frontal neocortex of γ2I77lox mice. We assayed zolpidem-mediated sleep in both groups using behavioural criteria and EEG analysis. In C57bl6 wild-type mice, harbouring the wild-type γ2F77 subunit, zolpidem (5 mg/kg) injection produced sleep as assessed from the EEG, with a latency of approx. 2 minutes. In γ2F77I mice, however, zolpidem (5 mg/kg) produced no effect within the first half hour: the mice were zolpidem-insensitive. In mice with zolpidem sensitivity selectively placed into histaminergic neurons, zolpidem caused sleep onset at approx. 10 minutes after injection. We found that this is approximately the same sleep latency produced with an H1 histamine receptor antagonist, pyrilamine (approx. 12 minutes). This suggests that a considerable amount of zolpidem's sedative effects arise from blocking histaminergic neurons. Similarly, for frontal cortex "γ2 swap" mice, zolpidem also caused sleep onset after approximately 15 minutes. Our results demonstrate that both neurons in the frontal cortex and histaminergic neurons in the hypothalamus and are key targets of zolpidem-mediated sleep induction.

Title: Ultrastructural signatures of sleep and wake in neuronal cell bodies of mouse frontal cortex

Authors: *L. DE VIVO, G. TONONI, C. CIRELLI
Dept. of Psychiatry, Univ. of Wisconsin, Madison, WI

Abstract: Cortical activity and brain metabolism are higher during wake than during NREM sleep, and whole cortex transcriptomics studies show that sleep and wake are associated with the upregulation of genes belonging to different, often complementary functional categories. Yet, it remains unknown whether there are ultrastructural signatures that can distinguish sleep and wake at the single neuron level. Here we searched for those signatures by using electron microscopy to measure number and size of mitochondria, resting and active lysosomes, lipofuscins and multivesicular bodies (MVBs) in the cell body of layer II pyramidal neurons. Organelles were examined in frontal cortex (20 cell bodies/mouse) of YFP-H adolescent mice (1 month old) after: i) 6-8 hrs of sleep (S, n=4 mice); ii) 6-8 hrs of acute sleep deprivation (SD, n=4 mice); iii) 5 days of chronic sleep restriction (sleep reduced to ~30% of baseline values) enforced using forced locomotion and exposure to novel objects (CSR, n=5 mice); iv) more than 32 hrs of recovery sleep after chronic sleep restriction (RS, n=4 mice). Mitochondria. In CSR a shift of the entire mitochondrial population toward bigger sizes was observed relative to S ($p=0.0022$), together with the presence of extra large mitochondria. Some of these changes persisted even after several hours of RS. Lysosomes. After acute SD, fewer but bigger resting lysosomes were observed relative to S (decreased density $p=0.0024$, increased size $p<0.0001$;), while after CSR resting lysosomes did not differ from S. By contrast, active lysosomes were smaller but more numerous after CSR than after S ($p<0.0001$), and they were bigger after SD than after S ($p<0.0001$). Lipofuscins. Lipofuscins granules were rare in adolescent mice (33 granules in total), but half of them were found in the cells of CSR mice (16 granules in 5 mice), while only 6 granules were identified in S (2 mice) and RS (2 mice), and 5 in acute SD (4 mice). MVBs. The density of all MVBs was lower in CSR relative to SR ($p=0.0062$). In particular, endosomal compartments with

less than 2 intra-luminal vesicles were significantly less numerous in CSR relative to S (p=0.0116) and RS (p=0.0001), while the density of endosomal compartments with 2 or more vesicles was lower after acute SD relative to S (p=0.032) and RS (p=0.025). In S and RS, 10% of all MVBs underwent an invagination and a similar percentage underwent back-fusion. After both acute SD and CSR, an increase in the percentage of back-fusing MVBs was observed. These data show that frontal cortex pyramidal neurons respond to acute and chronic sleep loss by changing the size and/or the density of organelles implicated in energy production and in the turnover of cellular components.

Title: Projections from dorsal deep mescencephalic nucleus (dDpMe) to nucleus pontis oralis (PnO) utilize inhibitory and excitatory neurotransmitters

Authors: *G. A. MARKS[1,2], C.-L. LIANG[1,2]
[1]Res., VA North Texas Hlth. Care Syst., DALLAS, TX; [2]Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Both lesion and pharmacological inhibition of neurons in dDpMe resulted in an induction of REM sleep. The sublaterodorsal nucleus (SLD) also has been identified in the rat as a REM sleep induction zone partly due to the action of locally applied GABAa receptor antagonists inducing a short latency onset of a REM sleep-like state. It has been hypothesized that a critical source of GABA to SLD underlying the negative control of REM sleep is from the dDpMe. A long-lasting increase in REM sleep also resulted from application of GABAa antagonists to PnO. This GABAa receptor mediated REM sleep increase is blocked by the cholinergic receptor antagonist atropine. We previously published a study of the dDpMe projection to SLD utilizing orthograde tract-tracing, immunohistochemistry and confocal microscopy. Here utilizing the same techniques and tracer ejections, we examined dDpMe

innervation of PnO. Male, Long-Evans Hooded rats (N=4) underwent stereotaxic surgery in which the orthograde tracer biotinylated dextran amine (BDA, 10k) was iontophoretically ejected into the dDpMe to visualize varicose axon fibers in ipsilateral PnO. Six days later, rats were intracardialy perfused with fixative under pentobarbital anesthesia and coronal sections (20 um) obtained through the PnO. Tissue was prepared for fluorescence immunohistochemistry and visualized with laser scanning, confocal microscopy (LSM 510). Antibodies against the vesicular GABA transporter (VGAT) and vesicular glutamate transporter-2 (VGLUT2) were used to visualize glycine/GABA and glutamate presynaptic varicosities, respectively. These preliminary data yielded a sampled mean of 215.4 BDA labeled varicosities per section of PnO (12 fields/section). Significantly greater VGLUT2 double labeled varicosities were observed (36.5±11.1) than double-labeled VGAT (27.5±9.8)(t-test for dependent means; r=0.996). The four ejection sites in dDpMe resulted in approximately 50% more BDA labeled varicosities in SLD than in PnO, and 200% more for both VGLUT2 and VGAT double labeled varicosities in SLD than in PnO. At least some VGAT double labeled varicosities were observed apposed to the membrane of presynaptic cholinergic terminals in PnO. We hypothesize interactions among dDpMe, SLD and PnO constitute an important part of the brainstem REM sleep control network. GABAergic neurons in dDpMe may act to modulate acetylcholine release in PnO to promote and inhibit REM sleep. Glutamatergic dDpMe neurons may act in PnO to promote wakefulness.

Title: Optogenetic activation of melanin-concentrating hormone (MCH) containing neurons powerfully increases sleep in rats

Authors: *C. A. BLANCO-CENTURION[1], D. PELLURU[1], R. KONADHODE[1], M. LIU[1], A. VAN DEN POL[2], P. SHIROMANI[3]
[1]Psychiatry and Behavioral Sci., Med. Univ. of South Carolina, Charleston, SC; [2]Yale University. Sch. of Med., New Haven, CT; [3]Ralph Johnson VAMC, Charleston, SC

Abstract: MCH neurons are the only phenotype of neurons that induce both NREM and REM sleep in response to optogenetic stimulation (Jego, Glasgow et al. 2013, Konadhode, Pelluru et al. 2013). Indeed, sleep is induced against a strong circadian waking drive suggesting that this is a principal group responsible for sleep (Konadhode, Pelluru et al. 2013). The initial studies were performed in mice, and for the results to be valid the sleep induction must be replicated in other species. Therefore, the present study used a proven MCH promoter (Van den Pol, Acuna-Goycolea et al. 2004) to insert the gene for channelrhodopsin-2 in MCH neurons in rats. CSF levels of MCH and orexin were also measured at 6h intervals to determine oscillations of these peptides in conjunction with sleep-wake. Ten Long-Evans rats were administered rAAV-MCHp-ChR2-EYFP bilaterally in the lateral hypothalamus (LH), and implanted with sleep-wake electrodes and bilateral fiber optic probes (400 μm) in the LH. Subsequently, at the start of the lights-off (night) period the rats were stimulated with 5, 10 or 30 Hz (random order) of blue light pulses (10 msec duration). The light pulses were delivered for 1 minute every 5 minutes for 24h, and 48h elapsed between the three stimulation rates. Throughout the experiment the rats were maintained on a 12-12h light-dark cycle with food and water available ad libitum. We found that at night optogenetic activation of MCH neurons (10 Hz) significantly increased both NREMS ($P=0.002$) and REMS ($P = 0.014$). Sleep was increased because the wake bouts were shortened (-50%) and the number of both NREMS (>150%) and REMS (>300%) bouts increased. During the day the optogenetic activation of MCH neurons at 5 Hz significantly increased REM sleep ($P<0.02$) During the day when the stimulation train occurred during NREMS, REMS was promptly induced (>200%) although the length of the REMS bout was not increased. In a separate group of rats the activity of single neurons was recorded in freely behaving rats in conjunction with optogenetic stimulation. Light directly activated some neurons and decreased the activity of wake-active neurons. CSF levels of orexin and MCH were opposite each other and correlated with the sleep-wake cycle. Our studies have shown that all of the MCH neurons need not be activated to induce both NREM and REMS. This indicates the potency of MCH neurons in suppressing the action of all arousal neurons. By driving sleep in another specie that sleeps, these results cement the status of MCH neurons as sleep neurons in network models of sleep-wake regulation. Pharmacological activation of MCH neurons could potentially counteract insomnia.

Title: Optogenetic activation of MCH neurons simultaneously with DREDD-induced inhibition of LC neurons has an additive effect in enhancing both NREM and REM sleep

Authors: *P. J. SHIROMANI[1], E. VAZEY[2], D. PELLURU[2], R. KONADHODE[2], M. LIU[2], G. ASTON-JONES[2], C. BLANCO CENTURION[2]
[1]Psychiatry, VA - Med. Univ. of South Carolina, Charleston, SC; [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: New genetically engineered tools, such as optogenetics and DREDD, permit specific phenotypes of neurons to be manipulated. We optogenetically activated neurons containing melanin concentrating hormone (MCH) and found a robust increase in both NREM and REM sleep (Konadhode et al. 2013). In particular, the increase in sleep was induced at night when the animals were awake indicating that MCH neuron activation can be driven to suppress the activity of all of the arousal neurons. There are a number of phenotypes of arousal neurons and to identify where MCH neurons are most effective we combine optogenetics and DREDD. We start with the LC where the noradrenergic neurons are active during waking and virtually silent during sleep, especially REM sleep. We hypothesize that MCH neuron activation combined with LC inhibition would have an additive effect on sleep. In tyrosine hydroxylase-Cre Long-Evans rats (gift from Diesseroth) the LC neurons were targeted by directly injecting rAAV-hSyn-DIO-hM4D(Gi)-mCherry in the LC. This delivered the inhibitory DREDD receptor to TH-Cre neurons in the LC. In the same rats, rAAV-MCH-ChR2-EYFP was injected bilaterally into the lateral hypothalamus. This delivered the excitatory light-activated ChR2 into MCH neurons (see Konadhode et al., 2013). The experiments were started three weeks later at lights-off. Initially, baseline sleep recordings were made (12:12 light on cycle). Then light stimulation (473 nm light; 10ms duration pulse; 1 minute on every 5 minutes for 5h; 5Hz), vehicle (IP injection), CNO

(3mg/kg;IP), or CNO+light was administered. Preliminary data are in 3 rats employing a repeated measures design. Sleep during the first 6h was analyzed based on the time-course of CNO's effect. During the first two hours inhibition of LC (DREDD) by itself did not induce NREM or REMS. However, during this same time period MCH neuron activation (optogenetics)+LC inhibition (DREDD) increased NREM and a four-fold increase in REMS indicating an additive effect. In the 3rd hour LC inhibition by itself did not induce REMS whereas MCH neuron activation+LC inhibition increased REMS two-fold. It was not until the 4th hour that LC inhibition by itself increased REMS. These results demonstrate that MCH neuron activation coupled with inhibition of target arousal neurons can be used to ferret out the target site where MCH neurons most potently act to initiate NREM and/or REMS. The time-course of increase in NREM and REMS can serve to identify the relative contribution of specific arousal neurons in the sleep process. This has advantage over method referred to as ChR2 circuit mapping (CRACM) which involves stimulating ChR2 containing terminals at target sites.

Title: Optogenetic activation versus inhibition of melanin-concentrating hormone (MCH) containing neurons in MCH-Cre mice

Authors: *R. KONADHODE[1], D. PELLURU[2], C. BLANCO-CENTURION[2], M. LIU[2], A. VAN DEN POL[3], P. SHIROMANI[4]
[2]Dept. of Psychiatry, [1]Med. Univ. of South Carolina, Charleston, SC; [3]Dept. of Neurosurg., Yale Univ. Sch. of Med., New Haven, CT; [4]Ralph H. Johnson VA Med. Ctr., Charleston, SC

Abstract: In current models of sleep-wake regulation only one group - the VLPO, is listed as driving sleep. However, their status in the sleep process is unknown since these neurons have never been selectively manipulated. There are other neurons that become active during sleep (Hassani et al. 2009).One such phenotype contains MCH and it is intermingled with orexin neurons in the lateral hypothalamus. Last year we discovered that optogenetic activation of MCH neurons in WT mice robustly increased both NREM and REM sleep (Konadhode et al. 2013). The effects were evident during the animal's normal waking cycle indicating that the MCH neurons can effectively silence all of the arousal neurons. In our published report we used an MCH promoter to insert channelrhodopsin 2 (ChR2) into the MCH neurons. The advantage of this approach is that it opens explorations into other animals besides mice (see adjacent poster), but not all MCH neurons may contain the light-sensitive opsin. To optogenetically manipulate a larger percentage of MCH neurons we test our hypothesis in MCH-Cre mice. Independent groups of MCH-Cre mice were administered either excitatory (rAAV-EF1a-DIO-hChR2(H134R)-EYFP) or inhibitory (rAAV-EF1a-DIO-eArch3.0-EYFP) opsins into the LH and implanted with sleep recording electrodes. Three weeks later a 48 h baseline sleep recording was obtained (0 Hz). At the start of the lights-off (night) period the mice were stimulated with 5, 10 or 30 Hz (random order) of blue or yellow light pulses (10 msec duration). The light pulses were delivered for 1 minute every 5 minutes for 24h, and 36h elapsed between the three stimulation rates. Activation of MCH neurons (10Hz) for the 12h night period significantly decreased waking ($P<0.009$; n=6), increased NREM ($P<0.014$) and REMS ($P<0.049$). Activation during the second half of day cycle had no effect on NREM or REMS. Both these results in MCH-Cre mice are consistent with and support our report in WT mice. Preliminary data analysis indicates a trend to sleep less and more waking in response to inhibition of MCH neurons. Histology is pending and will identify the number of MCH neurons containing the reporter gene, a proxy marker of the light-sensitive opsins. Our combined studies in WT rats (Blanco-Centurion et al. sfn abstract 2014) and mice (Konadhode et al., 2013), and in MCH-Cre mice (this study) demonstrate conclusively that activation of MCH neurons at night shortens wake bouts, hastens sleep onset and increases the percent of both NREM and REMS. Pharmacological activation of MCH neurons could potentially treat insomnia.

Title: High throughput behavioral sleep assay for larval zebrafish

Authors: *K. KARLSSON, Dr.[1], A. ÁGUSTSDÓTTIR[2], H. THORSTEINSSON[2]
[1]Sch. of Sci. and Engin., [2]Reykjavik Univ., Reykjavik, Iceland

Abstract: Currently we describe a set-up for automated parallel 2304 larval zebrafish sleep-wake recording and sleep-wake modulating drug screening. Fertilized embryos are collected using a custom built embryo collector that yields up to 5000 embryos a day. The embryos are incubated at 28.5° C for 120 hrs and then placed in 96 well-plates by a custom built dispenser which utilizes a cost-effective break beam detection system. Next, twenty-four 96 well-plates are placed in light and temperature controlled recording apparatus which is fitted with 24 separate cameras for behavioral data collection and a microfluidics dispenser. After a 24 hr acclimation period, drugs are dispensed to the wells, and the larvae are recorded for 24 hrs. In a typical run each group comprises 16 larvae. Each drug is applied in three dose sizes, in addition to 3 control groups (47 different drugs in a single run). Behavioral data is collected using the Noldus Ethovision image analysis module but analyzed for sleep percentage, sleep fragmentation, average sleep and wake bout length, and sleep latency, using custom written software. Following automated analysis a report is generated highlighting drugs of interest. Future developments include adaptation of the assay to other CNS disorders with a behavioral phenotype such as ALS and epilepsy.

Abstract: We developed a noninvasive, high-throughput piezoelectric system that distinguishes sleep and wake in mice with high accuracy. A piezoelectric sensor placed at the bottom of the mouse cage records gross body movements, while an automatic classifier analyzes signal features and differentiates sleep from wake. Sleep signals are characterized by specific features of the signal waveform when the dominant motion is the mouse breathing rhythm. The classifier correlates approximately 95% with EEG and 90-95% with human observation. This system has been used in a variety of studies, including quantitative trait loci mapping of sleep-related traits, as well as characterizing sleep in mouse models of Alzheimer's disease, traumatic brain injury, and other disorders. We are expanding the system to identify other behaviors such as grooming and locomotion, as well as being able to differentiate REM from NREM sleep. Quality control is an important factor in high-throughput systems. In the piezoelectric system the signal may be erroneous for a variety of reasons, such as faulty wire connections, electronic interference, and mice with weak or unusual breathing patterns. In the past, assessments of signal quality were subjective. Recently we developed a more robust quantitative measure of signal quality, which takes into account the distribution and response of decision statistics over multi-day recordings and assigns a score from 0 to 1. A higher score indicates that the mouse sleep and wake behaviors generated more distinct decision statistics. Then we use a threshold for rejecting poor quality signals. The data confidence metric was developed to provide a well-defined signal quality measure for the Knockout Mouse Phenotyping Program (KOMP2), which aims to characterize a variety of physiological and behavioral phenotypes in over 5000 single-gene

knock-out mouse lines during this phase of the project. The piezoelectric sleep phenotyping system is part of The Jackson Laboratory pipeline, which characterizes over 200 phenotypes. The data from this pipeline can be used to elucidate the physiological and behavioral effects of single genes, as well as find correlations and connections between different genes and phenotypes. We present the results of the sleep phenotyping performed thus far in this project.

Title: A system for applying sleep deprivation to a single animal in a group-housed environment

Authors: *D. A. JOHNSON, H. P. HARMON, S. GABBERT, E. L. AKERS, D. V. AILLON, D. A. JOHNSON, P. A. PETILLO, E. NAYLOR
Pinnacle Technology, Inc., Lawrence, KS

Abstract: Social isolation of rodents results in physiological deficiencies including altered sleep patterns. Characterization of the beneficial effects of social housing compared to social isolation for sleep and sleep-related disorders is difficult. For example, sleep deprivation of a single animal within a group housed setting requires tracking and identification of multiple animals, and the selective deprivation of the target animal with minimal interference to others. We designed an automated grouped-housing system that facilitates a variety of interventions to a single animal within a social setting, including the ability to selectively sleep deprive individual members of an experimental cohort. Animal movement was tracked using high-definition video cameras. RFID tags were used to differentiate animals when video tracking was lost, usually

when animals slept in piles. Sleep deprivation was achieved using a robotic arm that simulated gentle handling via a 0.75" diameter spring-loaded cylinder at the end of the arm. Evaluation of the total amount of sleep was based on inactivity automatically measured from the video stream. In real time, when the software indicated that the target animal was inactive (no motion greater than a 5 pixel change over 40 seconds), the animal was gently nudged by the robot arm until movement was resumed. Two independent trials successfully tracked a single rat within its cohort over a three day period and selectively sleep deprived this target animal. All animal studies were performed at the University of Kansas Animal Care Facility and approved by the University of Kansas IACUC. Two cohorts of four rats were implanted with RFID tags and socially housed in a 2' x 2 'x 1.5' cage with food and water available ad lib. After recording 24 hours of baseline activity, six hours of sleep deprivation was applied ending at lights off, which was followed by 24 hours of recovery. The amount of sleep following the end of the deprivation period was compared to the sleep measured from the same animal during the equivalent time period of the baseline day. In cohort 1, the target animal increased sleep time during recovery by 65%, while the target animal in cohort 2 increased sleep time by 22%. In both cohorts, the number of sleep bouts increased by about 40%. The grouped-housing system proved successful in depriving a specific animal within a cohort of four, and demonstrates the utility of the design to effectively apply selective interventions within a social environment. **SUPPORT:** This research was supported by NIH grant #1R43MH098595.

Title: Characterizing the continuous behavioral and physiological dynamics of the sleep onset: A novel behavioral and computational approach

Authors: *M. J. PRERAU[1], K. HARTNACK[1], G. OBERGON[1], A. SAMPSON[1], M. BIANCHI[2], J. ELLENBOGEN[3], P. PURDON[1]

Abstract: The act of falling asleep is a continuous, dynamic process involving multiple behavioral and physiological systems. Standard methods for characterizing the sleep onset process (SOP) do not incorporate current knowledge of the neurophysiological dynamics governing the wake/sleep transition, and fail to integrate information from both behavioral and physiological data. To keep pace with our scientific understanding, we developed a physiologically-principled model of the SOP within a statistically-principled Bayesian framework. Our empirical model of the SOP integrates information from both behavioral and physiological observations, combining simultaneously recorded EEG, EMG, and behavioral task data to estimate the instantaneous probability that a subject is awake. We fit the model to the EEG, EMG, and respiratory data from 10 healthy subjects. As subjects fell asleep, they performed a novel task, which uses breathing as a prompt for behavioral response and thus removes the need for any arousing external sensory stimuli. The model output successfully captured the continuous dynamics of the SOP, significantly outperforming standard clinical metrics in predicting behavior. By performing a cross-subject alignment of EEG activity with respect to response probability, we revealed a subset of subjects with significantly lower alpha power compared to the other subjects at identical levels of wakefulness.

Title: Validation of an assessment strategy to accurately measure sleep in non-human primates from actigraphy data

Authors: *T. J. GAUGHAN[1], D. B. KAY[4], M. PONGIBOVE[2], B. KREIDER[1], N. ROCKCASTLE[3], N. D. RYAN[3], J. L. CAMERON[3]

Abstract: Omnidirectional accelerometers (i.e. actigraphy) are widely used to measure activity levels in humans and animals. Because activity levels are highly correlated with sleep-wake patterns, actigraphy has also proved a useful noninvasive means of characterizing sleep. However, established algorithms and scoring criteria for assessing sleep from actigraphy have only been developed and validated for humans. The goal of this study was to identify and validate an algorithm to identify sleep in non-human primates from actigraphic measurement. In our study, adult female cynomolgus monkeys (Macaca fascicularis) wore collars housing accelerometers (Actical®, Philips Respironics Inc., Pittsburgh PA). Activity counts were recorded in 60 second epochs and downloaded with Actiware® software. Behavioral sleep was monitored continuously for 18 hours from late afternoon until mid-morning in each animal using infrared videography. Videos were scored frame-by-frame as either sleep or wake by three scorers (inter-rater reliability was 0.94). For sleep in monkeys, we tested a range of scaling multipliers for the Actiware algorithm, seeking out the highest ratio of sensitivity to specificity in the monkey data. The sensitivity of the original, unaltered Actiware algorithm to detect video-defined monkey sleep was 95.8%, but the specificity was only 46.3%. Kappa was k=0.49, but the low specificity means that there was a tendency to misidentify wake, further evidenced by a 35.9% specificity during the night that only rose to 48.8% during the day. After optimizing the equation for cynomolgus monkeys using a series of different scaling multipliers, the best multiplier for the night (lights off) period was M = 1.4, that resulted in a sensitivity of 74.4% and a specificity of 74.3%. Kappa for this form of the equation was k=0.5. The best multiplier for the day (lights on) period was M=0.08, which resulted in a sensitivity of 72.1% and a specificity of 70.5%, with an overall kappa of k=0.57. Thus, different parameters appear to be necessary to accurately determine sleep-wake states in the monkey in the night vs. day from actigraphy, reflecting differences in activity in these two time periods. By using monkey-optimized algorithms, specificity of sleep determined from actigraphic measures is considerably improved compared to the algorithm optimized for humans.

Title: Using whole-brain computational modelling for identifying hubs necessary for transitioning between sleep stages measured with MEG

Authors: *A. B. STEVNER[1,3], G. PIANTONI[4], G. COLCLOUGH[2], M. WOOLRICH[2], C. PARSONS[1,5], J. CABRAL[1,5,6], E. VAN SOMEREN[7], Y. VAN DER WERF[7], G. DECO[6], M. L. KRINGELBACH[1,5]

Abstract: Sleep in normal adults is characterised by highly consistent state-transitions in the brain over time. Compared to the descent to sleep, which is, at least partly, a voluntary act, the switching between sleep stages appears almost mechanistic. The temporal order and relationship between the brain states of various sleep stages are remarkably constant. Describing the whole-brain activity of individual sleep stages was one of the first merits of electroencephalography (EEG), and more advanced forms of neuroimaging have expanded our understanding of the spatiotemporal unfolding of sleep. Yet, the mechanisms underlying, and brain regions orchestrating the transitions between wakefulness and the various sleep states remain unresolved. Understanding this may lead to important insights into not only the fundamental principles of the human brain function but also the causes of sleep disorders. Viewing the brain as an intricately connected network, in which activity occurs as a result of communication between parts of this network has helped the investigation of spontaneous brain activity. By combining analysis of structural imaging data, such as diffusion tensor imaging (DTI), and functional imaging data, such as functional Magnetic Resonance Imaging and magnetoencephalography (MEG), computational modelling has successfully been applied to describe how spontaneous dynamics

can arise from the structural properties of the network. Modelling of whole-brain activity can assist in elucidating the causal links facilitating the transitions between brain states of sleep. In computational terms the aim is to understand the interplay between integration and segregation in the brain and to find the important binding regions that are necessary and sufficient for network transitions between states. In the current study we used MEG to measure whole-brain activity of 11 healthy adults that went through the different phases of sleep. We obtained the spatiotemporal dynamics of brain activity by extracting the slow fluctuating changes in the Hilbert power envelope of frequency filtered and beamformed time-series. A Hidden Markov Model (HMM) makes it possible to resolve non-stationarity of functional networks. Thus each sleep stage was tested as individual transient states of the network. Finally, we applied a whole-brain computational model that allowed us to identify the necessary and sufficient brain regions binding information across the brain and facilitating the transitions between brain states during sleep.

Title: Two different mechanisms alternate during the slow oscillation

Authors: *E. MUNRO[1], T. KHODAI[2], S. SAKATA[2], T. TOYOIZUMI[3]
[1]RIKEN Brain Sci. Inst. - Wako, Saitama, Japan; [2]Univ. of Strathclyde, Glasgow, United Kingdom; [3]RIKEN Brain Sci. Inst., Wako, Japan

Abstract: A large amplitude slow oscillation (<2 Hz) is seen during slow-wave sleep and under anesthesia throughout the cortex. Within the slow oscillation UP phases are characterized by

global spiking while DOWN phases are characterized by global silence. It is currently unclear whether this slow oscillation is generated by the cortex alone or through interactions between the thalamus and cortex. In our study, applying independent component analysis (ICA) to recordings from urethane-anesthetized rat neocortex reveals two different mechanisms for slow oscillations. The mechanisms are distinguished by two key neural sources identified by ICA: a strong broad source centered in layer 5 (BL5) and an apparent sub-cortical source producing a clock-like 3.5 Hz oscillation which resembles hippocampal theta oscillations (SUB). While these two sources are independent on a timescale of milliseconds, they are anti-correlated and alternate on a timescale of minutes. The BL5-dominated slow oscillation often resembles cortically generated oscillations: UP phases are initiated in the infragranular layers akin to traveling neocortical waves, and the oscillation is relatively slow. The SUB-dominated slow oscillation can resemble thalamo-cortically generated oscillations: UP phases are initiated in granular as well as infragranular layers, and the oscillation is faster and relatively regular in some experiments. These findings suggest that both hypothesized mechanisms for the slow oscillation are at work in the cortex - in alternation.

Title: Comparison of corticocortical coherence between spontaneous and recovery sleep-wake states in rat

Authors: *D. PAL, B. SILVERSTEIN, A. LEE, U. LEE, G. MASHOUR
Dept. of Anesthesiol., Univ. of Michigan, Ann Arbor, MI

Abstract: Background: Sleep deprivation induces functional deficits at multiple organizational levels ranging from molecules to behavior. Some of these deficits, especially neurobehavioral and cognitive, have been documented to persist even after the recovery of sleep architecture. Electroencephalogram (EEG) based brain connectivity measures can provide insights into the interaction and causal relationships between different brain regions and may reveal differences in

functional states that remain undetected by coarse EEG analysis. To the best of our knowledge, there has been no comprehensive study to characterize brain connectivity during spontaneous sleep-wake (S-W) states and the recovery period after total sleep deprivation (TSD). Therefore, we characterized and compared the corticocortical connectivity between spontaneous S-W states and the S-W states during recovery from 9 h of TSD. Methods: Male Sprague Dawley rats (n=7) were instrumented to record EEG from frontal, parietal, occipital cortices, and electromyogram (EMG) from nuchal muscles. After 7-10 days of post-surgical recovery, monopolar EEG (0.1-300 Hz), bipolar EEG (0.1-100 Hz), and EMG (1-100 Hz) were recorded across 24 h light-dark period (lights on at 6 am). Thereafter, the rats had 9 h of TSD through gentle handling between 9 am - 6 pm. After TSD, the rats were allowed ad libitum sleep and electrophysiological recordings were conducted for 24 h. Bipolar EEG and EMG were used for classifying the S-W records into wake (W), slow wave sleep (SWS), rapid eye movement sleep (REMS), and intermediate state (IS). Monopolar EEG was used for measuring changes in corticocortical coherence, a measure of non-directional brain connectivity. Paired t test was used for statistical comparisons. Results: As expected, after TSD there was a rebound increase in SWS, REMS, and IS ($p<0.05$). The differences were significant only for the 12 h recovery period (dark phase) immediately after the completion of TSD. Broadband (0.5-115 Hz) coherence analysis for the recovery period showed a significant ($p<0.05$) suppression of coherence during SWS and REMS as compared to spontaneous sleep. Percent S-W states in the post-TSD light phase were not statistically different from the pre-TSD light phase, indicating behavioral recovery from the effects of TSD. However, coherence during SWS and REMS in the recovery light phase remained significantly suppressed ($p<0.05$). Conclusions: Despite the recovery of sleep macroarchitecture after TSD, changes in corticocortical coherence persist. Such changes may underlie persistent cognitive deficits and motivate further study of corticocortical connectivity during recovery sleep.

Title: REM-sleep latency predicts napping improvement on planning ability

Authors: *M. WONG[1], E. LAU[2]
[1]Psychology, Univ. of Hong Kong, Hong Kong, Hong Kong; [2]Psychology, The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: E.08. Biological Rhythms and Sleep E.08.f. Sleep: Behavior REM-sleep latency predicts napping improvement on planning ability Objective Basic cognitive functions, including memory and attention, were found to improve after sleep when compared to wakefulness. We investigated whether sleep also facilitated higher-order cognitive function such as planning ability, which is subserved by the prefrontal cortex. Methods Fifty healthy adults (aged 17-25, 60.7% female) completed two different sets of the Tower of London task(ToL) separated randomly by either a 90-minute nap (Nap, n=25) or wakefulness (Wake, n=25). The number of steps and RTs in completing the tasks were used as outcome measures of their planning ability. Results The two groups were matched on age, sex, BMI and average 5-day actigraphy-measured sleep duration (ps>.05). The groups did not differ in the change in RT, t(48)=.599, p=.551, but in steps, t(48)=2.011, p=.048, with the nap group having decreased steps and the wake group having increased steps post-condition, indicating improvements and deteriorations, respectively. Reduction in steps was associated with shorter REM-sleep latency in the nap group, r(23)=.546, p=.016. Conclusion This was the first study demonstrating the benefits of daytime napping, particularly REM-sleep on planning ability. While previous studies showed that executive function deficits in sleep-restricted and clinical populations (e.g. Attention Deficit Hyperactivity Disorder) were correlated with REM-sleep latency, our data shed light on the potential use of a daytime nap to reverse executive function deficits through its impact on REM-sleep.

Title: Cortical dynamic of an EEG high frequency band during rapid eye movement (REM) sleep

Authors: *A. SÁNCHEZ LÓPEZ, L. C. CERVANTES, M. ESCUDERO
Neurociencia Y Comportamiento, Univ. of Seville, Seville, Spain

Abstract: Electroencephalographic activity (EEG) remains one of the main physiological activities used in the identification of neurofunctional states. Here we present a detailed study of the high frequency EEG along different vigilance states in the rat. Five animals were implanted with electrodes for the recording of the EEG, neck muscle activity and search coils for the recording of eye movements by mean of the scleral search coil technique. A spectral analysis of the EEG signals was performed revealing the existence of a frequency band peaking between 120 and 140 Hz which characterized REM sleep. In order to study the cortical dynamics of this frequency band, another nine animals were implanted with 18 EEG epidural electrodes. High frequency oscillations showed the highest amplitude in the centro-parietal cortex, just previous to lambda. This high frequency oscillations occurred in bursts in synchrony with oscillations in the theta band. A high coherence among locations in a same hemisphere but not between hemispheres characterized high frequency oscillation cortical activity. Looking for the origin of the high frequency oscillations, another four animals were implanted with electrodes in the cortex and hippocampus to study this frequency band and its relation to theta in these two structures. The power of the high frequency was higher in the cortex than in the hippocampus and a high coherence was found between every hippocampus and the ipsilateral cortex. Nevertheless, electrolytic lesions in the hippocampus produced no changes in cortical high frequency, suggesting that this frequency band in the cortex must have a generator independent from hippocampus. Finally, two additional animals were implanted with 4 electrodes in each thalamus. No high frequency was recorded by any of these electrodes during REM sleep. In conclusion, the high frequency band recorded in the EEG during REM sleep seems to have a cortical origin.

Title: Insights into local properties and synchrony of sleep spindles from ECoG in humans

Authors: *G. PIANTONI[1], E. HALGREN[2], S. S. CASH[1,3]
[1]Massachusetts Gen. Hosp., Boston, MA; [2]UCSD, La Jolla, CA; [3]Harvard Med. Sch., Boston, MA

Abstract: During non-REM sleep, neuronal firing is grouped by the slow oscillations at around 1 Hz, and sleep spindles, 0.5-2s long bursts of oscillatory activity between 11 and 18 Hz. Spindles are thought to arise from the interplay between thalamic and cortical neurons and are hypothesized to be involved in a wide variety of fundamental processes including the solidification of learning during sleep. However many of the physiological mechanisms and characteristics of spindles remain poorly understood. The spatial extent of spindle activity, as one key feature, has been the object of substantial debate, with conflicting evidence pointing both to an increase in synchronization, assessed with scalp EEG, and to strong regional localization, as measured by MEG and intraparenchymal depth electrode recordings (iEEG). Here, we examine spindle localization and synchrony across broad areas of neocortex using recordings from, on average, 80 electrodes (ECoG) placed directly on the pial surface in six patients undergoing evaluation for intractable epilepsy. The research was approved by the local institutional review board and electrode placement was determined solely by clinical criteria. At least one hour of visually scored sleep was included in the analysis. Spindles were automatically detected on each electrode independently, based on custom code. Spindles were considered synchronous when two spindles on separate channels overlapped in time. We observed that spindles were more likely than expected by chance to appear at the same time over multiple cortical locations. However, when we estimated the distribution of spindles in relation to the number of active electrodes, we observed that there was a strong positive skew. This indicates that most spindles were synchronous only in one or a few channels at the same time but some spindles were widely distributed. This distinction between focal spindles and distributed spindles was further investigated by measuring the spreading over cortical regions with a 3D reconstruction of the electrode locations and by comparing it with the underlying anatomical structures. These results indicate a dynamic interplay between local properties of focal spindles and widespread synchrony of global spindles. We suggest that the multiple spatial scales at which sleep oscillations operate might provide a flexible framework to support the many

functions ascribed to sleep and to spindles in particular, such as sensory gating, memory consolidation, and synaptic homeostasis.

Title: Differences between transcranial magnetic stimulation-evoked brain activity during N2 and N3 sleep measured by electroencephalography

Authors: *J. O. NIEMINEN[1,4], O. GOSSERIES[1,2], F. SICLARI[1], M. BOLY[3], M. MASSIMINI[5], G. TONONI[1]
[1]Dept. of Psychiatry, [2]Dept. of Psychology, [3]Dept. of Neurol., Univ. of Wisconsin, Madison, WI; [4]Dept. of Biomed. Engin. and Computat. Sci., Aalto Univ., Espoo, Finland; [5]Dept. of Clin. Sci. "Luigi Sacco", Univ. degli Studi di Milano, Milan, Italy

Abstract: Combined transcranial magnetic stimulation and high-density electroencephalography (TMS-EEG) is a non-invasive technique that allows assessing changes in brain activity that occur in response to the stimulation of the cortex. In earlier studies, TMS-EEG has been used to reveal differences between wakefulness, rapid-eye-movement (REM) sleep, and non-REM (NREM) sleep. TMS-evoked brain activity in NREM sleep has been described to be less complex than the response evoked during REM sleep or wakefulness, paralleling the reduced level of consciousness. However, previous studies did not differentiate between light (stage 2) and deeper (stage 3) slow wave sleep. In this study, we investigated differences between TMS-

evoked activity in NREM stage 2 (N2) and NREM stage 3 (N3) sleep on healthy adults. TMS was targeted on the precuneus using navigated TMS and the magnetic resonance images of the subjects. Brain activity was recorded using a 60-channel TMS-compatible EEG. The online EEG recording was used to detect sleep-stage transitions; after the subjects entered N2 or N3 sleep, the brain state was let to stabilize for at least 5 minutes before TMS was applied. A single TMS session consisted of about 150 biphasic pulses with an inter-stimulus interval of 2 - 2.3 seconds. In a typical night, 5 to 10 TMS sessions were recorded. After each TMS session, the subject was awakened to ask for a dream report in order to correlate the TMS-EEG responses with the level of consciousness. After removing bad EEG channels and trials contaminated by artefacts, the data were filtered and baseline-corrected. The TMS-evoked responses were studied at the sensor level using the global-mean-field-amplitude (GMFA) measure. Our preliminary results suggest that the TMS-evoked EEG response during N3 sleep appears larger and slower than during N2 sleep. The GMFA is higher in N3 than in N2 sleep, and the peak latencies vary between the sleep stages. Further analyses are currently undergoing to quantify these brain activity changes and to correlate them with the level of consciousness and the absence or presence of dream reports. TMS-EEG might provide valuable information for characterizing underlying neurophysiological differences during sleep.

Title: Steady-state visually evoked potentials as a method for studying information processing during sleep

Authors: ***J. NORTON**, S. UMUNNA, T. BRETL
Univ. of Illinois, Urbana, IL

Abstract: Sleep is a rapidly reversible period of altered consciousness during which awareness of external stimuli is greatly reduced. This reduction in awareness is caused by an inhibition of

information processing during sleep. Event-related potentials (ERPs) have provided a key research tool in the investigation of the extent to which information processing is inhibited during sleep. The majority of research in this area has concentrated on the auditory and somatosensory modalities; the elicitation and detection of visual ERPs during sleep has been unreliable. To improve the reliability of recording visual ERPs during sleep we have developed a head mounted stimulation system for the elicitation of steady-state visually evoked potentials (SSVEPs), expanded the number of occipital electroencephalograph (EEG) channels recorded during polysomnography, and implemented a detection system based on canonical correlation. To validate our system we collected experimental data from eight individuals during non-paradoxical sleep. Results demonstrate a significant and frequency specific increase in the correlation between participants' recorded EEG data and the visual steady-state stimuli during sleep. Our system provides a promising platform for the further study of visual information processing during sleep.

Title: Co-activated yet disconnected: Neural correlates of eye closure during sleep deprivation

Authors: J. ONG[1], D. KONG[1], T. T. Y. CHIA[1], J. TANDI[1], B. T. T. YEO[1,2], *M. W. CHEE[1]
[1]Duke-NUS Grad. Med. Sch., Singapore, Singapore; [2]Natl. Univ. of Singapore, Singapore, Singapore

Abstract: When an individual is deprived of sleep, the duration spent during eye closure increases. More pronounced eye closures are linked to periods of diminished responsiveness even to auditory stimuli (Ong, et al., 2013). Here, we studied BOLD signal changes accompanying eye closures in sleep deprived healthy young adults seeking to understand these might be related to diminished responsiveness. 18 undergraduates underwent two 6-minute

resting-state scans in darkness after being kept awake for ~24h. Although instructed to keep their eyes open, multiple epochs of spontaneous eye closure were observed. A trained observer scored 4-second epochs of eye video recordings as 'Eyes Closed' (EC) or 'Eyes Open' (EO). To model BOLD activity during EC periods, a random-effects GLM-based analysis was employed using a boxcar regressor corresponding to the length of each EC epoch convolved with a hemodynamic response function. To investigate the effect of eye closure duration on BOLD signal changes, event-related activity time-locked to the start of each 0.5-4s, 4-8s and 8-12s EC epoch was determined by signal averaging. In addition, EO and EC epochs were extracted for computation of functional connectivity maps within nodes of the 'default-mode' (DMN) and dorsal attention network (DAN). BOLD signal during EC contrasted to EO epochs revealed extensive activation and deactivation in multiple brain regions. There was pronounced deactivation of the thalamus, which could reflect the transition between wakefulness to sleep and closure of sensory gates. Paradoxically however, there was increased activity in hippocampal and parahippocampal areas, and in the sensorimotor, somatosensory, visual extrastriate and auditory cortices, which could suggest a switch to a dissociated interoceptive state characterized by multisensory activity (Marx et al., 2003). Further evidence of dissolution of cognate processing lay in the increased co-activation of both DMN and DAN regions, which could represent 'wake-state instability' (Doran, et al., 2001). In addition, longer duration eye closures were associated with increased BOLD peak amplitude and latency. Finally, eye closure was also associated with reduced functional connectivity within both the DMN and DAN. Together, these findings show that during drowsiness, dramatic local changes in BOLD signal and global reduction of coupling within attentional networks can be observed during periods of eye closure. These changes likely represent a shift to interoceptive processing as well as state-instability in drowsy sleep deprived persons.

Title: The effects of non-oscillating transcranial direct current stimulation on sleep in rats

Authors: L. KALVI, M. ECKERT, K. ALI, *M. TATSUNO
Dept. of Neurosci., Univ. Lethbridge, Lethbridge, AB, Canada

Abstract: Accumulating evidence supports the idea that sleep plays an active role in memory formation, suggesting that external manipulations, such as transcranial direct current stimulation (tDCS), applied during sleep may alter memory consolidation. Indeed, studies in humans and rodents have shown that transcranial application of oscillating potentials during sleep can alter endogenous brain oscillations and enhance memory retention. At the same time, tDCS applied during sleep may disrupt sleep architecture and have a negative effect on memory performance. As the effect of tDCS during sleep has not yet been investigated systematically, the aim of this study was to determine the effects of non-oscillating tDCS on sleep properties in rats. We hypothesized that non-oscillating tDCS during NREM or REM sleep would also affect fundamental brain oscillations and modify sleep architecture. Local field potentials were recorded from the cortex and hippocampus of rats during daily 3 hour sleep sessions. After habituation to the recording room, rats underwent a period of baseline sleep recordings followed by two weeks of stimulation sessions in which 5 minutes of mild non-oscillating tDCS was administered during REM or NREM sleep. Using a within-subjects design we found that many measures of sleep architecture, such as total sleep time, percentage of REM and NREM sleep, duration of REM and NREM episodes, and REM and NREM density, were not affected by tDCS either during REM or NREM. To determine the effects of stimulation on oscillatory activity, we compared power spectra following stimulation episodes with corresponding periods of sham "stimulation" during baseline days. Unlike oscillatory stimulation, tDCS during NREM sleep had no effect on delta power but decreased gamma power. On the other hand, tDCS during REM sleep did not affect power in the wide range of frequencies (delta to gamma). To investigate if stimulation affected interactions between the hippocampus and cortex, we computed the cross-correlation of hippocampal sharp wave-ripples (SPWRs) and cortical K-complexes. We found that SPWRs tended to occur around K-complexes but tDCS did not affect this timing. Contrary to previous studies in which rats engaged in learning tasks exhibited SPWRs that tend to precede K-complexes, our data from rats not engaged in any learning showed that SPWR's were equally likely to occur just prior to or after a K-complex. Taken together, these results suggest that sleep architecture is very robust to mild non-oscillating tDCS. It is possible that oscillating current is necessary to modify sleep.

Title: The effects of sleep deprivation on pre and post-training in a one-trail discriminative learning task

Authors: J. J. IZYGON, D. M. NGHIEM, J. SHAHIN, D. MCGHIEY, C. MADISON, A. MASOOD, M. HENCEROTH-CHOMIAK, G. SRINIVASARAO, D. H. MALIN, *C. P. WARD

Abstract: Experimental models of sleep deprivation have been shown to adversely affect memory consolidation in the brain. The present study explored the effects of a pre/post-training sleep deprivation period on a one-trial discriminative learning task. 27 male Sprague-Dawley rats, 4 months old, were randomly assigned to three groups: a control group, a pre-training sleep deprived group, and a post-training sleep deprived group. The behavioral task involved a training trial where rats were able to explore a five arm radial maze in order to discover the location of a food reward. Rats were either sleep deprived 24 hours prior to training or 24 hours after their training. Regardless of their condition, each group performed a retention trial 24 hours after the training trial where rats had to find the food reward in the same arm as before. Latency to find the food reward and number of incorrect arms entered were recorded. Rats were housed in a 12:12 light/dark cycle and trials occurred at the end of the dark cycle and sleep deprivation began at the start of light cycle. All groups showed a decrease in latency and errors from training to retention ($F(1,22)=20.288$, $p<.001$; $F(1,20)=16.028$, $p<.001$ respectively) indicating that the rodents learned the location of the food reward with one training trial. There was no significant main effect among the three groups in latency or errors ($F(2,22)=1.341$, $p=.282$; $F(2,20)=0.160$, $p=.489$ respectively). There was also not a significant group X trial interaction in latency or errors ($F(2,22)=3.21$, $p=.055$; $F(2,20)=0.742$, $p=.489$ respectively). Previous research has shown that spatial memory in a task such as the water maze is impaired by sleep deprivation. However, sleep deprivation did not impair memory consolidation in the present one-trial spatial task. This task is different than other tests of spatial memory (e.g., water maze) in that it can be learned in a single trial. This task also differs from other one-trial tests (e.g., contextual fear) in that it relies on positive reinforcement. While sleep deprivation often interferes with performance on tasks

that rely on the hippocampus (water maze, contextual fear, social transmission of food preference), sleep deprivation did not interfere with performance on the one-trial task. Likely, this is due to the multi-modal aspect of the one trial task and while sleep deprivation may cause impairment in hippocampal function, rodents were able to recruit motor and visual discrimination memory systems for task performance.

Title: Effect of immune challenge and/or REM-sleep restriction on memory, anxiety and helplessness

Authors: *S. A. CASTILLO-GARCIA[1], E. BECERRIL[2], J. VELAZQUEZ-MOCTEZUMA[3], L. PAVON[2], E. DOMINGUEZ-SALAZAR[3]
[1]NEUROCIENCIAS, BIOLOGIA DE LA REPRODUCCION, UNIVERSIDAD AUTONOMA METROPOLITANA, IZTAPALAPA, Distrito Federal, Mexico; [2]Inst. Nacional de Psiquiatria Ramon de la Fuente, Mexico City, Mexico; [3]Univ. Autonoma Metropolitana- Iztapalapa, Mexico City, Mexico

Abstract: One-third or more of the global population suffer from significant sleep loss by vocational or lifestyle reasons. Rapid eye movement (REM) sleep loss is associated with memory deficits and behavioral changes related to alteration in the brain neurochemistry. REM sleep loss also has been highly associated with the induction of immune changes including cytokine release and leukocytosis. Here short term memory, spatial memory, anxiety and helplessness (depression) were evaluated in Wistar Kyoto male rats under three experimental conditions for periods of 15 or 21 days of REMr: 1) REM sleep restriction (REMr), performed by the island technique, in a daily schedule of 20 hours of REMr and 4 hours of rest during 15 or 21 days; 2) Ovalbumin (OVA) administration at days 1 and 8 and at days 1, 8 and 15; and 3)

REMr with ovalbumin (REMr/OVA) at the same times than the other groups. A control group without manipulation was included. During the last seven days of sleep restriction and/or treatment with ovalbumin, short term memory was evaluated by the object recognition task; anxiety with the elevated plus maze; spatial memory with the Morris water maze, and helplessness (or depression) with the Porsolt test. Our results showed that by 15 days REMr impaired spatial learning and decreased anxiety, apparently helplessness (depression) also diminished; OVA attenuated these effects observed in REMr rats, but OVA by itself did not show any significant effect. However, the group treated with OVA by 21 days showed memory/learning deficits, these effects were eliminated with REMr. Also, REMr/OVA group by 21 days showed low levels of anxiety. REMr group by 21 days did not show any behavioral changes as compared to intact controls. In conclusion, the memory/learning changes induced by REMr can be attenuated or eliminated by the immune challenge at 15 days, and the effect of OVA administration was mitigated by REMr at 21 days. The effects on anxiety or depression depend of the duration of REMr or OVA treatment.

Title: Effects of chronic sleep restriction on cardiac and thermoregulatory functions in rats

Authors: *T. BAH, S. DEURVEILHER, E. E. EGOM, B. RUSAK, R. A. ROSE, K. SEMBA
Medecine, Dalhousie Univ., Halifax, NS, Canada

Abstract: Chronic sleep restriction (CSR) has been linked to cardiovascular morbidities (tachycardia, cardiac arrhythmias, and heart failure) and other physiological abnormalities. To study the autonomic impacts of CSR and underlying mechanisms, we continuously monitored electrocardiogram (ECG) and body temperature (BT) in rats before, during, and after a "3/1" protocol of CSR (continuous cycles of 3 h of sleep deprivation [SD] using slowly rotating wheels, followed by 1 h of sleep opportunity) for 4 days. We previously showed that this

protocol initiated both homeostatic and allostatic changes in sleep parameters and psychomotor vigilance task performance. Adult male Wistar rats were implanted with transmitters to monitor ECG, BT, and gross motor activity under a 12 h light/12 h dark cycle. A CSR group (n = 9) was recorded during 2 baseline days, followed by 4 days of the 3/1 protocol, and during 7 subsequent recovery days. A wheel-running control (WRC) group (n = 5) underwent the same experimental procedures except that they could turn the wheels freely for the first 6 days of recording and during a preceding 5 day period of habituation. Transthoracic echocardiography was conducted immediately before transmitter implantation and again at the end of the experiment to assess cardiac morphology and performance. As expected, the WRC rats showed increased heart rate (HR) and BT in the dark phase, when they were active, compared to the light phase. In the CSR rats, HR and BT increased when they were forced to walk during SD periods, in both the light and dark phases. When the CSR rats had the opportunity to sleep between SD periods, their HR decreased in both the light and dark phases but, unexpectedly, their BT remained as high as during SD periods, regardless of the time of day. This elevated BT in the CSR rats continued for several days after CSR, more noticeably in the light phase, despite the lack of forced activity. Thus, BT returned to baseline levels by the 5th day of recovery, whereas HR returned to baseline levels by the 4th day. Echocardiography one week after CSR showed signs of cardiac hypertrophy compared to baseline levels (increases in left ventricular wall thickness, ejection fraction, and fractional shortening). These data indicate that the 3/1 CSR protocol for 4 days resulted in alterations in both cardiac and thermoregulatory regulation that lasted 4-7 days after CSR. These alterations in autonomic functions may be part of the mechanisms by which CSR can promote cardiovascular disease in people.

Title: Phenotypic characterization of sleep, circadian rhythm, and drug response in MitoPark mouse, a model of Parkinson’s disease

Authors: *N. SAKAI, N. CHAN, S. NISHINO
Stanford Sleep and Circadian Neurobio. Lab., PALO ALTO, CA

Abstract: Hypersomnia can affect 20-50% of patients with Parkinson's disease (PD) and in 1 to 4% of the patients, culminates in sleep attacks. However, the pathological mechanism involved in hypersomnia and drug-induced sleep attack is unknown. A MitoPark mouse has been validated to show the progressive development of key PD features due to the selective loss of midbrain DA neurons. We therefore evaluated age-dependent changes in sleep, circadian rhythm, and drug response in MitoPark mice. Adult male mice (n=8 each for control and MitoPark mice) underwent surgery for EEG and EMG electrodes and E-mitters. Baseline sleep was recorded at 10 (absent), 15 (mild), 20 (moderate), and 25 (severe) weeks of age. Sleep deprivation was performed by gentle handling for 6 hours after one full day of baseline. Another set of mice was kept under constant dark conditions for 3 weeks from 11 and 21 weeks of age. Three doses of ropinirole, a non-ergot dopamine D2-like receptor agonist, were administered before the light off at 13, 17, 21, and 25 week olds. MitoPark mice showed an age-dependent decline of up to 60% in locomotor activity following a new cage environment, while there was no difference between control and MitoPark mice in the spontaneous locomotor activity through 24 hours on the day of baseline in all ages examined. MitoPark mice had normal amounts, and natural diurnal distributions, of wakefulness and sleep in the 12:12 LD condition at 10, 15, and 20 weeks of age. There was also no difference in the responses to 6-hour sleep deprivation. Once the movement abnormalities severely exacerbated at 25 weeks, the sleep fragmentation and a decrease of amount spent in NREM sleep occurred during light periods in the MitoPark mice. There was no abnormality in the circadian rhythm through the course of motor symptoms. Ropinirole induced the opposite effect on locomotion between genotypes, and these changes were age-dependent. In control mice, the middle and high doses (2 and 20 mg/kg) of ropinirole significantly decreased locomotion at all ages, while MitoPark mice showed a significant increase of locomotion by the high dose of ropinirole at 21 and 25 weeks of age. The vigilance changes after ropinirole injections are currently under analysis. Sleep abnormalities were observed in the MitoPark mice only at 25 week old, and it is not certain if this correlates to sleepiness in human subjects. The sleepiness could not be caused solely by the loss of midbrain DA neurons. Since the sleepiness observed in PD could be triggered by both a function of disease as well as its treatment, age-dependent changes in response to ropinirole may explain the mechanism of drug-induced sleep attacks in PD.

Title: Chronic sleep deprivation alters theta and gamma powers during REM sleep in mice

Authors: B. KIM[1,2], Y. KIM[3], *E. HWANG[1], R. STRECKER[3], R. MCCARLEY[3], J. CHOI[1,4]
[1]39-1 Hawolgok-dong, Seongbuk-gu, Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Sch. of Med., Yonsei Univ., Seoul, Korea, Republic of; [3]Dept. of Psychiatry, VA Boston Healthcare Syst. & Harvard Med. Sch., Brockton, MA; [4]Dept. of Neural Sci., Univ. of Sci. and Technol., Daejon, Korea, Republic of

Abstract: Chronic sleep restriction (CSR) has been shown to impair people's health and cognitive functions, as well as change sleep homeostasis. Previous studies have shown that CSR may impair non-rapid eye movement (NREM) sleep generation in addition to reducing NREM delta power. However, little is known about how CSR alters rapid eye movement (REM) sleep or EEG power spectra during REM. Here, we used a high-density EEG method in freely behaving mice to assess the REM sleep response to CSR. Mice (N=9) were sleep deprived daily for 18-h using periodically rotating wheels, followed by 6-h of sleep opportunity that started at the beginning of each light period. This sleep restriction (SR) protocol was repeated for 5 consecutive days. High-density EEG was analyzed for only 2-h of each 6-h sleep opportunity (1-3h after the initiation of sleep opportunity), whereas conventional EEG data using skull screw electrodes was analyzed for the full 24-h experimental days. The REM sleep time during the daily 6-h sleep opportunities increased as the SR days progressed, compared to the corresponding baseline levels. A power spectral analysis of the high-density EEG revealed that low theta power (5-7 Hz) increased significantly in the frontal cortex on SR day 1, then continuously decreased on SR3 and SR5; high theta power (7-10 Hz) was persistently elevated throughout all SR days, especially in the centro-parietal cortex. A close examination of theta oscillation revealed a transition from unimodal to bimodal oscillation showing that a peak frequency at 7 Hz during baseline was split into two peak frequencies at 7 and 9 Hz. Regarding REM gamma power, a gradual but significant increase in low gamma power (30-50 Hz) was

observed near the prefrontal cortex especially on SR3 and SR5, while robust increases in high gamma power (70-100 Hz) were observed most significantly in the centro-parietal cortex on SR3. Additionally, the analysis of the cross-frequency coupling between theta phase and gamma power showed that modulation of theta on gamma oscillation was not altered during CSR. Thus, CSR produces opposite effects on the low and high theta power of REM sleep in mice. In addition, this study indicates that CSR significantly increases REM gamma power while 18-h of acute sleep deprivation does not. Further studies are needed to determine if REM high theta power and gamma power actually correlates with the behavioral sleepiness and cognitive impairments observed in CSR.

Title: The effects of sleep deprivation on spatial representations in young and aged adult mice during an object-place recognition task

Authors: *R. K. YUAN, I. A. MUZZIO
Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Sleep is thought to play a key role in memory consolidation. Research has shown that neuronal ensembles activated during navigation are reactivated during sleep, and that sleep deprivation causes deficits in several hippocampus-dependent tasks. However, the direct effects of sleep deprivation on cellular activity are still unclear. Our preliminary findings indicate that sleep deprivation affects place cell stability, a correlate of spatial memory that affects the reliability of a cell firing. Additionally, in agreement with the existing literature showing that older subjects tolerate sleep deprivation better than younger subjects, we also found that aged mice show more resistance to sleep deprivation than younger animals. We are currently exploring the effects of sleep deprivation on learning by testing how the cellular alterations produced by sleep deprivation correlate to behavioral performance on an object recognition task. On day 1, C57BL/6 male mice were habituated to a novel environment, in which they subsequently explored 3 objects over the course of 3 consecutive sessions. Immediately after the

last object session, mice were sleep deprived for 5 hours, then returned to their home cages. On day 2, mice were reintroduced to the environment for a single test session in which one object was displaced. Sleep deprivation was induced using an automated system consisting of a cylindrical enclosure with a continuously rotating panel that spanned the enclosure, preventing the animal from maintaining a sleeping posture. Control mice were tested at the same time intervals and spent the same amount of time in the context and deprivation chamber but were not sleep deprived. We anticipate that the results of this study will provide important information about the role of sleep on cognitive performance in young and old animals.

Title: Environmental enrichment reduces sleep deprivation induced impairments of attention and recall in the novel object recognition task

Authors: J. W. CORDEIRA[1], J. M. MCNALLY[1], J. T. MCKENNA[1], C. V. BAGLINI[2], *R. E. STRECKER[1], R. W. MCCARLEY[1,2]
[1]Res. & Psychiatry, VABHS & Harvard Med. Sch., BROCKTON, MA; [2]Stonehill Col., Easton, MA

Abstract: The novel object recognition task (NOR) has been widely used to test recognition and working memory in rodent models of CNS disorders. In phase 1 of the NOR, two identical objects are presented simultaneously to allow object familiarization. Subsequently, when both a

familiar and a novel object are presented in phase 2, time spent investigating the novel object typically increases. Sleep deprivation (SD) following the initial associative learning in phase 1 has been shown to impair object recall in phase 2, an effect thought to reflect interference with memory consolidation. Attention in humans and rodents is also impaired by sleep deprivation as assessed using operant tasks (e.g., the psychomotor vigilance task); however, the NOR task is preferable to use in rodents as it does not require any training or reinforcement. Here we assessed the impact of 24h SD placed either before, or after, NOR phase 1 in mice ($N \geq 8$/group). Mice were sleep deprived by the movement of an activity wheel in which they were housed using a schedule of 3s on and 12s off for 24h. The frequency and time mice spent investigating each object was accurately determined using infrared beam breaks. Mice in the environmental enrichment condition were group housed with several toys (e.g., nesting material, running wheel, etc.) that were alternated weekly for 8 weeks prior to the NOR experiment. As previously reported, SD placed after phase 1 significantly impaired object recall in phase 2. SD prior to NOR phase 1 significantly decreased the amount of time spent per object investigation in phase 1. We interpret this finding to indicate that sleep deprived mice had an impaired ability to attend to the objects. Consistent with the observation that 24h SD prior to phase 1 impaired attention (and presumably learning), we observed that object recognition (memory) 1h later in phase 2 was also impaired. SD mice that received environmental enrichment, however, displayed object recognition in phase 2 that resembled that of untreated control mice. Specifically, ~66% of the object investigation time was spent on the novel object compared to 50% (chance level) in the sleep deprived mice. Preliminary data also indicate that high frequency cortical EEG activity evoked by novel object investigations is altered by SD. In summary, the findings suggest that: 1. the NOR task can be used as a high throughput assay of attention in mice and it is sensitive to impairments produced by SD, and 2. environmental enrichment can reverse the cognitive impairments produced by 24h SD in the NOR task.

Title: Mice exposed to predator threat display protracted sleep disruptions

Authors: A. PATEL, R. SHARMA, P. SAHOTA, *M. M. THAKKAR
Neurol., HSTMV Hospital/University of Missouri, COLUMBIA, MO

Abstract: BACKGROUND: Post-traumatic stress disorder (PTSD) is a severe debilitating disorder which develops after an individual experiences a life threatening event. PTSD is characterized by hyperarousal, sleep disruptions, flashbacks (re-experiencing trauma) and avoidance to trauma associated stimuli. Although several animal models have been developed and used, most models involve physical pain and discomfort. In contrast, the predator threat (predator odor) model is considered highly relevant since it does not involve pain or discomfort rather; exposure to predator threat (cat, fox or coyote odor) is innately life-threatening, fearful and ecologically relevant. Rodents exposed to predator odor display several symptoms of PTSD including fear, exaggerated startle response (hyperarousal) and anxiety. Although sleep disturbances are considered to be hallmarks of PTSD, sleep has never been examined in the predator threat model. This study was designed to examine the effects of a single exposure to predator threat on sleep-wakefulness in C57BL/6J mice. METHODS: Using standard surgical procedure, mice were instrumented to record hippocampal EEG and EMG to examine sleep-wakefulness. Mice were exposed to contextual conditioning by replacing their recording cages with contextual cages (recording cages wrapped with aluminum foil on the bottom and outside half). After allowing 30 min of exploration, PTSD mice were exposed to predator threat by spreading soiled cat litter in their (contextual) cages. Controls were exposed to clean/unused cat litter. After 90 minutes, contextual cages were replaced with original recording cages and mice were left undisturbed for 4 days. Fear learning was verified on day 5 by housing the animals in contextual cages. Hippocampal EEG and EMG were continuously recorded for 5 days. RESULTS: As compared to controls (N=4), PTSD mice (N=5) exposed to predator threat displayed a significant ($p<0.05$) and a protracted increase in the wakefulness along with a concomitant reduction in sleep, on all 5 days during the light period including during conditioning and testing. These results support the relevancy of predator threat model in mimicking human PTSD. CONCLUSIONS: A single exposure to predator threat results in severe and protracted sleep disruptions.

Title: Acute dietary manipulations alter sleep/wake architecture in mice

Authors: *I. J. PERRON[1,2], P. FENIK[1], S. VEASEY[1], A. PACK[1]
[1]Ctr. for Sleep and Circadian Neurobio., [2]Neurosci. Grad. Group, Univ. of Pennsylvania, Philadelphia, PA

Abstract: There is a strong association between sleep and metabolism, though most studies have focused on how sleep disruption impacts metabolic function. Exploring the reciprocal relationship--how acute dietary changes influence sleep architecture--will complete our understanding of the sleep and metabolism interaction and may provide novel therapies for patients with sleep disorders and metabolic syndromes, including obesity. In this study, we used a within-animal approach to investigate how acute dietary manipulations affect sleep/wake behavior. Briefly, adult mice were implanted with EEG/EMG electrodes to monitor sleep/wake states. Following baseline sleep recording, mice were randomized to either a 25-hour food removal (FR) or one week of high fat diet (HFD). Mice were then returned to regular chow for one week before being switched to the other dietary manipulation. Diet had differential and significant effects on total wake time in the dark phase ($p < 0.01$, Friedman), with FR trending towards increased wake ($p < 0.08$, Wilcoxon Rank). HFD mice displayed increased sleep fragmentation in the dark phase, evidenced by increased wake bout number and decreased wake bout length ($p < 0.02$ and $p < 0.04$, respectively). Additionally, the multiple sleep latency test showed a significant diet interaction for sleep propensity at the beginning of the dark phase ($p < 0.05$). Diet did not affect total wake and sleep time during the light phase. Taken together, this study provides a foundation for exploring molecular mechanisms and brain regions that influence diet-induced changes in sleep/wake architecture.

Title: The long term effects of early rearing environment on daytime and nighttime behavioral activity of adult male rhesus monkeys (Macaca mulatta) across the lifespan

Authors: *P. J. PIERRE[1], A. J. BENNETT[2]
[2]Psychology, [1]Univ. of Wisconsin-Madison, Madison, WI

Abstract: In humans, early life adversity is associated with deleterious health outcomes across the lifespan. Young nursery-reared animals are reported to be more reactive than their mother-reared counterparts, but show less gross motor activity. Previous studies have evaluated the effects of differential early rearing experience on infant and juvenile behavior in monkeys, relatively few have examined their persistence through adulthood. Thus, little is known about differences in physical health, activity, and morbidity in later life. In this study, activity levels of adult male rhesus macaques with different early infant experiences, either mother-reared (n=6, MR) or nursery-reared (n=6, NR), were measured yearly in their home cage environments over the span of the 6 years from 10 to 16 years of age. The age range is comparable to young adulthood through middle-age in humans. Behavioral activity was recorded at 2-min intervals with a Actiwatch™ actimeter for 30 consecutive 24hr periods. The 24hr activity count averages were calculated for the measures: total activity, daylight and night-time activity. As expected, all monkeys were more active during the light portion of the light:dark cycle. Daytime activity decreased significantly with age ($F(5,50)=3.51$, $p=.008$). Analysis of the dark phase of the light cycle revealed no differences in behavioral activity between the two early rearing groups. Few differences between the two rearing groups in activity levels were observed, suggesting that early rearing does not produce long-lasting effects on baseline home cage activity levels in adulthood. These data provide evidence that monkeys with differential early rearing experiences exhibit similar activity patterns in adulthood and into the middle-age period of declining activity. Taken together with previous reports, our data suggest that rearing group differences in motor activity observed in the infant and juvenile period are not maintained as animals progress to adulthood and that activity differences later in life may be "reactive," requiring a salient environmental challenge to be observed.

Title: Dim light at night reduces the amplitude of the sleep wake cycle in rats

Authors: D. STENVERS[1], R. VAN DORP[2], A. L. OPPERHUIZEN[3], E. FLIERS[1], P. H. BISSCHOP[1], J. H. MEIJER[2], *A. KALSBEEK[4,3], T. DEBOER[2]

Ctr., Leiden, Netherlands; [3]Hypothalamic Integration Mechanisms, Netherlands Inst. for Neurosci. (NIN), Amsterdam, Netherlands; [4]Amsterdam Med. Ctr. (AMC), Dept Endocrinol. and Metabolism, Amsterdam, Netherlands

Abstract: Millions of people around the world are exposed to dim light at night (dLAN). Light is the major synchronizer of the central circadian pacemaker in the hypothalamic suprachiasmatic nucleus (SCN) that regulates sleep-wake behavior, but also hormone rhythms and daily energy metabolism. In principle light at night might adversely affect many of these rhythms. In the current study we investigated the effects of dLAN in a rat model. We exposed male Wistar rats to either a regular 12:12 light (200 lux):dark (0 lux) cycle (LD) or a 12:12 light (200 lux):dim light (5 lux) cycle (LDim). In a first group, electrodes were implanted for 24-h EEG and EMG sleep-wake recordings at baseline, and at day 1, 7 and 14 in LDim. In a second group, circadian rhythmicity was assessed by passive infrared monitoring (PIR) of locomotor activity for 2 months (14 days LD, then 36 days LDim, then 12 days constant darkness [DD]). In a third group, the effects on food intake and energy expenditure were monitored for 72 h in calorimetric cages at baseline, and after 1, 7, and 14 days in LDim, with animals on either a regular chow or a high fat diet. At the end of the experiments, animals were sacrificed: trunk blood was collected and white adipose tissue was weighed. The EEG recordings showed that LDim exposure immediately reduces the amplitude of the daily rhythm of REM sleep on day 1, and gradually reduces the amplitude of the daily rhythms of NREM sleep and wake in the course of 14 days in LDim. Fourier analysis showed that within NREM sleep EEG the rhythm amplitude of 0.75-4.0Hz and 16-19 Hz power density was reduced, the latter indicating reduced

internal circadian rhythm strength. Indeed, PIR recordings of the LDim animals showed a reduced amplitude of the daily rhythm in activity with an underlying free running rhythm of ~26 h, next to the 24 h rhythm imposed by the LDim. After transfer to DD some animals were arrhythmic, some showed a sudden phase shift and some showed a normal transition to a free running rhythm. In the calorimetric cages, animals showed a reduced amplitude of the daily rhythms in food and water intake and energy expenditure. However, this did not affect body weight or body fat distribution. Our results show that in rats dLAN dramatically reduces the amplitude of the daily rhythm of sleep-wake behavior, food intake and energy expenditure, probably due to a reduced output strength of the central clock rhythm. The dual rhythms observed in the current study are very similar to the LD-dissociated rhythms of forced desynchronized rats, in which rhythm separation is due to a desynchronization of the ventrolateral and dorsomedial subpopulation of SCN neurons, suggesting that a similar desynchronisation may occur due to dLAN.

Title: Gender effects in the decline of slow-wave sleep during adolescence

Authors: *J. GAINES, J. FERNANDEZ-MENDOZA, A. N. VGONTZAS, D. LIAO, E. O. BIXLER
Penn State Col. of Med., Hershey, PA

Abstract: The relatively higher proportion of slow-wave sleep (SWS) in adult women compared to men has been well-documented. The time at which this dimorphism occurs, however, is not clear. While previous studies in adolescents have addressed this question, they are limited by selective cohorts and small sample size. The aim of this study was to characterize the decline of SWS with age in a large cross-sectional population of adolescents. A sample of 421 adolescents (ages 12-23y, mean 17.0 ± 2.3y; 53.9% male) from the Penn State Child Cohort, a representative general population sample, underwent a single 9-hour polysomnography (PSG) recording. Multiple linear regression models for percentage of SWS versus age were generated separately for males and females, adjusting for race. Linear regression models for SWS across age suggest that while males at age 12 have more SWS than females, males undergo a more rapid reduction cross-sectionally across adolescence (-2.64% per year versus -0.96% per year in females). The interaction between age and gender on SWS was significant ($p < 0.001$), and remained when controlling for Tanner (pubertal) stage. According to the models, it is at age 17.1y that the genders diverge, with males henceforth having a lower proportion of SWS. Importantly, this loss across age was not accompanied by a change in total sleep or wake time during the night. This gender divergence may signal the initiation of dimorphic sleep patterns seen in adulthood and may also shed light on underlying mechanisms of human brain maturation, especially those related to development of mental and physical health problems.

Title: Sleep quality and alcohol use in older adults of Mexico City

Authors: *M. M. MELENDEZ[1,2], A. GALLEGOS-CARI[1], N. HERNANDEZ-LLANES[1], R. CAMACHO-SOLIS[1], J. VELAZQUEZ-MOCTEZUMA[4], A. JIMENEZ-ANGUIANO[4], J. SANCHEZ-SOSA[3], G. BORGES[5], M. MEDINA-MORA ICAZA[5]

Mexico; [4]UNIVERSIDAD AUTONOMA METROPOLITANA - IZTAPALAPA, MEXICO CITY, Mexico; [5]INSTITUTO NACIONAL DE PSIQUIATRIA "RAMON DE LA FUENTE MUÑIZ", MEXICO CITY, Mexico

Abstract: Elderly population represents a challenge for health systems, because aging is associated with significant changes in health, including changes in sleep architecture and patterns. In addition, quality of life and sleep can also be altered by the consumption of alcohol and other drugs. In Mexico City lives around 500 thousand people over 65 years old, but there is a lack of information about alcohol use and misuse in Mexico City. The aim of the present study was to assess the association between sleep quality and alcohol use, abuse and dependence among older people of Mexico City. Method: Cross-sectional probabilistic house survey with a simple random representative sample of 2501 older adults residents of Mexico City. 2,098 agreed to participate with a response rate of 83.9%. Only those who accepted the informed consent were included in the study. Sociodemographic data were collected, sleep quality was assessed with the Pittsburgh Sleep Quality Index (PSQI) and a cut point of 5 or more were considered to indicate bad sleep quality. A survey form was designed to collect information about current (last 12 months) and lifetime (anytime in life) alcohol drinking. Association analysis between sleep quality and alcohol drinking patterns was made using the Odd Ratios (OR). Results: Descriptive statistics of sociodemographic variables were determined and the prevalence of alcohol and subjective sleep quality were obtained. OR between substance use and subjective sleep quality index was applied. The prevalence in the past year for alcohol consumption was 32.3%. Alcohol consumption variables like use lifetime (OR = 1.608, 95% CI = 1250-2068), hazardous drinking lifetime (OR = 1.748, 95% CI = 1345-2270) and alcohol dependence (OR = 1.684, 95% CI = 1055-2688) lifetime were significantly associated with poor subjective quality of sleep. Risky alcohol consumption in the past 12 months was also associated (OR = 1.609, 95% CI = 1051-2462) with poor subjective quality of sleep. Conclusion: The results showed an association between poor subjective quality of sleep and alcohol consumption in older adults. The results of this study provide information on possible areas of intervention that need to be taken into account by public policy makers to plan programs of care and treatment of older adults. It is also necessary to understand the underlying physiological causes between substance use and sleep disorders in older adults and its relationship to other diseases.

Title: Spontaneous glial calcium waves in cerebellar cortex *in vivo* reduce blood vessel diameter possible via constriction of pericytes

Authors: *C. MATHIESEN[1], B. L. LIND[2], A. BRAZHE[3], B. GESSLEIN[2], M. LAURITZEN[2,4]
[1]Neurosci. and Pharmacol., Panum Inst., Copenhagen, Denmark; [2]Translational Neurobio., Univ. of Copenhagen, Copenhagen, Denmark; [3]Univ. of Moscow, Moscow, Russian Federation; [4]Glostrup Hosp., Glostrup, Denmark

Abstract: Intercellular glial Ca2+ waves (GWs) constitute a signaling pathway between glial cells, and between glia, neurons and blood vessels. We report here that GWs which occur spontaneously in cerebellar cortex of aged mice *in vivo* reduce arteriole and capillary diameters through activation of pericytes. The activation of GWs are known to be associated with reduced oxygen tension. We tested two hypotheses: 1) GWs decrease vessel diameter via activation of pericytes, and 2) GWs reduce oxygen tension directly (re-establish ion gradient) and indirectly (reduce oxygen supply). We used two-photon imaging of cerebellar cortex of aged anaesthetized NMRI and NG2-DsRed (red fluorescent pericytes) mice. Bolus injection of Ca2+ indicator (Oregon Green BAPTA) was used to identify GWs as propagating Ca2+ signals in Bergmann glia. Line analysis was used to measure vessel diameter and oxygen tension was monitored using a Clark-type electrode. Calcium activity in pericytes were measured pixel-by-pixel in Dsred-pericyte-positive cells. In wild-type NMRI mice 3-5% of spontaneous GWs induced local constriction of capillaries and arterioles in a restricted part of the vessels, indicating that contractile elements were activated. ATP-evoked GWs were associated with a decrease in oxygen tension, indicating an increase of CMRO2 and a reduced perfusion. GWs - blood vessel interaction was then further evaluated using NG2-DsRed mice with red fluorescent pericytes, showing that the constriction associated with pericyte location. Conclusion: 1) GWs reduce arteriolar and capillary diameters by activation of pericytes. 2) GWs were associated with prolonged reduction in tissue oxygen tension. The increased GW activity during aging, lowered blood oxygen saturation, and self-amplification by GW-induced constriction suggests a relation to brain pathology.

Title: Development of newly optical imaging systems of simultaneous measurement of changes in cerebral oxygen metabolism and hemodynamics by awake-mice

Authors: ***T. MATSUURA**[1,2], H. TAKUWA[2], A. NISHINO[1,2], Y. TAJIMA[2], H. ITO[2]
[1]Fac Engin, Iwate Univ., Morioka, Japan; [2]Dept Biophysics, Natl. Inst. Radiol Sci., Chiba, Japan

Abstract: Hemodynamic response associated with neural activity has been investigated using positron-emission tomography (PET) and functional magnetic resonance imaging (MRI). Especially, PET allows the measurement of cerebral blood flow (CBF), cerebral blood volume (CBV) and cerebral metabolic rate of oxygen (CMRO2) in human and plays an important role to understand a mechanism of neurovascular coupling in clinical research. On the other hand, in animal studies, there is no optical imaging system, which evaluates changes in CBF and CBV, and oxygen metabolism, from the same brain area under awake condition, although they can be useful for investigating the mechanism of neurovascular coupling. In the present study, we tried to develop the simultaneous measurement method of laser speckle imaging (LSI) and intrinsic optical signal imaging (IOSI), which was verified by laser-Doppler flowmetry (LDF), during cerebral activation induced by whisker stimulation using awake-mice. Moreover, to measure oxygen metabolism, flavoprotein autofluorescence imaging (FAI) was performed from the same brain area as LSI and IOSI measurements. The increase in CBF according to LSI was correlated with that by LDF. Similarly, the increase in CBV obtained by IOSI was also correlated with RBC concentration change measured by LDF. The change in oxygen metabolism by FAI was correlated with that in CBF obtained by LSI, whereas the change in CBF was greater than that in oxygen metabolism. We revealed that the relationship between oxygen metabolism evaluated by FAI and CBF as measured by our system was in good agreement with the relationship between CMRO2 and CBF in human PET studies. In conclusion, our measurement system of CBF, CBV

and oxygen metabolism is not only useful for studying neurovascular coupling, but also easily corroborates human PET studies. All experiments were performed in accordance with the institutional guidelines on humane care and use of laboratory animals and were approved by the Institutional Committee for Animal Experimentation.

Title: Coupling of spontaneous and sensory evoked hemodynamic signals to neural activity in the barrel cortex of the awake mouse

Authors: *A. WINDER[1], P. J. DREW[1,2]
[1]Ctr. for Neural Engin., [2]Neurosurg., Penn State Univ., University Park, PA

Abstract: Increases in cerebral blood flow, volume and oxygenation follow sensory evoked neural activity, but it is unknown whether this neurovascular coupling holds for spontaneous neural fluctuations. Understanding whether the neurovascular relationship remains unchanged during spontaneous fluctuations in neural activity is important for the interpretation of resting state fMRI signals. We sought to determine if spontaneous fluctuations in cerebral blood volume (CBV) were driven by neural activity by simultaneously measuring CBV, using intrinsic optical signals, and neural activity in the barrel cortex of alert, head-fixed mice. Gamma-band power of the local field potential (LFP) and CBV were positively correlated in the absence of sensory stimulation or volitional behavior. We calculated the hemodynamic response functions (HRF), which relate the increase in blood volume to neural activity, using data from three different

behavioral states (sensory stimulation, volitional whisking, and resting behavior). All three behaviors yielded the same HRF, indicating that neurovascular coupling is the same for spontaneous and sensory evoked behavior. In order to determine how well CBV fluctuations represent neural activity, we predicted the measured hemodynamics by applying the HRF to neural activity for each behavior type. The trial-average sensory evoked hemodynamics were well fit by the trial-average neural activity (R^2=0.7±0.20), however the correlation was much lower on a trail-by-trial basis (R^2=0.30±0.57). Spontaneous hemodynamic signals were not well predicted from spontaneous neural activity (mean R^2=0.02±0.11) during individual trials. These findings are consistent with the presence of a separate, additive, uncorrelated hemodynamic signal which is of similar magnitude as the neurally evoked changes in blood volume. Thus, hemodynamic signals are coupled to neural activity on average, but isolated changes in hemodynamic signals cannot be taken as reliable indicators of changes in neural activity.

Title: fMRI measurements of spiking vs. synaptic activity in the rat olfactory bulb

Authors: *A. J. POPLAWSKY[1], H. FUKUDA[1], S.-G. KIM[1,2]
[1]Radiology, Univ. of Pittsburgh, Pittsburgh, PA; [2]Biol. Sciences, Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci. (IBS), SKKU, Suwon, Korea, Republic of

Abstract: Introduction Functional magnetic resonance imaging (fMRI) measures the hemodynamic response to neural activity; but more evidence is needed to understand the relative contributions of spiking and synaptic activities to neurovascular coupling. The olfactory bulb is

an ideal model system to study this issue because spiking activity from mitral cells (output neurons) can be selectively decreased while preserving synaptic activity. In particular, odors excite olfactory receptor neurons that project to the olfactory bulb through the olfactory nerve layer and form excitatory synapses with the apical dendrites of mitral cells in the glomerular layer, which descend through the external plexiform layer and initiate action potentials to cortical targets at the mitral cell layer. In addition, inhibitory granule cells are excited by anterior commissure (AC) stimulation, which form dendro-dendritic synapses with mitral cells in the external plexiform layer and inhibit mitral cell spiking. **Methods** In anesthetized Sprague-Dawley rats, excitatory and inhibitory pathways were preferentially activated with individual and simultaneous stimulations of odor (5% amyl acetate in mineral oil) and electrical stimulation of AC, respectively; and the cerebral blood volume (CBV)-weighted fMRI responses were compared. This contrast-enhanced fMRI technique was previously shown to have increased sensitivity in capillaries near the site of neural activity. High-resolution fMRI experiments (110x110x500 μm^3) were performed at 9.4 T. **Results** fMRI signals increased for the individual stimulations of odor and AC in layers specific to neuro-modulation. Particularly, activation peaked in olfactory nerve and glomerular layers for odor, and in granule cell layer for AC. To assess the relative contributions of spiking activity to the hemodynamic response, differential analysis was performed between the sum of the individual stimulations and the simultaneous stimulation ($[Odor_{alone} + AC_{alone}] - Odor+AC_{together}$), where odor-evoked mitral cell spiking activity should be suppressed in the $Odor+AC_{together}$ condition, but remain intact in the $[Odor_{alone} + AC_{alone}]$ condition. We observed significant fMRI responses in glomerular, external plexiform, mitral and granule cell layers (one-sample t-test, $p<0.05$), with the most significant difference occurring at the site of output spiking activity (mitral cell layer: $p = 0.007$, $0.28 \pm 0.08\%$ fMRI signal change). At this layer, $3.71 \pm 0.37\%$ signal change is attributed to synaptic activity ($Odor+AC_{together}$). **Conclusions** Our preliminary results indicate that synaptic activity is the dominant source of the hemodynamic response.

Title: Neural correlates of spontaneous BOLD fluctuations: A simultaneous LFP-fMRI investigation in the nonhuman primate

Authors: *N. HASHEMI[1,3], R. M. HUTCHISON[4,3], J. S. GATI[3], R. S. MENON[3], S. EVERLING[1,2,3]
[1]Neurosci., [2]Physiol. and Pharmacol., Univ. of Western Ontario, London, ON, Canada; [3]Robarts Res. Inst., London, ON, Canada; [4]Dept. of Psychology, Harvard Univ., Cambridge, MA

Abstract: Resting-state fMRI (rs-fMRI) is widely used to explore functional connectivity (FC) between brain regions and is being applied to characterize alterations in the coupling patterns across neurological and psychiatric diseases. However, the neural basis of spontaneous low frequency blood-oxygen level dependent (BOLD) rs-fMRI fluctuations is poorly understood, limiting the interpretation that can be made from the findings. Here, we acquired rs-fMRI data in macaque monkeys together with simultaneous recordings of local field potential recordings. Multiple scans (40, 150 vol, TR = 2 s) were acquired from two macaque monkeys (M. fascicularis) anesthetized at 1% isoflurane in a 7T Agilent scanner. Local field potentials were recorded in prefrontal area 8d using bilaterally implanted 16-channel multi-electrode laminar arrays. BOLD fMRI data were preprocessed using standard resting-state analysis techniques without global mean signal regression and normalized to a standardized atlas. After removal of gradient artifacts, band-limited power was computed by band-pass filtering the signal in different frequency bands (delta: <4 Hz, theta: 4-7 Hz, alpha: 8-16 Hz, beta: 24-36 Hz, gamma: 44-56 Hz), rectifying the signal, and resampling it every 2 s. We then convolved the band-limited power LFPs with a standard double-gamma hemodynamic response function (HRF) to account for the hemodyamic lag and used these timecourses together with the timecourse of the BOLD signals in the vicinity of the electrodes as predictors in a regression model for FC analysis. For the BOLD signal in area 8d, we found strong, distributed FC with the medial parietal lobe, the inferior temporal lobe, and areas in the superior temporal sulcus, a pattern consistent with our early work in a larger sample of monkeys. Critically, we observed connectivity maps with the same spatial topology when using the power envelops of LFPs in the alpha and beta frequency bands. Our results suggest that intrinsic connectivity networks may be specifically driven by unique LFP profiles that are dominated by alpha and beta frequency bands unique to different networks.

Abstract: Introduction: High-resolution functional magnetic resonance imaging (fMRI) operates in a regime with low signal levels and requires long readouts that lead to T2* signal decays that can reduce performance. Accordingly, there is a need to compare the performance of the most popular acquisition schemes for fMRI: echo-planar imaging (EPI) and spiral at high spatial resolution. Methods: We compared the performance of these trajectories for 1.2-mm sampling fMRI using a moving-dot stimulus presented alternately to left-and-right visual fields with a 24-s period. This stimulus evokes a strong response in visual areas that was quantified by calculating a functional contrast-to-noise ratio (CNR). Measurements were performed in early visual cortex and superior colliculus (SC) using 8-12 quasi-axial slices. CNR data was obtained for EPI as well as both single- and dual-echo variants of spiral trajectories. Echo time was first adjusted for each trajectory to achieve optimal CNR. Comparisons were then obtained over many scanning sessions in which each trajectory variant was compared (at its optimal echo time) against a single-echo spiral-out used as a reference. This data was obtained for three subjects using a Siemens Skyra 3T scanner. Results: Figure below shows ratio of CNR obtained for each sequence variant to the reference CNR. The preliminary data show that dual-echo spiral out offers the best performance in SC, significantly outperforming both EPI and single-echo spiral trajectories. Pure spiral-in trajectories perform comparatively poorly. Analysis of data in visual cortex is underway, and further sessions on additional subjects are planned.

Title: Investigating the spatiotemporal characteristics of the bold and the non-bold response across cortical layers in awake marmosets

Authors: ***C. C.-C. YEN**, D. PAPOTI, A. C. SILVA
NINDS/LFMI/CMS, Natl. Institues of Hlth., Bethesda, MD

Abstract: Blood oxygenation level dependent (BOLD) functional magnetic resonance imaging (fMRI) has a strong prognostic potential in ischemic stroke due to its non-invasive nature, high spatial resolution in differentiating cortical layers, high sensitivity to changes in hemodynamics, and unlimited penetration depth. However, reports of the spatiotemporal characteristics of the cortical fMRI response are sparse and non-conclusive. For instance, there is no consensus about the onset time (OT) of the BOLD fMRI response across each cortical layer. One source of contamination to BOLD fMRI is the inflow effect, which may contribute differently at the pial

surface versus parenchyma due to the different orientation of tangential pial vessels and penetrating cortical vessels. To address these concerns, we adopted a dual-echo sequence to separate the pure-BOLD component from non-BOLD components, including the inflow effect, and used it to map laminar BOLD responses with high spatiotemporal resolution in conscious, awake marmosets, a small New World non-human primate model of increasing value to neuroscience. Four adult male marmosets were acclimated to head restraint by custom-built helmets in the sphinx position inside a horizontal 7T/30cm MRI spectrometer. High-resolution BOLD functional images were obtained every 200ms using a dual-echo gradient-recalled EPI sequence from a single coronal slice. The median and ulnar nerves were noninvasively stimulated by pairs of electrode pads placed across both wrists. The bilateral stimulus paradigm consisted of 4s off, 4s on and 24s off epochs. AFNI and Matlab were used for processing the data, calculating the pure-BOLD (T2*) and non-BOLD (S0) components, laminar segmentation and statistical analysis. Robust BOLD responses were bilaterally detected in primary and secondary somatosensory areas. Laminar OT values were determined to be 1.4s in layers 1 to 3, 1.2s in layer 4 and 1.6s in layers 5 to 6, which was consistent with the order previously reported in rodents by our group. Robust pure-BOLD responses were observed across all layers except layers 1 and 2, which showed an insignificant pure-BOLD response but a strong and delayed non-BOLD response. We have demonstrated the feasibility of measuring the dynamics of pure-BOLD and non-BOLD changes across the cortical layers of conscious, awake marmosets. A significant contribution of the non-BOLD component was found on the superficial layers, which may be attributed to the inflow effect from pial vessels running tangentially to the cortex and perpendicular to the imaging plane. Therefore, caution should be exercised when measuring the laminar onset time of BOLD fMRI.

Title: Mechanisms of neurovascular maturation in the developing brain

Authors: *M. G. KOZBERG[1], Y. MA[1], M. A. SHAIK[1], C. N. LUNARDI[2], A. J. GOMES[2], E. TFOUNI[3], E. M. C. HILLMAN[1]

Abstract: Localized changes in brain blood flow are the basis of signals measured using functional magnetic resonance imaging (fMRI). In adults, this 'hemodynamic response' consists of an increase in blood delivery in regions of increased neural activity occurring in response to somatosensory stimulation. However, prior work from our laboratory in a rodent model has demonstrated that neonatal neurovascular coupling is still maturing post-natally, progressing from an entirely inverted response at postnatal day 7 in mice (P7) and P12 in rats to an adult response by approximately P23. We hypothesize that these differences in neurovascular coupling are due to underlying differences in neural activity, communication between neurons and vasculature, and/or the vasculature itself. We are studying developing neural activity in parallel to hemodynamic activity using exposed-cortex wide-field multi-spectral optical intrinsic signal imaging of hemoglobin absorption with interleaved fluorescence imaging in Thy1-GCaMP3 mice. These mice express a genetically encoded calcium sensor in cortical pyramidal neurons. We observed localized neural activity from P7 to adulthood, while hemodynamic responses were initially absent and increased with age. Although spatiotemporal differences in the developing neural response were observed, these changes cannot fully account for the changing hemodynamic response leading to our continued study of the vasculature. As the hemodynamic response matures, we found that functional hyperemia is initially localized to the capillary bed and/or diving arterioles and there is a marked lack of dilation in pial arteries. Based on these findings, we hypothesize that the mechanism of increasing functional hyperemia throughout development may be related to the development of cortical arteries both morphologically and functionally. Using in-vivo two-photon microscopy, we quantified changes in pial vascular architecture and found that despite large changes in pial venous and capillary architecture, the distribution of pial arteries in rats is consistent from postnatal day 12 to adulthood. We are now examining whether these arteries are physically able to dilate. Arterial function is being assessed in-vivo through the application of both endothelium-dependent and endothelium-independent vasodilators to the cortex and the quantification of resulting arterial diameter changes. We are also exploring potential changes in vascular function using a novel light-activated nitrosyl nitric oxide donor. We will present the results of our analysis aiming to understand the relationship between developing neural activity and vascular function.

Title: Development of long-term two-photon awake imaging in marmosets: A novel optical imaging model for studies of cerebral microcirculation and neuroglial activation in primates

Authors: ***T. P. SANTISAKULTARM**, J. L. CIUCHTA, J. PARK, S.-H. CHOI, A. C. SILVA

Abstract: Two-photon Excited Fluorescence (2PEF) microscopy is a nonlinear optical imaging technique that allows visualization of cellular structure and function located deep within the cortex, and followed longitudinally over days to months. Recently, transgenic marmoset models of Parkinson's disease, Alzheimer's disease, amyotrophic lateral sclerosis, and schizophrenia have been successfully produced, providing a research biological model that closely mirrors the human. In the present work, we aim to develop a longitudinal approach to quantify cerebral hemodynamics and neuronal activity in awake marmosets. An adult marmoset was gradually acclimated to a custom-designed, body and head restraint in the sphinx position for up to two hours, over a period of three weeks. Following behavioral training, AAV2/1-GCaMP5G virus was injected into the somatosensory cortex, and a 12-mm diameter polyetheretherketone cranial chamber was implanted over Broadman Area 3b, along with a headpost at the medioposterior to stabilize imaging (Figure 1A). After 10 days of recovery, 2PEF of intravenously labeled blood plasma revealed vascular topology and enabled linescan measurement of red blood cell (RBC) motion in microvessels 500 μm below the cortical surface in awake marmosets. 99.5% of capillaries had RBC flow during the awake imaging, indicating a robust blood flow distribution. Capillary density was 5,601 capillaries/mm3. Neurons exhibited fluorescence changes, both spontaneously and in response to electrical stimulation to fore paw (Figure 1B). Fraction of responsive neuronal dendrites was 0.45. The volume of GCaMP5G expression was estimated to be 3 mm3 using post-mortem immunohistochemistry (Figure 1C). These results demonstrate the capability to perform long-term 2PEF imaging of cerebral microcirculation and neuronal activity

in awake marmosets. This work provides a novel and insightful imaging technique to assess neurovascular coupling at the spatial resolution of the neurovascular unit, and allows for investigation of critical mechanisms in many neurological disorders.

Title: Neurovascular coupling and decoupling in the cortex during voluntary locomotion

Authors: *B.-X. HUO[1], J. B. SMITH[1], P. J. DREW[1,2]
[1]Ctr. for Neural Engin., [2]Neurosurg., Pennsylvania State Univ., University Park, PA

Abstract: Functional brain imaging techniques, such as fMRI, rely on localized hemodynamic responses to infer neural activity in the brain. The relationship between hemodynamics and neural activity, known as neurovascular coupling, has been widely assumed to be a one-to-one mapping, with increases in neural activity driving increases in blood flow and volume. Here, we tested whether neurovascular coupling holds true in frontal and sensorimotor cortex during natural behavior, using head-fixed mice engaging in voluntary locomotion. We recorded the

cerebral blood flow and volume changes in both frontal and parietal cortices in animals installed with bilateral, thinned-skull windows using intrinsic optical imaging; and local field potential (LFP) and multi-unit activity (MUA) in either frontal or parietal cortex in animals implanted with chronic stereotrodes. We found that locomotion induced increases of gamma-band power of the LFP and firing rate in both frontal and parietal cortices. Increased neural activity was paired with a subsequent hemodynamic response in the parietal cortex, particularly in the forelimb and hindlimb representations in the sensorimotor cortex. However, in the frontal cortex, the hemodynamic response is largely absent, regardless of the duration of locomotion. Our observation challenges the consensus that increases in neural activity are always accompanied by increases in blood flow and volume in the cortex. It also calls for caution when interpreting the functional brain imaging results.

Title: Depth and tissue variations of BOLD signal reliability in human visual cortex

Authors: *J. KIM, D. RESS
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Motivation: At conventional spatial sampling (~3 mm), the BOLD response includes contributions from superficial vascular sources (extra-pial tissue), white matter, as well as the desired gray matter. It is therefore of strong interest to quantify the contributions of these various tissues to the BOLD response and its signal reliability. We measured the BOLD hemodynamic response function (HRF) in visual cortex using high-resolution fMRI, then performed non-parametric statistical analyses to characterize the reliability of the HRF amplitudes and timing as a function of tissue type and gray-matter depth. Methods: Stimulus is a series of 1.7-s pulses of 4-Hz flickering dots followed by 26-s blank periods. High-resolution (0.8-mm voxels) fMRI data

is obtained using a 3T Siemens scanner and an interleaved spiral acquisition to produce ~100 HRFs/session. A self-reciprocal depth coordinate is calculated from a high-resolution (0.7 mm) volume anatomy using a weighted signed-distance approach. HRFs are averaged together as a function of tissue depth in visual areas V1-3, allowing us to distinguish between tissue types. Amplitude and timing parameters are extracted from the HRF. We use bootstrapping to estimate the distribution for each HRF parameter. The variability of each parameter is quantified by its 68% confidence intervals. Reliability is defined as the ratio of the average measured value of a parameter to its variability Results: HRF amplitude reliability showed a sharp maximum in the center of the gray matter (Fig. A). The reliability of the HRF timing showed a much broader maximum extending through the superficial and intermediate gray matter (Fig. B). Distributions of both parameters (insets) were markedly non-Gaussian in extra-pial tissue (orange) and white matter (green). Conclusion: Amplitude reliability may correlate to the vascular density that is highest in the intermediate gray matter, while temporal reliability is high throughout the gray matter. Noise distributions are complex and multi-modal outside the gray matter.

Title: Comparison of five different anesthetics for phMRI using nicotine challenge

Authors: *J. K. HUTTUNEN[1], J. PAASONEN[1], R. SALO[1], K. LEHTIMÄKI[3], E. JOHANSSON[4], M. M. FORSBERG[2], O. GRÖHN[1]
[1]A. I. Virtanen Inst., [2]Sch. of Pharm., Univ. of Eastern Finland, Kuopio, Finland; [3]Charles River Discovery Res. Services Finland, Kuopio, Finland; [4]AstraZeneca R&D Mölndal, Mölndal, Sweden

Abstract: In animal functional imaging studies the choice of anesthetic is perhaps the single most important decision in the experimental design, since the exact effects of anesthetics to metabolism and neurotransmitter systems and therefore to the expected results are often unknown. The aim of this study was to investigate the blood oxygenation level dependent (BOLD) signal changes under different anesthetics with a nicotine challenge in order to find optimal experimental conditions for a pharmacological magnetic resonance imaging (phMRI) study. Altogether 79 male Wistar rats (353 ± 32 g) were used with different anesthesia protocols. After surgery isoflurane was continued for one group (ISO, n= 7) and for the rest anesthesia was switched to either α-chloralose (AC, n = 7), medetomidine (MED, n = 7), thiobutabarbital (TBB, n = 17) or urethane (URE, n = 41). All animals were ventilated except two groups under URE and TBB. MRI measurements were performed with 7 T Bruker PharmaScan. Functional data were acquired using BOLD, cerebral blood flow (CBF) and cerebral blood volume (CBV) methods. A bolus of nicotine (hydrogen tartrate salt 0.25 mg/kg) was administered intravenously. Positive BOLD response was observed in all animals except in a subgroup of TBB animals where the response showing both positive and negative signal changes were seen. Maximum BOLD changes for the groups are as follows: MED 4.5 ± 1.1 %, TBB first group 6.6 ± 2.5 %, TBB second group -1.5 ± 0.6 %, TBB (not ventilated) 4.9 ± 0.7 %, URE (not ventilated) 9.3 ± 2.3 %, URE 9.0 ± 1.9 %, and ISO 2.2 ± 1.0 %. Maximum positive BOLD response was measured 58 ± 13 s after the nicotine injection. Saline control injections did not cause detectable signal changes. In addition, local field potential (LFP) from somatosensory cortex was measured simultaneously with BOLD (URE, n = 6). Nicotine decreased the spectral power of slow potentials. Additionally, nicotine increased the spectral power at range of 13-70 Hz and this effect lasts over the recording period. With pretreatment of mecamylamine no clear decrease in slow potentials can be seen. Mecamylamine itself decreased the spectral power of 13-70 Hz dramatically and diminished the nicotine response in this range. The BOLD responses in every rat highly resemble the measured spectral power at range of 13-70 Hz. The results revealed significant differences in the responses of acute nicotine challenge with different anesthesia protocols. Despite the fact that the exact mechanisms of action of anesthetics are still mostly unknown, the phMRI method with careful study design has great potential in brain mapping and characterization of drug effects.

Title: Imaging brain microvascular dynamics using CellVizio confocal endomicroscopy in hypertensive rats *in vivo*

Authors: *D. N. MAYOROV, J. F. R. PATON, S. KASPAROV
Physiol. & Pharmacol., Univ. of Bristol, Bristol, United Kingdom

Abstract: We first evaluated the feasibility of morphometric analysis of brain microvasculature in normotensive and spontaneously hypertensive (SH) rats in cortical and brainstem slices from P21-P45 pups using confocal microscopy (Leica SP5). The changes in vascular diameter in response to application of vasodilator agents, adenosine and sodium nitroprusside, were assessed after vascular pre-constriction with a thromboxane agonist U46619. Treatment with U46619 (100 nM) constricted arterioles to 90 ± 4% and 92 ± 3% of the resting diameter in normotensive and SH rats, respectively. Adenosine (1 μM) reversed the U46619-induced vasoconstriction by 55% and 25% in normotensive and SH rats, respectively. Sodium nitroprusside (1 μM) produced little effect on the U46619-induced vasoconstriction in both groups. Next, brain vasculature of anaesthetized rats was visualized using intravenous FITC-dextran and imaged using a fiber probe-based confocal laser endomicroscopy (CellVizio, Mauna Kea Technologies). Pial microvessels of the ventral or dorsal medulla oblongata, and the cortex were imaged in normotensive and SH rat pups (P21-P45) using S-1500, Mini-Z and Z reusable fiberoptic probes (Lateral resolution: 3.5 μm; field of view: 325 to 650 μm) coupled to a 488 nm laser scanning unit (CellVizio). In addition, beveled probes S-300/B and S-650/B (300 and 650 μm tip diameter, respectively) are being used to visualize the vascular tree in the Z-dimension. Vascular contractility is now being assessed using application of U46619 (100-500 nM), adenosine (1-10 μM) and sodium nitroprusside (1-10 μM) and data compared with that from brainstem slice preparations. Currently, we are working to adapt this method for morphometric analysis of the brainstem capillary bed. CellVizio confocal endomicroscopy provides a promising approach for

imaging and morphometric analysis of brain microvasculature *in vivo*. This approach will be useful to investigate changes in vascular reactivity of the cerebral microcirculation in hypertension and other vascular pathologies *in vivo*.

Title: Neural correlates of single-vessel hemodynamic responses *in vivo*

Authors: P. O'HERRON, P. CHHATBAR, M. LEVY, A. SCHRAMM, *P. KARA
Neurosci., MUSC, CHARLESTON, SC

Abstract: The activation of neurons in the cerebral cortex creates a demand for energy that is met by a local increase in blood flow. Hemodynamic imaging techniques, e.g., fMRI, use these vascular signals to infer the location and strength of neural activity. However the precise spatial scale and types of neural activity that drive vascular responses are still largely unknown. The relative roles of synaptic activity and action potential (spikes) activity in generating hemodynamic signals has been examined by combining hemodynamic measures with electrode recordings of spikes and local field potentials (LFPs). But due to the low spatial resolution of fMRI and intrinsic signal optical imaging methods, the relatively sparse sampling of neurons with electrodes, and the uncertainty about what LFPs represent, these studies have generated considerable controversy. Additionally, although the response selectivity profiles of individual neurons have been studied extensively, they have never been characterized for vascular signals at the resolution of individual blood vessels. Using *in vivo* two-photon microscopy, we measured blood flow changes in individual vessels and correlated them with the synaptic (using the fluorescent glutamate sensor iGluSnFR) and spiking activity (using fluorescent calcium sensors) in the surrounding neural tissue. We measured sensory-evoked vascular, spiking and synaptic activity in the cat primary visual cortex, where neurons are clustered by their preference for

stimulus orientation. We show that blood flow changes in parenchymal vessels (located within neocortical layer 2/3) have orientation preferences that match those of the surrounding neural tissue. Pial surface vessels were highly responsive to sensory stimuli but unlike parenchymal vessels, surface vessels had no orientation selectivity. Importantly, our preliminary data indicate that the orientation selectivity of parenchymal vessels matches the selectivity of glutamate release integrated over a region of a few hundred microns surrounding the vessel, whereas spiking responses were always more selective, regardless of the spatial scale over which they were integrated. These results indicate that hemodynamic signals from individual parenchymal vessels in the neocortex closely follow local excitatory synaptic activity rather than spikes. Unraveling the spatial range over which individual blood vessels may pool specific types of neural signals will allow for more accurate decoding of synaptic and spiking activity from hemodynamic signals.

Title: A new non-linear model of the fmri bold response

Authors: ***J. PORTES**[1], C. B. AMOOZEGAR[2], B. R. CHEN[2], M. G. KOZBERG[3], M. S. SHAIK[2], E. M. C. HILLMAN[4]
[1]Biomed. Engineering, Columbia Univ., New York, NY; [2]Biomed. Engin., [3]Neurosci., [4]Biomed. Engin. and Radiology, Columbia Univ., New York, NY

Abstract: Blood flow in the brain changes when the brain exhibits neuronal activity. Stimulus-evoked fMRI measures these hemodynamic changes as a proxy for neuronal activity. Better understanding the cellular and vascular mechanisms that drive blood flow changes in the working brain will enable improved interpretation of fMRI data. While many have assumed that the fMRI response can be modeled as a linear convolution of a hemodynamic response function (HRF) and a neuronal input function, numerous studies have noted both spatial and temporal non-linearities in the response. For example, short duration visual stimuli lasting a few milliseconds can evoke an almost identical fMRI BOLD response to stimuli lasting 1-2 seconds, while longer duration stimuli yield responses with increasing peak amplitudes. In recent work from our lab, we have proposed a new cellular mechanism for neurovascular coupling that involves signal propagation within the vascular endothelium. This mechanism introduces a new basis for the spatiotemporal evolution of the hemodynamic response to stimulation in the brain, as well as a biological basis for the non-linear properties of the BOLD signal. To test our hypothesis, we have developed a new non-linear model of the BOLD response using high spatiotemporal resolution exposed cortex optical imaging data in rodents. We have found that our model can accurately predict many of the complex features of the hemodynamic response to stimuli of varying durations, and is wholly consistent with the involvement of the vascular endothelium in neurovascular coupling. Results and validation of this model will be presented.

Title: A rubber hand illusion: Lateralization of brain area that is associated with the body image

Authors: *Y. KODAN[1], A. MITANI[1], R. NAKAI[2], T. INO[3]
[2]Kokoro Res. Ctr., [1]Kyoto Univ., Kyoto City, Japan; [3]Neurol., Rakuwakai-Otowa Hosp., Kyoto, Japan

Abstract: The feeling of bodily self-attribution is critical for our daily interaction with the outside world. In experimental studies, subjects have perceived touch sensations as arising from a rubber hand when the rubber hand and their own real hand are repeatedly brushed in synchrony

with the real hand hidden from view. This rubber-hand illusion provides a cue for studying the bodily self-attribution. In the present study, using functional magnetic resonance imaging, we investigated whether there were any brain areas related with producing the bodily self-attribution. Eleven right-handed healthy subjects participated in the imaging experiments. The study was performed in conformity with the Declaration of Helsinki, and approved by the Ethics Committee of the Kyoto University Graduate School and Faculty of Medicine (E1287-1). All subjects gave informed written consent prior to participation. We performed both visual and somatic rubber-hand illusion tests (Ehrsson et al., 2005): there were four experimental conditions. In visual rubber-hand illusion tests, (1) the right rubber hand was aligned to the subject's own right hand and the experimenter synchronously brushed the rubber hand and the subject's hidden right hand, and (2) the left rubber hand was aligned to the subject's own left hand and the experimenter synchronously brushed the rubber hand and the subject's hidden left hand. In somatic rubber-hand illusion tests, the subjects were blindfolded and (3) the experimenter moved the subject's right hand holding a brush so that it brushed the left rubber hand and synchronously brushed the subject's left hand with another brush, and (4) the experimenter moved the subject's left hand holding a brush so that it brushed the right rubber hand and synchronously brushed the subject's right hand with another brush. Each experiment was conducted as a block design. We hypothesized that brain areas related with producing the bodily self-attribution would be activated during four illusion conditions. Such activation was detected in the right medial prefrontal cortex. The right medial prefrontal cortex may play a key role in the mechanism for bodily self-attribution.

Title: Parametric application of transcranial alternating current stimulation leads to selective increases in BOLD signaling

Authors: *C. WALKER[1], N. POLIZZOTTO[2], V. SHARMA[2], E. SANTARNECCHI[4], A. ROSSI[4], S.-G. KIM[3], R. CHO[2]

[1]Psychology, [2]Psychiatry, [3]Radiology, Univ. of Pittsburgh, Pittsburgh, PA; [4]Dept. of Medicine, Surgery, & Neurosci., Univ. of Siena, Siena, Italy

Abstract: Non-invasive neural stimulation techniques have received renewed interest as causal probes of brain function as well as being studied as a clinical therapeutic approach. Transcranial alternating current stimulation (tACS) offers the promise of a frequency-specific approach targeting specific networks underlying cortical oscillations. However, the effects of frequency specific stimulation on broader cortical network function are unknown. To investigate this question, we collected functional magnetic resonance imaging (fMRI) data from 10 participants while applying 1,500 μA currents with sinusoidal waveforms with frequencies of 2, 6, 10, 20, and 40 Hz. tACS electrodes were placed over the inion and at the base of the neck in an effort to confine stimulation to occipital visual areas. Participants completed a backward-masked, visual discrimination task, with stimulation on vs. off blocks counterbalanced across subjects. Across all participants, response times and accuracy were relatively unchanged. However, fMRI data revealed significant tACS by visual stimulus interactions to 2 and 40 Hz stimulation across a broad set of cortical regions. For both frequencies, blood-oxygen level dependent (BOLD) signaling increased in anterior cingulate cortex. During periods of 2 Hz stimulation, BOLD signaling also increased in the right superior and inferior middle temporal, fusiform, and lingual gyri as well as the right claustrum and cuneus. For 40 Hz stimulation, BOLD signals were increased along several midline regions including anterior cingulate, precuneus, and the right parahippocampal gyrus, thalamus, and caudate. No frequency was found to enhance BOLD activity in primary visual areas. Taken together, these findings suggest that, while tACS may affect neural function on a local circuit level, such changes are not detectable with fMRI. Rather, the local influence of tACS is more likely manifest in downstream enhancement of cortical function resulting in increased BOLD signaling in higher level regions along the ventral visual processing pathway. That these effects are frequency specific increases our understanding of how tACS may be used to stimulate both local and network functioning in the brain, and highlights the need for a more thorough understanding of how such stimulation techniques affect neural processes.

Title: Old habits die hard: what happens when predictive relationships change in a probabilistic sequence learning task?

Authors: *S. A. KISER[1], K. M. O'NEIL[1], R. L. M. FULLER[1], D. V. HOWARD[2,3], J. H. HOWARD, Jr.[1,2,3,4]
[1]Psychology Dept., The Catholic Univ. of America, Washington, DC; [2]Psychology, [3]Neurol., [4]Ctr. for Brain Plasticity and Recovery, Georgetown Univ., Washington, DC

Abstract: Implicit probabilistic sequence learning (IPSL) is a specific type of implicit learning that involves extracting statistical regularities from sequences of events and is important for a variety of life skills. We are able to learn statistical regularities amidst distraction and in a continuously changing environment. The present study investigates how an altered probabilistic learning environment affects IPSL. To accomplish this, we modified the Triplets Learning Task (TLT) to incorporate changing stochastic relationships among events across sessions. Fifteen college-aged participants completed three, 500-trial sessions of the modified TLT. On each trial three consecutive "lights" called triplets appeared on a computer screen. Participants observed the 1st two "cues" and responded to the 3rd, "target" by pressing a corresponding key. Unbeknownst to them, the 1st light predicted the target location on 80% of the trials and any other location on 20% of the trials. In order to introduce changes to the predictive relationships in the task, high and low triplet type (TT) frequencies from the 1st session were reversed in the 2nd session and then restored in the final session. Therefore, in the 2nd session all formerly high frequency triplets became low frequency and some formerly low frequency triplets became high frequency. In the 3rd session, TTs reverted back to their initial frequencies from session one. Reaction time (RT) data were analyzed using a 2 (TT: high vs low) X 6 (Epoch: 2 epochs per session) repeated measures Analysis of Variance. Results showed that participants became faster with practice as evidenced by a significant main effect of Epoch ($p<0.001$). A marginally significant interaction between TT and Epoch suggests that participants learned to differentiate high from low frequency events ($p=0.076$). However, the overall main effect of TT was not significant ($p=0.836$). Close inspection of the mean RT to different TTs across Epochs revealed learning occurred in the 1st session. However, during the 2nd session participants did not adapt fully to the reversed predictive relationships, still responding more rapidly to triplets that had originally been high frequency, even though they were now occurring with low frequency. Finally during the 3rd session, when the original frequencies were restored, the reaction time difference between high and low frequency was smaller than at the end of the 1st session. We interpret these results as showing that, on average, participants are slow to adapt to changes in

stochastic relationships within the learning environment. Implications related to the unlearning of procedural skills are discussed.

Title: Adult age differences in white matter integrity and implicit probabilistic sequence learning

Authors: ***K. L. SEAMAN**[1], C. M. STILLMAN[2], D. V. HOWARD[2], J. H. HOWARD, Jr.[1,2,3]
[1]Psychology, The Catholic Univ. of America, Washington, DC; [2]Psychology, [3]Neurol., Georgetown Univ., Washington, DC

Abstract: Many everyday tasks, including language acquisition and acquiring new skills, involve learning predictive relationships in the environment, often without explicit awareness. Although often characterized as being preserved with age, consistent age-related deficits in implicit sequence learning have been found (e.g. Howard & Howard, 1997) and have been associated with decreased white matter integrity (Bennett, Madden, Vaidya, Howard, & Howard 2011). While implicit sequence learning is traditionally measured using variants of the serial reaction time task, one critique of this work has been the strong motor component involved in these tasks. Recently, a new paradigm has been developed to ameliorate this called the Triplets Learning Task (TLT; Howard, Howard, Dennis, & Kelly, 2008). In the TLT, participants see two successive visual cues and then respond to a third, target event. Unbeknownst to participants, there is a statistical relationship between one of the cues and the target event, such that each of the four cue positions predicts one of four target positions 80 percent of the time. Furthermore, this task has recently been adapted for use in a scanning environment. Using this scanner-adapted version of the TLT, we investigated the effect of aging on white matter integrity and implicit sequence learning in a sample of healthy adults. First, as reported in Stillman et al.,

2014, we found significant age differences in implicit sequence learning, with young outperforming older adults by the end of training. Second, using Tract-Based Spatial Statistics (TBSS) on diffusion tensor images, we found significant age differences in the structural integrity of white matter as measured by fractional anisotropy (FA), with young having higher FA values than older adults throughout the brain. Finally, we found significant relationships between implicit sequence learning and white matter integrity, with greater learning scores being associated with higher FA. Collectively, these results are consistent with prior studies of white matter integrity and implicit sequence learning (Bennett et al., 2011), and demonstrate that these relationships still exist in a task without a strong motor sequencing component.

Title: Explicit, but not implicit motor sequence training contributes to choking under pressure due to large rewards

Authors: T. G. LEE[1], A. S. PANESCU[2], *S. T. GRAFTON[1]
[1]Psychological & Brain Sci., UCSB, SANTA BARBARA, CA; [2]Psychological & Brain Sci., Univ. of California Santa Barbara, Santa Barbara, CA

Abstract: Although increased motivation usually enhances performance, impaired performance can sometimes be seen *in situ*ations involving large rewards and high motivational states. Over thirty years of psychological research has provided scientific evidence of the anecdotally salient phenomenon of this "choking under pressure". However, the cognitive mechanisms underlying choking remain unclear. One proposed theory of choking asserts that reduced performance is due to an increase in explicit monitoring of a procedural skill. Here we tested whether explicit skill knowledge is a necessary prerequisite for choking under pressure. Two groups of participants

were trained across eight different blocks on three separate 8-item motor sequences in the discrete sequence production (DSP) task. Crucially, one group of participants (explicit training) was cued (using colored shapes) to the identity of the upcoming sequence just prior to each trial and they were told to attempt to learn the three sequences. The other group (implicit training) was given no cueing as to the identity of the sequences and was told the sequences were randomized. Following training, participants were asked to perform the same task for reward bonuses with time limits set on an individual-by-individual basis based on movement time at the end of training. Each trial was associated with a $5, $10, or $20 reward by a reward cue displayed just prior to the start of the trial. Explicitly trained subjects were able to modulate their performance (as measured by accuracy) based on the reward values displayed but displayed stereotypical choking behavior as indexed by reduced performance at the highest incentive level. However, implicitly trained subjects did not show any performance decrement for large rewards.]. These results suggest that skill metacognition can both positively and negatively impact performance in a feed-forward manner and that knowledge of expected ability in a motor skill can contribute to choking under pressure.

Title: Cortical representations of motor sequence features

Authors: *D. M. MUSSGENS[1], F. ULLÉN[1], C. I. BAKER[2]
[1]Neurosci., Karolinska Institutet, Solna, Sweden; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Performing movements in a sequential order involves numerous cortical and sub-cortical areas. However, the exact type of information that is represented in these areas is not fully understood. Neuroimaging studies comparing trained and untrained sequences are partly inconclusive since both regional increases, decreases or no change of activity were reported. The interpretation of these findings is further complicated by difficulties in separating sequence specific activity from other, non-sequence specific processes such as general motor output, attention, sequence difficulty or salience. In primary and supplementary motor cortex (M1 and SMA), sequence training leads to a stabilization of the spatial response pattern, even in the

absence of mean activity changes. This suggests that these areas represent learned motor sequences via distributed and robust patterns of activity. Yet, it remains unclear how these representations relate to sequence structure and how they are influenced by motor performance. The aim of this study is to 1) Investigate how different features of motor sequences such as familiarity (trained/ novel) and similarity (similar/ different) are represented in cortical activity patterns and 2) Characterize how these representations change with improvements in performance over the course of a session. Healthy participants were trained explicitly on three 8-element sequences (one reference, one similar and one different) of key presses using a serial reaction time task. After two days of training they underwent fMRI scanning while performing the trained as well as three (untrained) control sequences which were constructed according to the same criteria. The sequence sets used for training and control were counterbalanced across participants. We used multi-voxel pattern analysis to compare the cortical activity patterns for all sequences with each other. In M1, SMA and parietal cortex, this revealed that 1) Representations of trained and untrained sequences can be clearly distinguished 2) Trained but not untrained sequences correlate more strongly with themselves than with other sequences (they are more discriminable) 3) Changes in the performance of untrained sequences (faster RTs) are accompanied by changes in cortical representations 4) Similar sequence content is not reliably translated into similar cortical activation patterns. This suggests that cortical representations of motor sequences relate more strongly to sequence performance than to its structural content.

Title: Motor sequencing in the human cerebellum: How movement predictability and effector influence activity

Authors: *C. J. LOPRESTI[1], T. ALVAREZ[2], J. FIEZ[3]
[1]CNUP, [2]Psychology, [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Previous research has shown there are somatotopic maps within the human cerebellum and that neural activity within the cerebellum is sensitive to whether a movement sequence is predictable or unpredictable. It is unclear, however, whether the same regions that exhibit effector-specific activity also exhibit sensitivity to movement predictability. The present study addresses this question. We scanned twelve subjects using functional magnetic resonance imaging (fMRI) while they performed four motor-based tasks: predictable finger tapping, unpredictable finger tapping, predictable tongue movements, and unpredictable tongue movements. These motor tasks were guided by both visual and audio cues. In the finger task, subjects were shown a cartoon hand with an arrow pointing to which finger they should tap in time with a tone (one tone every 0.66 s). In the tongue task, subjects were shown a cartoon mouth pointing to where they should place their tongue in time with the tone. In the predictable condition, the arrows rotated clockwise. In the unpredictable conditions, the arrows appeared randomly, although still concurrent with the tone. Pre-processing and data analysis were completed using the AFNI processing stream. We performed a two-way ANOVA ($p < 0.001$, corrected for multiple comparisons) with Effector (finger, mouth) and Task (predictable, unpredictable) as factors. In line with known somatotopic organization, regions within right lobule V demonstrated stronger activation for finger vs mouth and regions within bilateral lobule VI had greater activation for mouth vs finger (Stoodley et al., 2012; Grodd et al., 2001). Our results were further confirmed by the meta-anayltic database Neurosynth which overwhelmingly associated hand keywords with our finger > tongue cluster and articulatory keywords with our tongue > finger cluster. Both effector-specific clusters demonstrated only weak sensitivity to predictability; instead, predictability modulated a separate region within left lobule VI. This region was significantly active in both tasks and had greater activity for unpredictable movements irrespective of whether subjects performed the movement sequence with their fingers or tongues. These results suggest that different loops within the cerebellum are sensitive to movement execution versus motor sequencing demands.

Title: Competitive neurocognitive networks underlying sequence learning

Authors: *D. NEMETH[1,2], K. JANACSEK[2], B. POLNER[3], Z. A. KOVACS[4]
[1]Psychology, [2]Inst. of Psychology, Eotvos Lorand Univ., Budapest, Hungary; [3]Dept. of Cognitive Sci., Budapest Univ. of Technol. and Econ., Budapest, Hungary; [4]Dept. of Psychiatry, Univ. of Szeged, Szeged, Hungary

Abstract: Human learning and memory depend on multiple cognitive systems related to dissociable brain structures. These systems interact not only in cooperative but sometimes competitive ways in optimizing performance. Previous studies showed that manipulations reducing the engagement of frontal lobe-mediated explicit, attentional processes could lead to improved performance in striatum-related procedural learning. In our study, hypnosis was used as a tool to reduce the competition between these two systems. We compared learning in hypnosis and in the alert state and found that hypnosis boosted striatum-dependent sequence learning. Since frontal lobe-dependent processes are primarily affected by hypnosis, this finding could be attributed to the disruption of the explicit, attentional processes. Our result sheds light not only on the competitive nature of brain systems in cognitive processes, but also could have important implications for training and rehabilitation programs, especially for developing new methods to improve human learning and memory performance.

Title: A secondary task induces offline learning of motor sequences following a three-minute delay

Authors: *Y. DU, J. E. CLARK
Kinesiology, Univ. of Maryland, College Park, MD

Abstract: Many have suggested that the acquisition of motor sequences in adults is driven by online and offline learning. Online learning requires iterative computations based on trial and error, but allows performance to improve quickly within a single learning session (i.e., the first few learning blocks). In contrast, offline learning leads to the improvement in performance after a latent period without practice, but it does not occur until at least 4 hours after the initial acquisition. However, in our previous study we observed when online learning is not effective (e.g., in children), offline learning takes place following a delay of 3 minutes. This evidence leads to the hypothesis that offline learning in the early stage of sequence acquisition is inhibited by online learning. To examine this hypothesis, two groups of adults were asked to perform a serial reaction time (SRT) task that requires foot stepping movements. There were eight learning blocks and a three-minute break was added between each two consecutive blocks. In the first five learning blocks (B1 - B5), one group performed the foot stepping SRT task alone (single-task group), while the other group concurrently performed the foot stepping SRT and a secondary tone-counting tasks (dual-task group). In additional three blocks (B6 - B8), both groups performed the foot stepping SRT task alone. Through the whole session, the stimulus followed the same pattern except in B5 and B7. The mean reaction time (RT) of B5 or B7 was compared to the mean RT of other blocks to assess learning. As revealed by the difference in RT between B4 and B5 and between B6 and B7, we found that the single-task group had greater learning than the dual-task group. In addition to the mean RT, we examined the progressive changes of RT within and between blocks. It was found that participants in the single-task group progressively reduced RT within each block. This online process, however, vanished in the dual-task group even after the secondary task was removed. Instead, we observed an offline RT improvement following each three-minute break. Furthermore, when both groups performed the foot stepping SRT task alone, the introduction of the novel sequence in B7 interfered with the learning in the single-task group, while the learning in the dual-task group was stable. These results suggest that a secondary task disrupts the online learning process. In addition, when online learning is impaired, offline learning that follows an interval of minutes emerges to secure effective learning and enable the performance to be more resistant to interference.

Title: Effects of interference on implicit and explicit motor sequence learning

Authors: ***X. LI**, S. M. MORTON
Physical Therapy, Univ. of Delaware, Newark, DE

Abstract: Motor sequences can be learned explicitly or implicitly based on conscious awareness of the sequence. Retention of a learned motor sequence can be interfered with when two sequences are learned in quick succession. For instance, retrograde interference, or reduced retention of sequence A, happens when learning sequence A is followed immediately by learning sequence B. The goal of this study was to determine whether retention of implicit and explicit sequence learning was affected differently by retrograde interference. Thirty-two young healthy volunteers participated in two test sessions 24 hours apart. They were divided into two groups (control, interference) and two learning conditions (explicit, implicit). For all subjects, stimuli were presented as asterisks which appeared in one of four locations on a computer screen. Subjects were instructed to respond by pressing the corresponding key on a keyboard as quickly and accurately as possible. The sequence was a 12-item set of asterisk positions presented in a repeated blocked pattern, with random stimuli presented before and after. The interference group learned two different sequences on day 1 (sequence A, 5-minute break, sequence B); the control group did not learn a second sequence. On day 2, both groups were tested on sequence A. In the explicit condition, subjects were told there would be a period of time when the stimuli would be presented in a repeating sequence and the start of the sequence was indicated by a change in color of the asterisk. In the implicit condition, subjects were not told there would be any pattern to the presentation of stimuli and the asterisk colors always remained the same. Response times and accuracy were recorded for each trial. Skill level was measured as the difference in mean response times between sequence A and random trials at the end of each session. Retention was measured as offline gains, or the difference between skill levels on day 1 versus day 2. Results revealed a significant group × condition interaction, indicating that the amount of offline gain reduction caused by interference varied based on whether the sequence was learned explicitly or implicitly. Specifically, in the explicit condition, interference had no effect on offline gains. In contrast, there was a strong trend for interference to reduce offline gains if the sequence was learned implicitly. Overall, results suggest that sequence learning under implicit conditions is more susceptible to interference than explicit conditions. We postulate that explicit awareness of the sequence may engage additional memory systems during learning which reduces forgetting or facilitates consolidation.

Title: The role of the prefrontal cortex in sequential memory formation and consolidation

Authors: *K. JANACSEK[1], G. G. AMBRUS[2], W. PAULUS[2], A. ANTAL[2], D. NEMETH[3]
[1]Eotvos Lorand University, Inst. of Psychology, Budapest, Hungary; [2]Dept. of Clin. Neurophysiol., Georg-August Univ., Göttingen, Germany; [3]Inst. of Psychology, Eotvos Lorand Univ., Budapest, Hungary

Abstract: Sequence learning is crucial in everyday life from childhood to old age; it underlies the acquisition of motor, cognitive, as well as social skills. Previous studies have shown the involvement of the fronto-striatal circuits in this type of learning. The specific functions of the components of these circuits are, however, still debated. The aim of the present study was to investigate the role of the prefrontal cortex (PFC) in implicit sequence learning and consolidation. Healthy, young adults were trained on a probabilistic sequence learning task. Anodal transcranial direct current stimulation (tDCS) over the left or right dorsolateral PFC (DLPFC) was applied during the training in order to modify learning-related cortical plasticity in the targeted brain regions by increasing neural excitability. Performance was retested after a 2-hour stabilization period and a 24-hour retention period. We found a trend for the higher engagement of the right PFC leading to enhanced sequence learning. In contrast, the higher engagement of the left PFC induced by the anodal tDCS led to a weaker performance in the retention phase suggesting disturbed consolidation. These results highlight an interhemispheric competition between the underlying memory systems.

Title: Transient but consistent dynamic changes in motor cortex activity in repeating a trained and novel movement sequence

Authors: *E. GABITOV, D. MANOR, A. KARNI
Univ. of Haifa, Haifa, Israel

Abstract: An almost universally accepted tacit expectation is that practice-related changes and memory consolidation processes should be reflected in the average brain activity in brain areas relevant to task performance. Motor cortex (M1) plasticity has been implicated in motor skill acquisition and its consolidation. Nevertheless, no consistent pattern of changes in the average signal, related to motor learning or motor memory consolidation following a single session of training, has emerged from imaging studies. Here we explored the engagement of motor mnemonic processes as expressed in dynamic changes of on-line activity in M1. To this end, we scanned participants, using fMRI, during the paced performance of a finger-to-thumb opposition sequence (FOS), intensively trained a day earlier (T-FOS), and a similarly constructed, but novel, untrained FOS (U-FOS). Both movement sequences were performed in pairs of blocks separated by a brief rest interval (30 sec). Behaviorally, in addition to within-session 'online' gains expressed immediately after training, most participants expressed delayed, consolidation-phase, gains in the performance of the T-FOS on the day after training; the performance of the U-FOS on the second day was significantly slower, less accurate and more variable. Motor experience was not expressed in the average signal intensity evoked in M1. Surprisingly, although signal variability tended to decrease with performance, its magnitude and pattern did not differ for the two sequences. The two sequences were, however, differentiated in the pattern and magnitude of short-term brain activity modulations in response to task repetition. In M1, the execution of the T-FOS was characterized by a pattern of relative enhancement between blocks in a pair. Moreover, these across-blocks enhancement effects were positively correlated with the magnitude of each participant's overnight delayed gains and not with absolute performance levels. During the execution of the U-FOS there was no significant between-blocks modulation of the average signal but repetition had distinctive within-block effects; there were significant signal decreases within the first block, but not in the block following the brief rest interval. These

within-block effects reappeared in subsequent runs. Thus, task repetition, in different time frames, may uncover robust patterns of brief but recoverable changes in task-evoked neural activity reflecting local M1 dynamic processes related to levels of experience, learning and memory. Averaging over single events or blocks may not capture the dynamics of motor representations that occur over multiple time-scales.

Title: Reduction of primary motor cortex cTBS excitability predicts benefit of feedback for retention of sequence knowledge

Authors: *A. D. STEEL[1], L. WILKINSON[2], E. MOOSHAGIAN[2], T. ZIMMERMANN[2], A. KEISLER[2], J. D. LEWIS[2], E. M. WASSERMANN[2]
[2]NINDS, [1]NIH, Bethesda, MD

Abstract: Continuous theta burst transcranial magnetic stimulation (cTBS) can reduce excitability in motor cortex (M1) for up to sixty minutes. During this time, subjects have reduced motor evoked potentials (MEPs), a local effect on corticospinal neurons, and show impairment in performance on some cognitive tasks, which effect might be due to local or distant (network) effects. Despite widespread cTBS use, there are no reports on whether MEP reduction is related to cognitive impairments from M1 inhibition. We delivered cTBS over motor M1 before participants performed a serial reaction time task with and without monetary reward/punishment feedback. MEPs were collected before cTBS, immediately afterward, after learning (30 min), and at 45 min. cTBS significantly reduced MEP amplitude, which persisted at 45 min, and impaired mean group retention of task knowledge. There was no correlation between MEP amplitude reduction and retention of learning overall. However, subjects who showed more reduction in MEP amplitude at 45 minutes post-cTBS also showed more improvement at retention performance with task feedback ($r=0.81$; $p < .0001$). One explanation for this correlation is that susceptibility to local synaptic change (inhibition) from cTBS is associated with susceptibility to other drivers of plasticity, e.g., rewarding feedback. MEP reduction does

not reliably predict the intensity of changes in cognitive networks from inhibitory M1 stimulation.

Title: Effects of moderate physical activity on learning a simple movement sequence

Authors: ***S. PANZER**[1,2], C. WEICH[2], F. MARSCHALL[2]
[1]Sportsciences, [2]Saarland Univ., Saarbrücken, Germany

Abstract: There is empirical evidence that physical activity (PA) induced an increase in the cerebral blood flow which is associated with the Brain Derived Neurotrophic Factor, a protein which supports nerve growth and neural plasticity as a basis function for learning. Learning a movement sequence involves a development of a memorial representation which is important for sequence execution. But until now, little is known about PA and the development of a sequence representation. The purpose of the present experiment was to determine effects of moderate PA on the development of a representation of a simple movement sequence. Participants were 38 students (mean age: 23.4 yrs; SD: 2.3 yrs; 19 females). All participants were instructed to perform a maximal step test on a bicycle ergometer, to determine maximal power output (MPO). From the MPO moderate PA was calculated 70% of the MPO. All PA was performed on a bicycle ergometer. In a learning and transfer design, participants were randomly assigned to one of five practice groups where continuous (70%) and intermittent (60% - 80%) PA was systematically varied before acquisition and/or before the retention and transfer tests between the groups. The learning task was to reproduce a 1300 ms spatial temporal sequence pattern of elbow flexions and extensions. After acquisition (99 trials), all participants performed a retention test and two effector transfer tests (9 trials each) to distinguish the dominant representation for sequence production. The mirror effector transfer test required the same pattern of muscle activation and limb joint angles as required during acquisition (motor representation). The non-

mirror transfer test required movements to the same visual-spatial locations experienced during acquisition (visual-spatial representation). The results indicated that participants of all groups increased their performance during acquisition, $F(10,320)= 97.19$, $p<.01$, regardless if they had previous PA or not. The analysis of the retention and transfer tests revealed a main effect of test $F(2,64)= 27.95$, $p<.01$. Post-hoc tests indicated that all groups performed the retention test superiorly compared to the two transfer tests. All other tests failed to reach significance. These findings showed that regardless if performers had moderate PA or not, or the positioning of PA, they rely on a visual-spatial and a motor representation for sequences production. Moderate PA had no beneficial and no detrimental effects on the development of a visual-spatial or motor sequence representation. The results provided a substantial amount of guidance in how the training of a movement sequence and PA can be scheduled.

Title: Anticipatory and carry-over coarticulation in sequential human arm movements

Authors: E. NOWAK, B. GRIMME, H. REIMANN, *G. SCHONER
Ruhr-Universität Bochum, Bochum, Germany

Abstract: One of the most typical properties of natural human movements is that one movement is not independent but involved in a sequence of other movements. A movement segment can affect its successor (carry-over coarticulation) or its predecessor (anticipatory coarticulation). In redundant motor systems coarticulation can be found at the level of end-effector trajectories and at the level of joint angles. As anticipatory and carry-over coarticulation influence movements at different points in time, a comparison between them can help us to understand the generation of movement better. To examine both kinds of coarticulations in sequential human arm movements two slightly different experimental setups were used. In each setup a cylindrical object was moved from a starting position to a position at the center (first sub-movement) and from there to a final position (second sub-movement). To analyze carry-over coarticulation six starting points

were arrange at 2, 4, 6, 8, 10 and 12 o'clock. The final targets were at 2, 6 and 10 o'clock. To examine anticipatory coarticulation the starting position was always arranged at 6 o'clock, while the final positions were at 3, 6, 9 and 12 o'clock. To ensure complete attention to the task, the targets were given by visual cues that had to be memorized and were removed before each trial. To uncover coarticulation at the level of joint angle configurations, we applied an analysis of motor equivalence based on the concept of the uncontrolled manifold. We decomposed the difference between joint configurations in different conditions into components that leave the position of the transported object invariant (UCM) and those that affect the position of the object (ORT). Motor equivalence is observed when this difference lies more in the UCM than in the ORT (same spatial trajectory, but moving through different joint configurations). Direction-dependent coarticulation was visible at the level of the end-effector and at the level of joint angles. However the preparation of a movement seems to be distinctly different from its post-processing. While carry-over coarticulation was mainly visible in the joint angles, it was different for anticipatory coarticulation. Here the influence at the level of the end-effector was more distinct.

Title: A hierarchical model of human motor learning that combines high-level symbolic motor planning and low-level control of actuators

Authors: ***E. ABRAMOVA**[1], A. FAISAL[1,2,3]
[1]Computing, [2]Bioengineering, Imperial Col. London, London, United Kingdom; [3]MRC Clin. Sci. Ctr., Hammersmith Hosp., London, United Kingdom

Abstract: Many real-world control problems involve complex, nonlinear and often unknown dynamics, such as those encountered in many engineering areas. In contrast to artificial systems, the human brain translates and learns across levels of representation optimally and with ease: at the behavioral level we often plan and specify tasks symbolically (e.g. "grab cup", "pour coffee")

(Daw et al., 2005), while at the level of actuation the brain continuously controls our 650 skeletal muscles (Todorov, 2004). It has been shown that mammals learn optimal action selection in symbolic serial decision making tasks by effectively implementing reinforcement learning algorithms (Schultz et al., 1997; Clascher et al., 2010). At the same time, the brain controls the redundant degrees of freedom of reaching movements in a manner well predicted by linear optimal feedback control theory (Todorov, 2004; Scott 2004). Given these findings, we propose a hierarchical, neurobiologically inspired, framework which enables us to learn optimal control of nonlinear systems with unknown dynamics while reducing the large computational costs and heuristic tuning that are often associated with numerical approximations. Our model - Reinforcement Learning Optimal Control (RLOC) - uses a top-level reinforcement learner (putatively located in the basal ganglia (Schultz et al., 1997)), which selects symbolic actions, each corresponding to a low-level locally optimal linear feedback controller (putatively implemented across M1, pMC and spinal cord (Scott, 2004)). RLOC uses low-level motor experience to learn the system dynamics for local optimal linear control, as encountered in human reaching movements. The learning loop between action selection and actuator control is closed with the high-level reward signal driven by the low-level optimal control costs, which enables the system to learn the global optimal sequence of local linear controllers. Our model can learn, starting from unknown task dynamics, the nonlinear optimal control of planar arm reaching movements and the pendulum-on-a-cart swing up and balance problem - producing a global policy for optimal task control for many starting states in a single learning run. The system learns quickly and finds solution rivaling/beating the performance of existing state-of-the-art nonlinear control algorithms (which have full knowledge of the dynamics) (Todorov et al., 2005), while outperforming monolithic reinforcement learning approaches (Doya, 2000). Our model demonstrates how experimentally established findings in symbolic reinforcement learning and linear optimal control of movements can be combined to learn nonlinear controls.

Title: Motor learning in hemiparesis following stroke

Authors: *R. M. HARDWICK, V. A. RAJAN, P. A. CELNIK
707 N Broadway, Johns Hopkins Univ., Baltimore, MD

Abstract: It has been proposed that motor learning is an important component of the motor recovery process following stroke (Krakauer, 2006; Carr & Shepherd, 1989). However, it is difficult to determine whether stroke patients with hemiparesis have impairments in motor control alone (i.e. execution deficits), whether their motor control deficits affect their motor learning (i.e. because performance is poor learning is decreased), or whether patients have specific deficits in motor learning itself. This limited understanding is likely due to the performance confound as well as an overlap between the importance of regions lesioned in hemiparetic stroke in both motor control *and* motor learning. Previous studies examining this question have been unable to clearly dissociate the effects of impaired motor control on motor learning (Winstein et al., 1999; Platz et al., 1994; Takahashi & Reinkensmeyer, 2003; Schaefer et al., 2009). A task that accounts for differences in participant speed and accuracy (i.e. skill) could clarify how stroke affects motor control *and* learning. Here we examined motor learning in stroke survivors using a skill learning task that controls for deficits in motor execution. We hypothesized that motor learning would not be affected by impairment level if we controlled for execution deficits. We determined the functional impairment of 14 chronic unilateral stroke survivors using the Fugl-Meyer (FM) assessment. Then we split the participants into groups with mild impairment (mean FM=61±4) and severe impairment (mean FM=30±10). Participants sat with their affected arm supported by a Kinarm robotic exoskeleton and performed isometric elbow flexion contractions to move an on screen cursor to target locations. Initial skill was assessed by having participants perform the task at a range of tempos paced by a metronome, allowing us to produce a speed-accuracy function. Participants then completed four consecutive daily training sessions, in which they practiced performing the task as quickly and as accurately as possible. A final session examined post training skill by determining a second speed-accuracy function. Preliminary results indicate participants with mild impairment could successfully complete trials at faster speeds than participants with severe impairments. However, training led to error rate improvements of similar magnitudes in both groups. These data suggest that learning mechanisms following stroke are intact once we account for differences in execution. Therefore, differences in motor learning ability cannot explain why some stroke patients recover more than others.

Title: Effects of short and long term motor learning on cortical structure

Authors: *A. TREFLER[1], C. THOMAS[2], E. AGUILA[1], M. KING[1], P. MODI[2], C. PIERPAOLI[2], C. I. BAKER[1]

Abstract: A large number of studies have used magnetic resonance imaging (MRI) to detect structural changes in the adult brain following training programs that span from hours to weeks. However, the strength of the evidence from these MRI-based studies is often limited, particularly with regard to the specificity of any training effect on brain structure (Thomas and Baker, 2012). Here, we used a longitudinal within-subjects design to investigate the topography of short-term (1 hour) and long-term (1 hour/day for 1 week) training-dependent structural changes in a group of 18 healthy adults. To test the specificity of training-related changes in the brain, we used a lateralized motor-sequence learning task that required participants to master the ability to rapidly input a specific 8-digit sequence, using only the left hand. For each participant, we acquired 2 sets of T1-weighted structural MRI data, (a) before any training (baseline), (b) after a control task, (c) after short-term motor learning and, (d) after long-term motor learning. For each participant, we compared cortical thickness before and after training with cortical thickness before and after equivalent control time periods. Participants showed a strong effect of training in terms of reduced reaction time and increased accuracy that was specific to the trained hand and the type of motor sequence (trained versus untrained). Longitudinal analysis of cortical thickness revealed apparent changes in brain structure that included motor cortex in addition to other areas. However, the topography of the training-related changes differed between the short-term and long-term training programs and also differed between the different datasets collected in each scan session. Further, apparent changes in cortical structure were also observed in the control comparisons, particularly the long-term. These findings suggest that despite strong evidence for the behavioral effects of training, the evidence for concomitant changes in brain structure, as measured with structural MRI, do not appear to be robust.

Title: Effect of experimental muscle pain on the acquisition and retention of locomotor adaptation

Authors: J. BOUFFARD[1], S. E. SALOMONI[2], K. TUCKER[2], W. VAN DEN HOORN[2], *C. MERCIER[1], J.-S. ROY[1], P. W. HODGES[2], L. J. BOUYER[1]
[1]CIRRIS - Laval Univ., Quebec, QC, Canada; [2]Univ. of Queensland, Brisbane, Australia

Abstract: Background and aims: It is well established that pain can influence motor control. However, the effect of pain on our ability to learn new motor tasks remains unclear. Previous studies have used different pain models and motor tasks, reporting conflicting results. We have shown that tonic CUTANEOUS pain undermines the retention of locomotor adaptation. The **aim** of the present study was to evaluate if similar effects are observed when pain is induced into a MUSCLE directly involved with the motor learning paradigm. **Methods:** Forty healthy participants walked on a motorized treadmill on two consecutive days while wearing a robotized ankle-foot orthosis on their right leg. Each day, participants walked for 5 minutes before (Baseline) and during (Adaptation) exposure to a force field that was applied during the swing phase and resisting ankle dorsiflexion. During the Adaptation period, participants were instructed to "overcome the perturbation and walk as normally as possible". On day 1, participants performed the task either without (n=23) or with (n=17) pain induced by infusion of hypertonic saline in their right tibialis anterior muscle (ankle dorsiflexor). To evaluate the retention of motor learning, participants repeated the force field adaptation task without pain on day 2. Movement error during swing was calculated as the absolute difference (error) between Baseline and Adaptation ankle joint angular trajectories. A three-way ANOVA (Day: 1 vs. 2; Time: early vs. late adaptation; Group: pain vs. no pain) was performed to compare the progression of movement error between groups, both during acquisition and retention. **Results:** Participants improved their performance with training and showed retention of the motor task (main effects of Time and Day; $p<0.01$). A significant Day x Group interaction ($p=0.045$) suggested a difference in the level of retention between groups. Despite similar movement errors for both

groups on day 1 (p=0.810), post-hoc analyses showed a trend for better performance of the pain-free group on day 2 (p=0.076). **Conclusion:** Consistent with our previous work using cutaneous pain, acute experimental muscle pain hinders the retention of a locomotor adaptation task, even though performance during acquisition is not significantly affected.

Title: Autonomic arousal during implicit associative learning predicts risky behavior

Authors: *A. B. FORMAN-ALBERTI, B. HINNANT
Psychology, The Catholic Univ. of America, Washington, DC

Abstract: Variability in the tendency to engage in risk-taking behavior exists, with some individuals being more risk-seeking and others being more risk-averse. The degree to which people are able to subconsciously detect and learn from somatic cues in different contexts may explain some of this variability. However, no research to date has explored whether individuals' autonomic arousal during implicit learning is related to their tendency to make risky decisions and their engagement in risky behavior. Thus, the current study examined whether young adults' autonomic activity at rest and during implicit associative learning predicted their ability to learn implicitly as well as their engagement in risky behavior and substance use. Parasympathetic activity (i.e. respiratory sinus arrhythmia or RSA) was recorded at rest and while participants completed three computerized tasks: the Triplets Learning Task (TLT; Howard, Howard, Dennis & Kelly, 2008), which assesses implicit learning, and the Iowa Gambling Task (IGT; Bechara, Damasio, Damasio, & Anderson, 1994) and the Balloon Analogue Risk Task (BART; Lejuez et al., 2002), which measure risky decision making and behavior. Participants also completed a self-report measure assessing frequency of substance use once the physiological data collection period ended. Results indicated that greater resting RSA predicted increased levels of substance use and poorer implicit learning. Furthermore, the interaction between resting RSA and RSA reactivity during learning predicted risky behavior on the BART, with those individuals who had low baseline RSA and less RSA withdrawal during implicit learning showing the greatest

amount of risky behavior. These findings help to fill an existing gap in the literature by illustrating that a relationship exists between parasympathetic activity, implicit learning, and engagement in risky behavior. Furthermore, these results demonstrate that levels of parasympathetic activity associated with advantageous behavior may differ depending on whether the information to be learned in a particular context is implicit or explicit.

Title: Implicit sequence learning in Parkinson's disease: Intraindividual variability in reaction time

Authors: *K. R. GAMBLE[1], T. J. CUMMINGS, Jr[2], S. E. LO[3], J. H. HOWARD, Jr[4,5,1], D. V. HOWARD[1]
[1]Psychology, Georgetown Univ., Washington, DC; [2]Psychiatry, [3]Neurol., MedStar Georgetown Univ. Hosp., Washington, DC; [4]Psychology, The Catholic Univ. of America, Wasington, DC; [5]Neurol., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Behavioral research generally reports means or medians or interindividual standard deviation of performance to describe group data. However, it has been suggested that intraindividual variability may be a better indicator of cognitive function. Intraindividual variability is a measure of transient or state differences that may fluctuate within a task or even from task to task. While this variability measures short-term fluctuations, it has been shown to be a stable and reliable characteristic of individuals. Research suggests that this type of variability is related to brain structure or function, and may even be related to changes in neurotransmitters, such as dopamine. In the present study, we examined the differences in intraindividual variability between healthy older adults and people with Parkinson's disease (PD), a group known to have significant declines in striatal dopamine. To our knowledge, this is the first study to examine intraindividual variability in a sequence learning task in a group of people with Parkinson's disease. There were 27 medicated PD participants, in Hoehn and Yahr stages 1 to 2.5, and 30

age- and education-matched healthy older adults in this study. Participants completed three sessions of the Triplets Learning Task (TLT), an implicit sequence learning task that has a reduced motor component. We examined intraindividual variability in overall reaction time in the TLT using two measures, individual standard deviation (the standard deviation around each individual's mean RT) and coefficient of variance (an individual's standard deviation divided by their mean RT). In both measures of intraindividual variability, we found that response times in the PD group were more variable than in the control group, and this difference increased over the course of training. Thus, performance in a learning task was more variable in a PD than a control group, which may be due to a greater amount of fatigue in the PD group, or perhaps to dopamine decline over the course of training in PD participants as the effectiveness of their medication decreased.

Title: Practice structure improves transitional memory through increased cortico-subcortical coupling with the premotor cortex

Authors: *S. S. SONG[1], S. J. GOTTS[2], E. DAYAN[1], L. G. COHEN[1]
[1]Human Cortical Physiol. and Stroke Neurorehabilitation Section, NIH/NINDS, Bethesda, MD; [2]Lab. of Brain and Cognition, NIH/NIMH, Bethesda, MD

Abstract: Learning relies on successful formation of transitional and ordinal memories (Conway and Christiansen 2001, Song and Cohen 2014, Terrace and McGoningle 1994). The influence of practice structure on these memories and the underlying systems-level neural substrates are not known. Here, we studied the influence of practice structure on learning of transitional and ordinal memories that compose skill. Human subjects were trained to learn motor sequences under varied (mixing sequences) or grouped (grouping sequences) practice schedules (Shea and

Morgan 1979) while they were scanned using functional magnetic resonance imaging (fMRI). Transitional and ordinal memories were assessed 30 minutes and one week after the training session. We report that: (a) Varied practice improved transitional but not ordinal memory, (b) coupling of the left dorsal premotor cortex with thalamus and right cerebellum, lingual and cingulate network increased during varied practice, and (c) across subjects, the greater the transitional memory, the stronger this coupling. Thus, practice structure benefits one type of memory but not another that composes skill and in proportion to coupling within a cortico-subcortical network linked to the premotor cortex. These results could contribute to understanding mechanisms by which different memories are influenced by practice schedules in neurorehabilitation after brain injury.

Title: Oscillatory cortical dynamics of implicit learning in patients with schizophrenia

Authors: *L. B. HINKLEY[1], S. VINOGRADOV[2], M. FISHER[2], D. MIZUIRI[2], B. BIAGIANTI[2], S. NAGARAJAN[2]
[1]Radiology, UC San Francisco, SAN FRANCISCO, CA; [2]UCSF, San Francisco, CA

Abstract: An emerging hypothesis in the neuropathology of schizophrenia is that alterations in oscillatory activity contribute to cognitive and behavioral symptoms prevalent in the disorder. More specifically, high frequency neural activity (e.g. gamma) is thought to be impoverished in the condition, with these deficits contributing to cognitive impairments found in this population. Here, we use magnetoencephalographic imaging (MEGI) to test the hypothesis that impoverished oscillatory activity over frontal cortices impedes implicit skill learning in schizophrenia. MEG data was collected using a 275-channel biomagnetometer (VSM MedTech) during a modified serial reaction time task (SRTT) using manual or vocal movements. Individuals were instructed to respond to a short vowel (/e/, /i/, /o/, /u/) presented in the auditory domain at the beginning of each trial. Subjects either responded by speaking the vowel they have

heard (vocal), or pressing a button (manual) corresponding to one of four spatial locations. Stimuli were either presented randomly or in an eight-step movement sequence. Whole-brain oscillatory power changes were examined in the beta (12-30Hz), gamma (30-55Hz) and high gamma (65-115Hz) bands. Patients with schizophrenia failed to show learning effects for either response modality as a group ($p>0.05$) in comparison to healthy controls. Neurophysiologically, during the response phase, a decrease in beta power and an increase in high-gamma power localized to bilateral frontal cortex in healthy controls around movement onset. Deviations in oscillatory power in both frequency bands were observed in patients with schizophrenia during the learning phase over the same points in time. This data indicates that impairments in recruiting high-frequency neural synchrony translates into a deficit in cognitive learning at a rapid pace. These neuroimaging-based markers have the potential to track recovery following cognitive-based rehabilitative paradigms.

Title: Aerobic exercise and implicit learning in healthy young adults

Authors: C. G. WAMBACH[1], C. M. STILLMAN[1], J. H. HOWARD, Jr.[3], *D. V. HOWARD[2]
[1]Psychology, [2]Georgetown Univ., Washington, DC; [3]Psychology, The Catholic Univ. of America, Washington, DC

Abstract: Behavioral and neuroimaging data suggest that aerobic exercise benefits cognitive functioning. However, most studies have focused on executive functions in special populations, such as children and older adults. In this study we investigated whether aerobic exercise is associated with better implicit learning in healthy young adults. Implicit learning, which occurs without awareness or intent, relies on several brain substrates overlapping with those previously

shown to benefit from aerobic exercise. We thus predicted that exercise would be positively related to implicit learning in our sample. We tested 27 undergraduates from Georgetown University who did not participate in varsity sports. Participants completed the EPIC-Norfolk Physical Activity Questionnaire (EPAQ2), an extensive, validated self-report questionnaire that measures activity levels in total energy expenditure. Participants then completed the Triplets Learning Task (TLT), a measure of implicit sequence learning. In this task participants view four open circles on the screen that fill in sequentially red, red, then green and respond only to the green target. Unbeknownst to them, the first red cue predicts the location of the green target 80% of the time, forming a high probability (HP) "triplet". The remaining 20% of the time the target will appear in one of the three other locations, forming a low probability (LP) triplet. Implicit learning is measured by comparing reaction time to HP vs. LP triplets. To replicate previous experiments, participants also completed the Flanker Task, a measure of executive function, cognitive control. In this task, participants respond to the direction of a center arrow as quickly as possible. In each trial, the center arrow is flanked by stimuli that are pointing in congruent, incongruent, or neutral directions to the center arrow. Cognitive control is measured by subtracting reaction time to congruent trials from that of incongruent trials, with lower scores indicating better control. As predicted, we found a significant positive correlation ($r = 0.486$, $p = 0.018$) between activity levels and implicit sequence learning. However, we did not find the expected relationship between activity levels and cognitive control. This failure to replicate positive associations with cognitive control and the small sample size call for replication with a larger sample. Nonetheless, our results suggest that regular aerobic exercise may be associated with better implicit learning. Our findings also highlight the need to include measures of implicit learning in future randomized trials, to determine whether aerobic exercise also improves implicit forms of learning.

Title: Prefrontal and cerebellar contributions to oculomotor rule learning: An eye-tracking fMRI study

Authors: G. P. D. ARGYROPOULOS, J. L. MILLS, *N. RAMNANI
Dept. of Psychology, Royal Holloway Univ. London, London, United Kingdom

Abstract: Cerebellar Crura I/II are interconnected with prefrontal areas and may play important roles in skilled cognitive operations. In instrumental learning, memory-guided response selection is preceded by processes that establish rules through trial-and-error. Previous studies suggest that these may require, respectively, cerebellar and prefrontal circuitry. We used event-related fMRI to record activity timelocked to visual cues that arbitrarily instructed the selection of oculomotor responses. We isolated and compared rule-related activity evoked by cues that resulted in correct, memory-guided response selection, and cues that resulted in erroneous responses in which subjects had still not established the correct response through trial-and-error.20 subjects were scanned with fMRI (1100 whole-brain EPI images; TR=2s; 3T Siemens Trio) during trial-and-error learning (trial structure: visual cue; variable delay; 'Go!' trigger; saccade; feedback [positive; negative; null]). Variable delays permitted activity time-locked to cues to be isolated from 'Go!' response-related activity. Rules: arbitrary cue-location associations. Cues: Either fully (FR) or partially reinforced arbitrary symbols (PR; 20% of trials, ensuring sufficient incorrect responses), or arrows directly specifying target location (CTR). fMRI analysis: EPI images were preprocessed and analysed in SPM8. 1st-level GLM modelled cue-activity for correct responses to FR, PR, CTR, and incorrect ones to FR and PR; all other events, confounds. Following 2nd-level random effects ANOVA, SPM t-contrasts compared successful and erroneous response selection preceding saccades: FR,PR correct > FR,PR incorrect; FR,PR incorrect > FR,PR correct (FWE correction: $p<.05$). *Incorrect > correct rule processing:* Activations were found bilaterally in the caudal (BA8, frontal eye fields), and in mid-portions (BA46) of the middle frontal gyrus which extended into the inferior frontal gyrus on the left (BA45).There were no cerebellar activations. *Correct > incorrect processing:* Activations were present bilaterally in Crus I, but not in these frontal lobe areas. Cerebellar Crus I may play a role in memory-guided selection of oculomotor responses. Activity in middle and inferior frontal gyrus may be related to the requirement to select between competing responses when the correct one is unknown (the predominant cause of errors in this study). Activity in cerebellar Crus I may reflect selection following a constrained search through a set of well-learned associations.

Title: Mechanisms of large-scale network switching in task engagement and conscious report

Authors: ***W. R. XIAO**[1], W. C. CHEN[1], R. E. WATSKY[1], R. KIM[1], E. A. B. LEVINSOHN[1], J. L. GERRARD[2], D. D. SPENCER[2], H. BLUMENFELD[1,2,3]
[1]Neurol., [2]Neurosurg., [3]Neurobio., Yale Univ., New Haven, CT

Abstract: The mechanism by which perceived stimuli are processed and encoded into consciousness has been extensively studied with behavioral tasks. The addition of imaging and electrophysiology can elucidate the temporal and spatial location of the sequences necessary for the entire mechanism of consciousness. We believe that the mechanisms of global large-scale network-switching in the brain are similar to transient conscious events and with the transition that occurs between the passive resting state and active task engagement. We have developed a behavioral task paradigm in a mixed block and event-related design employing conscious report of a face stimulus titrated to threshold perception levels. In our task, each subject's subjective perception of the stimulus is validated by objective accuracy in locating the stimulus in one of four possible locations. The task takes place over either a distracting background involving a movie on marine life or a less distracting background of static. We also vary the duration of delay between stimulus presentation and probe questions. In using this task in normal subjects we saw no differences in overall performance with probe delay or with different backgrounds. As further validation of the behavioral task we found that even though only half of the presented stimuli were reported as perceived, nearly 100% of perceived stimuli were located accurately, while stimuli that were not perceived were located at chance levels. We have recruited 3 subjects with intracranial electroencephalography (icEEG) recordings to perform this task. We have confirmed event-related potentials and frequency modulations in response to the face stimuli and task transitions. Additional analyses are aimed at further elucidating the activity changes associated with transitions from rest to task, and during transient consciously reported events. In ongoing studies we hope to pair the behavioral task with additional icEEG recordings as well as with functional magnetic resonance imaging (fMRI) to determine the sequence of changes underlying and large-scale network switching during task engagement and conscious events.

Title: Mechanism of impaired consciousness in typical childhood absence seizures

Authors: *J. N. GUO, R. KIM, S. JHUN, W. XIAO, E. FEENEY, X. BAI, M. NEGISHI, M. J. CROWLEY, L. C. MAYES, R. T. CONSTABLE, H. BLUMENFELD
Yale Univ., New Haven, CT

Abstract: Seizures of childhood absence epilepsy are marked by brief impairments of consciousness and by 2.5-4 Hz spike-and-wave discharges on electroencephalography (EEG). While previous imaging studies of absence seizures show a widespread involvement of cortical and subcortical areas, how these changes are related to ictal behavior is unknown. Prior studies with limited sample size have shown occasionally spared task performance during absence seizures. However, the mechanism for this variability in ictal behavioral impairment is not understood. To examine this, we performed two studies: 1) simultaneous behavioral, 32-lead EEG, and fMRI recordings in 36 patients and 2) separate out-of-magnet 256-lead EEG recordings with concurrent behavioral testing in 15 patients. Tasks included a repetitive tapping task and a more difficult continuous performance task requiring greater attentional vigilance. 579 seizures were captured in Study 1 and 150 seizures were captured in Study 2. Greater task difficulty and longer seizure duration were correlated with worse ictal behavioral performance. For both tasks, patients showed a bimodal distribution with most seizures exhibiting either fully spared or fully impaired performance. K-means clustering analysis of fMRI data revealed sequential activation of three known networks: 1. default mode network, 2. task-positive network, and 3. primary sensorimotor and thalamic network. Intensity of involvement for all three networks was larger in seizures with impaired task performance. Quantitative analysis of

high-density EEG revealed frontal predominance in seizure power within the 2.5-4 Hz range. Intensity of EEG power changes in anterior, middle, and posterior leads also were larger for seizures with impaired behavioral performance for both tasks. Finally, the larger amplitudes of both EEG and fMRI in seizures with poor performance occurred at or even preceding seizure onset, suggesting the pre-seizures state may determine seizure severity. Childhood absence epilepsy has significant affective and cognitive effects on patients and impairs their quality of life. Understanding the mechanism of loss of consciousness during childhood absence seizures may allow for development of improved therapeutics for this disorder.

Title: Phenomenal consciousness created by decoded neurofeedback

Authors: *K. AMANO[1], T. WATANABE[2], K. SHIBATA[2], M. KAWATO[3], Y. SASAKI[2]
[1]Ctr. for Information and Neural Networks (CiNet), Osaka, Japan; [2]Brown Univ., Providence, RI; [3]Advanced Telecommunications Res. Inst. Intl., Kyoto, Japan

Abstract: Introduction: One of the serious controversies on consciousness is whether it is possible to identify the presence of so-called phenomenal consciousness or qualia, which is defined as contents of conscious experience independent of access to the experience via cognitive functions including top-down attention and working memory. Although several researchers claim that the neural representation for phenomenal consciousness is distinguishable from that for other cognitive functions (Lamme, 2003; Kanai and Tsuchiya, 2012), phenomenal consciousness has never been created or identified. Here we took a causal approach called decoded fMRI neurofeedback (DecNef) to create phenomenal consciousness. First, we induced

V1/V2 neural representation of color by DecNef without subjective report about perceived color. By doing this, we can isolate the neural representation independent of access. Then we tested whether the induced representation corresponds to phenomenal consciousness by asking subjects to report perceived color. Methods: After conventional retinotopic mapping, we built a decoder to discriminate stimulus color (red vs green) from V1/V2 fMRI signals. Then we conducted an fMRI DecNef experiment, in which subjects learned to regulate their brain activity during the presentation of an achromatic vertical grating based on the feedback disc. The disc size approximately represents the similarity between the V1/V2 activation patterns during the grating presentation and those corresponding to red grating. In a post-test stage, subjects indicated the perceived color of an achromatic vertical/horizontal grating. Results and Discussion: The mean red likelihood (i.e. magnitude of red representation) was significantly increased by DecNef training, indicating that subjects internally created association of vertical gratings with the neural activity corresponding to the red color. However, during the training, subjects did not spontaneously report any color. In the post-test stage after the training, subjects chose red significantly more frequently than green for the achromatic vertical grating. We confirmed that the red likelihoods for an achromatic grating during the DecNef induction were highly similar to those during the perceptual color test, and the only difference was whether subjects were asked to report color or not. These results clearly indicate that the neural representation corresponding to phenomenal consciousness of red color was created and retained in the early visual cortex. The representation was read out or accessed when subjects were required to report and therefore attend to the color.

Title: The influence which rubber hand illusion gives the hand capacity

Authors: *T. YUDA[1,2], M. OSUMI[1], S. MORIOKA[1]
[1]Kio Univ., Nara-Ken, Japan; [2]Rehabil. Dept., Nishiyamato Rehabil. Hosp., Kitakaturagi-gun, Japan

Abstract: Background and aim of the study: The change in body ownership by the rubber hand illusion (RHI) has been reported to be due to a decline in skin temperature (Moseley GL, 2008) and a rise in the sharp pain threshold (Hegedus G, 2014). However, the relationship of hand capacity (HC) and the change in body ownership by RHI has not been investigated. The purpose of this study was to investigate the influence which RHI gives the HC. Methods: The subjects were 14 right handed healthy adults (mean age ± standard deviation : 27.5 ± 3.9 years). The subjects sat in front of a framework containing two identical compartments. In the right compartment, a left rubber hand (RH) was placed in an identical configuration. The experimental phase consisted of two blocks corresponding to the two experimental conditions (synchronous and asynchronous). Both the synchronous and the asynchronous conditions started with a 5-min stroking period, during which all of the fingers of the RH and the unseen left hand were stroked by two brushes; these strokes were either synchronous, to induce the RHI, or asynchronous. Before starting the experimental phase, a proprioceptive drift (PD) and HC were measured in all subjects. After the induction phase, PD and skin conductance response (SCR) were measured, and participants reported their perceptual experiences that were associated with stroking by answering a questionnaire. The evaluation of SCR, the amplitude of the largest SCR 0.03 greater than microsiemens that occurred 1-5 s from pinprick to the RH was scored as a response to that stimulus. In addition, uncomfortable feelings in each condition were measured with an 11-step numeric rating scale (NRS). The HC was compared before and after the experiment with paired t-tests. The HC variation difference was compared with an independent t-test for each condition. The Pearson product-moment correlation coefficient was used to evaluate the correlation between HC and uncomfortable feelings, PD, and SCR. Results: HC was not significantly different between the synchronous and asynchronous conditions ($p = 0.05$). Subjective illusion strength significantly differed between the synchronous and asynchronous conditions ($p = 0.01$). A significantly positive correlation was found between HC and uncomfortable feelings in the asynchronous condition ($r = 0.6$, $p < 0.04$). There were no significant differences in PD, SCR, or uncomfortable feelings between the two conditions ($p > 0.05$). Conclusion: These results suggested that the change in HC was related to emotions, such as uncomfortable feelings rather than a change in body ownership by the RHI.

Title: The effect of emotional valence on nonconscious visual memory activity

Authors: *S. KARK, S. D. SLOTNICK, E. A. KENSINGER
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Most studies of recognition memory examine activity that is greater for correctly recognized items (hits) than for incorrectly forgotten items (misses) or correctly rejected lures (CRs). While these studies focus on the neural processes that support the ability to consciously recognize past events, there can also be unconscious influences from the prior study episode, as evidenced by repetition priming effects. Prior work has demonstrated priming effects in early visual regions (Slotnick & Schacter, 2006), the amygdala (Yang, Cao, Xu, & Chen, 2012), and the hippocampus (Hannula & Ranganath, 2009) - regions important in conscious recognition of emotional information (Keightley, Chiew, Anderson, & Grady, 2011). In the present functional magnetic resonance imaging (fMRI) study, we investigated the effect of emotion on nonconscious memory effects. Specifically, we examined whether repetition priming effects were modulated as a function of emotional valence. Seventeen participants (aged 19-35) studied International Affective Picture System (IAPS) images that had negative, positive, or neutral valence (i.e., they viewed each line-drawing outline immediately followed by the complete photo). After a 20-minute delay, participants were shown the line-drawing outlines of the previously studied photos and outlines of photos they never studied. For each item, participants made an old-new recognition judgment and a sure-unsure confidence rating. As repetition suppression effects are known to occur for forgotten items, priming effects were identified by comparing CRs to misses. The contrast of CRs > misses, collapsed across valence and confidence, revealed priming-related activity in the amygdala, early visual regions (BA18 and BA19), the insula, and the hippocampus, which is consistent with previous findings. A region-of-interest (ROI) analysis was conducted based on the magnitude of activity in each of these regions as a function of valence. We observed significant priming effects for negative items but not positive or neutral items in the amygdala and BA18 (there was also a significant Region x Valence x Response Type interaction). These ROI results suggest that the amygdala and BA18 mediate nonconscious memory for negative stimuli to a greater degree than positive or neutral activity. That is, even when participants have no conscious memory of previously viewing the stimuli, there are still influences of the prior stimulus exposure on sensory and affective processes, and some of these influences appear to be largest when stimuli are negative.

Title: Damage to the medial prefrontal cortex is associated with impaired autonomic responses to music-evoked autobiographical memories

Authors: *A. M. BELFI, D. TRANEL
Univ. of Iowa, Iowa City, IA

Abstract: Music is strongly intertwined with memories - for example, hearing a song from your wedding can transport you back in time, triggering the sights, sounds, and feelings of that night. Music-evoked autobiographical memories (MEAMs) are often vivid and rich with episodic details. Why does music evoke such vivid, detailed memories? We have posited that emotion is a critical part of the mechanism underlying the relationship between music and vivid memories. To investigate this issue, we studied patients with focal brain damage to the medial prefrontal cortex (mPFC), a key brain region for both emotion and autobiographical memory. Previous research has shown that individuals with damage to the mPFC have impaired emotional responses to many stimuli, including music (Johnsen et al., 2009). These individuals do not show autonomic responses to emotional events, findings that have been interpreted as reflecting impaired 'somatic markers' to emotional stimuli. Additionally, these individuals have impaired (less vivid) MEAMs. We therefore predicted that individuals with damage to the mPFC will have impaired autonomic responses to memory-evoking music. Participants with damage to the mPFC, brain-damaged and normal comparison participants listened to 30 songs that were popular during the years when the participant was between the ages of 15-30. After each clip, participants described memories that were evoked and rated how strongly they felt any emotions associated with these memories. During the experiment, skin conductance was recorded as a measure of emotional response. We found that normal and brain-damaged comparison subjects showed greater skin conductance response (SCR) during music that evoked memories as compared to music that did not evoke memories. This effect was not seen in the mPFC group. Additionally, the mPFC group had significantly lower SCRs to music that evoked memories than both comparison groups. However, when comparing the participants' ratings of emotional strength, we saw no significant group differences. That is, patients with mPFC damage had decreased emotional responses to MEAMs (as indexed by SCR) but did not show decreased

subjective emotional ratings. These findings can be taken to indicate that individuals with damage to the mPFC have an impaired "somatic markers" to memory-evoking music, despite reporting normal subjective ratings of felt emotions. This supports the proposal that the mPFC is a critical structure for autonomic responses to emotional stimuli, and that these responses are crucial for vivid music-evoked autobiographical memories.

Title: Pragmatic: A probabilistic and generative model of areas tiling the cortex

Authors: *A. G. HUTH, T. L. GRIFFITHS, J. L. GALLANT
UC Berkeley, Berkeley, CA

Abstract: In many regions of the cortex, functional representations appear to be organized into maps: retinotopic maps in visual cortex, tonotopic maps in auditory cortex, and somatotopic maps in somatosensory and motor cortices. However, because both anatomy and functional representation differ across individuals, it is notoriously difficult to define maps and areas consistently across subjects. Furthermore, only a small number of functional maps and areas have been discovered thus far, and much of cortex remains poorly understood. To solve these problems we developed PrAGMATiC: a probabilistic and generative model of areas tiling the cortex. This hierarchical Bayesian model assumes that the cortex is tiled with functional areas, and the precise organization of these areas in each subject is drawn from a single underlying probability distribution. Parameters of this distribution specify the functional properties of each area and the approximate anatomical distance between each pair of areas. This model avoids the lossy process of projecting each individual brain into a common anatomical space (e.g. MNI coordinates). Model parameters are learned using a Markov chain Monte Carlo technique similar to contrastive divergence learning for Boltzmann machines. Once the parameters have been learned, this generative model can be used to predict how functional representations are organized in new subjects whose data were not used for parameter estimation. Model

performance can then be assessed by comparing PrAGMATiC predictions to the actual data for the held-out subjects. We applied PrAGMATiC to datasets from two fMRI voxel-wise modeling experiments: one in which subjects watched natural movies, and one in which subjects listened to natural narrative stories. For both experiments, we estimated voxel-wise models that predict BOLD responses based on the semantic content of the stimuli. In both datasets, PrAGMATiC revealed dozens of cortical areas with consistent functional properties and anatomical locations across subjects. In the speech dataset, consistent functional areas tile much of the prefrontal, parietal, and temporal cortices. In the movie dataset, consistent functional areas tile anterior occipital cortex, posterior temporal cortex, and parietal cortex. Finally, the parameters of the PrAGMATiC models reveal which specific semantic categories_such as numbers, places, or people_are represented in each functional area. These results show that PrAGMATiC is a revolutionary new tool for identifying functional areas both at the individual and group level, and that it provides a powerful method for interpreting voxel-wise modeling results.

Title: Using multivariate pattern analysis to investigate memory reactivation during sleep

Authors: ***J. W. ANTONY**[1], L. R. PILOTO[3], K. A. PALLER[1,2], K. A. NORMAN[3,4]
[1]Interdepartmental Neurosci., Northwestern Univ., Chicago, IL; [2]Psychology, Northwestern Univ., Evanston, IL; [3]Princeton Neurosci. Inst., [4]Psychology, Princeton Univ., Princeton, NJ

Abstract: To understand the role of sleep in memory processing, we aim to track reactivation of specific memories during sleep and to relate this reactivation to subsequent memory. The necessary technology to do this already exists in animal studies: Cellular recordings during sleep in rodents have demonstrated replay of specific neuronal patterns that were present during

learning. However, evidence for reactivation of specific memories in humans is currently lacking. To address this gap, we set out to track memory reactivation in humans by applying multivariate pattern analysis (MVPA) to EEG data. Specifically, we queried whether wakeful brain patterns re-emerged after presenting learning-related cues to participants during sleep. While awake, participants viewed 48 famous faces and scenes while EEG data were acquired from 64 channels, and event-related spectral perturbation (ERSP) values were used to train a face/scene classifier. Participants over-learned associations between those pictures and unique sounds, and then learned the location of those pictures on a spatial grid. Participants then took an afternoon nap. During slow-wave sleep, we presented half of the associated sounds from each category. After a 2.5-hr post-nap delay, participants took a recall test for all the picture locations. We predicted that sounds would trigger reactivation of associated faces and scenes during sleep, and that the degree of measured reactivation would influence subsequent recall. To investigate whether learning-related patterns re-emerged during sleep, we found the time (post stimulus onset) and frequency bins that yielded the best face/scene discrimination during wake, and we used data from these time / frequency bins to create spatial templates of ERSP feature values (across the 64 electrodes) for faces and scenes. We then matched these category-specific spatial templates to data from different time and frequency bins acquired during sleep. This approach instantiates the idea that face and scene processing are associated with distinct spatial patterns of activity that are preserved across wake and sleep, but these "signature" patterns might appear at different times post-stimulus-onset during wake vs. sleep, and they also might be manifest in different oscillatory frequencies. Preliminary results indicate that wakeful patterns re-emerge during sleep at above-chance levels. Further analyses will assess other approaches to measuring reactivation, and also the extent to which neural reactivation relates to subsequent memory retention on an item-by-item basis.

Title: Default mode network activity precedes attention lapse in healthy subjects

Authors: *R. C. PHILLIPS, T. SALO, C. S. CARTER
Neurosci., UC Davis Neurosci., Davis, CA

Abstract: During sustained attention tasks the mind tends to wander towards salient internal thoughts. Mind wandering has been associated with activity in the default mode network (DMN) but the evidence for how this network interacts with the Task-Positive Network (TPN) is mixed. Previous research has demonstrated clear anticorrelations in the BOLD signal of these networks during resting state, suggesting that the DMN may suppress the TPN, resulting in an attention lapse. However, co-activation of these networks has been observed during mind wandering, indicating the possibility that the TPN is active during executive processing of internal distractors. We sought to test whether attention lapses on a cognitive control task are correlated with DMN activity, and whether this activity is accompanied by suppression of the TPN. Twenty-two subjects were presented with the AX-Continuous Performance Task (AXCPT) while in a 3-Tesla MRI scanner. During AX/BY trials, there is no competing impulse that would tempt an incorrect response, and subjects generally display a high level of correct responses on these trials. Therefore, incorrect responses on these trials likely represent disengagement with the external task as attention turns to internal distractors. We used SPM8 to model lapse trials, as well as correct AX/BY trials. We contrasted lapse trials and correct trials in order to determine which areas of the brain displayed increased activity prior to a lapse response. We compared the BOLD signal time course from voxels in the DMN and TPN during our task to determine the degree of anticorrelation between these networks during task performance. We observed significant activation in the medial Prefrontal Cortex, a prominent hub of the DMN, at a threshold of $p<.05$, FDR. We also observed activation of the Posterior Cingulate Cortex at a lower threshold of $p<0.001$. We observed no suppression of TPN regions. Our time course analysis revealed that during correct trials, these networks are clearly anticorrelated, but not during lapses. These results suggest that default mode network activity plays a role in the focus of attention, which may be switched from an external task towards distracting internal thoughts. Our results indicate a further avenue of study in order to determine whether attention lapses only arise spontaneously, or whether they can be induced in response to salient internal distractors.

Title: The effect of short-term meditation training on attentional blink

Authors: *F. LUO, S. WANG, J.-Y. WANG
Key Lab. Mental Hlth., Inst. Psychology, Chinese Acad of Sci., Beijing, China

Abstract: Back ground: Evidence have been provided that short-term meditation training could alter attention processing. Hence, the question arises as to whether the effect could also be manifested in the attentional blink task. The present study used a modified "target-mask, target-mask" (TM-TM) paradigm to test the effect of a 6-day meditation training on the reduction of the susceptibility to the attentional blink. Method: forty-one healthy meditation beginners participated in this experiment. They were assigned into a meditation training group (mean age 22, SD 1.62, 6 male and 14 female) or an attention task group (mean age 21.67, SD 1.56, 9 male and 11 female). The meditation group received meditation training (30 min per day) for 6 days. The control group was given an attentional task with a similar time schedule. All participants finished two "TM-TM" attentional blink tasks, one before and one after the 6-day training period. In the TM-TM paradigm, participants initiated each trial by pressing the space bar. The four-item sequence (T1, M1, T2, M2) began after a variable delay (100 ms, 200 ms, or 300 ms). We created three levels of T1 difficulty (easy, medium, and hard) by co-varying the the duration of T1 and M1 (45/45, 30/60, and 15/75 ms, respectively). The inter-stimulus interval between T1 and M1 was always maintained at 30 ms. T2 and M2 were fixed at the level of 30/60 ms. On each difficulty level, the stimulus onset asynchrony (SOA) between T1 and T2 varied between five levels (135 ms to 615 ms, in steps of 120 ms). Each of the 15 conditions of Difficulty × SOA were composed of 20 test trials. All trials were mixed and randomly presented in one block so as to avoid any predictive allocation of attention resource before a given trial. Thus, the change in attentional blink magnitude corresponding to T1 difficulty could only be attributed to the improved processing efficiency but not the changing of resource allocation for T1 or T2. The T2 accuracies were calculated at 15 conditions respectively on the trials that T1 were correctly identified and were analyzed with a 3 (difficulty) ×5 (SOA) × 2 (test time) × 2 (group) mixed ANOVA. Results: The results revealed that T2 accuracy of the 'hard' condition was significantly improved only in the meditation group, although it was enhanced in both groups under easy and medium condition. Post hoc test showed that under the 'hard' level, meditation training could significantly improve T2 accuracy when the SOA was 255 and 375 ms. Conclusion: These observations support that short-term practice of meditation could enhance the efficiency of information processing and help to overcome attentional limitation in the temporal domain.

Title: Risk-taking behaviors relate to functional connectivity in striatal and fronto-parietal networks in adolescence

Authors: *A. A. BATO[1,3], D. SARPAL[2], M. A. BLAIR[1,3], K. BEECHER[4], J. NAIDICH[4], A. K. MALHOTRA[1,3,5], K. H. KARLSGODT[1,3,5]
[1]Psychiatry Res., [2]Psychiatry, Zucker Hillside Hosp., Glen Oaks, NY; [3]Psychiatric Res., North Shore-LIJ Feinstein Inst., Manhasset, NY; [4]Radiology, North Shore-LIJ Hlth. Syst., Great Neck, NY; [5]Hofstra North Shore LIJ Sch. of Med., Hempstead, NY

Abstract: Adolescence is a pivotal period of development, characterized by an increase in white matter integrity and decrease in regional grey matter thickness particularly in networks associated with higher-level functioning and complex cognitive processes. Among these are the fronto-parietal network involved in executive functioning and control, as well as the orbitofrontal-striatal network known to mediate reward sensitivity; both networks are instrumental in decision making, but they do not complete maturation until early adulthood. However, during adolescence individuals are already beginning to be held responsible for important decisions, and poor self-regulation may result in being exposed to riskier and potentially disadvantageous situations. Evidence shows that the development of the reward and executive control networks occur at different rates within healthy adolescents, resulting in a period characterized by an increase in reward sensitivity but a lack of executive control. Given this evidence, we investigated the correlations between functional connectivity in these networks and risk-taking behaviors within a group of healthy adolescents between the ages of 12 to 21. To characterize individuals' propensity for riskiness, we utilized the Balloon Analogue Risk Task (BART) for its consistent prediction of self-reported risky behaviors. We then identified regions of interest in both the striatal network (Di Martino 2008) and fronto-parietal network (Owen 2005) to pinpoint the reward and executive control circuits. With these regions of interest, we used resting state fMRI and a seed-voxel analysis with nine nuisance signals based on the

methods developed in the NITRC 1000 Functional Connectome project and covaried by age, sex, and mean performance in the BART. This initial analysis showed better performance in the BART was correlated with stronger connectivity in the executive control network. Likewise, ventral striatal seeds showed negative correlations with areas involved in cognitive control in individuals with better BART performance. This indicates that it is not just stronger connectivity in the fronto-parietal executive network, it is also the better coordination between this network and the orbitofrontal-striatal reward network that contributes to more beneficial risk behaviors. Due to the limited data on functional connectivity and its relationship to BART performance, continued assessment of self-reported behaviors and risk measures will assist in further understanding the relationships between these two networks and risk.

Abstract: Introduction: Compulsive behaviours are typical symptoms of Obsessive Compulsive Disorder (OCD) that reflect difficulties to commit to ultimate decisions. They may be conceptualized as a means to accumulate sufficient evidence prior to a decision. Here we investigate the process of evidence accumulation in OCD in perceptual discrimination and

probabilistic reasoning, hypothesizing impairments in both decision types. **Methods:** Twenty-eight OCD patients and 35 healthy control subjects were tested with a low-level visual perceptual task (random dot motion task), whereby different coherent levels for motion were defined to measure high and low uncertainty, a probabilistic reasoning task (jumping to conclusions task) and two response conflict tasks as control tasks (flanker task and probabilistic selection task). Logistic regression analysis across all coherence levels (which accounted for visual detection threshold) and hierarchical drift diffusion modeling (HDDM) were used to characterize response strategies between patients with OCD and healthy controls in the random dot motion task. **Results:** OCD patients compared to healthy volunteers were more cautious in weighing the alternatives and accumulated more evidence particularly to high uncertainty in the visual perceptual but not in the probabilistic reasoning task (longer reaction time and response time intercept). This behaviour was consistent across behavioural and computational approaches and was more evident in patients with higher compulsivity scores. The HDDM analysis further showed higher decision threshold, or evidence needed to make a decision, in patients under high uncertainty and slower drift rate, reflecting poorer quality of evidence, under low uncertainty. With incentives to emphasize speed, patients decreased the decision threshold relative to healthy volunteers, accumulating less evidence, under low uncertainty, without compromising accuracy. These findings were unrelated to visual perceptual deficits and response conflict. **Conclusions:** This study extends the assessment of evidence gathering in OCD from probabilistic to perceptual decisions. Using both behavioural and computational approaches we highlight impairments in evidence accumulation in OCD and an influence of uncertainty. We further emphasize that OCD patients are sensitive to explicit salient incentives on the speed-accuracy tradeoff, improving evidence accumulation and shifting away from pathological internal monitoring. These findings may have relevance for therapeutic approaches.

Abstract: Impulsivity is a complex scientific construct that entails many behavioral proclivities. One important aspect of impulsivity is information sampling, sometimes referred to as reflection impulsivity. Previous work has shown that several groups with impulse control disorders show decreased information sampling in the beads (or urn) task and increased novelty preference in a reinforcement learning task in which novel options are occasionally introduced. Functional imaging of these tasks has implicated frontal-striatal circuits, and PET studies comparing patients with impulse control disorders to matched control groups have shown differences in the dopamine system. To further clarify the role of dopamine in these tasks, we have carried out behavioral studies in healthy subjects in whom we will also characterize dopamine signaling. We have focused on 3 information sampling tasks and the novelty task. The information sampling tasks include the beads task, the secretary task, and a perceptual inference task. Behavioral findings in the current sample (n=20; 11 female), replicate previously identified effects in patient groups separately tested on each task. In the beads task, subjects were less accurate ($F_{1,15}$=21.8, p<0.001), and sampled a greater number of items ($F_{1,15}$=20.5, p<0.001) when provided with less information. They also chose to sample a greater number of items under conditions in which they lost money ($F_{1,15}$=16.2, p=0.0011). In the secretary task, subjects sampled more items when the item list length was greater ($F_{1,19}$=7.07, p=0.0155). Also, there was an interaction between the variation of the items in the list and the list length ($F_{1,19}$=9.78, p=0.0055). The perceptual inference task revealed that subjects were more accurate ($F_{6,108}$=586, p<0.001) with smaller reaction times ($F_{1,15}$=46.0, p<0.001) under less ambiguous conditions. In the novelty task, participants selected novel choice options more often than the best alternative option. We will also characterize dopamine tone by measuring presynaptic DA stores and synthesis with fluorine-18 FluoroDOPA positron emission tomography (PET) in these same individuals, and examine correlations between dopamine signaling and behavioral performance in the tasks.

Title: Does working memory capacity mediate age and performance on the Balloon Analogue Risk Task (BART)?

Authors: *M. BLAIR[1,3], A. A. BATO[2,3], A. K. MALHOTRA[2,3,4], K. H. KARLSGODT[2,3,4]

Abstract: Adolescence is a key stage of development of the executive control and reward circuits of the brain, two systems heavily involved in decision making. Previous studies show that decision making ability does not fully develop until after adolescence, resulting in increased risk taking during this period. The Balloon Analogue Risk Task (BART) is a computerized program used to measure risk taking propensity. Participants inflate balloons with different likelihoods of popping and must decide when to stop the inflation in order to earn the most possible points. This analysis aimed to determine if there is a relationship between age and BART performance, and if so, what specific cognitive functions contribute to that relationship. A sample of 34 healthy individuals between ages 8-21 recruited from an ongoing study at Zucker Hillside Hospital was administered the BART and two neuropsychological tasks targeting working memory: Wechsler Spatial Span and Letter-Number Span. BART performance was measured by the coefficient of variation in adjusted pumps, a measure of response consistency, to infer how well participants learn which balloons are more likely to pop and consistently apply that knowledge over the course of the task. A formal mediation model was used to test the impact of working memory on the relationship between age and BART performance. Using an approach by Baron and Kenny, a series of mixed effects regression models were performed: 1) whether age is associated with BART, 2) whether age is associated with working memory, and 3) whether age remains significantly associated with BART after adjusting for working memory. We found that age was no longer related to BART performance after controlling for working memory, indicating that the relationship between age and BART performance may be mediated by working memory capacity. The success of this mediation model implies that working memory has an impact on risk taking propensity. Future analyses will apply this model to a larger sample as well as test whether working memory mediates a relationship between age and real-life risk taking behaviors, and other aspects of BART performance. If working memory ability continues

to show a significant relationship with risk behavior, this knowledge may help inform the development of interventions to enhance working memory in particularly risk-vulnerable populations.

Title: Neural and behavioral indices of value- and urgency-dependent saccade prioritization in humans: Behavioral 'types' and conversion through implicit training

Authors: *A. BLANGERO, S. P. KELLY
Dept. of Biomed. Engin., City Col. of New York, New York, NY

Abstract: The representation of value, and its influence on behavior, is affected in several psychological disorders from depression to risk seeking behavior and addiction. We sought a neural marker of the spatial representation of the relative value of action targets using electrophysiology, eye tracking and psychophysics in humans. In the main experiment, we presented 15 subjects with two colored circle targets to the left and right of central fixation. After 800 ms delay, the fixation point changed color to that of one of the two targets, instructing to make a fast and accurate saccade to that target. Each color was associated with a different number of points (5/40 pts), awarded if the saccade was made within a 250-300ms deadline. On target presentation, we found a novel, transient positivity (~300ms) contralateral to the position of the higher-value target over lateral parieto-occipital scalp (PCP). The amplitude of this signal correlated with the difference in reaction time (RT) distribution between saccades to high and low value targets. Exploring individual differences revealed three distinct behavioral 'types.' Four subjects showed no effects of value on RT or accuracy (hereby labeled 'Conservatives'). Most of our subjects were 'Opportunists', displaying a clear RT difference between values and more erroneous saccades toward the high value target. Finally, 2 subjects were 'Extremists', who never acted towards the low value. Of these 3 groups, only Opportunists had the PCP signal.

Additional experiments in Opportunists showed that both a tight deadline and large value difference are necessary to elicit both the PCP and behavioral prioritization, which were absent when either was removed (no deadline or 20/25pts). Finer manipulation of these parameters in psychophysical tests with 2 subjects revealed that each could exhibit any behavioral type given appropriate parameters. Further, both Extremists and Conservatives could be induced to exhibit opportunistic behavior with urgency and/or relative value adjustments and, interestingly, exhibited a hysteresis effect whereby they retained such opportunistic behavior for the original parameters after training. They now exhibit a significant PCP for the original parameters. However, while Opportunists ceased exhibiting a PCP when converted to Conservatives, they still exhibited a strong PCP when induced to behave as extremists (deadline <200ms). This series of simple experiments provides a handle on value representation and its incorporation into processes underlying timely target-directed actions, and could lead to novel assays in psychological disorders associated with maladaptive decision making.

Abstract: Introduction: Internet Gaming Disorder (IGD) causes significant public mental health problems worldwide, especially in Korea. It is important to compare characteristics of IGD with those of substance addiction in order to elucidate the pathophysiology of IGD. In this

study, we explored the resting-state brain activity using regional homogeneity (ReHo) of functional magnetic resonance imaging (fMRI) among patients with IGD, those with Alcohol Use Disorder (AUD) and healthy controls. **Method**: Sixteen male patients with IGD (21.63 ± 5.92 years), 14 male patients with AUD (28.64 ± 5.92 years), and 15 healthy male controls (25.40 ± 5.92 years) were included in this study. All patients were seeking treatment at our clinics due to their excessive Internet game use or alcohol drinking. **Result**: The IGD group showed a significant ReHo decrease in the right superior temporal gyrus (STG) and increase in the posterior cingulate cortex (PCC) compared with healthy controls. The AUD group showed significant decrease in the anterior cingulate cortex (ACC) and increase in the PCC compared with healthy controls. **Conclusion**: These results showed neurobiological similarity and disparity of resting-state fMRI features among IGD, AUD and healthy controls. These findings may contribute to elucidate the pathogenesis and neurobiological underpinning of IGD.

Title: Age-related striatal dedifferentiation and frontal overactivation during choice value processing

Authors: *Y.-S. SU[1], T.-L. TAI[1], J. O. S. GOH[1,2,3]
[1]Grad. Inst. Brain & Mind Sci., Natl. Taiwan Univ. Col. of Med., Taipei, Taiwan; [2]Neurobio. and Cognitive Sci. Center, Natl. Taiwan Univ., Taipei, Taiwan; [3]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: The dopaminergic system, which includes the ventral striatum and prefrontal cortex, is involved in value prediction during choice processing. Aging is known to decrease dopamine availability and efficiency in this fronto-striatal choice processing system. In this study, we postulated that this reduction in dopamine efficacy may lead to dedifferentiation or reduced selectivity of value encoding in older adults relative to younger adults. In tandem, there may be age-related overactivation in other frontal areas possibly reflecting compensatory processing for

reduced value encoding fidelity. We conducted a functional magnetic resonance imaging (fMRI) experiment using a lottery-choice task to investigate age-related neural differences related to choice value processing. 31 healthy younger adults (mean age: 23.75 yrs; SD: 2.11 yrs; 10 males) and 25 older adults (mean age: 68.46 yrs; SD: 4.05 yrs; 7 males) saw numbers depicting the probability (5 levels) of winning and losing a specified points value (3 levels). They chose whether to accept or decline each offer, then outcome feedback was provided. During the task, five functional EPI scans were acquired per participant with 218 volumes each scan, 2s TR, 38 axial slices, and 3.4375*3.4375*4 mm3 voxels. Behaviorally, older adults were more likely to accept choices coding low probabilities of winning compared to younger adults, with relatively longer response times in low probability conditions as well. As expected, whole-brain analysis of fMRI data revealed less sensitivity to increasing probability levels in older compared to younger adults in the ventromedial prefrontal cortex (VMPFC) and nucleus accumbens (NAcc). In addition, dorsal lateral prefrontal cortex (DLPFC) showed overactivation in older relative to younger adults particularly for responses to low probability conditions. Further correlation analysis showed that older adults with higher DLPFC responses to low relative to high probability conditions tend to accept more low probability conditions. Our findings show that older adults have more difficulty in effectively processing choice values, and specifically overvalue low probability choices. Importantly, our study uncovers a novel neural mechanistic link between age-related dedifferentiation in value encoding in the VMPFC and NAcc and overactivation in the DLPFC in relation to risky decision behaviors in old relative to younger adults.

Title: Attentional effects of stimuli induced craving in people with marijuana use disorders

Authors: ***F. H. TSOI**, A. SHEVORYKIN, S. SINGH, E. CABREJA, C. PEREZ, L. M. RUGLASS, R. D. MELARA
City Col. of New York, New York, NY

Abstract: Marijuana is the most frequently used illicit drug in US. As of 2003, an estimated 3.1 million people were daily marijuana users (Office of Applied Studies, 2003). It is important to understand what cues are more salient for psychological craving. A desire to smoke marijuana has been associated with exposure to marijuana-related cues (Gray et al., 2008; Gray et al., 2011; Nickerson et al., 2011). When presenting marijuana-related cues in a variety of sensory modalities, the cues elicited an increase in self-reported craving (Filbey et al., 2009). In a virtual reality study that exposed participants to multiple sensory and social cues, cannabis users reported higher craving levels and attention to cannabis cues in comparison to neutral cues (Bordnick et al., 2009). In fact, desiring marijuana was more prevalent when it was more difficult to obtain, implying increased craving due to the lack of availability (Shrier et al., 2012). The current study was a preliminary data analysis collected from a larger study on attentional bias and marijuana cue reactivity. The goal was to examine the relationship between measures of marijuana craving and various subscales on the Marijuana Craving Questionnaire (MCQ) for those with and without Marijuana Use Disorders (MUD). 36 participants who were matched on age, ethnicity, years of education, and gender were screened for eligibility and diagnosed using the Structured Clinical Interview for DSM-IV. They then completed a modified Flanker task, which presented three lines one after the other and asked the participant to decide on the orientation of the middle line while a positive, negative, neutral, or marijuana cue flashed with it. After completion, participants rated each marijuana and neutral cue on how much it makes them crave marijuana. Participants completed the MCQ pre and post experimental task. The repeated measures MANCOVA with the MCQ as a covariate revealed a significant interaction between cue type and group ($p<.001$, $R2=.80$) and a main effect of cue type on the craving ratings ($p<.001$, $R2=.86$). People with MUD showed an increase in craving level after viewing marijuana cues compared to neutral cues; control participants had no increase in craving after viewing either type of cues. The main effect of group on accuracy on the task was marginally significant ($p=.07$). People with MUD had overall lower accuracy on the task for both cues in comparison to controls. Results showed that craving for people with marijuana use disorder is influenced by viewing marijuana-related cues. For treatment, it may be important to help marijuana users who are attempting to quit to avoid cues that may trigger relapse.

Title: Towards a study of compared EEG activity during logical reasoning tasks between champions of the Logic Olympiad and regular students

Authors: *V. REYES[1], J. CASTRO-MANZANO[2], J. CASTILLA-CASTILLA[3], C. PERALTA-UTRILLA[3], J. MEDINA-DELGADILLO[2]

Abstract: Electroencephalogram (EEG) is a non-invasive, economical and reliable method that allows us to represent electrical brain activity with high temporal resolution. The EEG signal portraits cerebral changes on frequency bands associated to cognitive tasks. Based on the Neural Efficiency Hypothesis, which suggests that there is a lower cortical activation in subjects with higher levels of intelligence, in this work we registered the brain electrical activity of 20 regular undergraduate students and 20 champions of the International Logic Olympiad from the Master category. EEG activity was recorded over 14 scalp locations during rest (3 minutes) and during performance on 10 visually presented logical tasks (10 minutes). The latency and the accuracy of the responses were also measured. Preliminary results show an increase in posterior alpha power during the resting period in undergraduate students. There was also a decrease in lower alpha and an increase in beta activity in anterior brain areas during the solving of logical reasoning. This change is probably associated with attentional demands; however, we still need to evaluate the champions before advancing further conclusions. Results from the champions are being currently analyzed. Financial support UPAEP 30108-1030

Title: Degradation of subjective value judgements in patients with behavioral variant frontotemporal dementia

Authors: *T. A. BISBING, C. T. MCMILLAN, J. P. POWERS, N. SPOTORNO, M. GROSSMAN
Neurol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Orbitofrontal cortex (OFC) has been implicated in various aspects of decision-making, including the evaluation of value. The nature of value can be subjective (e.g., an individual prefers one item over another item) or objective (e.g., one item is more valuable than another item). In this study we evaluate the dissociation between subjective and objective value in behavioral variant frontomteporal degeneration (bvFTD) patients who have neurodegenerative disease in OFC. Subjective preference for junk foods, sports, vegetables, and flowers was assessed in comparison to objectively ordered stimuli such as circle diameter and line length. bvFTD patients (N=18) and demographically-comparable healthy controls (N=21) were asked to judge all possible pairs of seven stimuli from each of these six categories. For each pair, they were asked to select one of the images based on either their own preference (requiring the assignment of a subjective value to each stimulus). If participants can maintain a stable subjective value for each stimulus within a set, then a linear preference should emerge within each set. Patients with bvFTD performed more poorly than controls at consistently judging the subjective values ($U(37) = 31.5$, $Z = -4.485$, $p < .001$), however, they did not differ from controls in their ability to judge the relative magnitude of circle diameter and line length ($U(37) = 182.5$, $Z = -.396$, n.s.). We conclude that disease in OFC may selectively impair subjective value with relative preservation of objective value. Together these findings suggest that these two sources of value have distinct neuroanatomical correlates.

Title: Temporal discounting of future rewards in behavioral variant frontotemporal dementia and Alzheimer's disease

Authors: *K. RASCOVSKY[1], J. W. KABLE[2], R. KAZINKA[2], E. MORAN[1], C. OLM[1], J. GLASENBERG[1], A. BOLLER-HEWITT[1], C. T. MCMILLAN[1], R. CLARK[3], M. GROSSMAN[1]
[1]Dept. of Neurol. and Penn Frontotemporal Degeneration Ctr., Univ. of Pennsylvania Sch. of Med., Philadelphia, PA; [2]Dept. of Psychology, [3]Dept. of Linguistics, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Although patients with behavioral variant frontotemporal dementia (bvFTD) are known to make impulsive social and financial choices, few systematic studies have measured impulsivity in bvFTD using objective patient-based tasks. We administered the Delay Discounting Task (DDT) to evaluate temporal discounting of future rewards in patients with mild bvFTD (n=17, MMSE=24), Mild Cognitive Impairment / Alzheimer's disease (AD/MCI) (n=22, MMSE=24) and 20 matched elderly controls. Participants were asked to make 51 hypothetical choices between small immediate and larger delayed monetary rewards (e.g., "would you prefer $18 today or $30 in 67 days?"). Discount rates were estimated by fitting a logistic regression that assumes a person's decisions are a stochastic function of the difference in subjective value between the two options. We assumed that subjective value (SV) is a hyperbolic function of the reward amount (A) and delay (D): SV = A/(1+kD), where k is the participant's

discount rate (larger k values indicate greater discounting of future rewards). Mann-Whitney tests revealed that bvFTD patients had higher discount rates (k median=0.257) compared to elderly controls (k median=0.009, $p<.05$) and AD/MCI patients (k median=0.016, $p<.05$). Discount rates were not significantly different for AD/MCI patients and controls ($p>.05$). 10 bvFTD and 10 AD/MCI patients had high-resolution structural imaging within 1 year of the DDT. A non-parametric permutation analysis (RANDOMISE) constrained to regions of reduced gray matter in bvFTD related high discount rates to bilateral atrophy in orbitofrontal cortex, right insula, anterior cingulate and lateral prefrontal cortex. In conclusion, bvFTD patients showed greater discounting of future rewards compared to elderly controls and AD/MCI patients. These findings are consistent with the functional neuroimaging literature relating temporal discounting to a fronto-striatal network associated with value-based decision-making. Further studies should explore whether high discount rates in the DDT relate to real-life impulsive behaviors in bvFTD.

Title: Neuroanatomical changes in behavioral variant frontotemporal dementia correlate with risk-related behavior

Authors: *J. POWERS, C. T. MCMILLAN, K. RASCOVSKY, L. BURKHOLDER, M. GROSSMAN
Neurol., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: OBJECTIVE: To evaluate neuroanatomical correlates of risk-related decision-making in behavioral variant frontotemporal dementia (bvFTD). BACKGROUND: BvFTD, a clinical syndrome associated with frontotemporal lobar degeneration, is characterized by changes in personality, social conduct, and executive functioning. Patients exhibit impulsive and inflexible behavior as well as impaired decision-making. The Balloon Analogue Risk Task (BART) assesses decision-making in a risk/reward paradigm. Little work has been done to investigate gray matter (GM) regions associated with BART performance in bvFTD. Furthermore, while bvFTD patients have considerable white matter (WM) disease, the relationship between BART performance and WM disease has not been investigated in bvFTD. METHODS: A modified version of BART was collected on 23 patients with bvFTD and 24 demographically comparable healthy seniors. For each trial in this computer-based task, the participant pumps up a virtual balloon to accrue points. The participant must continuously decide whether to end the trial by adding the accrued points to their bank or continue pumping to potentially earn more points. However, the number of pumps required to pop a balloon varies and is unknown to the participant, and no points are earned for trials in which the balloon pops. A Mann-Whitney U test was used to compare final bank totals between bvFTD and controls. Higher bank totals correspond with more successful decision-making. Also, pumping behavior was examined between earlier and later trials to assess learning. T1-weighted structural images and 30-directional diffusion-weighted images were acquired for these bvFTD patients and 36 demographically comparable healthy seniors. GM density and fractional anisotropy (FA) were assessed in bvFTD relative to healthy seniors and BART bank total was related to GM density and FA in bvFTD using regression analyses. RESULTS: BART bank total was decreased in bvFTD relative to behavioral controls, and while controls increased pumping behavior throughout the task, bvFTD patients showed no change. GM density and FA reductions were widespread in bvFTD throughout frontal and temporal GM and WM, respectively. BART bank total was associated with GM density in right orbitofrontal cortex and anterior insula and reduced FA in left superior longitudinal fasciculus and frontal body of the corpus callosum in bvFTD. CONCLUSIONS: Patients with bvFTD demonstrate impairments in risk-related decision-making and adaptive learning. BART performance in bvFTD is associated with frontotemporal network structures involved in risk-related decision-making and adaptive learning.

Title: Dopamine D2 receptors, reward discounting, and B-cell function in obese and normal-weight humans

Authors: *D. M. GREDYSA[1], S. EISENSTEIN[2], A. ARBELAEZ[3], J. KOLLER[2], J. PERLMUTTER[4], S. MOERLEIN[5], E. BIHUN[2], S. RANCK[2], A. BISCHOFF[4], T. HERSHEY[2]

Abstract: Insulin acts in the brain to regulate dopamine (DA) tone and signaling and DA-mediated behaviors. While this relationship has been shown in animals, research in human populations is lacking. Obesity is associated with altered insulin sensitivity and pancreatic B-cell function, and it has been hypothesized that altered DA receptor levels in the brain may underlie obesity-related phenotypes, including altered reward discounting. Thus, our objective was to investigate whether obesity and B-cell function affect human brain reward circuitry and reward behavior via DA D2 receptors (D2R). Participants were obese (N=22; BMI>30) and normal-weight (N=15; BMI<28) adults without type 2 diabetes and other medical conditions. B-cell function was derived from an oral glucose tolerance test (OGTT) using the Disposition Index (DI), a composite measure of insulin sensitivity and secretion. Reward discounting was measured with the probabilistic (PRD) and delayed (DRD) reward discounting tasks. Participants underwent positron emission tomography scans using a D2-specific receptor ligand, [^{11}C](*N*-methyl)benperidol (NMB). D2R binding potentials (BPs) were computed in reward-related regions of interest (ROIs; putamen, caudate, and nucleus accumbens) using the Logan graphical

method with cerebellum as the reference region. All analyses controlled for age, gender, BMI and education. Results showed that obese and normal subjects differed only in BMI and B-cell function; there were no differences in reward discounting (PRD, DRD) or D2R levels in any ROI. In the total sample, DRD correlated with DI (r=.39, p=.031) and putamen D2R BP (r=–.37, p=.051), such that greater reward discounting related to lower B-cell function and higher D2R levels in putamen. In the obese group alone, DRD correlated with DI (r=.51, p=.037) and putamen D2R BP (r=–.57, p=.025), such that greater reward discounting related to lower B-cell function and higher D2R levels in putamen. When also controlling DI, PRD correlated with D2 BP in putamen (r=–.62, p=.019) and caudate (r=–.62, p=.017), such that greater reward discounting related to higher D2R levels in putamen and caudate. B-cell function was not related to D2R BP in any ROI in any group. These preliminary findings indicate that in obese and normal subjects, greater reward discounting was associated with higher D2R binding in the striatum and lower pancreatic B-cell function, independent of BMI. This suggests that individual differences in D2R levels and B-cell function may underlie altered reward behavior in humans, but that these phenotypes are not unique to common obesity as has been reported.

Title: The mechanism underlying quota-dependent modulation of risk-attitude and its deficit in the Pathological Gambling

Authors: *A. FUJIMOTO, H. TAKAHASHI
Kyoto Univ., Kyoto-Shi, Japan

Abstract: Patients with pathological gambling (PG) tend to continue gamble in spite of negative experiences and then provoke tragic consequences such as bankruptcy or family breakdown. Such puzzling risk-seeking in PG patients is considered to be based on the distorted cognition so-

called ‘chasing’, in which patients believe that the only way to recover financial loss is continuing gamble. Although many studies investigated the biased cognition in PG, the critical mechanism remains elusive. To elucidate the mechanism of ‘chasing’ from novel aspect, we tested the ability to modulate risk attitude depending on the quota severity in the PG group (n=21) as well as in the healthy control (HC) group (n=29) using a newly-developed gambling task under fMRI scanning. In this task, participants were required to choose between risky and safe options on every trial and achieve stage-quota that was assigned from 7 different levels in advance to each stage. Hence, participants needed to truck remaining point and trial number (trial-quota) and utilize sure and risky choices flexibly to maximize the chance of stage clear. The HC group tended to take sure (high expected-value) options when trial-quota was moderate and take risky (high magnitude) options when trial-quota was severe, suggesting quota-dependent modulation of risk attitude in healthy population. The PG group, on the other hand, chose risky option frequently when trial-quota was moderate, suggesting that PG patients had less ability to modulate risk attitude toward current quota adaptively. Thus, ‘chasing’ might be partially induced by inappropriate risk-taking due to disability of quota-dependent behavioral modulation. We also conducted fMRI experiments during task execution and showed that several areas including the dorsal anterior cingulate, insula and dorso-lateral prefrontal cortex reflected quota severity in HC group. This correlation was attenuated in PG group, implicated the neural bases of disability to modulate risk attitude depending on quota. Altogether, our results would reveal the mechanisms underlying ‘chasing’ in PG patients, and potentially provide new therapeutic target to recover ability to modulate risk attitude depending on the quota severity.

Title: Dopamine mediates reward-dependent incentivisation of effort in Parkinson’s disease

Authors: *T. T.-J. CHONG, V. BONNELLE, S. MANOHAR, K.-R. VEROMANN, K. MUHAMMED, M. HUSAIN
Univ. of Oxford, Oxford, United Kingdom

Abstract: Humans adapt the degree of effort they are willing to expend according to the rewards they expect to receive. Data from animal studies suggest that dopamine might be a key neurotransmitter involved in such incentivised decision-making. Here, we examined the extent to which the striatal neurodegeneration in Parkinson's disease (PD) disrupts the processing of effort and reward, and how dopamine may ameliorate such disruption. Patients with PD ($N = 22$) were tested ON and OFF their usual dopaminergic medication, and their performance was compared to healthy age-, gender- and education-matched controls ($N = 22$). Notably, none of our participants were apathetic or depressed, as assessed by standard clinical measures. In our task, participants had to decide whether they would be willing to exert one of six pre-specified levels of effort (as measured by force exerted on a hand-held dynamometer) to obtain one of six pre-specified stakes. For each participant, we estimated the effort level at which the probability of accepting a given stake was 50% (i.e., the effort 'indifference points' for each stake). Our key finding was that dopamine in PD exerts a motivating influence on choice behaviour. Specifically, patients ON medication were willing to invest greater effort for a given stake compared to when they were OFF. Importantly, this result could not simply be accounted for by differences in physical strength. Furthermore, compared with controls, the incentivising effect of dopamine was stake-dependent. For the lowest stake, patients with PD were less motivated than controls, regardless of whether they were on dopamine. However, this was overcome at higher stakes, when patients ON dopamine were willing to expend even greater effort compared to their healthy counterparts. Our results emphasise that motivational deficits may be present subclinically in PD, and independent of a syndrome of apathy or depression. In addition, we show that dopamine can enhance motivation towards effortful actions in PD, with its effects being most pronounced when the stakes are high. Notably, the incentivising effect of dopamine in our task was evident even prior to action initiation (i.e., during choice behaviour), suggesting that dopamine sets a variable gain on salience attribution depending on the rewards available. Overall, we conclude that motivational deficits are more prevalent in PD than previously thought, and that dopamine enhances the willingness to work for reward in a reward-dependent manner.

Title: Dissociable mechanisms of value-based decision-making in children: My own will or my Mom's choice?

Authors: *S.-L. LIM[1], A. S. BRUCE[1], J. B. CHERRY[1], N. HASS[1], S. N. BALAKRISHNAN[2], A. M. DAVIS[3]
[1]Dept. of Psychology, Univ. of Missouri - Kansas City, Kansas City, MO; [2]Mechanical and Aerospace Engin., Missouri Univ. of Sci. and Technol., Rolla, MO; [3]Pediatrics, Univ. of Kansas Med. Ctr., Kansas City, MO

Abstract: Value-based decision-making is one of most important developmental tasks that children need to master. Through early learning experiences, children learn how to make optimal choices in a given environment with specific information. Particularly, food-related decisions in children are of great importance, because these can set up lifelong patterns of health-related behavior. However, healthy (optimal) food choices of children often require high-level cognitive regulation (e.g., choosing non-tasty but healthy lunch menu at school cafeteria), which may posit inevitable bounded rationality. The objectives of this project are to determine the computational and neural mechanisms underlying food decision-making processes in children using a human fMRI task. Seventeen healthy children between the ages of 8-14 made a series of food choices for 60 items (= eat or not) in two different conditions (children's own choice vs. guessing mom's choices for them) after providing separate taste and health ratings for each item. Our preliminary results (n=17) showed marked, dissociable behavioral and neural patterns between the two choice conditions. Child participants used primarily taste values when they made their own choices, which was accompanied by ventromedial prefrontal cortex (vmPFC) activations. Interestingly, when projecting what foods they believed their mother would choose for them, child participants used both taste and health values, which was accompanied by orbitofrontal cortex (OFC) and dorsolateral prefrontal cortex (dlPFC) activations. Understanding developmental mechanisms of value-based choices in children will have critical importance for improving health behavior choices in early development and in designing health behavior interventions accordingly.

Engineering, Univ. of Florida, Gainesville, FL; [6]Dept. de Psiquiatría, Escuela de Medicina, Ctr. Interdisciplinario de Neurociencia, Pontificia Univ. Católica de Chile, Santiago, Chile

Abstract: Obsessive-compulsive disorder (OCD) is a common and chronic condition that can have disabling effects throughout the patient's lifespan. Typical obsessions include doubts, recurring thoughts with a connotation of violence, sexuality, religion and fear of contamination.

Actual or perceived threat of contamination can elicit several emotions, particularly disgust. Heightened disgust feelings towards disgust-inducing stimuli are commonly observed in self-report measures of OCD patients. A neural model based on recent studies of neuroimaging implicates that anterior insula has a role in disgust processing. Increased blood oxygen level dependent (BOLD) signal activity in the anterior insula could be implicated in the OCD psychopathology. In the current study, we applied real-time functional magnetic resonance imaging-brain-computer-interface (rtfMRI-BCI) to help OCD patients to achieve down-regulation of the abnormally high BOLD activity in anterior insula in the presence of disgust provoking stimuli. To explore the effects of rtfMRI-BCI-neurofeedback training in OCD symptomatology, several pre- and post-training measures were performed, e.g. confronting the patient with a disgust/anxiety inducing real-world object, ratings towards disgust provoking

pictures, physiological responses during these evaluations (heart rate, skin conductance, eye-tracking measurements) and general clinical evaluations. Preliminary results of the study (3 patients-2 female) show that OCD patients can gain self-control of the activity of anterior insula, albeit to different degrees with rtfMRI-BCI. In two patients who showed higher ability to regulate the activity of insular cortex, learned down-regulation led to significant positive changes in behavior: patients displayed less anxiety while confronted with a disgust inducing object ($p<0.01$, for both patients). Behavioral changes also were confirmed by a modification of the ratings towards symptom provocation pictures ($p<0.01$, $p<0.05$ respectively) and heart rate measurements inside the scanner ($p<0.01$, $p<0.05$ respectively) between baseline and down-regulation of insular cortex. The 3rd patient did not show a significant difference in any measurement between pre and post-tests. None of the patients showed significant difference in skin-conductance measurements in pre- or post-test/baseline-regulation conditions. These results confirm that insula down-regulation is possible in patients with OCD. A controlled decrease of insula activation could be used for symptom alleviation at least in some subtypes of OCD patients.

Abstract: Objective: Positive and negative reinforcement provide a powerful source of information to adjust behavior to changing environments. Recently, it has been reported that in addition to food-related alterations (Stoeckel et al., 2008) individuals with obesity also show changes in the neural processing of non-food reinforcement stimuli. Increased neural responses during the anticipation of monetary gains and losses in the ventral striatum, orbitofrontal cortex (OFC), and inferior frontal gyrus (IFG) point at more generalized alterations in reinforcement processing (Balodis et al., 2013). In this study we investigated if these alterations in the neural processing of non-food reinforcement affect feedback-based learning and behavioral adaptation. Methods:19 obese (BMI >=30, 10 female) and 23 lean (BMI 18.5-24.9, 11 female) right-handed adults matched for age and educational background performed a probabilistic reinforcement learning task during fMRI scanning. In separate gain, loss, and neutral monetary reinforcement conditions participants learned to choose between a high and low reinforcement probability option in order to gain money, avoid loosing money, or receive neutral feedback. Final score and the percentage of advantageous choices were examined as measures of learning performance. ROI analysis of the mean time courses of areas relevant for reinforcement processing (e.g. Liu et al., 2011) was employed to analyze neural responses during the outcome processing phase. Results:Individuals with obesity showed a significantly decreased learning performance in gain and loss trials. ROI analysis revealed that the processing of monetary gains and losses was associated with an increased activation of the IFG in obese vs. lean participants. Additionally, individuals with obesity also exhibited higher activation of the medial OFC in response to monetary losses. A greater differentiation between the two types of negative outcomes was found in obese participants, showing significantly higher activation to the receipt of monetary loss than the omission of monetary gain in the anterior cingulate cortex, IFG, and medial OFC than lean controls. Conclusion:Obesity is associated with a decreased reinforcement learning performance. Altered neural representations of negative reinforcement in the medial OFC and increased involvement of areas of executive control point at alterations in feedback processing potentially influencing associative learning in obesity.

Title: Cannabis users failure to learn from errors associated with hypoactive dorsal ACC response

Authors: *R. HESTER[1], S. CAREY[2], L. NESTOR[3], J. JONES[3], H. GARAVAN[4]
[1]Dept. of Psychological Sci., [2]Univ. of Melbourne, Melbourne, Australia; [3]Trinity Col. Dublin, Dublin, Ireland; [4]Univ. of Vermont, Burlington, VT

Abstract: The chronic use of cannabis has been associated with attenuated error-related neural activity_particularly in the dorsal anterior cingulate cortex (dACC). Difficulty in modifying behaviour following an error is thought to be related to clinical impairments, such as perseveration, that are seen in substance abuse and other psychiatric disorders. Fifteen chronic cannabis users (four females, mean age = 22.40 years, SD = 4.29) and 15 control participants (two females, mean age = 23.27 years, SD = 3.67) were administered a visuospatial associative learning task that enabled participants to learn from their recall errors. Compared with controls, chronic cannabis users showed (1) lower recall error-correction rate and (2) hypoactivity in the dACC and left hippocampus during the encoding of error-related feedback. Furthermore, the difference in dACC activation between cannabis users and healthy controls varied as a function of error type, with the control group showing a significantly greater increase in activity from corrected to repeated errors than the cannabis group. The present results suggest that chronic cannabis users have poorer learning from errors, with the failure to adapt performance associated with hypoactivity in error-related dACC and hippocampal regions. The findings have implications for our understanding of the diminished capacity for learning from negative feedback seen in cannabis, and other forms, of dependence.

Title: Post-traumatic stress disorder (PTSD) and generalization of learned associations: More severe re-experiencing symptoms are associated with increased generalization

Authors: *C. E. MYERS[1,2], R. J. SERVATIUS[1,2], M. W. GILBERTSON[3], S. P. ORR[4]
[1]Dept. of Veterans Affairs, New Jersey Healthcare Syst., East Orange, NJ; [2]Neurol. & Neurosciences, New Jersey Med. School, Rutgers The State Univ. of New Jersey, Newark, NJ; [3]Dept. of Veterans Affiars, Manchester VA Med. Ctr., Manchester, NH; [4]Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA

Abstract: PTSD re-experiencing symptoms include intrusive memories of the traumatic event, which can be triggered by stimuli that reflect aspects of the traumatic event or can occur in the absence of external stimuli. At the same time, patients with PTSD often have impoverished memories for specific details of the traumatic event. One interpretation for this pattern invokes the concept of overgeneralization. Specifically, a traumatic memory is stored strongly but with minimal contextual and configural detail; later, other cues that would not normally evoke the memory now trigger recall. Contextual and configural information, which would normally help disambiguate memories, is unavailable. Re-experiencing symptoms may thus reflect a general memory bias against encoding contextual or configural information that is not limited to learning about traumatic events. In a prior study, we provided initial evidence for this possibility using an acquired equivalence task in which subjects learn cue-outcome mappings and then generalize learning about a subset of these cues to other "equivalent" cues. We found that veterans with more severe PTSD-related re-experiencing symptoms showed increased generalization. The present work examines a discrimination-and-transfer task in which subjects first learn to discriminate pairs of objects that differ in color or shape but not both. Subjects can either learn about configurations (e.g., choose one colored shape over a different colored shape) or can learn to ignore the irrelevant feature (e.g., given two objects of the same color, choose one shape over the other shape). Later, in an unsignaled transfer phase, irrelevant stimulus features are changed. Subjects who had learned to ignore the irrelevant features should perform well on transfer, while those who had learned about the configurations should perform near chance. We administered the discrimination-and-transfer test to 60 veterans (11.2% female, mean age 54.0 years) self-assessed for PTSD symptoms. Regression analysis revealed no relationships between PTSD

symptoms and initial learning; however, re-experiencing symptom scores significantly contributed to the prediction of transfer performance. Other PTSD symptom clusters (avoidance/numbing, hyperarousal) did not account for significant additional variance. These results suggest that re-experiencing symptoms reflect a general learning bias that promotes generalization at the expense of specificity. Future studies will be needed to determine whether this learning is a pre-trauma bias that confers risk for PTSD or emerges only after trauma exposure and PTSD symptoms development.

Abstract: Addiction in general, and opioid addiction in particular, are often conceptualized as behavioral strategies for avoiding negative experiences. In rodents, opioid intake has been associated with abnormal acquisition and extinction of avoidance behavior. The current study tested the hypothesis that these findings would generalize to human opioid-dependent subjects, possibly in a sex-related fashion. Here, 27 heroin-dependent male and female patients treated with opioid medication (recruited from Royal Prince Alfred Hospital, Sydney, Australia) and 26 healthy control subjects were given a computer-based task to assess avoidance behavior. On this task, subjects controlled a spaceship and could either gain points by shooting an enemy spaceship, or hide in safe areas to avoid on-screen aversive events. Results show that while groups did not differ on escape responding (hiding) during the aversive event, heroin-dependent males (but not females) made more avoidance responses during a warning signal that predicted the aversive event. This group was also slower to extinguish the avoidance response when the aversive event no longer followed the warning signal. This behavioral pattern resulted in reduced opportunity to obtain reward without reducing risk of punishment. Results also suggest that differences in avoidance behavior cannot be easily explained by impaired task performance or by exaggerated motor activity in male patients. In sum, this study is the first to provide evidence for abnormal acquisition and extinction of avoidance behavior in opioid-dependent patients. Interestingly, data suggest abnormal avoidance is demonstrated specifically by male patients. Findings shed light on cognitive and behavioral manifestations of opioid addiction, and may facilitate development of therapeutic approaches to help affected individuals.

Syst., Manhasset, NY; [3]Ctr. for Mol. and Behavioral Neuroscience, Rutgers Univ., Newark, NJ; [4]Al-Quds Med. Res. Center, Fac. of Medicine, Al-Quds Univ., Jerusalem, Palestinian Territory

Abstract: To better understand how depressive symptoms affect cognitive function in MDD, we evaluated two groups of subjects: medication-naïve patients with MDD and healthy control subjects. All were administered a category-learning task that allows for dissociation between learning from positive feedback (reward) versus learning from negative feedback (punishment). Medication-naïve MDD patients were impaired at learning from positive feedback as compared to healthy control subjects. However, there was no difference between MDD and healthy subjects in learning from negative feedback. Further, we examined the influence of the 3' variable number of tandem repeats (VNTR) polymorphism in the dopamine transporter gene (DAT1) on learning from positive and negative feedback in medicated patients with MDD. We grouped MDD and healthy subjects according to DAT1 VNTR genotype into 9-repeat carriers and 10-repeat homozygotes. MDD and healthy carriers of the 9-repeat allele, who presumably express less DAT1 and thus exhibit higher levels of dopamine, were more efficient in learning from positive feedback, whereas there was no difference between polymorphism carriers in learning from negative feedback. These findings highlight the importance of incorporating genetic profiles and studies of individual differences in future research on the relationship between psychiatric symptoms and cognitive function in MDD.

Title: The neural correlates of simulated drug choice in human addiction

Authors: *S. J. MOELLER[1], A. B. KONOVA[2], M. A. PARVAZ[1], M. MISYRLIS[2], K. E. SCHNEIDER[1], F. D'OLEIRE UQUILLAS[1], N. ALIA-KLEIN[1], R. Z. GOLDSTEIN[1]
[1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Stony Brook Univ., Stony Brook, NY

Abstract: Drug-addicted individuals often choose drug reinforcers over alternative reinforcers, a choice bias associated with addiction severity and its underlying neurobiological mechanisms. Yet, the neural correlates of drug-biased choice as related to value computation in the brain have not been identified. Here we investigate such value-based choice in individuals with cocaine use disorder (iCUD), using an fMRI task inspired by the neuroeconomics of simple choice. During this task, 10 iCUD (active and abstinent users) and 11 healthy controls (HC) viewed images depicting food (e.g., hamburger), threat (e.g., pointed gun), or cocaine (e.g., pipe); their preferences (*Strong No*, *No*, *Yes*, or *Strong Yes*) to view these salient images compared with a neutral reference image (wicker basket) were recorded on each trial. Choice ratings and reaction times (RT) (choice latency) were each analyzed with 3 (Picture: food, threat, drug) × 2 (Group: iCUD, HC) ANOVAs. Results showed that food choice ratings eclipsed cocaine- and threat choice ratings across groups (Picture main effect: $p<0.001$); iCUD also provided higher choice ratings than HC across pictures (Group main effect: $p=0.013$). Although the interaction did not reach significance in this preliminary sample, planned comparisons indicated that the group main effect was largely driven by iCUD's higher choice ratings for cocaine images ($p=0.096$; all other $p>0.25$) – particularly in active users (active>abstinent>HC; linear contrast: $p=0.021$). For RT, the longest RTs were on food trials, differing significantly from RTs on cocaine (but not threat) trials across groups (Picture main effect: $p<0.001$). A significant interaction ($p=0.021$) showed that whereas iCUD did not differ in RT between cocaine- and food trials, HC had slower RTs on food- than cocaine trials ($p<0.001$). Thus, all participants showed the highest preference and slowest RTs for viewing food images (indicative of their high subjective value), and iCUD also showed the expected cocaine choice bias relative to HC. Data collection is ongoing for a larger participant sample; further, fMRI analyses will model each picture type as modulated by the respective choice ratings, which will then be compared between groups. We expect that iCUD, during cocaine choice trials, will show activation in regions implicated in value computation [e.g., ventromedial prefrontal cortex (PFC)] and reduced activation in regions implicated in self-control (e.g., dorsolateral PFC). In sum, this fMRI task in iCUD is an important step forward (toward modeling real-world cocaine choice) from classical fMRI tasks of passive cue reactivity (which do not require evaluation of alternatives).

Title: Tight together: cross-level coupling during voluntary modulation of theta oscillations

Authors: ***J. BAGDASARYAN**[1], M. VALDERRAMA[2], K. LEHONGRE[1], V. NAVARRO[1,3], M. LE VAN QUYEN[1]
[1]Inst. Du Cerveau Et De La Moelle Epiniere (ICM), Paris, France; [2]Univ. de Los Andes, Bogotá, Colombia; [3]Epilepsy Unit - CHU Pitie-Salpetriere, Paris, France

Abstract: The idea of voluntary control of neural activities has long been validated in human and animal studies. The modulation of oscillatory activity in the theta frequency range (4-8 Hz) has attracted particular interest due to its numerous possible applications in disorders or general cognitive boosting. Yet, we still lack understanding of the neurophysiological mechanisms entrained during such self-regulation of neural activity. To investigate how the modulations are organized at different spatiotemporal scales, simultaneous data from scalp, depth-, and micro-electrodes from 5 epilepsy patients undergoing presurgical evaluation were recorded while subjects were performing training of theta amplitude enhancement in the superior temporal cortex. Within successful sessions (test/baseline ratio > 1.2), periods with high theta power were detected for further analysis (> 3 SD of baseline). Spatial analysis has shown that modulatory effects were not limited to the training electrode but propagated to neighboring electrodes within 1-2 cm of cortex. The relationship between theta power and event duration was proportional, indicating that a certain temporal delay is needed to unfold maximal theta power. Subsequent spectrum and time-frequency representations revealed the concurrent presence of higher-frequent oscillations in the gamma range (30 - 40 Hz) occurring even prior to maximal theta power. Analysis of the cross-frequency-coupling showed that gamma responses were phase-amplitude

modulated on the ascending phase of the theta cycle. Similar responses were observed for multi-unit activity, where spike-timing was theta-phase-modulated only during successful trials. In accordance with recent proposals (1), we observed the interaction between large-scale (slow oscillatory activity) and local activity (higher oscillatory or cellular activity) in the form of theta-gamma coupling and phase modulation of cellular responses during trained modulation of theta activity. We argue that this tight coupling between spatiotemporal scales is a candidate mechanism for downward causation during self-regulatory processes of brain activity. Title: Thalamocortical alpha rhythms reflect attention and predict reaction times

Authors: *S. HAEGENS[1,2], P. LAKATOS[2], M. DING[3], C. E. SCHROEDER[1,2]
[1]Dept. of Psychiatry, Columbia Univ. Med. Ctr., New York, NY; [2]Cognitive Neurosci. and Schizophrenia Program, Nathan Kline Inst., Orangeburg, NY; [3]Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: Accumulating evidence suggests that oscillatory brain activity in the alpha frequency band (8-14 Hz) reflects functional inhibition (Haegens et al., 2011): decreased alpha facilitates processing whereas increased alpha functions to suppress task-irrelevant and distracting input. To examine this “functional inhibition” hypothesis, we analyzed data collected in monkeys trained to perform an intermodal (visual/auditory) selective attention task, which required them to attend to and discriminate stimuli within one modality, while ignoring stimuli in the other modality. Data consisted of intracortical linear array multi-electrode recordings (150 or 200 μm

inter-contact spacing) sampled from three macaque monkeys in the primary visual (V1) and auditory cortices (A1) and in the lateral geniculate nucleus (LGN). The analysis of laminar profiles of "local" field potentials (LFP) and multi-unit activity (MUA) was augmented by current source density (CSD) analysis of the LFP profile. We analyzed four conditions: (1) attend auditory, (2) attend auditory with visual distracters, (3) attend visual, and (4) attend visual with auditory distracters. As we have shown before (Bollimunta et al., 2011), alpha power in V1 LFP was modulated according to the attended modality: alpha was stronger when attending to auditory stimuli (and ignoring visual) as compared to attending to visual stimuli. Here we replicate this analysis for A1, and show lowest alpha power for attend auditory as compared to visual conditions. Recordings in the LGN showed increased alpha power during the visual distracter condition compared to the other conditions. As an additional step, we asked how (slow) fluctuations in ongoing alpha activity correlate with task performance in terms of reaction times to targets. We find that high alpha power in the non-attended modality (i.e., V1 for auditory and A1 for visual stimuli) corresponds with faster reaction times. This effect was most apparent in supragranular layers. These results support the notion that alpha reflects a mechanism of functional inhibition, with increased alpha in task-irrelevant regions suppressing distracting input, subsequently leading to improved behavioral performance. Title: The role of low frequency oscillations in attentional modulation in area mt

Authors: M. ESGHAEI[1], *M. DALIRI[2,1], K. MABOUDI[1]
[1]Sch. of Cognitive Sci., Inst. for Res. in Fundamental Sci., Tehran, Iran, Islamic Republic of;
[2]Iran Univ. of Sci. and Technol., Tehran, Iran, Islamic Republic of

Abstract: Neural oscillations are prominent components of activity in brain areas, which are contributed mainly by non synaptic events. It has been proposed that these oscillations are recruited by attention, to modulate neuronal activities in different brain cortical areas. Different frequency bands of local field potentials (LFP) are representatives of these oscillations. Increase and reduction of oscillatory neuronal synchronizations in high and low frequency bands, respectively, has been suggested as main effects of attention, indicating the role of high frequency in expense of suppression of low-frequency oscillations. More recently, some experimental evidence challenged this finding with demonstrating a profound role of low frequency oscillations in modulation of neuronal activities. In our experiment, we recorded actions potentials and LFPs from the middle temporal area of a macaque monkey, during a spatial attention task. Two random dot patterns were presented simultaneously in either sides of a fixation spot. One of them was located inside the receptive field of recorded neurons and the other outside. While fixating, monkey had to attend to one of the stimuli, based on a given cue in the beginning of each trial, resulting in two attention conditions; attended and unattended. The task of the monkey was to detect a slight change in the target stimulus. All trials were split into different categories, based on their reaction times (RTs). After filtering the LFP signals in different frequency bands, instantaneous phase and amplitude of each signal were extracted using Hilbert transform. Time points within a window of 500 ms before stimulus onset were considered in our analyses. We tried to decode the RT category of each trial, in the two attention conditions, using linear SVM classifier. We also performed a time resolved analysis to find temporal patterns of the decoding performances. We assessed the performances by cross-validation. Our results demonstrate that phase of low-frequency bands, in particular theta (4-8 Hz) and alpha (8 - 12 Hz) predict the RT in the attended condition, better, in comparison with the unattended condition ($p<10\text{-}10$). Furthermore, the performances for these bands start to increase at about 300 ms before the stimulus onset in the attended condition, while we observed no specific temporal patterns in performances for the unattended condition. The resulted performances and temporal patterns indicate that attention changes state of the network just before the stimulus onset and therefore, assists the neural processing. These findings can be evidence for roles of low-frequency oscillations in attentional modulations of neural activities.

Title: Slow fluctuations underlying information processing in macaque monkeys

Authors: *C.-G. YAN[1], A. BARCZAK[1,2], S. HAEGENS[1,4], M. P. MILHAM[1,5], F. X. CASTELLANOS[1,3], C. E. SCHROEDER[1,4]

Abstract: Resting state fMRI (R-fMRI) studies report slow hemodynamic fluctuations on scales not typically associated with behavior, as low as 0.01~0.1Hz. Although uncertainty exists about the precise neurophysiological bases of slow hemodynamic fluctuations, both R-fMRI fluctuations and their electrophysiological counterparts have clear impacts on perception, cognition and behavior. Here, we examine slow fluctuations in behavioral reaction time (RT) and activity rates, as well as their relationship with underlying neuronal activity. Two monkeys were presented with random streams of 'standard' (86%) and 'oddball' (14%) visual and auditory stimuli. The monkey pressed a switch to initiate stimulus presentation and released it upon detecting an oddball. In continuous good performance (<5% misses) of the intermodal task over 5-8 min periods, we find slow fluctuations in reaction time (RT) on the scale of the hemodynamic fluctuations noted in R-fMRI studies. RT varies over a range of ~200 ms (~40% of the mean RT), showing significant peaks (via permutation tests) throughout the low frequency range we sampled, with a cluster centering at 0.03Hz. Slow fluctuations in concurrently recorded multiunit activity (MUA) from V1 during the task, are positively correlated with the slow RT fluctuations in about half of the experiments, although this relationship is not significant in the remainder of the passes. To further explore the slow fluctuations in behavior and ongoing electrophysiological activity, we analyzed another data set with two monkeys performing a visual search task. The monkeys faced a grey video screen with four low contrast grey discs. A target (red dot) was hidden in one of the discs and only appeared when the monkey fixated in the central part of the "target" disc for at least 100ms. We observed slow fluctuations in the saccade rate (with a peak around 0.025 Hz) similar to the slow fluctuations seen in the first task. We also found a negative correlation between saccade rate and pupil diameter. MUA amplitude in V1 was also negatively correlated with pupil diameter but positively related to saccade rate. As the pupil diameter is considered to reflect sympathetic arousal, it would appear that both saccade rate and MUA decrease during higher arousal periods. This is consistent with the first finding that MUA decreases during fast RT epochs. Our findings underscore slow activity fluctuation effects in behavior and their underlying neurophysiological events occurring at faster scales, and support the view that the brain slowly shifts between dynamic states.

Title: The role of fast-spiking parvalbumin interneurons and gamma rhythms in attention and behavior

Authors: *H. KIM, M. CARLÉN
Karolinska Institutet, Stockholm, Sweden

Abstract: Cortical fast-spiking parvalbumin (FS-PV) interneurons are central in certain network processes, including the generation of gamma oscillations. However, it is becoming increasingly clear that interneurons have functions beyond network coordination in local circuitry. It has recently been demonstrated that cortical FS-PV interneurons are recruited at specific behavioral events and serve a direct function in behavior. Attention is a central cognitive process enabling goal-directed behavior. Earlier work has indicated the presence of prominent inhibition in medal prefrontal cortex (mPFC) during attentional processes, but the source and the role of inhibition in attention are still unknown. We hypothesized that FS-PV interneurons are involved in attentional processes and conducted extracellular single-unit recordings paired with optogenetics in the mPFC of PV-Cre mice performing an attention task (3-choice serial reaction time task, 3-CSRTT). During the task, animals are required to attend to a brief cue presented pseudorandomly at one of three holes in an operant chamber and to report the stimulus location by nose poking. Single units were recorded and FS-PV interneurons were identified through opto-tagging. The 3-CSRTT was divided into several specific epochs pertaining to behavior (e.g. precue period, cue nose poke, reward consumption) and the population activities were analyzed in relation to the epochs. We found that the FS-PV population responded selectively at distinct epochs of the behavior, including the precue period and after cue nose poke, pointing to a role for FS-PV interneurons in attention. In summary, our results suggest a direct function of mPFC FS-PV interneurons in different behavioral events, including attentional processes and goal-directed behavior, and possibly also in reward and/or reward anticipation.

Title: Time course of attentional modulations in primary visual cortex

Authors: *X. LI[1], M. JANSEN[1], R. LASHGARI[1,2], H. SWADLOW[1,3], Y. BERESHPOLOVA[3], J.-M. ALONSO[1]
[1]Dept. of Biol. Sci., SUNY Col. of Optometry, New York, NY; [2]Dept. of Biomed. Engin., Iran Univ. of Sci. and Technol., Tehran, Iran, Islamic Republic of; [3]Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Spatial attention is known to modulate the activity of single neurons in primary visual cortex (area V1) but it remains unclear how these modulations change over time. To measure the time-course of V1 attentional modulations, we trained two rhesus monkeys to pay attention for 1-3 seconds to one of multiple drifting gratings cued at the beginning of each trial. The monkeys were rewarded to maintain their attention for the entire trial and release a lever as fast as possible after detecting a change in either grating color or orientation. V1 single neurons were recorded with a chronically implanted array of multiple ultra-thin sharp electrodes that were independently moved through the depth of the cortex (Swadlow et al., 2005). The spike trains of each neuron were converted into a continuous spike density function to calculate mean rate (F0) and response power within a low frequency range (LF) containing the stimulus frequency and nearest harmonics (1-7.5 Hz). Attentional modulations were measured as a percentage of response change when attention was cued inside versus outside of the receptive field and the attentional time course was calculated by sliding a temporal window of 500 msec (10 msec steps) over the peri-stimulus time histogram (PSTH) of the attentional modulations. In 61 neurons, we were able to perform enough attentional measures (average: 891 trials) to reliably track the attentional time-course and measure it at different trial durations. The attentional time-course of single V1 neurons could be accurately fit with a Weibull function and the fits were generally more accurate for F0 than LF (mean R2 for 2-sec trials: 0.939 for F0 vs. 0.761 for LF, n=61), however, some neurons were better fit with LF than F0 and some neurons could not be fit with either method (e.g. neurons with highly rectified PSTHs because the response was zero for half of the trial).

Our results demonstrate that spatial attention increases the mean firing rate of the average V1 population roughly linearly over time, at a rate of 20% per 0.1 seconds (percentage relative to maximum modulation). The attentional modulation peaks around 0.5-1 seconds after the stimulus onset and then starts decaying around 1.5-2 seconds at a rate of 5% per 0.1 seconds. These measurements indicate that the attentional modulations change continuously during the full duration of 1-second trials, increase and then saturate in 1.5-2-second trials and increase, saturate and start decaying in 3-second trials. Therefore, we conclude that the effect of spatial attention in V1 neurons changes over time and peaks at the median duration of the trial set used in the attention task.

Title: Assessing removal of illumination as a signal: Effects of loss of basal forebrain corticopetal cholinergic neurons

Authors: *J. A. BURK, D. OTOYA, C. LEONG, A. NG, C. T. KOZIKOWSKI
Psychology, Col. of William & Mary, Williamsburg, VA

Abstract: In the vast majority of experiments assessing visual attention in animal models, tasks are employed that require the detection of a stimulus that was previously absent. Relatively few experiments have employed procedures where the signal is the removal of a previously presented stimulus. In the present experiment, we modified a previously validated measure of a visual attention that required detection of a signal (illumination of a central panel light for 500, 100 or 25ms) from “blank” trials when the light was not illuminated. Loss of basal forebrain corticopetal cholinergic neurons has been shown to decrease signal detection in this task. We modified the task so that the central panel light was illuminated throughout the intertrial interval and a signal occurred when the light was turned off (4-s) whereas a blank trial occurred when the central panel light remained illuminated. Male FBNF1 hybrid rats were trained in this revised

attention task and then assigned to receive infusions of 192IgG-saporin or saline into the basal forebrain. Rats were retrained in the task after surgery and then received one session with a houselight flashing in the back of the chamber throughout testing and a second session with the signal decreased from 4-to 2-s. During presurgical training, we observed that animals required a longer signal to maintain stable task performance when the signal involved turning off the central panel light. Surprisingly, loss of basal forebrain corticopetal cholinergic inputs was associated with higher rates of signal detection compared with sham-lesioned animals, although this effect was attenuated with subsequent training. Flashing the houselight decreased accuracy on blank trials, but did not differentially affect lesioned and sham-lesioned animals. Signal detection accuracy significantly declined in both lesioned and sham-lesioned animals when the signal duration was decreased. Collectively, these results suggest that task manipulations appear to have similar effects whether the signal involves turning the central panel light on or off. However, the neural mechanisms that are engaged during these two types of tasks appear to be different. Future work in our laboratory will explore the role of basal forebrain noncholinergic neurons in performance of a task with turning the central panel light off serves as a signal.

Title: Cholinergic modulation of frontoparietal activity during the orienting and disengagement of attention in rats

Authors: *V. LJUBOJEVIC[1], P. LUU[2], P. R. GILL[3], L.-A. BECKETT[1], K. TAKEHARA-NISHIUCHI[1], E. DE ROSA[1]
[1]Dept. of Psychology, [2]Dept. of Physiol., Univ. of Toronto, Toronto, ON, Canada; [3]Rambus Labs, Rambus Inc., Sunnyvale, CA

Abstract: The frontoparietal cortices are thought to play a role in selective attention processes such as the orienting (OrA) and disengagement (DsA) of attentional focus (Thiel et al., 2004).

Yet, it is unclear how acetylcholine (ACh) input into the prefrontal (PFC) and posterior parietal (PPC) cortices modulates OrA or DsA. In the present study, we measured local field potentials (LFP) from the PFC and the PPC of rats performing a selective attention task. Further, we examined how cholinergic deafferentation of the PFC and the PPC affects both the behaviour and LFP activity associated with both aspects of attention. OrA and DsA were assessed using the Posner (1980) cuing task, a paradigm in which a subject responds to a target that is preceded by a spatially informative cue. OrA is isolated as speeding of reaction times (RT) after spatially informative cues (valid trial) compared to RT after non-informative cues (neutral trial) (Orienting Effect, OE=RTneutral-RTvalid). DsA is isolated as slowing of RT following the misleading cues (invalid trial) compared to RT after valid cues (Validity Effect, VE=RTinvalid-RTvalid). After the training on the CTD task male Long-Evans rats underwent either a selective cholinergic lesion reducing frontoparietal cortical ACh input (N=9), or a sham lesion surgery (N=8). Then, rats were implanted with cortical electrodes into the prelimbic PFC and the PPC and tested on the CTD. Histological analyses confirmed both the neurochemical and neuroanatomical specificity of the lesions and electrode placement respectively. We observed increased power of low-beta oscillations (12-18Hz) in the PFC after cue presentation that was associated with OrA (i.e. present on valid, but not on neutral trials). This pattern was observed in both groups of rats. Additionally, the size of the OE was equivalent between groups. We also observed increased power of high-beta oscillations (15-25Hz) in the PPC after target presentation that was associated with DsA (i.e. present on invalid, but not on valid trials). Interestingly, this DsA-associated brain activity was attenuated in lesioned rats. Also, lesioned rats had significantly slower RTinvalid and significantly higher VE than controls indicating behavioural deficit in DsA. In summary, this study uncovered distinct neural correlates of OrA and DsA. We found that the activity of neuronal population within the PPC was associated with the disengagement of attention from a spatial location, while the activity within the PFC was associated with the orienting of attention following spatially informative cues. Importantly, ACh input into PPC was necessary for successful and efficient DsA, while OrA was ACh-independent.

Title: Neural correlates of sustained attention in various modalities in rats

Authors: *D. WU, H. DENG, L. WEI, X. XIAO, Y. ZUO, Z. WANG
Inst. of Neurosci., Shanghai, China

Abstract: Sustained attention is a fundamental brain function, but our knowledge about its neural mechanisms is very limited. At the system level, previous studies have suggested that the anterior cingulate cortex (ACC) is a key brain region among those that generate the event-related potential of contingent negative variation (CNV) that is demonstrated to be caused by sustained attention. At the neuronal level, however, the limitations of the previous experimental strategies led to the lack of evidence for the potential causal relationship between ACC neurons and sustained attention. Thus, the present study aimed at the identification of the neurons responsible for sustained attention. We first developed a behavioral task to systematically study both visual and olfactory attention in rats. In our training procedure, rats should make a nose poke to a trigger aperture in front of the other three stimulus apertures to initiate the attention state that sustained for an appropriate time interval until the rats detected the location of the brief forthcoming stimulus. Then, using extracellular recording technology, we have sorted out a large number of neurons in the ACC and systematically studied response patterns of these neurons in both visual and olfactory sustained attention. The results showed that several types of neurons were involved in sustained attention. Generally, one type was excited and the other was inhibited during the time window of sustained attention despite of the modalities. More specifically, these neurons could be classified in terms of the onset of their responses to the sustained attention. Some neurons started to response before the trigger, some at the trigger and the others after the trigger. Also, the initiation time was related to difficulties of tasks: responses in difficult task were initiated earlier than in easy task. In terms of the offset of their responses, there also existed three types: response ends at the poke of food tray, at the poke of stimulus aperture, and between the poke of stimulus aperture and food tray. In terms of sensory modalities, some neurons showed different firing rates during visual and olfactory attention, respectively. At the population level, the fano factor was reduced, and the correlation coefficient between pairs of neurons was induced during the sustained attention. Based on these response patterns of ACC neurons, we deduced that these neurons played central role in the initiation and maintenance of sustained attention. More data are needed to support these hypotheses. The present study provides a new insight for investigation of the micro-neural circuits of sustained attention.

Title: Emotional distracters and emotional state both influence spatial attention in macaque monkeys

Authors: *J. SHARMA[1], R. LANDMAN[2], M. SUR[3], R. DESIMONE[2]
[1]Picower Inst. For Learning & Memory, MIT & MGH, CAMBRIDGE, MA; [2]Brain and Cognitive Sci., McGovern Inst. of Brain Res., Cambridge, MA; [3]Brain and Cognitive Sci., Picower Inst. for Learning and Memory, Cambridge, MA

Abstract: Faces with emotional expression, even when irrelevant to the ongoing task, are known to act as potent distracters. The influence of affective stimuli is further modified by the emotional state. However it remains debatable whether this process is automatic and reflexive or dependent on the duration of exposure. Here we varied emotional content in face pictures used as distracters to test their influence on behavioral performance on a spatial attention task in monkeys. We sought to vary monkeys' emotional state by intranasal administration of the neuropeptides, Oxytocin (OT) and Vasopressin (VP). OT and VP are key emotional regulators implicated in producing opposing effect on anxiety and social stress. The task required monkeys to monitor one of two gratings for a subtle color change and were rewarded for making a saccade to target grating when the change occurred. Two irrelevant images of monkey faces with threatening, fearful or neutral expression appeared between fixation-spot and gratings. Presence of affective faces for duration greater than 200 ms significantly reduced accuracy (d') and shortened reaction time (RT). Both OT and VP slowed RT and improved accuracy in trials with emotional faces, however in VP trials this effect was less dependent on exposure duration, particularly in presence of threatening faces. We also tested whether monkeys looking behavior showed particular bias towards emotional expression in a free choice paradigm. When presented with faces of conspecifics with or without emotional expression, in 2/3rds of the trials, they made the first saccade towards neutral face, but on average spent significantly greater time scanning the threatening or fearful faces. When all three expressions were presented, they chose to scan

threatening faces for far longer duration. Thus while early saccades showed tendency for active avoidance, persistent presence of emotional images required redirection of attentional resources, possibly an adaptive mechanism for active scanning of the perceived threat.

Title: Repeated sensory load post-weaning induces lasting alterations in attentional functions and BDNF expression

Authors: *I. HADAS[1], Y. AMITAI[2], A. ZANGEN[1]
[1]Ben Gurion Univ. In the Negev, Life Sci. D, Beer Sheva, Israel; [2]Hlth. sciences, Ben gurion university in the negev, Beer sheva, Israel

Abstract: Attentional functions are known to change during the life of an animal, yet these changes remain poorly understood. More specifically, it is unclear whether sensory loading post-weaning could ultimately impact attentional functions in adulthood. Here we demonstrate the plastic nature of attentional functions during development. We show that exposing rats to an attention-engaging non-ecological environment during a presumed critical developmental window changes performance in attention-stringent tasks and influences the degree of neuronal plasticity of attention-related brain systems in adulthood. Specifically, we show that, rats exposed to a continuous regimen of changing and salient olfactory stimuli Post-weaning, acquire the five choice serial reaction time task (5-CSRTT) faster than control, yet found to be more distractible, impulsive, and have more variable reaction times. Moreover, these behavioral parameters were found to be correlated with BDNF levels in the hippocampus, nucleus accumbens and frontal cortices. This finding implies for a possible primary cause for attention-related deficiencies in humans as well.

Title: 3D video analysis of object exploration in rats

Authors: *J. MATSUMOTO[1], T. UEHARA[3], S. URAKAWA[1], Y. TAKAMURA[1], T. SUMIYOSHI[4], M. SUZUKI[2], T. ONO[1], H. NISHIJO[1]

Abstract: Analysis of the trajectory provides insights into dynamic and complex brain activity responsible for spontaneous behaviors, as eye tracking has contributed to the investigation of the process underlying gaze control during scene perception. In this study, we developed a novel 3D video analysis system that could track the nose of a rat and applied it to analyze spatiotemporal patterns of object exploration. By means of this system, we analyzed object exploration of intact rats during a novel object recognition test, and compared the results in the intact rats with those in rats systematically injected MK-801. The 3D trajectory analysis revealed a specific pattern of object exploration in the sample phase of the novel object recognition test: intact rats first explored the lower parts of objects and then gradually explored the upper parts. The systematic injection of MK-801 suppressed changes in these exploration patterns. Comparison of these data with those analyzed by visual inspection of experts demonstrated that the system could precisely track the nose and detect the nose contact with an object. It is noted that the 3D system can reproducibly and accurately score the novel object recognition test, which represents an advance over previous scoring methods (visual observation and computerized 2D video analysis) in

which reproducibility and accuracy are incompatible. The results, along with those of previous studies, suggest that the changes in the exploration patterns reflect neophobia to a novel object and/or changes from spatial learning to object learning. These results suggest that the 3D system has the potential to facilitate future investigation of neural mechanisms underlying object exploration that result from dynamic and complex brain activity.

Title: Rapid species discrimination and individual recognition associated brain areas and components of event-related potentials in frogs

Authors: ***G. FANG**, P. YANG, Y. TANG
Chengdu Inst. of Biology, CAS, Sichuan, China

Abstract: Both species discrimination and individual recognition are crucial for survival and/or reproductive success. However, the neural mechanisms underlying these cognitive processes remained unclear. In this study we measured various components of the event-related potentials (ERPs) acquired from the telencephalon and mesencephalon of the music frog (*Babina daunchina*) during the non-reproductive and reproductive stages, elicited by conspecific calls and synthesized acoustic stimulus consisted of white noise (WN) with similar temporal structures as

the conspecific calls. Previous studies found that the males produce two types of advertisement call: calls from within nest burrows as highly sexually attractiveness (HSA) and outside as low sexual attractiveness (LSA). ERPs in response to stimuli showed that (1) amplitudes of N1 were significantly different between synthesized and conspecific sounds while no difference between HSA and LSA, indicating a fast process of auditory object discrimination at the species level around 100 ms; (2) amplitudes of P2 in the difference waves, defined as the amplitude elicited by one stimulus subtracted that by the other, between HSA and WN was significantly higher than that between LSA and WN in the right telencephalon, implying that individual recognition might be achieved in 200 ms; (3) latencies of P3 during reproductive stage were longer than those during non-reproductive stage in the left mesencephalon, suggesting the acoustic signal processing modulated by reproductive status. These results implied that both species discrimination and individual recognition might be accomplished very quickly in both the non-reproductive and reproductive stages and the related processes could be represented by the ERP components.

Title: Effects of attention and working memory in the different layers of monkey primary visual cortex

Authors: *T. J. VAN KERKOERLE[1,2], M. W. SELF[2], P. R. ROELFSEMA[2,3]
[1]Rockefeller Univ., New York, NY; [2]Vision & Cognition, Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [3]Ctr. for Neurogenomics and Cognitive Research, VU Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Selective attention enhances the processing of relevant versus irrelevant stimuli. It is thought to rely on feedback from higher cortical areas to early sensory areas but direct evidence

for this is limited. Working memory on the other hand, maintains task-relevant information for short periods of time when the stimulus is no longer present. Working memory has been suggested to involve similar top-down mechanisms and may therefore take place in the same areas that are used for perceptual processing. However, robust working memory traces in primary sensory areas have so far only been found using fMRI. It is therefore unknown if these signals are caused by subthreshold synaptic activity or by spiking activity. We here set out to investigate whether working memory traces are present in the spiking activity of neurons in monkey primary visual cortex (V1) and whether selective attention and working memory involve top-down processing by recording from all cortical layers at the same time. We used a curve tracing task which generates robust object-based attentional modulation in V1, enhancing spiking activity for a target versus a distractor curve. We now measured attentional modulation and also required the monkeys to memorize the stimulus during a delay so that we could examine working memory in V1. We observed highly significant working memory traces in the spike rate of monkey V1, although they were weaker than the attentional effects. This memory activity was briefly lost if we presented a mask but it returned afterwards. Thus, the working memory trace in V1 is not robust to sensory interference but it can be restored and therefore does not depend on an afterimage. We used a control experiment to demonstrate that the memory trace was unrelated to eye movement preparation. V1 has a clear laminar organization with feedforward projections targeting mainly layer 4C and feedback projections targeting layers 1-3 and 5. Laminar recordings therefore have the potential to distinguish between bottom-up and top-down processing streams. We investigated both spiking activity and the current source density (CSD), which reflects the synaptic input to the different layers. The laminar profiles of attention and working memory were highly similar, showing signatures of feedback processing for the full duration of the trial. These findings show for the first time that a robust working memory can be found in the spiking activity of V1 neurons. Moreover, we provide direct evidence that feedback processing to V1 is involved in both selective attention and working memory, indicating that these two cognitive functions share cortical mechanisms.

Title: Attention and normalization circuits in macaque V1

Authors: *A. THIELE[1], M. SANAYEI[2], J. HERRERO[2], C. DISTLER[3]
[1]Inst. of Neurosci., [2]Newcastle Univ., Newcastle upon Tyne, United Kingdom; [3]Neurobiologie, Ruhr-University Bochum, Germany

Abstract: Attention affects neuronal processing and improves behavioural performance. In extrastriate visual cortex these effects have often been explained by normalization models, which assume that attention influences the same circuit that otherwise mediates surround suppression. While normalization models have recently been able to explain attentional effects, their validity has not been tested against alternative models. Here we investigate how attention and surround/mask stimuli affect neuronal firing rates and orientation tuning curves in macaque V1. We trained 2 macaque monkeys in a covert top-down spatial attention task where they had to detect a stimulus (luminance) change at a cued location. Stimuli were either single oriented bars, or orientated central bars, which were surrounded by multiple pseudo-randomly oriented bars. Surround/mask stimuli provide an estimate to what extent V1 neurons are affected by normalization, which was compared to the effects of spatial top down attention. We recorded 105 neurons in two monkeys (62 in monkey 1, 43 in monkey 2).We found that the strength of attentional modulation was often correlated with the strength of surround modulation, suggesting that attention and surround/mask stimulation (i.e. normalization) use a common mechanism. To explore this in detail, we fitted multiplicative and additive models of attention to our data. In one class of model, attention contributed to normalization mechanisms, in a different class of model it did not contribute to normalization. Model selection based on Akaike's and on Bayesian information criterion demonstrated that for most V1 neurons the effects of attention was best described by additive models. Moreover, in most cells the effects were best described by models where attention did not contribute to normalization mechanisms.

Title: Frontal eye field correlates of salient distractor suppression during visual search

Authors: *J. D. COSMAN[1], J. D. SCHALL[1], G. F. WOODMAN[2]
[1]Dept. of Psychology, [2]Psychology, Vanderbilt Univ., Nashville, TN

Abstract: During visual search, the question of whether visual information that is salient, but task irrelevant, captures attention in a bottom-up manner has been long debated. Alternative views have proposed that this type of visual information can be effectively suppressed based on top-down goals. A great deal of behavioral and neuroscientific work has provided evidence for both views, suggesting that suppression and attentional capture may both be possible depending on task conditions or an individual's attentional state. In the current work, we examined visual responses of neurons in Frontal Eye Field (FEF), a region of prefrontal cortex thought to be critical for the instantiation of top-down control over attention, while macaque monkeys performed a visual search task in which an salient but task irrelevant singleton appeared on some trials. We observed that firing rates to salient distractors in a neuron's receptive field were suppressed relative to those for search targets, but not to the same extent as non-salient distractor items. This suggests that although salient but task-irrelevant visual signals are suppressed to some extent, this suppression is incomplete, which may be responsible for conflicting results in the cognitive science literature.

Title: Interactions between noncholinergic basal forebrain neurons and muscarinic receptors in attentional processing

Authors: *C. T. KOZIKOWSKI, E. L. WOLFE, P. G. YANEV, J. A. BURK
Psychology, Col. of William and Mary, Williamsburg, VA

Abstract: Numerous studies have provided evidence that basal forebrain corticopetal cholinergic neurons are critical for normal attentional performance. However, the role of noncholinergic basal forebrain neurons in attention has not been well-characterized. Moreover, evidence regarding interactions between cholinergic receptor activity and noncholinergic basal forebrain neurons remains scarce. In the present experiment, rats (n=15) were trained in a two-lever sustained attention task that required to discriminate between brief illumination of a centrally located panel light (500, 100, 25 ms) from trials when the light was not illuminated. After reaching criterion performance, rats received infusions into the basal forebrain of saline (n=7) or the immunotoxin, GAT1-saporin (n=8), to lesion noncholinergic neurons. After re-establishing performance after surgery, all rats received systemic administration of the muscarinic receptor antagonist, scopolamine (0, 0.05, 0.20 mg/kg, ip). When attentional testing resumed after surgical recovery, lesioned animals' task performance did not significantly differ from sham-lesioned animals. However, following the highest dose of scopolamine, lesioned animals exhibited a larger decline in signal detection accuracy compared to sham-lesioned animals. Additionally, lesioned animals' omission rate was higher during injection sessions compared to sham-lesioned animals. These results suggest that noncholinergic basal forebrain neurons are not necessary for performance in a well-trained attention task. However, loss of these neurons renders animals' attentional performance more vulnerable to decreased cholinergic system stimulation. Finally, the lesion-induced increase in omissions may reflect a role for noncholinergic basal forebrain neurons in processes beyond attention.

Title: Selective attention independently modulates both spiking correlations and EEG oscillations

Authors: *A. C. SNYDER[1], M. A. SMITH[1,2,3]
[1]Dept. of Ophthalmology, [2]Ctr. for the Neural Basis of Cognition, [3]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Selective visual spatial attention has been studied extensively at quite disparate scales of brain organization, from the large-scale networks observable using scalp EEG recordings in humans to the micro-scale networks of small populations of neurons observable using extracellular recordings with microelectrodes in monkeys. At the large-scale, retinotopic shifts in broad-band response and band-limited responses (e.g., power in the 8-12 Hz "alpha" band) have been linked to shifts in the locus of spatial attention. At the micro-scale, modulations of correlated trial-to-trial spiking variability ("spike count correlation"), consistent with an improvement in information processing, have been reported in monkeys performing a spatial attention task. To date these processes have only been studied independently. However, the fundamental mechanisms of spatial attention must involve the large-scale coordination of distant brain areas to balance the quality of processing in micro-scale circuitry and support goal-directed behavior. Thus, a comprehensive understanding of attention will require bridging these two scales. For this study we combined these two methods for the first time to study selective attention in monkeys, with the aim of relating the attention processes that have been independently studied across scales. We found that the relationship between EEG oscillations measured at the scalp and spike count correlation measured among small populations of neurons was not fixed, but instead varied depending upon the attention state of the animal. This suggests that the attention effects of EEG oscillations are not merely epiphenomenal reflections of underlying changes in spiking correlation, but rather that EEG oscillations and spike count correlation are indexing separable mechanisms of attention. For example, scalp EEG may reflect correlations among different subpopulations of neurons depending on the stimulus or the animal's cognitive state. In addition, the correlations among V4 neurons reflect only a small portion of the broader attentional network in the brain, which consists of vast numbers of neurons spread across numerous distant brain regions. Nonetheless, our findings support the

value of studying attention through the use of concurrent measurements of neural indices of attention across disparate scales.

Title: High-dimensional neural correlates of choice and attention in V4

Authors: *M. J. MORAIS[1,2], A. C. SNYDER[1,3], M. A. SMITH[1,2,3]
[1]Ophthalmology, [2]Bioengineering, [3]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Complex cognitive tasks, such as making decisions in the face of noise and ambiguity, or allocating visuospatial attention, are necessarily accomplished by the concurrent activity of large populations of neurons. Nevertheless, these processes have historically been studied mostly by observing the first-order firing rate statistics of single neurons. In experimental paradigms designed to study movement planning and perceptual decision-making, researchers have recently begun to use high-dimensional analyses to elucidate the coding strategies employed dynamically in the brain during these processes. For this study, our aim was to assay how well these approaches can reveal the mechanisms of spatial attention in an earlier stage of sensory

processing. We recorded populations of neurons using microelectrode arrays in V4 of macaque monkeys in a spatial selective attention task. We then employed targeted dimensionality reduction, a hybrid of principal components analysis (PCA) and multiple linear regression (MLR), to orthogonalize the trial-averaged population data according to particular task variables. Using dimensions associated with the animal's choice along with cue and target characteristics, we showed that differing trial outcomes were associated with differing trajectories through this reduced subspace. For example, when the animal made an incorrect choice given valid cue information, the corresponding neural trajectory reflected less pronounced encoding of cue information. When the animal made a correct decision given invalid cue information, the corresponding neural trajectory diverted mid-trial to reflect nascent encoding of a different target and different impending choice. In this way, trial outcomes were defined not in terms of individual neurons but as states of a larger population. Selective attention coordinates and engages networks of neurons distributed in far-ranging brain regions; as such, the high-dimensional analysis used in this study generalizes to higher-order cognitive phenomena. This indicates that spiking correlates of attention can be investigated in their native high-dimensional spaces in order to more fully characterize how networks of neurons dynamically shift their resources to meet cognitive demands in real time.

Title: Establishment of a touchscreen-based Variable Time Wait Task and Go/No-Go Task for mice to assess behavioral inhibition and sustained attention

Authors: *A. OKADA[1], T. ENDO[1], C. TOHYAMA[1], M. KAKEYAMA[1,2]
[1]Grad. Sch. of Medicine, Univ. of Tokyo, Tokyo, Japan; [2]Dept. of Neurobio. and Behavior, Grad. Sch. of Biomed. Sciences, Nagasaki Univ., Nagasaki, Japan

Abstract: Establishing reliable tests to assess behavioral inhibition and sustained attention in animal models is essential to elucidate the mechanisms of executive function deficits seen in patients with psychiatric disorders, such as attention deficit/hyperactivity disorder (ADHD). Here, we developed the 'Variable Time Wait Task' (VTWT) and 'Go/No-Go' (GNG) task using

a touchscreen device to assess behavioral inhibition and sustained attention in mice. Male C57Bl/6J (B6) mice and DBA/2J (D2) mice aged 10 weeks were tested in a chamber equipped with a touchscreen monitor. In the VTWT, touching a start cue (presented as white cross) initiated the trial, and a reward cue (presented as white panel) was displayed after a random variable blank period (1−3 sec, 3−5 sec, or 1−5 sec). In order to obtain a reward, mice had to withhold touching the start cue during the blank period and then touch the reward cue. In the GNG task, each mouse was assigned a Go or No-go stimulus. The stimulus consisted of either of the following visual cues; black and white stripes with upward motion and a still white windmill on a black background. Each trial is initiated with a start cue, and a Go or No-go stimulus was presented after a blank period. In order to obtain a reward, the mice had to touch the monitor in response to the Go stimulus and withhold touching during the No-go stimulus. In both of the tasks, the rate of correct response to the stimulus and the intra-individual variability of response latency to the reward cue were analyzed as an index of behavioral inhibition and that of sustained attention, respectively. In the VTWT, the B6 and D2 groups were able to wait for maximum duration of 5 sec with a final correct response of 70%. However, the intra-individual variability of response latency to reward cue in the D2 group was significantly greater than the B6 group, indicating decreased sustained attention in the D2 group. In the GNG task, the B6 and the D2 groups had scores from 0−10% (Session 1) to 70% (Final session) in the No-go correct response, while the Go correct response remained constant between 90 to 100% in both groups throughout the sessions. The intra-individual variability of response latency to the reward cue, i.e. Go stimulus, was again found to be significantly greater in the D2 group than the B6 group. In conclusion, our newly-developed tasks allowed us to assess the behavioral inhibition and sustained attention in mice, which are promising methods to elucidate the mechanisms of executive function deficits observed in patients with ADHD and other psychiatric disorders.

Title: Deficits on learing, memory, and attention in Wistar rats submitted to neonatal hypoxic-ischemia procedure

Authors: *L. BIZARRO[1], J. JABOINSKI[1], L. A. ALMEIDA[1], R. DECKER[1], P. MIGUEL[2], R. DIAZ[2], L. ORLANDI[2]
[1]Psicologia do Desenvolvimento e da Personalidade, [2]Ciências Morfológicas, Univ. Federal Do Rio Grande Do Sul, Porto Alegre, Brazil

Abstract: Hypoxic-ischemic (HI) events in neonates are one of the main causes of mortality and biological morbidity, it's implications comprise epilepsy, cognitive and motor deficits and cerebral palsy. The aim of this study was to investigate the effects of hypoxia-schemia on learning, memory and attention in rats. In this study were used Wistar rats (n=22) divided equally between two groups (HI=11 CTR=11). On the 7th post natal day (PND) they were submitted to the experimental HI procedure according to Levine-Rice's protocol. Between the 45th and 52nd PND the animals performed an object and a social recognition task. In the object recognition task we compared the time the animal spent investigating the familiar or the unfamiliar object, and for the social recognition task we compared the frequency of social behaviors directed to the familiar or the unfamiliar rat. From the 60th PND on, a 5-choice serial reaction time task (5CSRTT) was employed to assess visual attention. The animals were trained with food rewards to detect and respond to brief (1s) visual stimuli presented every 5s in one of five holes until a stable baseline was achieved by each rat. After that, four test sessions were performed with shorter stimulus durations (1s, 0.5 s) or manipulations in inter-trial-interval duration (7s, 2s), in a randomized order. HI group presented lower social recognition index ($t(20) = -3,147$, $p=0.005$), but not object recognition index ($t(20) = -1.366$, $p = 0.18$), although it spent less time investigating the objects than the CTR group ($t(20) = -2.885$, $p = 0.009$). The results in 5-CSRTT provided evidence of impairments in the performance of rats from HI group in acquisition of the task ($F(1,20) = 14.89$, $p = 0.001$). Also, in baseline and test sessions, the attentional performance of HI group was characterized by lower accuracy ($F(1,20) = 15.47$, $p = 0.001$), higher premature responding ($F(1,20) = 5.35$, $p= 0.031$) and increased latencies to respond correctly ($F(1,20) = 10$, $p = 0.005$) and to collect reward ($F(1,20) = 12.48$, $p = 0.002$). The only variables that showed main manipulation effects were total session lapse, trials and latency of reward, suggesting that the test conditions hindered the performance of both groups. The interaction between group and manipulation was showed only in omissions $F(4,80) = 3.15$, $p = 0.033$, in which the CTR group omitted more responses when the interval between trials was manipulated (shortened, in this case). The results suggest that neonatal HI events might produce deficits on social interaction, learning, and attention and increase impulsivity in adulthood.

Abstract: The role of norepinephrine (NE) in sculpting representations formed by the hippocampus remains poorly understood. Locus coeruleus (LC) neurons (the source of hippocampal NE input) are activated in response to novelty and induce both transient and long-term potentiation of the perforant path input to the dentate gyrus (DG), enhancing DG throughput. These effects suggest novelty-associated activation of the LC may induce a reset of representations in the DG (remapping), a possible mechanism for initializing new episodes. The distribution dynamics of the mRNA of immediate early genes Arc and zif268, allow us to map the activity history of individual neurons activated within the hippocampus of animals engaged in spatial processing using fluorescence *in situ* hybridization and confocal microscopy. Rats were placed in either (1) same context twice (A/A) or (2) two different contexts (A/B). Prior to placement in the second context, rats were infused bilaterally with glutamate in the LC (phasic activation). In addition, separate groups of rats were infused bilaterally with orexin A or bethanechol, (which increases tonic LC discharge) in order to assess remapping effects in the DG, CA1 and CA3 regions of the hippocampus. Preliminary data show that infusion of substances that up-regulate either tonic or phasic release of NE from the LC can drive remapping in the DG of animals in the A/A condition without affecting A/B animals, consistent with the notion of NE as a novelty "switch" for hippocampal circuits from retrieval to encoding.

Title: Attenuation of high-frequency (50-200 Hz) thalamocortical EEG rhythms by propofol is more pronounced for the thalamus than for the cortex

Authors: S. J. REED, *G. PLOURDE
Dept Anaesthesia, Montreal Neurol Hosp., Montreal, QC, Canada

Abstract: Background. Thalamocortical EEG rhythms in gamma (30-80 Hz) and high-gamma (80-200 Hz) ranges have been linked to arousal and conscious processes. We investigated the concentration-dependent effect of propofol on these rhythms to compare the relative sensitivity of cortex and thalamus. Methods. Adult male Long-Evans rats were chronically implanted with electrodes in somatosensory (barrel) cortex and ventroposteromedial thalamus. Propofol was given in target concentration mode. Spectral power was assessed during baseline, at four stable propofol plasma-concentrations (0, 3,6,9,12 μg/ml) and during recovery over four frequency ranges (30-50, 51-75, 76-125, 126-200 Hz). Unconsciousness was defined as complete loss of righting reflex. Multiple regression was used to model the change of power (after logarithmic transformation) as a function of propofol concentration and recording site. Results. Unconsciousness occurred at the 9 μg/ml concentration in all animals. For the 30-50 Hz range, propofol increased power in the cortex and decreased it in the thalamus. Cortical power in the 76-200 Hz range and thalamic power in the 51-200 Hz range decreased linearly as a function of propofol concentration. In all instances the concentration-effect slope for the thalamus was significantly steeper than for the cortex. Cortical power in the 126-200 Hz range and thalamic power in the 51-200 Hz range were significantly reduced during unconsciousness. The attenuation of cortical power in the 50-200 Hz range during unconsciousness was dependent on the phase of delta (0.5-3.0 Hz) power. Conclusions. Propofol causes a concentration-dependent attenuation of the power of thalamocortical rhythms in the 51-200 Hz range and this effect is far

more pronounced for the thalamus, which also provides a robust correlate of the hypnotic action of propofol.

Title: Sustained auditory attention and response anticipation in a two-alternative choice task, in rats

Authors: *L. F. MARCHELLI, G. F. XAVIER
Departament of Physiologi, Univ. of São Paulo, São Paulo, Brazil

Abstract: This study investigated sustained auditory attention in rats using a 3-hole nose poke operant task. The animals were individuallty trained to insert and maintain their noses within the central hole of the apparatus along the presentation of 4 to 9 "basal" beeps (6 KHz, 70 dB), the number of basal beeps varied unpredictably from trial to trial. Then, upon presentation of a 100-ms duration target beep which frequency could be either 3 or 10 KHz (70 dB), the rats had to remove their noses from the central hole and insert it within one of the lateral holes, left or right, depending on the frequency. The Reaction Time (time elapsed from presentation of the target stimulus up to removal of the nose from the central hole, RT) and Movement Time (time elapsed from removal of the nose from the central hole up to its insertion in one of the lateral holes, MT) were recorded. The ANOVA revealed a significant reduction of the RTs as a function of the number of basic beeps ($F_{5,12}=8.43$, $p=0.00126$); this RT reduction was stronger when the target beep was 10 KHz as compared to when it was 3 KHz ($F_{1,12}=115.70$, $p<0.0005$), i.e., RTs for 10KHZ target beep are bigger than RTs for 3KHZ target beep when the number of basic beeps was smaller than 7 and when the number of basic beeps was greater than 6 RTs were more similar. Relative to the MTs, ANOVA revealed lack of significant differences ($F_{1,12}=1,131$

p=0.3954). In contrast, relative to the percentage of correct responses, ANOVA revealed a significant number of basic beeps effect ($F_{5,12}=3.86$, $p=0.02558$) showing that better performance was achieved when the number of basic beeps presented before the target beep was smaller. Not surprising, this effect is related to a significant increase in the number of anticipation errors as a function of the increase in the number of basic beeps before presentation of the target beep ($F_{5,12}=5.80$, $p=0.00595$). Relative to the number of commission errors, ANOVA revealed lack significant number of basic beeps effects ($F_{5,12}=1.53$, $p=0.25019$). Even though RTs for 3 KHz and 10 KHz target beeps varied differently as a function of the number of basic beeps, data on accuracy of performance indicate that the subjects discriminated these beeps. Together, these results suggest that different behavioral strategies were adopted by the rats depending on the number of basic beeps presented before the target beep. Data suggest that when the number of basic beeps was smaller than 7 the subjects did orient attention to the impending target stimulus. In contrast, when the number of basic beeps was greater than 6, the rats seem to have abandoned orientation of attention and anticipated their response to the impending target, lending to deterioration of performance.

Title: Theta-gamma interactions in monkey visual cortex and their role in selective attention

Authors: *G. SPYROPOULOS[1], C. BOSMAN[2], P. FRIES[1,3]
[1]Ernst Struengmann Inst. For Neurosci. In Co, Frankfurt Am Main, Germany; [2]Cognitive and Syst. Neurosci. Group, Swammerdam Inst. for Life Sciences, Ctr. for Neuroscience, Univ. of Amsterdam, Amsterdam, Netherlands; [3]Donders Inst. for Brain, Cognition, and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: The presence of theta oscillations in the primate visual cortex has been mostly linked to the successful maintenance of tokens in working memory (1,2). Their relation to attention remains, however, unknown. To investigate that relation, we used dense subdural electrocorticography grids (ECoG) in two awake rhesus macaques. In particular, we recorded local field potentials from early (V1) and intermediate (V4) visual areas of the subjects' left

hemispheres while they were performing a selective attention task. LFP power spectra showed a peak in the theta-frequency band (3-5 Hz), predominantly in V1. Attention to the contralateral as compared to the ipsilateral stimulus reduced this theta rhythm. Phase-locking spectra showed a corresponding theta synchronization between V1 and V4, which was reduced by attention in one animal. The phase of V1 theta was correlated with the strength of the local narrow-band gamma rhythm and the V1-V4 gamma locking. The local theta-gamma interaction was reduced by attention. Also, the theta phase modulated the probability of gamma-phase resets, and this relationship was again reduced by attention. Thus, theta-rhythmic resets of the gamma phase were more prevalent in the absence of attention. This pattern of results might be parsimoniously explained by the following scenario: Each stimulus induces local gamma-band activity in V1, which in turn entrains a gamma rhythm in V4 (3). The V1 gamma-band activity is reset rhythmically in the theta-frequency range. This reset temporarily reduces local V1 gamma activity, V1-V4 gamma phase locking, and the corresponding V4 gamma activity. The resulting theta-rhythmic modulation of the local gamma rhythm might actually constitute the theta peak in regular power spectra (similar to the way in which asymmetric alpha oscillations constitute slow potentials - 4). The theta-rhythmic reset affects predominantly the gamma induced by the unattended stimulus, which explains the negative attention effects on theta-rhythmic gamma phase resets, on theta-rhythmic gamma amplitude and thereby theta power itself. Title: Basal forebrain responses to odorants and modulation of olfactory bulb function in mice

Authors: *X. ZHAN[1,2], P.-B. YIN[3], T. HEINBOCKEL[4]
[1]Dept. Physiol. & Biophysics, Howard Univ. Coll. Med., WASHINGTON, DC; [2]Anat. and Neurobio., Univ. of Maryland at Baltimore, Baltimore, MD; [3]Inst. for Systems Res., Univ. of Maryland, College Park, MD; [4]Howard Univ., DC, DC

Abstract: The basal forebrain is thought to be a critical center for attention, but the mechanism remains elusive. We propose that the basal forebrain is responsive to peripheral sensory stimulation, which can in turn modulate primary inputs. We tested this idea by examining olfactory bulb and basal forebrain interactions in two conditions: 1) odorant responses in the nucleus of diagonal band (NDB) and 2) responses to electrical stimulation in the basal forebrain in anaesthetized and awake behaving mice. In anaesthetized preparations, stimulation of NDB induced increased spiking activity in MOB neurons. About half of the units with excitation exhibited rhythmic oscillations, whereas the other units did not. NDB stimulation can change the oscillation frequency. The NDB-responsive neurons were mainly located in the mitral cell, internal and external plexiform layers. Results obtained by recording in awake behaving mice were similar to those in anaesthetized animals, but the excitatory responses were more robust, and more inhibitory units were found. In several units, the effect was attenuated by scopolamine, a competitive mAChR antagonist. We also presented animals with Sharpie alcohol mixtures (n-propanol, n-butanol and diacetone alcohol), which induced excitatory and inhibitory responses. Field potential analysis revealed different oscillation frequency components after the onset of either odorant or electrical stimulation in anaesthetized and awake animals. As basal forebrain has robust projections to the prefrontal cortex, our findings suggest it contributes to a topdown mechanism of attention modulation. In olfaction, it modulates early olfactory processing.

Title: Firing properties and immediate early gene mapping in hippocampal area CA2

Authors: *G. M. ALEXANDER, S. FARRIS, S. M. DUDEK
Natl. Inst. of Envrn. Hlth. Scienc, RTP, NC

Abstract: The function of hippocampal area CA2 in behavior has only recently begun to be assessed. Initial studies suggest that CA2 may function in social processing, as shown by the loss of social recognition memory in both the vasopressin 1B receptor knock-out mice (Wersinger et al., 2002) and in mice with CA2 output silenced by tetanus toxin expressed in CA2 pyramidal cells (Hitti and Siegelbaum, 2014). In addition, CA2 may function in spatial information processing, similar to CA1 pyramidal cells. Support for a role of CA2 in spatial processing comes from a knock-out mouse for regulator of G-protein signaling 14 (RGS14). In these mice, long term potentiation at the Schaffer Collateral-CA2 pyramidal cell synapse, absent from wild-type mice, is revealed. Perhaps as a consequence, these mice also display enhanced performance in the acquisition phase of a spatial memory task (Lee et al., 2010). Based on these findings, we hypothesize that CA2 functions in both social and spatial processing. To test this hypothesis, we have taken two independent approaches of querying CA2 pyramidal cell activity and exposed animals to various stimuli. First, we performed *in vivo* electrophysiological recordings from individual CA2 pyramidal cells in adult male Sprague-Dawley rats and asked how firing rate is affected by behavioral state as well as by spatial navigation, with or without exposure to social stimulation. Second, we exposed a separate group of male Sprague-Dawley rats to identical stimuli, and assessed brain sections for changes in immediate early gene (IEG) expression 5, 15 and 30 min after the exposure. Together, our data show that CA2 pyramidal neurons respond to spatial exploration and that additional social exposure does not enhance IEG expression or firing rate in CA2. Our data do suggest, however, that CA2 firing rate changes depending upon the behavioral state of the animal in a manner that differs from CA1. These results highlight the role of CA2 in processing spatial information but offer no further insights into its role in processing social information. Therefore, modulation of CA2 activity by social stimuli may be more subtle than a general increase in firing rate or may be affected during a later phase of consolidation or recall.

Title: Hippocampal memory codes regulated by NMDA receptor synaptic plasticity

Authors: ***M. LI**[1], H. ZHANG[1,2], H. KUANG[1,2], G. CHEN[1], J. Z. TSIEN[1]
[1]BBDI, Georgia Regents Univ., Augusta, GA; [2]Brain Decoding Ctr., Banna Biomed. Res. Inst., Xi-Shuang-Ban-Na Prefecture, China

Abstract: The CA1 region of the hippocampus is well known to be a crucial site for processing associative memories. From a structural perspective, memory is believed to be the storage of acquired information in a form of synaptic connectivity patterns via by NMDA receptor-dependent synaptic plasticity Here, by applying large-scale neural recording and dimensionality-reduction decoding algorithms, we investigate hippocampal CA1 activity patterns of trace fear conditioning memory code in inducible NMDA receptor knockout mice and their control littermates. Our real-time decoding analyses show that the conditioned tone (CS) and unconditioned foot-shock (US) can evoke hippocampal ensemble responses in control and mutant mice. Yet, temporal formats and contents of CA1 fear memory engrams differ significantly between the genotypes. The mutant mice with disabled NMDA receptor plasticity failed to generate CS-to-US or US-to-CS associative memory traces. Moreover, the mutant CA1 region lacked memory traces for "what at when" information that predicts the timing relationship between the conditioned tone and the foot shock. The degraded associative fear memory engram is further manifested in its lack of intertwined and alternating temporal association between CS and US memory traces that are characteristic to the holistic memory recall in the wild-type animals. We further investigate the electrophysiological properties of the pyramidal cell populations in control and mutant mice, the analyses reveal that the CA1 pyramidal cells in two genotypes show significant differences under various EEG oscillations. Thus, our study provide the first detailed description about how the content and temporal dynamics of real-time memory engrams are organized by the NMDA receptor-mediated synaptic plasticity, and how the responsive properties of hippocampal pyramidal cells change in NMDA receptor knockout animals.

Title: In-vivo predictive relationship from CA1 to CA3 in rodent hippocampus

Authors: *R. SANDLER[1], D. SONG[1], R. HAMPSON[2], S. DEADWYLER[2], T. BERGER[1], V. MARMARELIS[1]
[1]USC, Los Angeles, CA; [2]Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract: Information flow through the hippocampus has traditionally been viewed in the context of the trisynaptic pathway. However, there has long been evidence to support the notion that CA1 may also causally influence CA3 via backprojecting interneurons and feedback connections through the Entorhinal cortex (EC). Many studies have shown this pathway to spread seizures in hippocampal slice preparations. Furthermore, this pathway has been shown to be modified in-vivo depending on the behavioral state of the animal. However, no work has been done to explore the role of this feedback connection on the single neuron level, in the in-vivo nonpatholgical, nonperturbed brain. In order to examine this hypothesis, rodent hippocampal activity was recorded using a multi-electrode array from areas CA3 and CA1 during a behavioral task. Spikes were sorted, time-stamped, and discretized. Multivariate autoregressive (MVAR) models were constructed for all recorded spike trains in both possible directions: from CA3 to CA1 and from CA1 to CA3. Monte Carlo methods were used to prune out all non significant input cells and to remove all non significant models. Altogether, 311 MVAR models were estimated across 7 animals and 9 sessions. Our results showed 121/166 (73%) of CA3→CA1 models and 96/145 (66%) CA1→CA3 models to be significant. These results confirm the existence of a predictive relationship from CA1→CA3 in rodent in-vivo hippocampus on a single neuron level. This predictive 'Granger' style relationship comes from both truly causal connection such as those from the EC and from common inputs such as those from the Septum. A bidirectionally connected hippocampus gives rise to the notion of a hippocampal 'closed-loop' model through which the well-known hippocampal resonant modes can emerge. The feedforward and feedback (autoregressive) parts of all estimated MVAR models were examined in the frequency domain. It was found that CA3 autoregressive kernels had more power in the theta band than those of CA1. This supports experimental findings that CA3 is an endogenous theta pacemaker within the hippocampus. Furthermore, it was found that CA3→CA1 feedforward

kernels had more power in the beta band which suggests that CA3 also transfers information through the beta/low-gamma band.

Title: Memory consolidation during sleep slow oscillations

Authors: ***Y. WEI**, G. PRASHANTH, M. BAZHENOV
Cell Biol. and Neurosci., Univ. of California, Riverside, Riverside, CA

Abstract: Sleep is critical for regulation of synaptic efficacy, consolidation of memories and learning. It has been proposed that synaptic plasticity associated with sleep rhythms could contribute to consolidation of memories acquired during wakefulness. In this study, we present a thalamocortical network model of the slow-wave sleep activity characterized by repeatable (< 1 Hz) transitions between active (Up) and silent (Down) states of the network, to study memory consolidation. The model consisted of thalamic relay (TC) and reticular (RE) neurons; cortical pyramidal neurons and inhibitory interneurons organized within three layers of a cortical column. All neurons were modeled based on the Hodgkin-Huxley kinetics. Spike-timing dependent synaptic plasticity (STDP) was implemented to regulate synaptic efficacy. The network displayed stage 3/4 sleep-like activity with Up and Down states; Up-states were initiated randomly by stochastic spontaneous release in synaptic terminals. When a weak repetitive external stimulation was applied to only a few cells in the cortical network, the spatio-temporal pattern of Up-state propagation became organized. Probability of the Up-states onset near the stimulation site increased even when the stimulus was applied less frequently than a slow oscillation frequency. Because of the refractoriness properties of the network, a probability of the next active state initiation was higher for the network site that initiated activity at the previous cycle of oscillation. When STDP was implemented, there was a net decrease in synaptic strengths and, at the same time, an increase in the strength of specific synapses. The change in

synaptic weights between any two neurons was determined by direction of active state propagation and by distance between the neurons. Our study proposes a mechanism of how interaction between cortically generated slow waves and sparse external input, possibly representing input from hippocampal formation, may lead to reorganization of synaptic strength during stage 3/4 sleep, therefore, influence memory consolidation processes.

Title: Hippocampal ripples as inhibitory transients

Authors: *P. MALERBA[1], G. P. KRISHNAN[1], J.-M. FELLOUS[2], M. BAZHENOV[1]
[1]Cell Biol. and Neurosci., UC Riverside, Riverside, CA; [2]Psychology and Applied Mathematics, Univ. of Arizona, Tucson, AZ

Abstract: Sleep is known to be important for memory consolidation, and memories are thought to be stored in the hippocampus during wakefulness and "transferred" to cortex during sleep. Recently, memory replay - repeated sequences of pyramidal cell firing - has been demonstrated during sleep. Furthermore, sequence replay is associated with characteristic sleep oscillations, and tampering with replay can disrupt memory formation and consolidation. These results give rise to the hypothesis that replay may form the critical neural substrate of memory consolidation, but the mechanisms underlying sequence replay are still unknown. Among hippocampal-specific activity patterns, sharp-wave ripple complexes are brief high-frequency events, during which the firing sequences of previously activated cells are re-played. It is believed that sequence reactivation during ripples contributes to memory formation in the awake state and to memory consolidation during sleep. Ripples in the pyramidal layer of hippocampal area CA1 are believed to be triggered by a generalized excitatory event in area CA3. We develop a computational model of ripple generation to explore hippocampal sequence replay during sleep. Data suggests that during CA1 ripple events only a few pyramidal cells are recruited, and they spike at the peak of the event, while perisomatic interneurons are more broadly recruited and spike across the

duration of the event. In our model, broad generalized excitation from CA3 reaches CA1 cells and organizes the perisomatic interneurons in brief oscillatory transients, capable of sustaining high frequencies (150-200 Hz) only for about 50ms. Such high-frequency firing mediates high-frequency LFP oscillations in pyramidal neurons, and a subset of pyramidal cells is firing within the windows of opportunity left by the inhibitory activity. We compare and validate the properties of ripple generation in our model with data obtained *in vivo* using multi-tetrode recordings from non-anesthetized rats during awake and sleep states. In summary, our study proposes a novel mechanism of hippocampal ripple generation, consistent with *in vivo* data, and predicts a relationship between sequence replay in CA3 and CA1 hippocampal subregions.

Title: Characterization of a continuous sharp wave ripple state in rat hippocampus under isofluorane anesthesia

Authors: *B. R. LUSTIG, Y. WANG, E. PASTALKOVA
Janelia Farm Res. Campus, Ashburn, VA

Abstract: The rat hippocampus has a long history as a model system used in research towards understanding memory. Hippocampal firing patterns during various states of behavior as well as under different forms of anesthesia provide valuable insight into the physiological mechanisms at work in this important brain structure. We found in rats under relatively deep isofluorane anesthesia (~2%), the hippocampus becomes entrained in a state of continuous sharp wave ripples (c-SWR). We carried out electrophysiological recordings using linear silicon probes with 32 recording sites spaced 50 microns apart to characterize the laminar profile of activity during this c-SWR state. During the c-SWR state SWR events in CA1 are composed of a signature sharp wave reversal across stratum radiatum as well as a high frequency ripples in the pyramidal layer. Interestingly these SWR events occur in a continuous repetitive oscillation at a frequency of 10-15 Hz. We found bursts of firing in CA3 preceding many SWRs, consistent with the idea that synchronous firing in CA3 drives SWRs in CA1. In order to explore the mechanisms

involved in the c-SWR state we perturbed the hippocampal circuit using optogenetics. We found optogenetic activation of neurons in area CA3 injected with AAV1-Syn-ReaChr-mCitrine abolished the continuous SWR state while also evoking strong gamma (~50 Hz) oscillations in the stratum radiatum and stratum lacunosum of CA1. These results are in agreement with the idea that precise synchronous firing of CA3 neurons is necessary for the generation of SWRs during the isofluorane anesthesia induced c-SWR. Our results and characterization of the hippocampus under deep isofluorane anesthesia gives new insight into hippocampus under a particular brain state and may provide a useful model preparation for the investigation of physiological mechanisms at work during SWR generation.

Title: Hippocampal theta sequences reflect rats' spatial goals

Authors: *A. WIKENHEISER[1], A. D. REDISH[2]
[1]Univ. of Minnesota, Saint Paul, MN; [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Theta frequency (6-10 Hz) oscillations segment representations in the rodent hippocampus. Spatially-tuned pyramidal neurons (place cells) form temporally-structured spiking sequences bounded by theta oscillations (theta sequences). Theta sequences represent trajectories through space, suggesting an intuitive mechanism for planning and representing future actions. We tested if theta sequence look ahead (the distance that theta sequences extended beyond the rat's position) in dorsal CA1 was modulated by spatial goals. Rats performed a self-motivated foraging task, running laps around a circular track with three evenly spaced feeder sites, each with a unique delay length. Rats ran different patterns of trajectories between sites depending on their delay preferences; from any site, subjects could run to the next site (a one

segment trajectory), skip the next site and run to the feeder after that (a two segment trajectory), or skip the next two sites and complete a lap around the track, returning to the site initially departed from (a three segment trajectory). Theta look ahead was greatest for three segment trajectories, was shortest for one segment trajectories, and was intermediate for two segment trajectories. However, as rats neared their intended site, this effect was abolished, suggesting that look ahead tracked the distance to goals. Increased look ahead predicts that place fields traversed on longer trajectories should be larger, due to earlier activation of cells on approach to those fields. Place fields on three segment trajectories were significantly larger than those passed through on one segment trajectories. This effect also held on a trial by trial basis. The first spike on passes through fields during three segment trajectories occurred significantly earlier in the field than during shorter trajectory passes. The location of the final spike on passes through place fields was also modulated by goal destination, but the effect size was much smaller, suggesting that increased look ahead primarily affected the early portion of place fields, leaving the end intact. Many place cells undergo asymmetric expansion with experience. To test the interaction between expansion and look ahead modulation, we measured the relationship between lap number and place field center of mass, separately for each trajectory type. Expansion predicts a negative slope that is unaffected by current goal, while look ahead modulation predicts that line intercepts should vary with goal. Intercepts, but not slopes, were modulated by goal destination, suggesting that look ahead modulation occurred in tandem with, but separable from place field expansion.

Title: Systemic stimulation of α2 adrenergic receptors with clonidine affects oscillatory activity in the rat hippocampus during a spatial decision-making task

Authors: *S. AMEMIYA, A. D. REDISH
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Hippocampal oscillatory activity is thought to reflect dynamic cognitive processes during decision making. The hippocampus receives innervations of noradrenaline (NA) from locus coeruleus and physiological studies have reported that NA manipulation affects hippocampal oscillations. These data suggest a potential role for NA in hippocampus during decision making, however, few studies have examined involvement of NA in regulation of hippocampal activity during decision making. We examined the influence of the α2 adrenergic autoreceptor agonist clonidine on local field potentials (LFP) recorded from the hippocampal CA1, CA3, and fissure regions from rats running a decision-making task. Rats ran a modified Hebb-Williams maze, consisting of a changeable central path, a final decision point, and rewarded return rails leading to the start of the loop. On each lap, only one side or the other was rewarded. Three reward-contingencies were used: turn left, turn right, or alternate for reward. During the analyzed probe trials, the rewarded rule changed approximately halfway through the session. On this task, particularly after the switch in contingency, rats sometimes pause and orient back and forth at the choice points, a process termed "vicarious trial-and-error" (VTE). To manipulate NA transmission, clonidine (30 μg/kg) or vehicle was delivered intraperitoneally 30 min before the maze session. Oscillations in the theta (4-12Hz), beta (14-29Hz), slow gamma (30-55Hz), mid gamma (60-90Hz), and fast gamma (90-140Hz) ranges were examined. Theta asymmetry has been hypothesized to reflect changes in the phase modulation of oscillations. To measure the asymmetry of each theta wave, we calculated the ratio of the ascending (trough to peak) and descending (peak to trough) parts. Consistent with previous studies, clonidine suppressed the occurrence of VTE-like events. Neurophysiologically, clonidine decreased power in all frequency bands. At the final decision point, control sessions showed a decrease of power in beta and slow gamma oscillations and an increase of power in mid gamma oscillations in VTE-laps compared to non-VTE laps. These changes were suppressed by clonidine. Asymmetry of theta waves also showed position-dependent changes, and theta was more symmetric on VTE laps than on non-VTE laps around the choice point. These differences were decreased by clonidine. Our findings suggest that NA modulates hippocampal processing during decision making.

Title: Task-dependent changes in local field potential (LFP) coordination between orbitofrontal cortex and ventral striatum on contrasting decision-making tasks

Authors: *J. J. STOTT[1], A. P. STEINER[1], Y. A. BRETON[2], A. D. REDISH[2]
[1]Grad. Program in Neurosci., [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Synchronous neural activity is essential for supporting cognition and behavior. Oscillations in local field potentials (LFP) reflect coordination within and between brain areas. In order to study the interactions between brain networks involved in decision-making, we recorded LFP signals simultaneously from dorsal hippocampus (dHC), ventral striatum (vStr), and orbitofrontal cortex (OFC) in rats running different decision-making tasks. One set of rats ran the Spatial Adjusting-Delay Discounting task, which required rats to make binary choices between a small immediate reward and a larger, delayed, reward. Another group of rats ran the Restaurant Row task, in which rats made sequential choices about whether or not to wait through a delay to receive differently-flavored rewards. Power spectral density analyses (PSDs) in vStr showed strong gamma band power in the 50 Hz (γ50) and 80 Hz (γ80) range, consistent with previous reports. PSDs from OFC showed a peak only at γ50 in the Delay-Discounting task, but showed peaks at both γ50 and γ80 in the Restaurant Row task. The dominant frequency in dHC, measured near the hippocampal fissure, was theta (5-12 Hz) in both tasks. Cross-correlograms of LFP power confirmed the presence of fundamental frequencies at γ50 and γ80 in vStr, γ50 in OFC on the Delay-Discounting task, and both γ50 and γ80 on the Restaurant Row task. Additionally, these analyses indicated positive correlations between γ50 power and power in the 25 Hz frequency range in both vStr and OFC, as well as an anti-correlation between γ50 and γ80 power in vStr, similar to that reported previously. Interestingly, the OFC showed a task-dependent difference in its LFP spectra in the γ80 range. While γ80 power was clearly present in OFC on the Restaurant Row task, it was not present on the Delay-Discounting task. As a whole, cross-correlogram plots looked similar between vStr and OFC on the Restaurant Row task, but clearly differed for animals that ran the Delay-Discounting task. These differing 'signatures' in the correlation between frequencies may indicate different cognitive processing modes in the Restaurant Row and Delay-Discounting tasks.

Title: Orbitofrontal inactivation blunts flavor preferences in the Restaurant Row task

Authors: *Y. BRETON[1], B. SCHMIDT[2], A. D. REDISH[2]
[1]Neurosci., Univ. of Minnesota, Saint Paul, MN; [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: We used the Restaurant Row task to infer flavor-based preferences in rats. In this task, rats made stay/skip decisions at each of 4 zones in daily, hour-long sessions. Rats ran clockwise around an octagonal loop with 4 spokes, at the end of which, a feeder provided 2 food pellets of unique flavor (cherry, banana, chocolate, unflavored) after a random, cued delay. Zones were only activated in sequence. As the rat entered each zone, a sequence of tones cued the delay and counted down until a reward was delivered or the rat proceeded to the next zone. Delays of 1 to 30 seconds were presented in pseudo-random order at each zone. The rats' stay/skip decisions at each zone provided a measure of how long they were willing to wait for each flavor. We defined the threshold delay as the delay at which animals were willing to wait for 50% of rewards delivered. We defined decision instability as the proportion of zone entries that were inconsistent with the threshold for each zone. The variance in zone-related thresholds in a session quantified the degree to which flavor impacted stay/go decisions. Designer receptors exclusively activated by designer drugs (DREADDs) provide a means to probe how different brain regions contribute to decision-making. The designer receptor can transfect a spatially restricted region, and the associated designer drug can functionally and reversibly inactivate the transfected cells. This allows animals with unique flavor and amount preferences to serve as their own controls. The role of the orbitofrontal cortex (OFC) in flavor-based decisions is unclear. To examine this question, we analyzed performance on the Restaurant Row task when inactivating lateral OFC with inhibitory DREADDs exclusively activated by clozapine-N-oxide (CNO). We transduced DREADDs to the lateral orbitofrontal cortex (OFC) of 4 Brown-Norway rats. Before every daily session, rats received either 5mg/kg CNO or vehicle control, in experimenter-blind pseudo-random order, for 20 days. Analysis of overall thresholds showed that inactivation of the OFC mildly reduced overall thresholds, but reduced high thresholds to a greater extent than low thresholds. As a result, variance in thresholds reliably decreased. Our analyses showed no significant effect on decision stability. When rats approached zones at which the decision to stay or skip was difficult, they occasionally paused and looked back and forth, a behavior known as vicarious trial and error (VTE). OFC inactivation slightly increased VTE behavior.

Title: Silencing the rat medial prefrontal cortex decreases hesitation and impairs vicarious trial and error (VTE) behavior on the Restaurant Row task

Authors: ***B. SCHMIDT**[1], Y. A. BRETON[2], A. D. REDISH[2]
[1]Neurosci., Univ. Minnesota, Minneapolis, MN; [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: While at a choice point, rodents will often pause and orient towards potential routes, a behavior, termed vicarious trial and error (VTE), indicative of deliberative decision-making. During VTE, place cells in the hippocampus serially sweep forward towards the goal locations, neurophysiologically reflecting future options. Reward responsive cells in the ventral striatum also show firing at the choice point during VTE, neurophysiologically representing future potential rewards. The hippocampus and ventral striatum are both functionally and anatomically connected to the medial prefrontal cortex (mPFC). Although the hippocampus and ventral striatum show distinct neurophysiological activity during VTE, it remains unknown what role the mPFC plays during VTE. In order to examine the role of mPFC in VTE, we transduced DREADDs into the mPFC of rats and allowed them to run the Restaurant Row task. DREADDs are a state of the art, chemical-genetic method of silencing neurons by transducing a genetically modulated designer G-protein coupled receptor. DREADDs are solely activated by a systemic injection of the pharmacologically inert compound clozapine-N-oxide (CNO). DREADDs allows for a favorable temporal and spatial resolution for chronic, non-invasive, neuronal silencing. mPFC-DREADD transduced rats were trained on the spatial neuroeconomic task Restaurant Row. This task revealed individual preferences of reward flavor, the identification of value for each flavor and the cost the rat was willing to exert to receive it. On the Restaurant Row task rats ran on a circular maze with four evenly spaced spokes. At the end of each spoke, one of four different food rewards (cherry, banana, chocolate, unflavored) could be delivered. Each flavor was delivered at only one location. When the rat passed a spoke, a tone started to count down to

indicate the delay required before the reward would be dispensed. Delay at each encounter was selected independently from all other delays, spokes were only triggered in a clockwise order. The rats therefore encountered a serial set of choices of whether to wait out the delay for the food reward or skip the choice and move on to the next reward site. mPFC-DREADD transduced rats (n=4) given CNO showed reduced VTE behavior on the Restaurant Row task. Flavor preference was determined from the decision thresholds. CNO had no effect on flavor preferences for different food reward. CNO did increase decisive behavior by reducing the hesitation time before a decision was made. These behavioral data suggest that silencing the mPFC with CNO impairs deliberative decision-making in DREADDs transduced rats.

Title: Translating from rats to humans: A human foraging model of decision making

Authors: S. V. ABRAM[1], A. MACDONALD, III[2], *A. D. REDISH[3]
[1]Grad. Program in Psychology, [2]Psychology, Univ. of Minnesota, Minneapolis, MN; [3]Dept. Neurosci, Univ. Minnesota, MINNEAPOLIS, MN

Abstract: Translating animal models of decision-making for human use is difficult because of the different ethologies of different species. Typical temporal discounting paradigms require a forced-choice between two reward options of different value that are available at disparate time delays; however, these tasks fail to capture the dynamic nature of real-world scenarios that likely entail a series of stay/go decisions. Here, we extend the “Restaurant Row” task, in which rats encounter a series of flavored-food-locations (restaurants) and have the option of waiting out a signaled delay or skipping on to the next opportunity. Instead of food, human subjects foraged for information through an internet-like interface. This “Web-Surf” task allotted participants (N=38) 30 minutes to forage through four video galleries, each presenting a 4s clip from one of

four desirable categories (kittens, dance, bike-accidents, landscapes) as reward. Upon arrival at each gallery, subjects were informed of the delay before stimulus presentation. They then had the option to stay and wait for the video or skip on to the next gallery. Viewed videos were rated on a 1-5 scale with 5 being the highest. When transitioning between galleries, subjects clicked a series of "NEXT" buttons that were randomly positioned around the screen; this served as an analogue to the cost rats encounter when physically running a track between feeders. We assessed revealed preferences by calculating thresholds via fitting sigmoid functions. We then examined to what extent these thresholds (revealed preferences) correlated with average category ratings (stated preferences) to assess the face validity of the task. Revealed preferences corresponded with average ratings, with 78% of correlations above 0.50. Similarly, 68% of correlations between revealed preferences and post-test category rankings were above 0.50. Gender differences across certain categories were evident by thresholds and average category ratings: males consistently waited longer for bike-accident videos ($F[1,33] = 8.370$, $p < 0.01$) and landscape videos ($F[1,33] = 3.885$, $p = 0.057$). Similarly, males generally rated videos in these categories higher, bike-accident videos ($F[1,26] = 1.802$, $p = .19$), landscape videos ($F[1,26] = 16.118$, $p < 0.01$). Genders did not differ in preference for the animal or dance video categories.

Title: Does place field repetition impair spatial learning?

Authors: R. M. GRIEVES[1,2], B. W. JENKINS[2], E. R. WOOD[2], *P. A. DUDCHENKO[1,2]
[1]Univ. Stirling, Stirling, United Kingdom; [2]Ctr. for Cognitive and Neural Systems, Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Hippocampal place cells fire when an animal is in a particular area of an environment and are generally thought to support spatial cognition. Recently, Derdikman et al. (Nat Neurosci 12:1325-32 2009) showed that in a hairpin maze composed of a series of parallel alleyways,

place cells (and grid cells) tend to fire in multiple alleyways and at approximately the same spatial location relative to the boundaries of each alleyway. Spiers et al. (Cereb Cortex 2013 doi: 10.1093/cercor/bht198) found similar "place field repetition" as rats explored a multi-compartment environment composed of 4 identical parallel boxes connected by a corridor. This raises the question as to whether, under conditions in which place field repetition between compartments is observed, animals can discriminate between the compartments, or be trained to do so. We tested whether rats (n=6) could learn a spatially-guided odour discrimination task in an environment similar to that used by Spiers et al., with 4 boxes arranged parallel to each other. A second group of rats (n=6) was trained in the same environment with the 4 boxes arranged in a semi-circular formation to provide directional information; in this environment we would not predict place field repetition. In each box, 4 bowls of sand, each scented with a different spice were available. One of the 4 bowls of sand in each box was baited with a reward, and a different bowl was rewarded in each of the 4 boxes. Training was carried out in 3 stages. In the first stage, 2 boxes and 2 scents were used, and the rats were trained for 12 trials a day (6 in each box) until they chose correctly on 5/6 trials in both boxes (83%) on 2 consecutive days. The second stage involved 3 boxes and 3 odours, and the final stage involved discriminating between all 4 boxes and all 4 odours. All rats trained in the semi-circular configuration learned the task readily, taking 27 ± 4.9 (mean ± SD) sessions to complete all 3 stages. In contrast, the rats in the parallel configuration were significantly impaired; after 50 days of training, only 1 rat had reached criterion at all 3 stages (taking 50 days to do so). A further 2 rats had reached criterion at the 2 and 3 box stages, and the remaining 3 rats had reached criterion only at the 2 box stage. These results suggest that rats have difficulty discriminating environments in which place field repetition occurs. This difficulty increases with the number of compartments; however, with extended training some discrimination is observed. In contrast, spatial learning occurs rapidly in compartments that are oriented in different directions. Future experiments will test whether learning in parallel compartments elicits a more global place cell representation.

Title: Exploring the effects of disrupting the nucleus reuniens in rats on performance of hippocampus-dependent tasks

Authors: E. ALLISON[1], T. RIPARD[1], G. YUKHNOVICH[1], P. A. DUDCHENKO[3,1], *E. R. WOOD[2,1]
[1]Ctr. for Cognitive and Neural Systems, Univ. of Edinburgh, [2]Univ. of Edinburgh, Edinburgh, United Kingdom; [3]Sch. of Natural Sci., Univ. of Stirling, Stirling, United Kingdom

Abstract: The nucleus reuniens is thought to be a major route of information flow from the prefrontal cortex to the hippocampus because it is the site of a one synapse connection between the two areas. In addition, lesions or optogenetic inactivation of the nucleus reuniens cause a reduction in trajectory-dependent activity in hippocampal CA1 place cells (Ito et al. SFN 2013. Poster 769.11). Lesions of the nucleus reuniens might therefore block the prefrontal cortex input to the hippocampus, and reduce trajectory-dependent activity in the hippocampus. We tested whether the nucleus reuniens is necessary for acquisition and performance of a hippocampus-dependent task in which trajectory dependent place fields are observed. After lesioning the nucleus reuniens using ibotenic acid, we trained rats on a win-stay, lose-shift task in a double Y maze. The acquisition of this task is known to be hippocampus dependent. The reuniens lesion animals showed no differences in accuracy during acquisition or performance compared to sham operated control rats. This is surprising as it suggests that decreasing trajectory-dependent activity in CA1 place cells may not disrupt the ability of animals to learn the task. The double Y maze task could be solved either egocentrically or allocentrically, which may allow animals to compensate for any deficits. To test for deficits in allocentric navigation, we trained animals on a reference memory task in a water maze followed by a reversal of the platform location. Animals in the lesion group showed a significant initial impairment in learning the allocentric task but their performance was comparable to that of the control group after 3 days and there were no differences between groups during a reversal of the target location. Our findings are consistent with a role for the nucleus reuniens in the selection or performance of an allocentric navigation strategy, but suggest that it is not required for applying this strategy when the platform location is moved. Moreover, they suggest that any effects of nucleus reuniens lesions on the trajectory-dependent activity of place cells do not lead to impairments in a hippocampus-dependent win-stay, lose-shift task in which trajectory-dependent activity is normally observed. These findings suggest that prefrontal inputs to the hippocampus via the nucleus reuniens are not required for this task.

Neuroanatomy, Goethe-University, Frankfurt, Germany

Abstract: To investigate whether selective synaptic activities are required for the maintenance of a memory trace, we developed and applied a method called virus-delivered inducible silencing of synaptic transmission (vINSIST). Our vINSIST method is based on a novel destabilized tetanus toxin light chain variant (dsTeTxLC) with a very short half-life time (roughly 3 minutes for the new variant and roughly 6 days for the original one). The steady-state levels of dsTeTxLC are more than 2000-times lower than the original TeTxLC. We developed recombinant adeno-associated viruses (rAAVs) equipped with chemically-controlled genetic switches for inducible and reversible expression of the dsTeTxLC in the dentate gyrus (DG) granule cells of rabbits. Trace eyeblink conditioning consisting of a tone followed by an air-puff to the cornea of the eye with a 500 millisecond temporal interval resulted in robust memory formation for the conditioned eyeblink responses to the tone alone. *In vivo* electrophysiological recording of the DG-CA3 synapse in rabbits during the trace conditioning sessions, lasting several days, showed learning-dependent increases in both field excitatory field potentials (fEPSP) and conditioned eyeblink responses. After 'trace' eyeblink conditioning, we specifically silenced synaptic transmission (ST) of the DG mossy fiber (DG-MF) input onto CA3 neurons. As expected,

conditioned eyeblink responses to a tone were impaired after silencing of ST, and there were large decreases in fEPSP. However, after un-silencing of ST, we discovered that both fEPSP and memory retrieval were fully recovered. These results suggest that in spite of prolonged silencing of the ST, the previously formed memory trace was not lost; without evoked activity for a few days, the memory trace was fully recovered after unsilencing of ST. Consistent with published findings by the Delgado-Garcia lab, low TeTxLC expression induced a reduction in the pre- and postsynaptic markers of the DG-CA3 synapse; VGlut and PSD95 puncta corresponding to the DG-MF boutons and CA3 spines were both reduced by more than 30% and 20%, respectively. Preliminary results with long-term imaging of DG-MF boutons in organotypic cultures before and after silencing of ST show that the distribution of DG-MF boutons remain stable throughout a period of several days. With large reduction in VGlut and PSD95 puncta after silencing of ST, it is possible that there is a strong reduction in the synaptic weight parameters. It is thus tempting to speculate that after silencing of ST, memory trace for the conditioned eyeblink response can be re-assessed with a reorganized assembly of synaptic weights.

Title: Large environments reveal the statistical structure governing hippocampal representations

Authors: ***P. RICH**, H.-P. LIAW, A. K. LEE
Janelia Farm, Ashburn, VA

Abstract: The rules governing the formation of spatial maps in the hippocampus have not been determined. We recorded hippocampal neurons from rats exploring a novel, 48-meter-long track, exposing the large-scale structure of place field activity. Single-cell and population activity was well-described by a simple, two-parameter stochastic model. Individual neurons had their own characteristic propensity for forming fields randomly along the track, with some cells expressing

many fields and many exhibiting few or none. Due to the particular distribution of propensities across cells, the number of neurons with fields scaled logarithmically with track length over a wide, ethological range. These features constrain hippocampal memory mechanisms, may allow efficient encoding of environments and experiences of vastly different extents and durations, and could reflect general principles of population coding.

Title: Hippocampal memory prosthesis: Enhancing nonlinear dynamical identification of spike-timing-dependent plasticity

Authors: *B. S. ROBINSON, D. SONG, T. W. BERGER
Biomed. Engin., USC, Los Angeles, CA

Abstract: Insights into learning and memory can be gained with characterization of the activity-dependent requirements for persistent synaptic plasticity. There is evidence that the relative timing of pre-synaptic and post-synaptic spiking affects synaptic plasticity, however there are still many questions as to the nature of this relationship, especially in the mammalian brain during behavior. Here, we develop and analyze a framework to estimate the functional spike-timing-dependent plasticity (STDP) relationship from in-vivo behavioral spiking data. To assess the framework's estimation ability, we first simulate a model of a stochastic spiking neuron model with a pair-wise STDP learning rule. Subsequently, we analyze estimation feasibility of all model functions and parameters from spike timings. Resampled recorded hippocampal CA3 spiking data is used as input into the neuron model. For the STDP learning rule, the function of synaptic weight change vs. pre and post-synaptic inter-spike interval is not enough for full representation. In a STDP system with physiological input spike timing, the actual weight fluctuations and the stability of the system are dramatically affected by time course of plasticity

induction, weight saturation, and spike pairing scheme (all-to-all or nearest neighbor). We therefore additionally included a function for a realistic time course of plasticity induction, implemented a multiplicative weight saturation scheme, and simulated both all-to-all and nearest neighbor spike pairing schemes. All model functions and parameters were formulated and statistically estimated with Volterra kernels, basis function expansion and generalized linear model techniques from the modeled spike timings. Results demonstrate robust estimation of the pair-wise STDP function, as well as the plasticity induction time course. Accurate STDP function estimation was also reliable across spike pairing schemes, use of multiple inputs, and nonlinear multiplicative weight saturation. Furthermore, the amount of data necessary for the STDP function estimation was found to be three times as long for the nearest neighbor vs. all-to-all spike pairing schemes. The next logical step is to apply this estimation framework to in-vivo spike data from a learning task. Findings from such future studies could reveal insights into the activity-dependent nature of synaptic plasticity and be incorporated in the next-generation cortical prosthesis.

Title: Hippocampal memory prosthesis: Decoding and restoring hippocampal spatial memories with nonlinear dynamical modeling

Authors: *D. SONG[1], M. HARWAY[1], V. Z. MARMARELIS[1], R. E. HAMPSON[2], S. A. DEADWYLER[2], T. W. BERGER[1]
[1]Biomed. Engin., Univ. of Southern California, Los Angeles, CA; [2]Wake Forest University, Sch. of Med., Winston-Salem, NC

Abstract: To build a cognitive prosthesis that can replace the memory function of the hippocampus, it is essential to model the input-output function of the damaged hippocampal region, so the prosthetic device can stimulate the downstream hippocampal region, e.g., CA1, with the output signal, e.g., CA1 spike trains, predicted from the ongoing input signal, e.g., CA3

spike trains, and the identified input-output function, e.g., CA3-CA1 model. In order for the downstream region to form appropriate long-term memories based on the restored output signal, furthermore, the output signal should contain sufficient information about the memories that the animal has formed. In this study, we verify this premise by applying regression and classification modelings of the spatio-temporal patterns of spike trains to the hippocampal CA3 and CA1 data recorded from rats performing a memory-dependent delayed nonmatch-to-sample (DNMS) task. The regression model is essentially the multiple-input, multiple-output (MIMO) nonlinear dynamical model of spike train transformation. It predicts the output spike trains based on the input spike trains and thus restores the output signal. In addition, the classification model interprets the signal by relating the spatio-temporal patterns to the memory events. We have found that: (1) both hippocampal CA3 and CA1 spike trains contain sufficient information for predicting the locations of the sample responses (i.e., left and right memories) during the DNMS task; and more importantly (2) the CA1 spike trains predicted from the CA3 spike trains by the MIMO model also are sufficient for predicting the locations on a single-trial basis. These results show quantitatively that, with a moderate number of unitary recordings from the hippocampus, the MIMO nonlinear dynamical model is able to extract and restore spatial memory information for the formation of long-term memories and thus can serve as the computational basis of the hippocampal memory prosthesis.

Abstract: Early life experiences affect brain development and the appearance of neuropsychiatric disorders, which are often characterized by sex differences. Environmental enrichment (EE) has beneficial effects on brain plasticity and has been proposed as therapeutic intervention. Although brain connectivity and function exhibit marked sex differences, little is known about sex-related responses to beneficial EE stimuli. Our previous studies show that early exposure of male and female rats to EE resulted in enhanced serotonergic and dopaminergic activity and histamine modulation in their visual system,1,2. Herein, we investigate sex differences on cognitive performance and underlying neurochemical and molecular changes related to neuronal and synaptic structure and function. Forty-nine male and female Wistar rats were reared in a standard or enriched environment from P0-P90 and then subjected to the open field and novel object recognition tests. Hippocampus and prefrontal cortex (PFC) were used for: i) evaluation of serotonergic, dopaminergic and glutamatergic neurotransmission by HPLC-ED2 ii) molecular analysis of different cytoskeletal and synaptic proteins by immunoblotting. While corticosterone levels were marginally increased after EE in males only, we found no EE effects in the open field. Following EE, both sexes showed increased preference for a novel object. EE decreased glutamate levels in the female hippocampus and increased the serotonergic 5-HIAA/5-HT ratio in both hippocampus and PFC in comparison to control females. Interestingly, these EE effects on glutamate and serotonin were not found in males. In addition, EE enhanced the hippocampal dopaminergic DOPAC/DA ratio in both sexes. Western blot analysis of cytoskeletal and synaptic proteins revealed significant Sex x EE interactions for phosphorylated isoforms of the cytoskeletal protein Tau and NMDA receptor 2B in males and for synaptic protein PSD95 and p35/25, the activator of kinase cdk5, in females. While males had higher hippocampal levels of 5-HT1A than females, EE reduced them in both sexes. Present findings provide new insights into sex-specific molecular and neurochemical adaptations that underlie the cognitive-enhancing effects of EE. References 1.D. P. Bessinis, C. Dalla, Z. Title: Ionotropic glutamate receptor activity within the ventral tegmental area is required for the expression of ethanol conditioned place preference

Authors: *M. M. PINA, C. L. CUNNINGHAM
Behavioral Neurosci., OHSU, Portland, OR

Abstract: Exposure to drug-associated cues triggers the activation of excitatory inputs to midbrain dopamine (DA) cells that are believed to drive motivated behaviors such as drug seeking. Previous studies have demonstrated that blocking ionotropic glutamate receptors (iGluRs) within the ventral tegmental area (VTA) impairs the expression of conditioned place preference (CPP) with several classes of abused drugs. However, few studies have evaluated the contribution of intra-VTA iGluRs in ethanol-induced CPP. The present study assessed the role of intra-VTA iGluRs AMPA and NMDA activation in ethanol CPP expression. Under stereotactic guidance, adult male DBA/2J mice (n = 96) were implanted bilaterally with guide cannula aimed at the medial VTA and given 3-5 days to recover prior to the start of conditioning procedures. A two-compartment unbiased place conditioning procedure was used, where ethanol (2 g/kg) was paired with a distinct tactile cue. Conditioning sessions were run twice daily, with saline (CS-) trials occurring in the morning and ethanol (CS+) trials in the afternoon. Trials were conducted across two days for a total of two sessions of each type (2 CS+ and 2 CS-) and the place preference test was administered 24 h after the final conditioning session. Antagonists selective for AMPA/kainate (DNQX) and NMDA (D-AP5) were co-administered into the VTA immediately before the preference test. CPP expression was disrupted in animals that received intra-VTA infusions of the DNQX and D-AP5 cocktail in two different dose combinations ($p < 0.05$ for each dose). Increased ambulation was observed only at the higher doses of DNQX and D-AP5 (0.005 + 0.5 μg/side; $p < 0.05$) and not at the lower doses (0.001 + 0.1 μg/side) compared to vehicle-infused control mice. These results suggest that disrupted ethanol CPP expression was not due to a nonspecific effect of iGluR antagonism on activity. Our findings indicate that activation of NMDA and AMPA receptors within the VTA modulates the expression of ethanol-

induced CPP. This work further supports the hypothesized role of intra-VTA glutamate signaling in conditioned reward and drug-seeking behavior. Combined with the literature, this work suggests that glutamatergic afferents of the VTA may be appropriate targets for treatments designed to reduce the cue-induced seeking behavior that contributes to relapse.

Title: Lycopene attenuates insulin resistance associated cognitive deficits in rats

Authors: *A. K. SACHDEVA, **K. CHOPRA**
Pharmacol., Panjab Univ., Chandigarh, India

Abstract: BACKGROUND Growing evidence supports the concept that Alzheimer's disease is fundamentally a metabolic disease. Epidemiological studies on cognitive impairment in patients with diabetes found evidence of cross sectional and prospective associations between type 2 diabetes and moderate degree of cognitive impairment, both for memory and executive functions. Several studies suggest that consumption of a fat rich diet leads to peripheral insulin resistance and impedes cognitive performance. Thus, the present study was designed to elucidate the role of NF-κB pathway in neuroprotective effect of lycopene in an experimental paradigm of insulin resistance in rats. METHODS Six-week-old male Wistar rats were fed with 15% fructose in drinking water for 24 weeks. Body mass, food and water intakes were measured regularly as well as plasma insulin levels, blood glucose levels, glycosylated heamoglobin levels, HOMA-IR levels and lipid profile levels were measured to ensure development of insulin resistance . Insulin resistance associated cognitive impairment was measured by using Morris water maze test (computer tracking using EthoVision software) and elevated plus maze on 24th week. Treatment with lycopene (1, 2 and 4 mg/kg) was initiated after 6th week of fructose administration and continued till end of the study. At the end of study, animals were sacrificed for estimating biochemical and molecular parameters. RESULTS Insulin resistance was evident at 6th week and persisted till end of study (24th week) as demonstrated by significant increase in body weight, plasma insulin levels, blood glucose levels, glycosylated heamoglobin levels, HOMA-IR levels and deranged lipid profile. Cognitive deficit was significantly evident at 24th weeks.

Fructose-induced neuronal deficits were coupled with significant alterations in oxidative-nitrodative stress along with suppression of NF-κB and its downstream mediators as TNF-α, TGF-β1, caspase-3 and IL-1β levels. Treatment with lycopene (1, 2 and 4 mg/kg) dose-dependently ameliorated emergence of insulin resistance-induced memory impairment along with mitigation of oxido-nitrosative stress mediated alterations in cytokine levels. CONCLUSION These findings indicate that chronic fructose consumption generated a condition of neuronal insulin resistance coupled with oxidative stress and neuroinflammation leading to cognitive deficits. Lycopene dose-dependently ameliorated these changes possibly through inhibition of NF-κB signaling cascade.

Title: Effect of kappa opioid modulation on forebrain dependent trace associative learning: An eyeblink conditioning analysis

Authors: *R. LOH[1], S. SHAH[2], R. GALVEZ[3]
[2]Mol. and Cell. Biol., [1]Univ. of Illinois: Urbana-Champaign, Urbana, IL; [3]Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: There have been several findings indicating a primary role for the opioid receptor system in the modulation of learning and memory. Spatial tasks, fear conditioning, and y-maze spontaneous alternation have all demonstrated that opioid modulation can impair task acquisition. We have recently demonstrated that administration of the opioid antagonist, naloxone, prior to training also retards the ability of mice to acquire whisker-trace eyeblink (WTEB) associations. However, Naloxone, at the concentration used fully antagonized all opioid receptor subtypes, thus the specific opioid receptor mediating this effect for WTEB is not known. Much of the current literature investigating opioid effects in learning and memory have focused on the mu opioid receptor; however, several reports have indicated that there is a likely role for the kappa opioid receptor in various behavioral learning paradigms. The following analysis utilized WTEB to examine the role of the kappa opioid receptor in forebrain-dependent trace associative learning. In WTEB, animals are trained to associate whisker stimulation (CS) with a

salient unconditioned stimulus (US) that causes an unconditioned response. After several trials in which the CS is paired with the US, the animal begins to exhibit a conditioned response in anticipation of the US. Separating the CS and US with a stimulus free trace interval makes this paradigm forebrain dependent by recruiting higher brain structures such as the hippocampus and neocortex. In the following study adult male C57BL/6J mice were randomly assigned to either (0, 2.5, 5.0, or 10mg/kg) doses of the kappa opioid antagonist NorBNI, or (0 or 5.0mg/kg) dose of the kappa opioid agonist u50,488h. Mice were then trained on WTEB. The 10mg/kg of NorBNI significantly retarded learning relative to saline controls, suggesting that the kappa opioid receptor is involved in the acquisition of forebrain-dependent associative learning. Interestingly, kappa agonist u50,488h did not show a significant effects on learning. This could likely be due to one of several factors unrelated to kappa modulation; such as potential limitations in the behavioral paradigm used. These data suggest that the kappa opioid receptor plays a role in acquisition of forebrain dependent trace associative learning. Further research will focus on determining the specific brain region and mechanism by which kappa is driving this effect.

Title: Can environmental enrichment alleviate adult learning impairments caused by adolescent nicotine exposure in rats?

Authors: *S. M. RENAUD, M. E. MILLER, S. B. FOUNTAIN
Psychology, Kent State Univ., Kent, OH

Abstract: Research has shown that adolescent nicotine exposure causes learning impairments in adult rodents. For example, adolescent nicotine exposure in rats produces sex-specific impairments of serial pattern learning in the serial multiple choice (SMC) task in adulthood (Pickens, Rowan, Bevins, & Fountain, 2013). Environmental enrichment, on the other hand, has been shown to reduce behavioral and cognitive deficits caused by aging or neurotoxins (Frick & Fernandez, 2003; Mesa-Gresa, Ramos-Campos, & Redolat, 2014). This study was designed to determine if exposure to enrichment could alleviate learning deficits in the SMC task caused by

adolescent nicotine exposure. To this end, female rats were randomly assigned to one of three conditions: no nicotine and no enrichment (control), nicotine with enrichment, and nicotine without enrichment. On postnatal days 21-89 (P21-89), rats experienced either an enriched environment or a standard environment. Environmental enrichment consisted of access to a running wheel, small hiding places, and toys to manipulate and chew. Enrichment was varied weekly so that cages always had 3 different toys and the same toys would not be encountered again for 3 weeks. The standard environment was never changed. On P25-59, all rats received twice-daily injections of 1.0 mg/kg nicotine or saline. Beginning on P90, enrichment was discontinued. On P90-95, rats were shaped to nose-poke for water. On P96-141, in the SMC task rats learned to nose poke receptacles on the 8 walls of an octagonal chamber in the pattern, 123-234-345-456-567-678-781-818, where digits represent the clockwise position of successive correct receptacles in the circular array and dashes indicate brief pauses. Rats had 90 minutes to complete up to 20 patterns daily for 900 total patterns. The pattern consisted of three element types, namely, within-chunk, chunk-boundary, and violation elements, used to assess different learning mechanisms. Adolescent nicotine exposure impaired chunk-boundary element acquisition. No effect of enrichment was found for any element type. Planned comparisons showed that nicotine with enrichment rats performed significantly worse on chunk-boundary elements than nicotine without enrichment rats on days 3-5, 7, 29, and 32 of acquisition. Thus, enrichment that did not facilitate pattern acquisition in rats not exposed to nicotine (see accompanying poster) also did not alleviate the deficits in serial pattern learning caused by adolescent nicotine exposure. It is possible that under conditions where enrichment does facilitate learning in rats not exposed to nicotine, enrichment might then alleviate nicotine effects.

Title: Interactions of behavioral training and ketamine administration on changes in parvalbumin positive neurons

Authors: *M. M. BOLTON, C. F. HEANEY, A. S. MURTISHAW, M. A. LANGHARDT, J. W. KINNEY
Psychology, Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: Ketamine is a high affinity non-competitive antagonist of the ionotropic N-methyl-D-aspartate (NMDA) glutamate receptor. Several previous investigations in our laboratory using chronic (15 days) subanaesthetic administration of ketamine have demonstrated learning and memory deficits in rodents. We have also repeatedly observed an increase in the number and altered position of parvalbumin (PV) positive neurons in the CA3 field of the hippocampus in ketamine treated animals. In our previous investigations, animals were being tested in behavioral tasks over successive days of ketamine administration. In order to determine if behavioral engagement during ketamine administration is necessary for the increase in PV neuron number or altered position, we performed no behavioral testing over 15 days of treatment and evaluated PV number and position. In addition, our timeline of the change in PV neuron number may be related to recent data indicating an antidepressant role of ketamine. Numerous recent clinical studies have demonstrated a rapid-acting antidepressant effect of subanaesthetic ketamine. There is also a growing literature that indicates the antidepressant effects of ketamine are lost following multiple infusions. There are limited data on the mechanisms responsible for both the antidepressant effects as well as the loss of these effects. In the current study, we were interested in if the change of PV neuron number and position observed in previous studies may influence antidepressant like behavioral changes due to ketamine. We performed the forced swim test to the groups of rats receiving 15 days of saline or ketamine. Results indicate that chronic ketamine administration without behavioral testing did not result in an increase in the number of PV neurons. Similarly, no differences in PV neuron position was observed in these studies. These data indicate that behavioral engagement throughout the course of ketamine administration is necessary in order to alter PV neuron number and position. In addition, our data demonstrate that in the absence of the change of PV neuron number chronic ketamine increased struggle time in the forced swim test versus controls.

Title: Relationship between astrogliosis in hippocampal formation and neural plasticity induced by acute treatment with Ginkgo biloba and acquisition of fear memory

Authors: M. A. S. TILGER, C. R. ZAMBERLAM, R. F. SILVA, *S. M. CERUTTI
Biol. Sci., Univ. Federal De Sao Paulo, Sao Paulo, Brazil

Abstract: The brain's ability to adapt and change its structure, connectivity and functional properties over time characterizes neural plasticity, which can be investigated using different approaches. Memory formation has been recognized as a stimulant of brain plasticity, which is often characterized by neuronal and glial adaptations. Our group has been evaluated neural plasticity by means of the analysis of behavioural and morphological correlates. The present study investigated the astroglial reaction employing glial fibrillary acidic protein immunohistochemistry (GFAP-IR) in the hippocampal formation. (CA1, CA3 and GD) with one dose before fear conditioning of EGb (250 mg/Kg, 500 mg./Kg and 1000 mg/Kg),vehicle (Tween® and Saline), agonists (10.0 mg/Kg Buspirone or 10mg/Kg N-methyl D-aspartate), antagonists (0.3 mg/Kg (S)-WAY 100135 or 3.0 mg/Kg Ro25-6981) of the 5-HT1ARs or NMDARs/GluN2B and antagonists+EGb ((S)-WAY+EGb or Ro+EGb) (n=3/group). Further, negative control groups (saline 0.9% i.p. and Tween 80 12% v.o.), no-footshock group (CS) and conditioned group (CS-US association) were used. Twenty-four hours after the behavioral experiments were performed, the rats (n=3/group) were deeply anesthetized and perfused with 4% paraformaldehyde. After decapitation, the brains were removed, post fixed, cryoprotected in 10% sucrose, frozen and stored at -80ºC until use. Adjacent serial 20-µm-thick coronal brain sections were obtained with a cryostat and mounted on gelatin-coated slices. These sections integrated two levels including formation hippocampal rostral and caudal (coordinates -2.04 to-4.20 mm from bregma). At each region, 4 fields were analyzed bilaterally. Images were acquired using AxioVision software (Carl Zeiss, Axion imager A2). ImageJ software was employed for quantification of the immunoreactive labeling in CA1, CA3 and GD. An increased number of GFAP-IR astrocytes were found in the CA1, CA3 and GD ($P<0.05$) of the EGb groups. GFAP-IR was increased in the CA3 and GD in Buspirone group ($P<0.05$). However, no significant changes were observed to NMDA groups ($P>0.05$). Additionally, the overexpression of GFAP was reversed by treatment with (S)-WAY 100135 or Ro25-6981 prior EGb. Our results provide further evidence that astroglial reaction in the hippocampal formation may be involved in neuroplastic response in those regions. The fear memory/treatment-dependent changes suggest that EGb might be effective for memory enhancement through its effect on the astrocytes cells which seems to be modulate by NMDA-type of glutamate as well as by serotoninergic-type 5HT1A receptors.

Title: Maintenance of memory functions by chronic administration of cilostazol, a phosphodiesterase 3 inhibitor, in aged mice models

Authors: ***S. YANAI**, K. KOJIMA, T. ARASAKI, S. ENDO
Tokyo Metropolitan Inst. of Gerontology, Tokyo, Japan

Abstract: The balance between adenylate cyclase and phosphodiesterases (PDEs) controls concentration of cAMP to modulate a variety of physiological functions including learning and memory. Thus, PDE inhibitors enhance cAMP actions through elevation of intracellular cAMP concentration. Inhibitors specific for PDE isoform have been developed for diseases. One of these inhibitors, cilostazol, a PDE3 selective inhibitor, is clinically effective to treat the heart failure and intermittent claudication. Recently, we reported that cilostazol enhanced hippocampus-dependent memory in young mice (Yanai et al., in press), however, its effects is unknown for the age-related memory impairments. We examined the effect of chronic administration of cilostazol as a potential therapeutic intervention for memory impairment in aged population by using two animal model; 23-month old C57BL/6J and 8-month old

senescence accelerated mouse prone 8 (SAM P8). For C57BL/6J mice, cilostazol (0, 0.3%, or 1.5%) had been administered for 10 months and they were subjected to the behavioral test battery at 23 months of age. Non-cilostazol-administered age-matched group showed impaired performance in the Morris water maze task compared to young control mice, however, the performance of 1.5% cilostazol-administered mice was similar to that of the young mice. No major influence of cilostazol was observed in the open field test, suggesting that chronic cilostazol administration does not have adverse effects on locomotor activity and anxiety. For SAM P8, cilostazol was administered for 3 months before the behavioral experiments. At the age of 8 months, they were subjected to the Pavlovian fear conditioning task. The 1.5% cilostazol-administered SAM P8 exhibited significantly higher conditioned freezing than the SAM P8 without cilostazol in both cue- and context-dependent memory tests. The performance of 1.5% cilostazol-administered SAM P8 was comparable to that of the control normal aging mice. In addition, the cilostazol-administered SAM P8 showed a significant increase in the number of phospho-CREB positive cells in hippocampal dentate gyrus. The results suggest that chronic cilostazol administration may prevent the age-related memory decline via modulating cAMP pathway including the phosphorylation of CREB.

Title: A calpain-2 selective inhibitor enhances learning and memory through prolonged ERK activation

Authors: ***Y. LIU**, Y. WANG, G. ZHU, X. BI, M. BAUDRY
Western Univ. of Hlth. Sci., POMONA, CA

Abstract: While activation of calpain-1 is necessary for the formation of long-term potentiation (LTP) elicited by theta burst stimulation (TBS) in field CA1 of hippocampus, activation of

calpain-2 during the 1 h-consolidation period after TBS limits the extent of synaptic potentiation, and its inhibition results in enhanced LTP. In LTP induction, calpain-1 activation results in SCOP truncation followed by ERK activation, whereas in the consolidation period, calpain-2 activation stimulates mTOR-dependent SCOP protein synthesis through calpain-mediated PTEN degradation, which limits the duration of ERK activation. To further evaluate the role of calpain in learning and memory, we injected mice intraperitoneally (i.p.) with different doses of a selective calpain-2 inhibitor (Z-Leu-Abu-CONH-CH2-C6H3(3,5-(OMe)2) (C2I), from 0.1 mg/kg to 10 mg/kg) 30 min before the training session. Treatment with C2I significantly increased freezing times in both context-and tone-elicited fear-conditioning paradigm at 0.1-0.3 mg/kg, and inhibited performance at doses above 1mg/kg, as compared to vehicle-treated mice. The differential effects of low and high doses of C2I on learning and memory match their inhibitory effects on calpain-2 and calpain-1. SCOP levels were significantly decreased and ERK phosphorylation significantly increased in dorsal but not ventral hippocampus 5 min after training, and levels of these two proteins returned to basal level 50 min after training. However, in mice pretreated with 0.3 mg/kg C2I, SCOP levels remained decreased and ERK activation elevated up to 50 min after training. These results demonstrated that a calpain-2 selective inhibitor enhances learning and memory by prolonging ERK activation in dorsal hippocampus.

Title: Effect of an N-methyl-D-aspartate receptor antagonist in animal models of schizophrenia: An immunohistochemical study in the rat

Authors: H. MATSUO[1], T. NISHIMORI[1], H. ABE[1], A. KURAMASHI[1], G. KOGANEMARU[1], H. FUNAHASHI[1], K. EBIHARA[1], T. IKEDA[2], *Y. ISHIDA[1]
[1]Dep Psychiatry, Fac of Med, Univ. Miyazaki, Miyazaki, Japan; [2]Div. Neurobiol, Fac of Med, Univ. Miyazaki, Miyazaki, Japan

Abstract: The antipsychotic agent is considered to have more desirable effects on the cognitive deficits in patients with schizophrenia, while dysfunction of the N-methyl-D-aspartate (NMDA) receptor has been associated with negative and cognitive symptoms in schizophrenia. Perospirone is an atypical neuroleptic with potent 5-HT2A and D2 receptor blocking actions, and can improve both positive and negative symptoms of schizophrenia (Ohno et al., 1997). To elucidate pharmacological profiles of perospirone, we examined the ameliorating effect of perospirone on methamphetamine-induced disruption of latent inhibition (LI) and the expression of c-Fos in rats. The disruption of LI was ameliorated in rats following administration of haloperidol or perospirone, and they significantly increased the number of c-Fos-positive cells in the nucleus accumbens shell, but not in the prefrontal cortex, the nucleus accumbens core and the amygdala. Moreover, the enhanced expression of c-Fos in the nucleus accumbens shell was furthermore increased by pretreatment with MK-801, an NMDA receptor antagonist, indicating that the nucleus accumbens shell plays a crucial role in the effect of antipsychotic agents through the NMDA receptors.

Title: Fear reducing effects of Souroubea Spp. and Platanus occidentalis in rats: Potential relevance for post traumatic stress disorder

Authors: *K. DELCELLIER[1,2], C. CAYER[3,2], P. KENT[3,2], J. ARNESON[3], Z. MERALI[3,2]
[1]Carleton Univ., Hull, QC, Canada; [2]Inst. of Mental Hlth. Res., Ottawa, ON, Canada; [3]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: The prevalence of anxiety disorders is rising rapidly in today's society, impacted greatly by recent times of civil unrest and war throughout the world. Many of the currently prescribed drug therapies for anxiety disorders are associated with aversive side-effects and lose efficacy with repeated administration. Ethnobotanical research has shown that anxiolytic properties of certain plants are of therapeutic relevance in treating anxiety symptoms. The

objective of the present study was to investigate the anxiolytic effects of a botanical blend ethanolic extract of a 1:1 Souroubea sympetala and Platanus occidentalis (Sycamore tree), which contains 15% of the previously identified anxiolytic principle; betulinic acid (BA). The three main facets of conditioned fear: fear memory expression, extinction and reconsolidation were investigated using the Fear Potentiated Startle (FPS) and Conditioned Emotional Response (CER) paradigms, based on their translational relevance to post traumatic stress disorder (PTSD) as exaggerated startle and avoidance are primary symptoms. In the case of fear memory expression, extinction and reconsolidation, the FPS and CER of the rats was measured through comparing the effects of the botanical blend ethanolic extract (7mg/kg), to diazepam (5mg/kg) or vehicle administration. Significant decreases in fear responses were observed throughout the three fear memory processes upon treatment of the botanical blend extract, effects similar to those observed with diazepam. These findings are consistent with previous pilot results whereby the dried raw plant materials of the botanical blend significantly reduced fear- and anxiety-like responses in rats. Although more research is needed in order to further the understanding of its mechanism of action, these results are promising and may offer a safe clinical alternative to treating anxiety disorders including PTSD.

Abstract: *Streptococcus pneumoniae* is a common cause of bacterial meningitis, with a high mortality rate and neurological sequelae. In contrast, folic acid plays an important role in neuroplasticity and the preservation of neuronal integrity. In the present study, we evaluated the influence of folic acid on memory, oxidative damage, enzymatic defence, and brain-derived neurotrophic factor (BDNF) expression in experimental pneumococcal meningitis. Male Wistar rats received either 10 µl of artificial cerebral spinal fluid or an equivalent volume of *S. pneumoniae* suspension at concentration $5x10^9$ UFCol/ml. The animals were divided into six groups: control, control/folic acid at 10 mg/Kg, control/folic acid at 50 mg/Kg, meningitis, meningitis/folic acid at 10 mg/Kg, and meningitis/folic acid at 50 mg/Kg. Folic acid was dissolved in distilled water and administered orally by gavage at a dose of 10 or 50 mg/Kg once per day for 7 days, at the same time the animals received ceftriaxone (100 mg/kg body weight given s.c., during 7 days) starting 18 h after the induction of pneumococcal meningitis. After 10 days, the animals were free from infection. We performed blood cultures that were all negative in this period and the animals were randomised and subjected to behavioural tests: open-field task and step-down inhibitory avoidance task. The animals that received folic acid at a dose of 10 or 50 mg, there was a reduction in both crossing and rearing during open-field task when compared with the training session, demonstrating habituation memory ($p<0.05$). During the step-down inhibitory avoidance task, there was a difference between the training and the test sessions, demonstrating aversive memory ($p< 0.05$). In the untreated meningitis group, there was no difference between the training and the test sessions, demonstrating impairment of habituation and aversive memory in this group. In the hippocampus, BDNF expression decreased in the meningitis group; however, adjuvant treatment with 10 mg/Kg folic acid increased BDNF expression in the meningitis group ($p<0.05$). Folic acid decreased lipid peroxidation, protein carbonylation, nitrate/nitrite levels, and myeloperoxidase activity and increased superoxide dismutase activity in the hippocampus ($p<0.05$). There is substantial interest in the role of folic acid and related pathways in nervous system function and in folic acid's potential therapeutic effects. Here, adjuvant treatment with folic acid exerted protective effects in experimental pneumococcal meningitis.

Title: Influence of norepinephrine, corticotrophin releasing hormone and corticosterone, individually and in conjunction, on the expression of hippocampal synaptic plasticity in tissue obtained from stressed versus non-stressed rats

Authors: G. E. FARMER[1], M. F. MIDKIFF[1], C. R. PARK[1], *D. M. DIAMOND[1,2]
[1]Psychology, Univ. South Florida, TAMPA, FL; [2]Res. and Develop., VA Hosp., Tampa, FL

Abstract: The onset of stress is accompanied by an increase in levels of multiple neuromodulators, each with a different time course in its effects on the hippocampus. Whereas norepinephrine (NE) and corticotrophin releasing hormone (CRH) are rapidly released in the hippocampus, corticosterone (CORT) exhibits a more delayed time course of action. The effects of NE, CRH and CORT on hippocampal plasticity are ordinarily assessed in isolation, but *in vivo*, these neuromodulators interact, potentially in a manner which is not predicted from their individual actions. Therefore, we assessed their effects, individually and in concert, on the hippocampus, *in vitro*. We also evaluated the influence of acute stress *in vivo* on the effects of these neuromodulators on synaptic plasticity, *in vitro*. Pairs of male adult Sprague-Dawley rats were transported to a holding room where one of the two rats was immediately anesthetized and decapitated (Group 1) followed by conventional hippocampal slice processing. The second rat remained in the holding room for 2.5 hr prior to slice preparation (Group 2). Long-term potentiation of the field EPSP in dorsal CA1 stratum radiatum was induced by primed burst (PB) stimulation, which consisted of one pulse followed 170 ms later by a 6 pulses at 100 Hz. Bath application of NE (10 μM) and/or CRH (125 nM) was initiated 5 min prior to PB stimulation and remained present for 10 min post-PB stimulation, for a total of 15 min. Bath application of CORT (30 nM), alone or in conjunction with NE or CRH, was initiated 2 min prior to PB stimulation and remained present for 10 min post-PB, for a total of 12 min. The magnitude of PB potentiation (PBP) was greater in Group 1 versus Group 2, which is consistent with previous work demonstrating the sensitivity of CA1 to acute stress. Bath application of NE blocked the reduction of PBP in Group 2. CRH had no effect on the differential expression of PBP in Groups

1 vs 2. CORT reduced PBP in all groups, alone or in conjunction with NE or CRH. NE + CRH produced an effect that was equivalent to NE, alone. This work illustrates that: 1) brief stress just prior to decapitation can inhibit hippocampal plasticity; and 2) an assessment of combinations of neuromodulators in conjunction with acute stress may yield insight into the dynamics, and complexity, of stress-plasticity interactions in the behaving animal.

Title: Chronic effects of the 'biased' 5-HT1A receptor agonists F15599 and F13714 on object pattern separation and core body temperature

Authors: *B. T. VAN HAGEN[1], N. P. VAN GOETHEM[1], R. SCHREIBER[2,3], A. NEWMAN-TANCREDI[4], M. VARNEY[4], J. PRICKAERTS[1]
[1]Dept. of psychiatry & neuroscience, Maastricht Univ., Maastricht, Netherlands; [2]Suadeo Drug Discovery Consulting LLC, Watertown, MA; [3]Dept. of Behavioral Physiol., Univ. of Groningen, Groningen, Netherlands; [4]Neurolixis Inc., Dana Point, CA

Abstract: Pattern separation, or the formation of distinct representations out of similar inputs, is an important hippocampal process implicated in memory formation. Impairments in pattern separation could underlie the cognitive symtoms of multiple disorders like PTSD and schizophrenia. Based on the distribution of the serotonin 1A receptor (5-HT1A¬R) in the brain, and the molecular and cellular mechanisms of this receptor, we hypothesized that it plays a role in pattern separation. Our previous research showed that the new, 'biased' 5-HT1A agonist, F15599, which preferentially activates postsynaptic cortical heteroreceptors, acute treatment improved rat performance in a new spatial object pattern separation (OPS) task. In contrast, F13714, which preferentially activates presynaptic autoreceptors, impaired performance in this task (Schreiber et al., 2013, Soc. Neurosci., #865.18). Herein, we investigated the effects of chronic treatment with F15599 and F13714 on spatial OPS performance in rats. We hypothesized that, through desensitization of presynaptic autoreceptors by F13714, the OPS performance impairment would ameliorate due to increased activation of postsynaptic receptors. Core

temperature measurents were included as a mechanistic readout of postsynaptic 5-HT1A¬R activation. An increase in hypothermia by F13714 treatment would reflect a shift to activation of more postsynaptic 5-HT1A¬Rs. 16 animals per condition were treated daily with i.p. injections of 0.32 mg/kg F15599, 0.02 mg/kg F13714 or vehicle (PBS). OPS performance was measured at day 1, 8 and 14 of treatment. Core body temperature was measured daily, 30 min after drug administration. The impairment in OPS performance with acute treatment of F13714 was replicated and subsequently a gradual increase of performance was found, resembling vehicle treatment at day 14. Body temperature dropped by one degree celcius from treatment day 4 onwards. F15599 showed an enhancement in OPS performance compared to vehicle acutely, and this was maintained through day 14. Body temperature initially dropped, but then rose with one degree compared to day 1. These results imply possible desensitization of presynaptic 5-HT1A¬Rs by F13714, leading to stimulation of postsynaptic 5-HT1A¬Rs which could explain the drop in temperature. The temperature data even suggest desensitisation of postsynaptic receptors, but this is not reflected in the behavioral data. Further studies, e.g., determination of the number of 5-HT1A¬Rs, are ongoing to better understand the potential desensitization of pre- and/or post-synaptic receptors.

Title: Evaluation the effect of tempol on learning and memory impiarment induced by sleep deprivation

Authors: *O. F. KHABOUR[1], K. H. ALZOUBI[2], A. S. ALBAWAANA[2]
[1]Dept. of Med. Lab. Sci., [2]Dept. of Clin. Pharm., Jordan Univ. of Sci. and Technol., Irbid, Jordan

Abstract: Sleep deprivation has been associated with learning and memory impairment through induction of oxidative stress so damaging the neurons and prevent firing. On the other hand, Tempol, a small membrane permeable redox-cycling nitroxide compound, that promotes the

metabolism of many reactive oxygen species (ROS), has antioxidant and neuroprotective effect that may antagonize this oxidative stress. In our study we hypothesize that chronic administration of tempol can prevent learning and memory impairment induced by sleep deprivation. This hypothesis was evaluated and possible molecular targets for tempol action were determined. Sleep deprivation was induced in rats using modified multiple plate form model. Tempol was administered to rats via oral gavage. Behavioral studies were conducted to test the spatial learning and memory using radial arm water maze. And at the end of the experiment, the hippocampus was dissected; BDNF protein, TBARS levels and antioxidant markers (GSH, GSSG, GSH/GSSG ratio, GPx, SOD, and catalase) were assessed. The result of this project revealed that chronic sleep deprivation impaired both short and long term memory ($P<0.05$), while Tempol treatment prevented such effect. Furthermore, Tempol normalized chronic sleep deprivation induced reduction in the hippocampus activity of Catalase ($P<0.05$), GPx ($P<0.05$), and SOD ($P<0.05$). Tempol also enhanced the ratio of GSH/GSSG in chronically sleep deprived rats treated with tempol as compared with only sleep deprived rats ($P<0.05$), without any effect on BDNF activity ($P>0.05$) or TBARS activity ($P>0.05$). In conclusion chronic sleep deprivation induced memory impairment, and treatment with Tempol prevented this impairment probably through normalizing antioxidant mechanisms in the hippocampus.

Title: SUVN-I1312004, Novel M_1 muscarinic acetylcholine receptor positive allosteric modulator: Potential for the treatment of Alzheimer's disease

Authors: *R. ABRAHAM, R. MEDAPATTI, R. KARTHIK GADI, V. RAVIRALA, S. YATHAVAKILLA, R. SUBRAMANIAN, R. CHOWDARY, M. ABDUL RASHEED, N. MUDDANA, S. GAGGINAPALLI, P. JAYARAJAN, R. NIROGI
Suven Life Sci., Hyderabad, India

Abstract: Muscarinic receptors namely M_1 is being actively pursued as target for improvement of cognition in elderly patients suffering from Alzheimer's disease (AD). Due to the conserved nature of the muscarinic receptors at the orthosteric site, allosteric site is being explored .

Targeting the less conserved allosteric site provides selectivity and advantage of obtaining pharmacological agents with lesser side effects. SUVN-I1312004 is selective M_1 muscarinic receptor positive allosteric modulator with no agonist like activity. SUVN-I1312004 was inactive at orthosteric receptor sites of M1-M5 protein, with % inhibition values <20% at 10 uM. In the functional reporter gene assay at human M_1 muscarinic receptor, SUVN-I1312004 shifted acetylcholine dose response towards leftward with a 57 fold shift of acetylcholine potency at 10μM and an EC_{50} (inflection point) of 337 nM and the effects were blocked by a selective antagonist, which proves that SUVN-I1312004 is a potent positive allosteric modulator of human M_1 muscarinic receptor. The pharmacokinetic and brain penetration properties were investigated in rats. SUVN-I1312004 had favorable pharmacokinetic profile and adequate brain penetration in male Wistar rats. Efficacy of SUVN-I1312004 was assessed in various cognitive tasks such as object recognition task (ORT) and fear conditioning assay. SUVN-I1312004 enhanced the discriminative index when administered alone and/or in combination with donepezil in ORT. SUVN-I1312004 enhanced the duration of freezing in the fear conditioning test, memory deficit being induced by scopolamine. It was found to be non- mutagenic in bacterial reverse mutation assay. SUVN-I1312004 is a novel, potent, selective, orally bioavailable and efficacious M_1-PAM that holds promise in the treatment of AD and dementia. SUVN-I1312004 is being further evaluated for various safety parameters.

Title: Responsiveness to restraint stress and scopolamine in simple learning and memory

Authors: *I. M. WHITE, Z. ABBOTT, J. B. DUTY, W. WHITE
Psychology, Morehead State Univ., MOREHEAD, KY

Abstract: The present study examined the interaction between stress and scopolamine in simple learning and memory. One group of Wistar rats was shaped to lever-press to receive food pellets, some subjects were exposed to a stress manipulation (restraint) whereas others were not, and then all subjects received training on a fixed ratio 5 (FR5). A second group was trained on FR5 until subjects reached behavioral criteria, they received either scopolamine or saline, all subjects received restraint-stress for a 30-min period, and then they received additional testing on FR5. The third group of subjects was trained on FR5, they received cortisol, yohimbine, or saline, and then they were tested on FR5. Performance measures included the mean latency of the first lever-press, the mean time required for five lever-presses (runtime), and the mean latency of food-retrieval. Stress disrupted acquisition of FR5, without affecting food retrieval or consumption. Scopolamine and stress disrupted maintenance of FR5 by increasing the first response latency, compared to saline control. Food retrieval was affected by scopolamine, but not by stress. Exposure to stress in conjunction with scopolamine injection produced a greater impairment in performance, compared to other conditions. Neither scopolamine nor stress affected runtime, whereas the combination of the two markedly increased runtime. Runtime was impaired by yohimbine-induced stress, but not by cortisol. Our data suggest that stress differentially modulates scopolamine-induced deficits and motivational state.

Title: Scopolamine impairs latent working memory in the water maze

Authors: *S. Y. JABITTA, J. J. IZYGON, D. M. NGHIEM, M. M. HENCEROTH-CHOMIAK, W. T. WILLIAMSON, D. H. MALIN
Univ. of Houston-Clearlake, Houston, TX

Abstract: The Morris water maze is routinely used to explore neural mechanisms of working memory. Humans can often acquire working memory relevant to performing a task without having to actually perform the task. This can be modeled in the water maze through direct placement on the escape platform, followed by assessing the subject's performance in swimming back to the platform. This sort of learning was studied in the water maze through a revised direct placement task with novel pre-training and control procedures. Muscarinic cholinergic mechanisms, which are inactivated by scopolamine, are essential to memory for standard working memory paradigms in the water maze. This experiment determined whether this would also be true for latent learning based on direct platform placement. The subjects were 18 Long-Evans hooded rats. All rats were pre-trained for three days in the escape procedure by swimming progressively longer distances back to the platform where they had been placed. During four days of working memory testing, 12 rats were trained by direct placement on the platform in a different quadrant within the maze each day. Six sham-trained rats were placed on a platform in a small cylinder in a different room. Five minutes later, all rats were placed in the full-sized water maze and assessed for path-length and latency to reach the escape platform. On two days, rats were injected i.p. thirty minutes before training with 1 mg/kg scopolamine hydrobromide in saline, and on the other two they received saline alone. The order of drug and saline injections was counterbalanced among subjects. ANOVA with one-repeated measures variable (drug) revealed a significant effect of drug, $p = 0.002$ and of training vs. sham-training, $p = 0.026$. Post-hoc pairwise comparisons indicated significantly lower escape latencies, $p < 0.01$, in the training plus saline condition than in the training plus scopolamine, sham-training plus saline and the sham-training plus scopolamine conditions. Accuracy scores (distance to platform/subject's path-length) were also significantly better in trained rats without scopolamine, $p < 0.01$ than all other conditions. There was a probe trial with the platform removed after the daily direct placement. Trained rats without scopolamine traveled a significantly, $p < 0.01$, longer path-length within the target quadrant and spent significantly, $p < 0.01$, more time there than trained rats with scopolamine and sham-trained rats without scopolamine. The overall results suggest that muscarinic cholinergic systems are essential to spatial learning by mere visual observation, as distinguished from trial-and-error learning.

Title: Modafinil as a neuroenhancer

Authors: *H. M. MURPHY[1], C. H. WIDEMAN[2]
[1]Dept Psychol, [2]Biol., John Carroll Univ., Cleveland, OH

Abstract: Modafinil, a schedule IV psychostimulant approved by the FDA to treat narcolepsy, has become popular among students as a neuroenhancer. It has been suggested that it facilitates cognitive functions, with pro-mnemonic effects and problem solving improvements. The purpose of the present experiment was to examine the influence of modafinil on working memory in rats. Six control and 6 experimental rats were placed into individual cages equipped with a running wheel to monitor activity. The study was divided into three different periods; 1) habituation - 1 week; 2) experimental - 3 weeks, in which a 64 mg/kg dose of modafinil was administered to experimental animals in a condensed milk treat; and 3) withdrawal - 5 days. During the experimental and withdrawal periods, the spatial working memory of the rats was tested utilizing the Morris Water Maze. A 2 hour delay period followed drug administration and a protocol for spatial working memory was employed. Three testing sessions were given during the experimental period and one testing session was given during the withdrawal period. Animals were given two trials in each session. The first was a sample trial in which animals discovered the location of the platform by trial and error and the second was a test trial in which animals were required to recall the location of the platform. Platform placement and starting place location of the rat were changed every session. Performance of control animals during the sample trial and the test trial for the four sessions of exposure to the maze showed no difference in time to reach the platform. Performance of experimental animals demonstrated faster attainment of the goal during the test period. During withdrawal, there was no significant difference in time between the two trials for animals that were previously given modafinil. Concerning wheel running, although both groups were similar during the habituation period, activity of the experimental group was significantly lower than the control group during the rest of the experiment. The results of this study support the hypothesis that modafinil has a positive effect on working memory in rats, specifically to increase short term, trial-dependent learning. It is suggested that benefits of modafinil can extend beyond its prescribed usage. Due to the significant decrease in activity, modafinil could become an advantageous medication to treat hyperactivity disorders and, because of lack of withdrawal symptoms, it could become a safe replacement for other psychostimulants. A cautionary note, however, is that the use of modafinil is extremely relevant in discussions related to ethical concerns associated with neuroenhancers.

Title: Involvement of BDNF in doxorubicin and cyclophosphamide-induced spatial cognition in rats

Authors: ***Y. KITAMURA**[1], S. YONEDA[1], I. MIYAZAKI[2], M. ASANUMA[2], T. SENDO[1]
[1]Dept. Clin. Pharm., Okayama Univ. Hosp., Okayama, Japan; [2]Dept. Brain Sci., Okayama Univ., Okayama, Japan

Abstract: We previously showed that chronic treatment with doxorubicin and cyclophosphamide chemotherapeutic agents (AC regimen) impairs spatial cognition in rats. The chronic administration of the AC regimen decreased serum brain-derived neurotrophic factor (BDNF) (but not hippocampal BDNF) protein levels and BrdU-positive cells in the dentate gyrus of the hippocampus. These behavioral changes may be attributed, in part, to decreased hippocampal neurogenesis, and chemotherapy may lead to these impairments by altering neurogenesis via peripheral BDNF. In the serum BDNF is stored in platelets and can bind to platelet receptors. On the other hand, romiplostim is a second generation thrombopoietin receptor agonist (TPO-RA) that mimics the function of TPO. TPO is the key regulator of the platelet production. We hypothesized that romiplostim blocked the decreasing effect of hippocampal neurogenesis and spatial cognitive impairment, based on treatment with romiplostim inhibiting the decrease in serum platelets caused by the AC regimen. [METHODS] Male Wistar rats were administered doxorubicin (2 mg/kg, i.p.) and cyclophosphamide (50 mg/kg, i.p.) once per week for 2 weeks. Romiplostim (30 μg/kg, s.c.) was administered once per week for 2 weeks before the AC regimen, and with the co-administration of the AC regimen. The novel place recognition task was performed in the 3th week. [RESULTS and DISCUSSION] Saline-treated rats spent significantly more time exploring an object moved to a new location than exploring the same object left in the old location in the novel location recognition test. This behavior was impaired following treatment with the AC regimen. Romiplostim improved the impairment of spatial cognition. Serum platelet counts and BDNF were decreased with the AC regimen. Romiplostim

increased these factors in normal rats. However, these factors significantly decreased with the AC regimen. [CONCLUSION] Our results show that chronic treatment with the AC regimen impairs spatial cognition in rats. These behavioral changes may be attributed, in part, to decreased hippocampal neurogenesis. In this study, we demonstrate that spatial cognition impairment is a possible mechanism by which the AC regimen decreases the effect of serum BDNF.

Title: Severe crossmodal object recognition impairment in ketamine-treated rats: Amelioration by α4β2 nicotinic receptor stimulation of the GABAergic system

Authors: ***J. M. CLOKE**, B. D. WINTERS
Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: The neural bases of multisensory integration impairments in schizophrenia are not well understood. Rats treated sub-chronically with NMDA receptor antagonists (e.g., ketamine), which model symptoms of schizophrenia, are impaired on a tactile-to-visual crossmodal object recognition (CMOR) task; this deficit is reversed by systemic nicotine, which can also attenuate cognitive impairment in patients with schizophrenia. Furthermore, cortical gamma oscillations mediated by parvalbumin-containing GABAergic interneurons (PV-INs) may be deficient in schizophrenia, potentially contributing to aberrant multisensory processing. PV-INs contain nicotinic acetylcholine receptors (nAChR). The current study assessed the receptor specificity of the ameliorative effect of nicotine in the CMOR task, as well as the potential for nAChR interaction with GABA and glutamate. Male Long-Evans rats were treated sub-chronically for 10 days with ketamine (30 mg/kg) or saline and then tested on the CMOR task after a 10-day washout. Systemic nicotine (0.2 mg/kg) given before the sample phase of the CMOR task reversed the ketamine-induced impairment, but this effect was blocked by co-administration of

the $GABA_A$ receptor antagonist bicuculline at a dosage (0.5 mg/kg) that itself did not cause impairment. Pre-sample systemic co-administration of the NMDA receptor antagonist MK-801 (0.001 & 0.01 mg/kg) did not block the remediating effect of nicotine in ketamine-treated rats. Finally, the selective α7 agonist GTS-21 (0.01, 0.03 & 0.1 mg/kg) and α4β2 nAChR agonist ABT-418 (0.06, 0.1 & 0.6 mg/kg) were tested, with only the latter reversing the ketamine impairment; bicuculline also blocked this effect. These results suggest that nicotine-induced agonism of α4β2 nAChRs ameliorates CMOR deficits in ketamine-treated rats via stimulation of the GABAergic system. Ongoing work is assessing similar interactions in the distributed network implicated in CMOR task performance, including the orbitofrontal, perirhinal, and posterior parietal cortices. Cortical dysfunction in these regions may contribute to the severe CMOR deficit apparent in ketamine-treated rats. The findings of this research may have important implications for understanding the nature and potential treatment of cognitive impairment in schizophrenia.

Title: Novel cognitive enhancer SAK3 enhances T-type voltage-gated Ca^{2+} channel current in Neuro2a cells expressed cav3.1 gene

Authors: *Y. YABUKI[1], M. WAKAMORI[2], K. FUKUNAGA[1]
[1]Pharmacol., Tohoku Univ., Sendai / Miyagi, Japan; [2]Oral Biol., Tohoku Univ., Sendai, Japan

Abstract: The T-type voltage-gated Ca^{2+} channels (T-VGCCs) are involved in the pathophysiology of epilepsy, pain and sleep. We recently elucidated the mechanism underlying cognitive enhancement of a novel Alzheimer disease drug candidate, ST101 which stimulates T-VGCC in mouse cortical slices and neuro2A cells over-expressed Cav3.1 (Moriguchi et al., J Neurochem 2012;121:44-53). We successfully synthesized another series of spiroimidazopyridine derivatives (SAKs), which are much stronger than ST101 in the stimulation of Ca^{2+} conductance of Cav3.1 channel. Therefore, acute ST101 treatment in the

hippocampal slices failed to potentiate the hippocampal long-term potentiation (LTP), whereas SAK3 treatment significantly enhanced the hippocampal LTP. The LTP enhancement by SAK3 was associated with an elevation of Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) activity in the hippocampal slices. We also confirmed that acute SAK3 administration enhanced hippocampal acetylcholine (ACh) release in olfactory bulbectomized (OBX) mice. Consistent with these observations, acute administration of SAK3 improved impairments of memory-related behaviors in OBX mice. The enhanced ACh release via T-VGCC is closely associated with CaMKII activation in the hippocampus, thereby improving cognitive impairments in the Alzheimer disease-like models. Taken together, SAK3, cognitive enhancer acting on T-VGCC can be a novel candidate of therapeutics for Alzheimer disease.

Title: The effect of waterpipe tobacco smoke exposure on learning and memory functions

Authors: *K. H. ALZOUBI[1], O. F. KHABOUR[2], E. A. AL HARAHSHAH[2]
[1]Dept. of Clin. Pharm., Jordan Univ. of Sci. & Technol., Irbid, Jordan; [2]Jordan Univ. of Sci. and Technol., Irbid, Jordan

Abstract: Tobacco smoking is a global health hazard that kills about 5 million peoples annually. Cigarette smoking and waterpipe smoking are the most popular methods of tobacco consumption. Waterpipe smoking is spreading noticeably especially among youth. In this study, we investigated if waterpipe smoking impairs learning and memory in the hippocampus. Additionally, possible molecular targets for expected learning and memory impairment were determined. Animals were divided into two groups; waterpipe tobacco smoke, and control. The waterpipe tobacco smoke group was exposed to smoke from the waterpipe by whole body exposure system 1hr, 5 days/wk, for one month. Behavioral studies were conducted to test the spatial learning and memory using the Radial Arm Water Maze (RAWM). Additionally, hippocampal BDNF protein levels and oxidative stress biomarkers (catalase, GPx, SOD,

TBARS, GSH, GSSG, GSH/GSSG ratio) were assessed. The result revealed that waterpipe tobacco smoke impaired short- and long- term memories. Moreover, result showed that waterpipe tobacco smoke induced reduction in hippocampal activity of catalase, SOD, GPx, GSH, and GSH/GSSG. The GSSG was significantly increased in waterpipe tobacco smoke group. No effects on the levels of BDNF or TBARS were observed. In conclusion, waterpipe tobacco smoking exposure induces memory impairment, which was correlated with significant changes in oxidative stress biomarkers.

Title: A negative allosteric modulator selective for the NR2b subtype of NMDA receptors impairs cognition in cynomolgus monkeys

Authors: *M. R. WEED[1], M. BOOKBINDER[1], J. POLINO[1], D. KEAVY[1], R. N. CARDINAL[3,4], J. SIMMERMACHER-MAYER[2], F.-N. LUAN[2], L. J. BRISTOW[1]
[1]Exptl. Biol. and Genomics, [2]Pharmaceut. Candidate Optimization, Bristol-Myers Squibb, Wallingford, CT; [3]Behavioural and Clin. Neurosci. Institute, Dept. of Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom; [4]Cambridgeshire and Peterborough NHS Fndn. Trust, Cambridge, United Kingdom

Abstract: Antidepressant activity of NMDA antagonists and negative allosteric modulators (NAMs) has led to increased investigation of their behavioral pharmacology. One well-characterized effect of non-selective NMDA antagonists is impaired cognition in multiple species. A few cognition studies with subtype-selective NAMs have reported mixed results with NR2b NAMs in rodents including increased impulsivity, no effect on cognition or even improvement of some cognitive tasks. In contrast, only one study of cognition in nonhuman primates was found using a selective NR2b NAM administered directly into the dorsolateral prefrontal cortex of macaques, and the compound impaired working memory performance [Wang et al., 2013, Neuron 77(4) 736-749]. The current study tested a selective NR2b NAM, CP 101,606 in two tests of cognition in cynomolgus monkeys. CP101,606 produced a selective impairment in memory in the NHP CANTAB list delayed match to sample (list-DMS) task.

Doses of CP 101,606 at 1, 3, 5.6 and 10 mg/kg impaired performance on trials with 20 and 45 second delays without affecting performance on trials with 2 sec delays. List-DMS impairment waned with longer pretreatments and lower plasma exposure with performance after 1 mg/kg returning to vehicle levels after 5 hours. In a separate cohort, CP 101,606 impaired performance on NHP CANTAB visuo-spatial Paired Associates Learning (vsPAL) test. vsPAL performance was impaired after 1 mg/kg on both initial accuracy (memory) and eventual accuracy (learning) components of the task with selective impairment of more difficult conditions. Whether selective NR2b NAMs impair cognition in humans has not been well studied, although supra-therapeutic doses of CP 101,606 have been reported to produce adverse events consistent with impaired cognition. Additional clinical studies should address this aspect of NR2b NAM pharmacology. The results of these studies clearly show that systemic administration of selective NR2b antagonists can cause transient cognitive impairment in multiple cognitive domains.

Abstract: Our previous study suggested that early dantrolene treatment reduced amyloid plaque burden and nearly abolished memory and learning loss in a triple transgenic Alzheimer's disease (3xTgAD) mouse model. In this study, we further investigated the long term treatment of dantrolene on amyloid pathology in the brain and on cognitive function. Fifteen month old 3xTg-AD mice and wild type controls were treated with oral dantrolene at 5 mg/kg or vehicle control twice per week for 6 months. Learning and memory were examined using the Morris Water Maze at 21 and 22 months of age. After the behavioral testing, hippocampal and cortical brain volumes were calculated with magnetic resonance imaging and motor function was evaluated using the rotorod. . The amyloid burden in the hippocampus was determined using immunohistochemistry. We found that dantrolene significantly decreased intraneuronal amyloid accumulation in the hippocampus. No significant differences could be detected in hippocampal or cortical brain volume, motor function or in cognition among all experimental groups, indicating that the mice were still pre-symptomatic for AD. Thus, long term dantrolene treatment significantly decreased the amyloid burden in aged 3xTg-AD mice prior to significant changes in brain volume, or cognition.

Title: Interferon-β1a-induced effects on memory and depression in model animals

Authors: *A. VAZQUEZ-ALVAREZ[1], D. PINEDA-VÁZQUEZ[2], E. LEON-CRUZ[2], I. TIBURCIO-DOMINGUEZ[2], R. MIRELES-LOPEZ[2], R. VAQUERO-GARCIA[2], C. REYES-VAZQUEZ[1]

Abstract: Both, neurotransmitters and cytokines affect their target cells through surface receptors and also by other molecular mechanisms. Cytokine receptors are present in neurons and glial cell populations in discrete brain regions. Moreover, the role of several cytokines in

hippocampal physiological processes, such as memory and learning, and their pathological involvement of cytokines in diseases like depression and epilepsy had been described. Then, interferon α; and some interleukins had effects on long-term potentiation (LTP) in the hippocampus. And some cytokines has a negative regulatory role in long-term memory acquisition. The most commonly used cytokine for the treatment of multiple sclerosis (MS) is interferon β−1a (IFNβ−1a); however, a common perception is that IFNβ−1a treatment is likely to increase memory alterations and depression during the course of MS treatment.To assess such perception we tested the effects of the chronic application of IFNβ−1a on memory, using an active avoidance test, and in inducing depression with the helplessness forced-swim. We used male Wistar rats of 100-120 g, kept according the SfN's Policies on the Use of Animals and Humans in Neuroscience Research. Rats received saline (SSI) or IFNβ−1a, 1 x 106 IU/kg subcutaneously during 7 days. In day 16 animals were trained in a standard active avoidance chamber with 2 compartments. Once animals crossed from a dark to a light compartment they receive three aversive stimuli (electric shock, 60 mV, 3s duration every min for 3 min). Animals were tested after 24, 48, 72 and 168 h the last subcutaneous administration. SSI rats significantly prevented ($P < 0.05$ Z test) aversive stimulus compared with those who received IFNβ−1a. In another experiment, rats were introduced in a water tank (20 l) at 20 °C, and its locomotor activity measured by an electronic device connected to a computer. In this experiment there were significant differences between the control and the treated subjects ($p<0.01$). Some side effects caused by the administration of IFNβ−1a were observed in rats as rhinorrhea, sneezing, loss of hair on the head region, diarrhea and weight loss. Studies in animals have demonstrated that acute activation of cytokines signaling in the brain in response to peripheral immune activation is associated with deficits in hippocampal dependent memory such as contextual fear conditioning. The present findings suggest that cytokines, such as IFNβ−1a, is able to activate neuronal circuits and neurotransmitters that organize physiological and pathological behaviors.

Title: Multi-modal spatial learning and memory in the split-brained cockroach, Periplaneta americana

Authors: *M. POMAVILLE, D. D. LENT
CSU Fresno, Fresno, CA

Abstract: The American cockroach, Periplaneta americana, with its large brain and demonstrated robustness to physiological manipulation, holds many advantages when exploring neural underpinnings of learning and memory. Understanding how neural circuits support various aspects and types of learning and memory is a tremendous challenge. It is often more efficient to experiment on animals such as the cockroach, to gain a basic understanding of how form follows function in neural systems. These experiments examine the interaction of multi-modal sensory acquisition, motor control, learning and memory systems and how they are organized in the brain of the cockroach. The antennal projection response (APR) is an established paradigm to explore learning and memory in the cockroach. It has been used to explore the neural basis of associations between olfactory and visual space and how this spatial encoding is integrated with motor, tactile, and proprioceptive cues. A series of experiments, each examining a different element of learning or memory in the cockroach, were performed using the APR in restrained cockroaches. These experiments were carried out on both intact brain animals, and animals which had a procedure done to divide the halves of the brain. The ability of the cockroach to learn a simple association of a light paired with an odor with sensory stimuli has been demonstrated in the split-brain cockroach, but more complex forms of learning and memory have not. Experiments here revealed multiple elements underlying complex spatial learning behavior, including, the role of unilateral and bilateral sensory acquisition and learning, memory localization within the brain hemispheres, memory transfer and interference, and the interaction of neural systems. The split-brain cockroach was developed to explore the neural basis of learning and memory. The split-brain strategy provides an obvious advantage in that it gives experimental tissue from one half of the brain and control (naive) tissue from the other half of the same brain. Neural tissue was extracted from trained cockroaches and analyzed. This analysis allowed for the examination of protein and structural changes in the brain associated with various learning and memory paradigms. The usage of split-brain animals in these experiments provided both a control and experimental specimen in one individual.

Title: Effects of field relevant concentrations of imidacloprid and clothianidin on bee neuronal function

Authors: *C. MOFFAT, M. J. PALMER, C. N. CONNOLLY
Neurosci., Dundee Univ., Dundee, United Kingdom

Abstract: Neonicotinoids are nicotinic acetylcholine receptor agonists displaying high affinity in insects. Worldwide, these insecticides are used in veterinary products and as agricultural pesticides. Their high affinity and specificity to insects has underpinned their commercial success but there are increasing concerns regarding their effects on important pollinators. While there is mounting evidence that sub-lethal doses of neonicotinoids can have detrimental effects on bees; there is continuing controversy over the precise levels of pesticides to which bees are exposed in the field and stemming from this the levels that reach bee brains. This study investigated the levels of imidacloprid: the archetypal neonicotinoid reaching bee brains upon environmentally relevant levels of exposure and the effects of concentrations within this range on neuronal health and function. Feeding experiments were conducted with *Apis melliferra* and *Bombus terrestris* using food laced with environmentally relevant levels of imidacloprid. Experiments revealed low levels in the brains of both species that were sufficient to cause rapid neuronal damage in *Bombus terrestris* only. Chronic exposure of cultured *Bombus* Kenyon cells to low (nM) imidacloprid produced vulnerability to normally sub-toxic insults. Electrophysiological recordings from *Bombus* Kenyon cells revealed that sub-nanomolar concentrations of clothianidin had an apparent desensitising effect on nicotinic acetylcholine receptors. In conclusion, exposure of bees to field-relevant levels of neonicotinoids may result in brain concentrations that affect neuronal function.

Title: Synaptic correlates of performance on an ecologically relevant visual discrimination task in the adult honey bee mushroom body

Authors: *B. N. VAN NEST, G. S. MARRS, S. E. FAHRBACH
Biol. Dept., Wake Forest Univ., Winston-Salem, NC

Abstract: The mushroom bodies (MBs) are paired regions of the arthropod brain associated with sensory integration and memory formation. The dendritic arborizations of the intrinsic MB neurons (the Kenyon cells) are in the calycal neuropil, where they receive sensory input from primary sensory neuropils and reward input from the subesophageal ganglion. Calycal neuropils are larger in honey bee foragers than in non-foragers, and generalist-foraging insect species tend to have larger MBs than specialist-foraging species, suggesting that larger neuropils facilitate learning of complicated foraging tasks. Prior studies have focused on the experiences that promote MB growth and the cellular processes that cause this growth. The consequences of MB growth for an individual, however, are largely unexplored. Experience clearly fine-tunes brain structure in animals, but how does this feed forward onto behavior? How does an insect benefit from enlarged MBs? We developed a challenging, field-based, visual discrimination task that mimics natural foraging behavior. Free-flying honey bee foragers from a field hive were naturally recruited by nestmates to an artificial flower patch, where they learned to associate the hue of an artificial flower with a sucrose reward. The patch contained 24 randomly arranged flowers, all identically scented with peppermint to aid in recruitment. Six flowers (25%) were painted one shade of green and contained a sucrose reward. The remaining 18 flowers (75%) were painted a similar shade of green and remained empty. The rewarding shade was alternated each day of the experiment but remained consistent throughout each bee's training. Each forager was allowed 12 visits to the flower patch, and total activity was closely monitored on all visits. Each bee was scored on how quickly the color/reward association was learned. This task revealed 3 behavioral cohorts: fast-learners (30% of those trained) learned the association in fewer than 6 visits; slow-learners (30%) took at least 6 visits to learn the association; and non-learners (40%) never learned the association. Learning scores were correlated with synaptic density in the visual region of the MB calyx (the collar), assessed by whole-brain immunolabeling for synapsin-1 (a synaptic vesicle-associated protein) and confocal microscopy.

Title: Dynamic levels of phosphorylated Apis mellifera CREB in inner compact cells of the honeybee mushroom bodies and their role in the stimulus responsiveness of an animal

Authors: *D. EISENHARDT, K. GEHRING
Biology, Chemistry, Pharm., Freie Univ. Berlin, Berlin, Germany

Abstract: The transcription factor cAMP-response element-binding protein (CREB) plays a role in the excitability of neurons and in long-term memory (LTM) formation. Phosphorylation of CREB by protein kinase A (PKA) enables the binding of co-factors such as the CREB binding protein (CBP) to CREB, thereby inducing CREB-dependent transcription. An increase of phosphorylated CREB (pCREB) is regarded as an indicator of transcriptional activation by CREB. CREB has been isolated from several insect species and plays a crucial role in LTM formation in fruit flies. Little is known about the role of CREB in insect behavior and the localization of respective CREB-dependent processes in the insect brain. In this study, quantitative western blot analysis and immunohistochemistry were used to characterize the localization of Apis mellifera pCREB (pAmCREB) in the honeybee brain and explore its functional role in behavior. Prominent Anti-pCREB immunoreactivity (IR) was found in the inner compact cells (IC), a particular Kenyon cell (KC) population in the mushroom bodies (MBs) receiving multimodal sensory input. The amount of pAmCREB in the central brain and the IC was affected by age but was not modified upon olfactory classical conditioning or unpaired odor and sucrose presentations. However, bees of the unpaired group that showed responses to an odor upon the presentation of a reward had increased pAmCREB levels in the central brain and the IC, in contrast to bees that did not respond to the odor at all. Thus, pAmCREB levels in the IC might play a role in reward-related behaviors.

Title: Cell polarity protein scribble is required for forgetting of olfactory memories

Authors: *I. CERVANTES-SANDOVAL, R. L. DAVIS
Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: Forgetting of continuously acquired memories is crucial for proper function of the memory system. Nevertheless, little is known about the molecular, cellular and circuit basis of memory forgetting. Here we showed that Scribble, a scaffolding protein known mainly for its role as a cell polarity determinant, is required for normal forgetting of olfactory memories in *Drosophila*. Knocking down Scribble in either dopaminergic or mushroom body neurons, important constituents of the learning and forgetting circuits, impairs normal memory loss. Additionally, epistasis experiments showed that Scribble works in line with dopamine signaling, previously described to regulate active forgetting. Functional imaging experiments demonstrated that this memory loss impairment is due to miscommunication between dopaminergic and mushroom body neurons. These observations indicate that Scribble is a new molecular component required for the normal propagation of the forgetting signal.

Title: PKMzeta is necessary for maintaining the long-term facilitation of glutamatergic synaptic inputs but not of somatic glutamate responses in the snail neurons

Authors: *P. M. BALABAN, M. LEMAK, T. KORSHUNOVA, M. ROSHCHIN, A. ZUZINA, A. TIMOSHENKO, A. MALYSHEV
Inst. Higher Nervous Activity & Neurophysiol. RAS, Moscow, Russian Federation

Abstract: In behavioral experiments it was shown previously that selective inhibitor of PKMζ Zeta Inhibitory Peptide (ZIP) impairs aversive context memory in terrestrial snail Helix lucorum. Long-term facilitation of excitatory (presumably glutamatergic) synaptic inputs from sensory neurons to giant premotor interneurons triggering tentacle withdrawal is supposed to be a basis of aversion learning and memory in terrestrial snails. We investigated whether PKMzeta takes part in maintenance of long-term facilitation in neural circuit underlying aversive tentacle withdrawal. Long-term facilitation of excitatory synaptic inputs to premotor interneurons was induced by high-frequency stimulation combined with 5 serotonin bath applications and lasted at least four hours. We found that bath application of 2*10-6 M ZIP at 90 min after tetanization reduced EPSP amplitude almost to the non-tetanized EPSP values. Application of scrambled ZIP peptide at the same concentration didn't affect the EPSP amplitude in comparison with saline or scrambled ZIP applications. Results support the idea of PKMζ involvement in post-induction maintenance of long-term synaptic plasticity in CNS of Helix. It was shown previously that repeated (1 per min) pressure applications of glutamate on the somatic membrane ("artificial synapse") of the giant premotor interneurons triggering tentacle withdrawal in the snail elicit local potentials that can be facilitated for hours by 5 2-min serotonin applications (Balaban et al.. Eur J Neurosci. 2004 Jan; 19(2): 227-33). We repeated similar experiments under ZIP/scrZIP added 120 min after the facilitating procedure. Obtained results showed that in conditions of "artificial synapse", facilitated responses to glutamate were not influenced by ZIP or scrZIP application. These results suggest that PKMzeta is not involved in postsynaptic plasticity of somatic glutamate responses in the snail neurons.

Title: miR-iab-8(4as)-3p is necessary during development in the αβ and α'β' mushroom body neurons for optimal learning and memory retention

Authors: *G. U. BUSTO, T. GUVEN-OZKAN, R. L. DAVIS
NEUROSCIENCE, THE SCRIPPS RESEARCH INSTITUTE, JUPITER, FL

Abstract: MicroRNAs (miRNAs) are small non-coding RNAs involved in the post-transcriptional regulation of gene expression. A compelling sum of data indicates a major role for those molecules in biological processes as diverse as development and tumorigenesis. Their pivotal role in organismal development as orchestrator of gene expression made them likely actors in neurodevelopment. We recently screened 134 individual miRNAs for functional involvement in *Drosophila* melanogaster memory using 'sponges' to inhibit their activity in the nervous system. Among the miRNAs identified, several were necessary during development for normal adult memory formation. We find that miR-iab-8(4as)-3p is necessary during development specifically in the αβ and α'β' mushroom body neurons. Inhibition of miR-iab-8(4as)-3p limits the formation of anesthesia-sensitive memory but does not alter odor or shock perception using an olfactory classical conditioning assay. Protein-synthesis dependent long-term memory is also impaired. Four potential target genes have also been investigated. These results highlight the role of a new miRNA that may be central for the development of mushroom body neurons, neurons critical for memory formation. More broadly, our results may offer new insights into the molecular mechanisms altered in the neurodevelopmental disorders that impair learning and memory.

Title: Neural pathways routing early memory decay in *Drosophila*

Authors: *Y. SHUAI[1], A. HIROKAWA[1], Y. AI[1], W. LI[2], Y. ZHONG[1]
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Rockefeller Univ., New York, NY

Abstract: Memory fades as time passes by. Emerging evidence suggests that memory decay is subserved by an "organized" active removal process. The *Drosophila* early olfactory aversive memory has been a leading model in studying this so-called "active forgetting", where small G-protein Rac and dopamine were found to be key regulatory signals. The existing data also suggest the mushroom body (MB) as an important brain locus for early memory forgetting. However, it is yet to be known at the MB micro-circuit level how neurons participating in forgetting segregate from and interact with those in memory. Here, we performed an extensive characterization of the MB circuits in forgetting. We first further delimited Rac function to the γ lobe subset of MB intrinsic neurons, which send parallel axons only to the MB medial lobes. To understand the involvement of MB extrinsic neurons (MBen), we then performed a behavioral screen of ~40 relatively specific MBen Gal4 drivers, which together cover the majority of MBen connected to the medial lobes. The screen uncovered two population of MBen that bi-directionally regulate early memory decay when inactivated and hyper-activated. The blockade of them does not affect learning, suggesting that the micro-circuit for forgetting are segregable from those for learning. Moreover, we provide anatomical and physiolgical evidence that they respectively intersect with the MB γ lobe and β' lobe, indicating that they interact with memory circuits of different stages. We propose that a forgetting micro-circuit embedded in the MB network guide early labile memory towards destruction.

Title: An importin role in long-term memory consolidation

Authors: *Q. LI[1], X. ZHANG[1], X. LIANG[1], L. WANG[1], Y. ZHONG[1,2]
[1]Tsinghua Univ., Beijing, China; [2]Cold Spring Harbor Lab., New York, NY

Abstract: It is believed that importin-mediated nuclear transport is important for long-term synaptic plasticity from invertebrates to mammals. Surprisingly, little is known whether importins participate in long-term memory formation. Here we report that an importin can bi-directionally regulate aversive long-term memory strength in *Drosophila*. We found acutely down-regulation of the importin during consolidation led to LTM defect, while up-regulation led to LTM enhancement. Moreover, this change on LTM strength was confined in mushroom body neurons. Thus, our results demonstrate a critical role of importins in memory consolidation.

Title: Octopamine's role in sexual behavior

Authors: *A. I. FERNANDEZ, J. LIM, J. JAMES, K.-A. HAN
Univ. of Texas At El Paso, El Paso, TX

Abstract: Octopamine (OA) is a major monoamine neuromodulator in invertebrates. It regulates numerous physiological processes including motivation, pheromone response, olfaction, ovulation, learning and memory. These processes are likely mediated by multiple OA receptors. There are four known OA receptors in *Drosophila*: OAMB, Octβ1R, Octβ2R, and Octβ3R. The goal of our study is to understand the mechanism by which OA regulates sexual behavior. To achieve the goal, we have investigated basal and high order courtship behaviors of the flies deficient in OA biosynthesis or individual OA receptors. For basal activities, we examined a male's behavior towards a female and measured duration and latency of courtship and copulation. We also performed the conditioned courtship test, in which male flies learn to modify their courtship activity after experiencing rejection from mated females. If the rejected males learned well, they will suppress courtship towards a virgin female. When subjected to basal and conditioned courtship assays, the OA receptor mutants, oamb, octb1r and octb2r, exhibited different phenotypes. Studies are in progress to identify specific behavioral components and relevant neural sites that the OA receptors regulate sexual behavior. This study is supported by the RISE NIH 5R25GM069621-11 and USDA NIFA2010-65105-20625 grants.

Title: Behavioral assays to study deficits in spatial cognition in *Drosophila* melanogaster

Authors: *J. APARICIO VALENZUELA, D. HWANG, D. D. LENT
CSU Fresno, Fresno, CA

Abstract: The fruit fly, *Drosophila* melanogaster, has proven to be a useful model organism in the study of many human disease processes and they are commonly used in both genetic experiments and neurological experiments. The most advantageous reason that *Drosophila* makes for a good model organism when looking at neurodegenerative diseases is that around 70% of disease-associated human genes have a fly homolog, which makes research with this organism very feasible. However, there is yet no easy measure of complex behavior and often we can only use basic measures to view decline in behavior and any quantitative measure of cognition in fruit flies is lacking. Most insects, including *Drosophila*, have very good learning

abilities. Experiments here quantified the behavior of flies in a place learning/spatial memory assays in order to elucidate cognitive traits. Using GAL4-UAS and GAL80 temperature sensitive mutants to express ectopic disease associated proteins (e.g. Tau & ABeta42) in specific brain regions in a set of experiments and the use of ion channel insertions in another set of experiments, aspects of spatial cognition in fruit flies were examined. Training flies in a place memory assays provided insight into issues of visual perception, visual learning and short-term memory. The use of long-term probe trials provided better understanding of processes of consolidation and long-term memory. This assay demonstrates variable rates of learning, variable disruption in short-term and long-term memory. These differences were attributed to differential expression of the ectopic proteins in the mushroom bodies and central complex of the flies. These brain regions were found to be individually important in certain elements of perception and learning. However, only when both regions were functionally intact was more complex spatial cognition revealed. This is one of the first studies to focus on cognitive decline in *Drosophila*. This has significance in that it relates to in that overexpression of proteins that cause neurodegeneration and dementia. By learning more about the molecular pathways and the quantitative expression levels of disease associated proteins in the nervous tissue of fruit flies and correlating that with a quantitative measure of spatial cognition, we can further enhance our understanding of neurodegenerative diseases in humans.

Title: Sleep pattern and hierarchical organization in Procambarus clarkii

Authors: K. MENDOZA-ÁNGELES[1], N. JIMÉNEZ-MORALES[1], G. ROLDÁN-ROLDÁN[2], *J. HERNANDEZ-FALCON[3]
[1]Facultad de Ingeniería, [2]Facultad de Medicina, Univ. Nacional Autónoma de México, México, Mexico; [3]Dept Physiol, Univ. Natl. Autonoma Mexico, Mexico, Mexico

Abstract: The main outcome of agonistic interactions is the establishment of a dominance relationship that determines access to resources. In crayfish, smell is the most important sensory cue in agonistic interactions. After several social interactions, crayfish triads establish a hierarchical order with one dominant and two submissive animals (submissive 1, and submissive 2). In a given group, hierarchy is stable when measured in repeated trials. When measured on a daily basis, the intensity of positive interactions (threats, attacks and fights) diminishes, while negative interactions (retreats and avoidances) increase. In sleep-deprived triads, positive interactions raise. The main goal of this work was to investigate the role of sleep deprivation in the establishment and maintenance of hierarchical organization of crayfish triads and its effects on olfactory threshold.We used male adult Procambarus clarkii triads in intermolt. We studied: a) The sleep pattern in isolated animals and when they were submitted to social interaction; b) Agonistic interactions in control and sleep-deprived triads, and c) The behavioral response to olfactory stimulus in control and sleep deprived individuals. Our results indicate that: a) Sleep-patterns in isolated animals are highly variable and dependent on the studied animal. However, when animals are submitted to social interactions, they show a fragmentation of the previous pattern and a reduction in total sleep duration, which are clearer in submissive 2 crayfish. b) As we have previously reported, positive contacts increase in sleep-deprived triads, in amount, intensity and duration of the encounters. We also found that negative contacts increase too. These results indicate that memory recognition among a triad is not impaired but disturbed by sleep deprivation c) Olfactory stimulation with urine from a dominant crayfish produces an escape tail flip in submissive animals. The latency for this response is longer in sleep deprived individuals than in control animals, the longest latencies were for submissive 2 animals. These results imply that submissive animals identify the dominant one through urine signals, and that sleep deprivation impairs olfactory perception.

Title: Defining the parameters through which sleep deprivation affects the induction of associative memory using *Aplysia* californica

Authors: *L. C. LYONS[1], R. T. WILLIAMSON[2], J. SANCHEZ-PACHECO[2], H. C. KRISHNAN[1]
[1]Dept. of Biol. Science, Program in Neurosci., [2]Dept. of Biol. Sci., Florida State Univ., Tallahassee, FL

Abstract: The induction and formation of memory represents a dynamic process modulated by multiple factors including the circadian clock and sleep. Defining the mechanisms through which endogenous factors target short and long-term memory formation is necessary for identification of approaches to improve memory and to mitigate the toll that modern society exacts upon individuals who are working longer hours or shift-work. Given the high degree of conservation underlying memory formation across species, the marine mollusk *Aplysia californica* with its relatively simple neural circuitry provides an ideal model for detailing *in vivo* interactions between sleep, the circadian clock and memory formation. We recently characterized sleep in *Aplysia* using behavioral criteria for defining invertebrate sleep (Vorster et al., 2014). *Aplysia* sleep appears dually controlled by the circadian clock and homeostatic processes with *Aplysia* sleep occurring solely during the night and rebound sleep occurring after sleep deprivation. Using an associative learning paradigm, learning that food is inedible, in which the animal associates a specific netted seaweed with the inability to swallow, we previously found that 9 hours sleep deprivation starting 3 hours after lights out in 12 h:12 h light-dark cycles was sufficient to block the induction of short and long-term memory. In our current research, we extended these studies to investigate the magnitude and timing of recovery sleep necessary following 9 hours sleep deprivation to restore the induction and formation of memory as well as the duration and timing of sleep deprivation necessary for inhibiting memory. We found that 9 h sleep deprivation persistently inhibited the induction of short and long-term memory for 24 hours following sleep deprivation, whereas similarly handled daytime control animals demonstrated robust STM and LTM. While over-training via additional training sessions was not sufficient to rescue the induction of long-term memory immediately after sleep deprivation, it was sufficient to ameliorate the persistent effects of sleep deprivation rescuing the induction of memory 24 hours after sleep deprivation. The persistent effects of acute sleep deprivation naturally reversed within 48 hours for both short and long-term memory. We also found that 6 hours sleep deprivation either during the first half or last half of the night was sufficient to block the induction of long-term memory. These behavioral studies have established *Aplysia,* with its relatively simple neural circuitry, as a valid model system for studying the interactions between sleep and memory formation.

Title: Robust neural and behavioral sensitization after peripheral, but not central, application of serotonin

Authors: *R. CROOK[1], P. PAREKH[3], M. LERNER[4], J. JO[2], L. KLAASSEN[5], E. T. WALTERS[1]
[1]Dept. of Integrative Biol. and Pharmacol., [2]Grad. Sch. of Biomed. Sci., Univ. of Texas Hlth. Sci. Ctr. At Houston, Houston, TX; [3]Intrnl. Med., Univ. of Texas Southwestern, Dallas, TX; [4]Temple Univ., Philadelphia, PA; [5]Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: Sensitization of defensive reflexes in *Aplysia* is a useful model to study fundamental mechanisms related to learning and memory and to injury-related phenomena such as chronic pain. Serotonin (5-HT) has well-studied facilitatory effects on central synapses of nociceptive sensory neurons in *Aplysia* and can also induce hyperexcitability in the soma and peripheral axons of these sensory neurons. However, little is known about the effects of central versus peripheral 5-HT delivery on defensive reflexes or the activity of peripheral axons. We used a reduced preparation of the pleural and pedal ganglia, the p9 nerve and the tail to test the effects of peripherally- and centrally applied 5-HT on reflex sensitization and afferent activity. Intracellular recordings from nociceptors were used to assess the effect of 5-HT application on the p9 nerve. Thresholds were decreased compared to baseline both in the presence of 5-HT and five minutes after washout. During application of 5-HT to a nerve segment with the tail but not the CNS attached, the first application of 5-HT to the nerve produced rapid and sustained increases in activity of unidentified axons in the p9 nerve compared to seawater treatment. Later applications produced progressively smaller increases. In tests where the tail was reversibly blocked by isotonic MgCl2 in nerve wells distal to the 5-HT application site, there was less afferent activity in the presence of 5-HT. After washout, there was no difference in the number of spikes produced by electrical nerve stimulation between 5-HT-treated and control preparations. We tested the effect on the tail withdrawal reflex (TWR) of applying 5-HT to the pleural ganglion, p9 nerve, or tail tissue. 5-HT applied peripherally to either the tail or the nerve had a stable enhancing effect on the TWR apparent within 30 minutes of 5-HT washout, persisting in the intermediate term (2-4 h) and longer term (up to 7 h). In contrast, applying 5-HT

centrally to the pleural-pedal ganglia had no effect on the TWR at any of time points tested. The inability of central 5-HT application to elicit behavioral sensitization combined with the persistence of peripherally-induced sensitization, suggests that 5-HT has complex effects within the CNS, including strong suppressive effects on defensive reflexes. It also points to a large role in long-lasting nociceptive sensitization from 5-HT and other injury-related signals on nociceptor terminals and axons in peripheral tissues.

Title: Single exposure to natural noxious stimuli produces short-term suppression of feeding in *Aplysia*

Authors: K. D. WOLFE, M. L. WAINWRIGHT, D. L. SMEE, *R. MOZZACHIODI
Dept. of Life Sci., Texas A&M Univ. - Corpus Christi, Corpus Christi, TX

Abstract: An increasing body of literature demonstrates that fear carries potent ecological consequences. Extensive work has detailed how prey respond with adaptive behavioral changes to various indicators of predation risk, including predator presence, predator kairomones, and alarm cues released by conspecific. Such behavioral responses include enhancing defensive behaviors like vigilance, defensive reflexes, or escape responses at the expense of non-defensive behaviors like feeding. However, most studies examined defensive behavioral changes during or immediately following cue detection, giving little attention to the persistence of modification in the intermediate or long term. Moreover, it is unclear to what degree and duration non-defensive behaviors, such as feeding, are altered following exposure to various chemosensory alarm cues. Using a well-studied neurobiological model organism, the sea hare *Aplysia californica*, we

sought to characterize the effects of single exposures to natural noxious stimuli on feeding behavior at different time points following exposure. We introduced *Aplysia* to the following stimuli: a natural predator, the lobster *Panulirus interruptus*, sub-lethal attacks and exposure to a novel predator, the blue crab *Callinectes sapidus,* and ink and opaline (alarm cues secreted by attacked *Aplysia* conspecifics). Feeding, quantified by measuring the number of ingestive radula movements (i.e., bites), was measured prior to and 15 min, 2 h and 24 h after exposure to one of the above treatments. Untreated animals served as controls. *Aplysia* attacked by blue crabs, exposed to lobsters, or presented with ink or opaline suppressed feeding between 15 min and 2 h, relative to unexposed animals. *Aplysia* did not suppress feeding following exposure to crabs. No stimulus induced intermediate or long-term changes in biting, as evidenced by the lack of feeding suppression between 2 h and 24 h following exposure. This finding suggests that single exposures to natural cues only produce short-lived behavioral changes, and that *Aplysia* differentiate the potential risk pervaded by various stimulus sources. Ongoing studies are investigating whether repeated exposures to select stimuli can extend feeding suppression for longer periods of time. Future experiments will characterize the neural mechanisms underlying feeding suppression induced by the above stimuli using *in vivo* recordings of nerve activity along the chemosensory pathway and from the motor outputs of the feeding neural circuit.

Title: Molecular correlates of long-term memory consolidation after a brief training of *Aplysia* with inedible food at night, with a protein synthesis inhibitor

Authors: R. LEVY[1], *A. J. SUSSWEIN[2,3]
[1]Goodman Fac. of Life Sci. and Gonda Brain Sci. Ctr., [2]Fac. Life Sci., Bar-Ilan Univ., Ramat-Gan, Israel; [3]Gonda Brain Res. Ctr., Bar Ilan Univ., Ramat Gan, Israel

Abstract: Training *Aplysia* with inedible food for 5 min or longer during the daylight hours leads to protein-synthesis dependent memory when measured 24 hrs later. In three conditions, memory is not produced: 1) when animals are trained at night; 2) when animals are trained in the presence of the protein-synthesis inhibitor anisomycin during the day; 3) when animals are trained for only 3 min during the day. However, a 3 minutes training at night with anisomycin produces memory 12, 24, and 36 hours after training. Long-term memory after training at night is not seen only after a brief training: a longer training also produces memory, provided that animals are treated with anisomycin. Thus, combining 3 variables that each alone blocks memory (brief training, night training, anisomycin) leads to memory. Memory was blocked by treating animals with the transcription inhibitor DRB, indicating that memory formation depends on transcription, and probably also on translation of the transcribed mRNAs when the effects of anisomycin during training wear off. We have examined molecular correlates of memory formation after training for 3 min at night after treatment with anisomycin. Using real-time PCR, changes in expression of a number of mRNAs whose synthesis is associated with memory formation were measured 2 hrs after training. Controls were treated with anisomycin at night. Training caused significant increases in the expression of *Ap*CEB/P, and of *Ap*CREB-1, but not of *Ap*CREB-2. Since both trained and untrained animals were treated with anisomycin, the increased expression of *Ap*CEB/P and *Ap*CREB-1 caused by training could not be attributed to anisomycin induced superinduction. The findings are consistent with the hypothesis that training at night is ineffective in producing memory because training causes the active synthesis of one or a number of proteins blocking memory formation. Anisomycin blocks synthesis of the blocker. In addition, proteins that must be expressed as a result of training during the day are already present at night, thereby allowing the training to produce long-term memory.

Title: Solute carrier protein is required in the adult mushroom body neurons for the regulation of *Drosophila* memory acquisition and memory loss

Authors: *Y. GAI, Z. LIU, M. CHAKRABORTY, R. DAVIS
Dept. of Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: Memory acquisition and loss are critical for animals to response properly to constantly changing environments. However, the underlying molecular mechanisms remain largely hidden, especially for memory loss. Until recently, few genes have been demonstrated to function in memory loss, including transcriptional repressors, cytoplasmic protein kinases and phosphatases, and trans-membrane adhesion molecules and receptors. In our current study, a *Drosophila* SLC (solute carrier protein) gene was identified by its function as a memory suppressor gene. RNAi knockdown of SLC in the CNS slowed both memory acquisition and memory loss relative to control flies. Spatial mapping studies identified the *Drosophila* mushroom bodies (MB) as the site for its memory suppressor function. Conversely, SLC overexpression in MB significantly accelerated memory loss. The memory enhancement phenotype occurring from SLC knockdown was completely rescued by a SLC overexpression transgene. Immunohistochemistry studies revealed broad expression of SLC expression in CNS but enhancement in the mushroom body dendritic area. Biochemical studies pursued by expression of *Drosophila* SLC in HEK 293 cells and fly primary neurons revealed the SLC transports L-carnitine, acetylcholine, betaine, dopamine, and histamine. Ongoing dietary supplementation experiments are establishing the relationships between different substrates and the SLC-related memory phenotype. Overall, this research provides insights into the nature of memory suppressor systems.

Title: Two cortical hedonic hotspots: Orbitofrontal and insular sites of sucrose ‘liking’ enhancement

Authors: *D. C. CASTRO, N. S. CHESTERMAN, M. K. H. WU, K. C. BERRIDGE
Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Over the last decade, the affective taste reactivity test, which measures the affective orofacial reactions to taste stimuli, has helped identify three subcortical "hedonic hotspots", or sites in which hedonic reactions can be neurochemically amplified, in the rat: one in nucleus accumbens, one in ventral pallidum, and one in the brainstem parabrachial nucleus. However, whether or not there are any cortical sites capable of generating a hedonic enhancement is still unknown. Neuroimaging work in humans has indicated two potential cortical sites especially code hedonic experiences of pleasant foods: orbitofrontal cortex (OFC) and insular cortex (IC). To determine whether these cortical areas contain causal hedonic hotspots, we performed targeted microinjections of the mu opioid receptor agonist DAMGO, or of the orexin receptor agonist Orexin-A in either OFC or IC before recording affective orofacial 'liking' reactions elicited by oral infusions of sucrose or quinine solutions. We found that injections of DAMGO or orexin into any mediolateral site in the rostral half of OFC enhanced positive hedonic reactions to sucrose, without altering disgust reactions to quinine. In contrast, any mediolateral microinjection site in the caudal half OFC actually suppressed hedonic reactions to sucrose (i.e., a hedonic coldspot). For motivation however, mu or opioid stimulation enhanced palatable food intake at all sites throughout OFC, both rostral and caudal. In insula, we found a hotspot in posterior IC (e.g., sensory/visceral IC) where both opioid or orexin agonist microinjections enhanced sucrose 'liking' reactions. Oppositely, we found a caudal coldspot in anterior IC (i.e., associated with disgust) where opioid or orexin microinjections suppressed hedonic reactions to sucrose. Altogether, these data support the existence of two novel hedonic hotspots in the cortex, one in rostral OFC, and one in caudal IC, and also identify suppressive cortical coldspots.

Title: Optogenetic VTA dopamine stimulation supports motivated 'wanting' for a reward but does not enhance hedonic 'liking'

Authors: *M. J. ROBINSON[1], D. C. CASTRO[2], K. C. BERRIDGE[2]
[1]Psychology, Wesleyan Univ., Middletown, CT; [2]Biopsychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Optogenetic stimulation (Channelrhodopsin) of ventral tegmental area (VTA) dopamine neurons in TH-Cre transgenic rats has been implicated in self-stimulation, but whether this same stimulation can enhance the rewarding properties of an external sensory reward such as sweet food remains unknown. First, we confirm that TH-Cre dopamine neuron activation supports self-stimulation, showing rats would touch a metal spout and also learn to go to a specific location to earn VTA laser stimulation. We further show that VTA stimulation causes enhancement of motivation to earn an external sucrose reward by increasing breakpoint in a progressive ratio task, and additionally amplifies and narrows motivated choice by making a rat intensely prefer to earn a VTA laser-paired sucrose pellet over an otherwise equal sucrose pellet alternative reward. The preference induction was even strong enough to cause a normally less desirable salt pellet to become preferred over sucrose. Finally, however, we show using the affective taste reactivity test, that dopamine laser stimulation in VTA DA neurons and in specific projections to the nucleus accumbens, fails to enhance hedonic 'liking' reactions to sucrose, even in the same rats that it made 'want' sucrose more. Altogether, these data implicate VTA dopamine in incentive motivation, but not hedonic impact, and help extend understanding of dopamine and reward.

Title: Optogenetic stimulation of central amygdala magnifies motivation and controls choice for cocaine reward

Authors: *S. M. WARLOW[1], M. J. F. ROBINSON[2], K. C. BERRIDGE[1]
[1]Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Psychology, Wesleyan Univ., Middletown, CT

Abstract: Normal motivation requires making choices among competing incentives. Pathologies such as drug addiction can be characterized by distortion of choice, and excessive desire focused inappropriately on one incentive at the expense of others. The amygdala has been implicated in assigning focused incentive motivation to a particular target on the basis of learned associations. We have previously reported that optogenetic ChR2 stimulation of the central nucleus of the amygdala (CeA) severely biases choice for a paired sucrose pellet over another identical sucrose pellet (Robinson & Berridge, 2014). Can CeA optogenetic stimulation also bias choice for earning one cocaine reward above others? Here we optogenetically stimulated CeA to create a focused pursuit of an arbitrarily designated cocaine reward. Rats were given a choice between earning two identical cocaine infusions, but only one cocaine option was accompanied by CeA laser stimulation. Rats intensely pursued the cocaine infusion accompanied by CeA laser stimulation while ignoring the otherwise identical cocaine infusion that had no laser. Furthermore, CeA stimulation amplified motivation to pursue cocaine in a progressive ratio test. Rats exhibited higher breakpoints for cocaine reward when accompanied by CeA laser stimulation than when cocaine was earned alone. Finally, this CeA amplification and narrowing of pursuit was not due to simple CeA reward effects, as rats did not self-stimulate in CeA nor did CeA laser induce a place preference. We propose that ChR2 stimulation of CeA can intensify and narrow the focus of incentive motivation for cocaine reward, just as it does for a natural sucrose reward.

Title: Stimulation of dopamine D3 receptors attenuates the expression of pavlovian conditioned approach responses and motivation for incentive cue presentation

Authors: *K. M. FRASER[1,2], J. L. HAIGHT[3], S. B. FLAGEL[4,1]
[1]Mol. and Behavioral Neurosci. Inst., Ann Arbor, MI; [2]Undergraduate Program in Neurosci., [3]Neurosci. Grad. Program, [4]Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Cues in the environment can guide behavior in adaptive ways, bringing one in close proximity to valuable resources (e.g. food, water, sex). However, some cues, specifically those that attain incentive salience, can gain inordinate control over behavior and direct actions in a maladaptive manner, as is evident in addiction and other disorders of impulse control. Reward cues acquire incentive salience via Pavlovian learning processes. Although a role for dopamine has been identified in these processes, it is still unclear as to which receptors are involved. Here we investigated the role of the dopamine D3 receptor in the attribution of incentive salience to discrete reward cues. To do this, we utilized an animal model that allows us to parse the neurobiological processes underlying the attribution of incentive vs. predictive value to a discrete cue paired with food-delivery. Outbred Sprague-Dawley rats were first characterized as sign- or goal-trackers based on 7 days of Pavlovian conditioning wherein brief presentation of a lever-cue was paired with delivery of a food reward. Sign-trackers attribute incentive salience to the reward-paired cue, as measured by interaction with the cue upon its presentation. In contrast, goal-trackers use the reward-paired cue merely as a predictor of reward delivery and upon its presentation orient behavior accordingly towards the food cup (i.e. the goal). Following acquisition of these respective conditioned responses, we used a within subject design to determine the role of the D3 receptor in the expression of sign- and goal-tracking behaviors. Increasing doses (0.01-0.32 mg/kg) of 7-OH-DPAT were administered and compared to the effects of vehicle injections on alternating days. We found that stimulation of the dopamine D3 receptor attenuates the expression of both of sign- and goal-tracking behavior. There was a dose-dependent effect on sign-tracking behavior, with the largest effects in response to the two highest doses of drug. Interestingly, goal-tracking was attenuated only at the lowest drug doses. To further examine the effects of D3 stimulation on the attribution of incentive salience to a discrete reward cue, we examined the effects of 7-OH-DPAT on the conditioned reinforcing properties of the lever-cue. Administration of the D3 agonist significantly attenuated the motivation to work for presentation of the lever-cue in sign-trackers, but not goal-trackers. This work highlights a role for the D3 receptor in the expression of Pavlovian conditioned approach responses and in the attribution of incentive salience to discrete reward cues.

Title: A role for negative reinforcement in AGRP neuron-mediated instrumental food seeking

Authors: *Z. HUANG CAO[1,2], J. BETLEY[1], S. M. STERNSON[1]
[1]Janelia Farm Res. Campus, Ashburn, VA; [2]Pharmacol., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Agouti related peptide (AGRP) neurons in the arcuate nucleus of the hypothalamus are sufficient to elicit avid food seeking and consumption behaviors. Recent data indicates that these homeostatic neurons transmit a negative reinforcement teaching signal in which increased AGRP neuron activity evokes an unpleasant internal state and reduction of AGRP neuron activity in hunger is reinforcing. One implication of AGRP neuron-mediated negative reinforcement is that, over multiple sessions, elevated food-seeking performance of instrumental actions is expected to require a decline in AGRP neuron activity. To test this, we used cell-type specific optogenetic manipulations of AGRP neuron activity during and following an operant task. Under food restriction, animals maintained high levels of lever pressing for food on a 15-day progressive ratio 7 schedule of food pellet reinforcement. Mice trained under food restriction but then re-fed ad libitum initially showed similarly elevated lever pressing during AGRP neuron photostimulation. However, subsequent tests with this protocol resulted in a progressive decline in lever pressing for food. Disruption of AGRP neuron-mediated negative reinforcement of instrumental food seeking was most sensitive to high effort motivated responding. These experiments indicate that elevated AGRP neuron activity during and following instrumental responding for food reduces the level of effort expended to seek and consume food, consistent with a role for negative reinforcement in AGRP neuron-mediated food seeking behavior.

Title: Identifying functional alterations in neuronal ensembles activated during 1-day acquisition of operant learning in rats

Authors: *L. R. WHITAKER, K. B. MCPHERSON, J. M. BOSSERT, Y. SHAHAM, B. T. HOPE
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Learned associations between environmental stimuli and rewards drive goal-directed learning and motivated behavior. These associations are thought to be encoded by specific patterns of sparsely distributed neurons called neuronal ensembles that are determined by the cues and reward. The question remains as to how neurons in these ensembles are functionally altered during learning, and which of these changes encode learned associations. The objectives of our study were to identify ensembles of neurons strongly activated during acquisition of operant learning, and then to determine functional alterations specific to these neuronal ensembles. During two days of magazine training, the Experimental group received food pellets in the magazine paired with a 5-second light cue every 4 minutes. The Control group was placed in the same environment with no light cue or pellets and instead received the same number of pellets in their home cages after the session. On test day, rats in the Experimental group were allowed to lever press for food pellets in the self-administration chambers for two hours with the 5-second light cue paired with each lever press. Rats in the Control group had access to the lever, but lever pressing did not elicit any cues or pellet release. The Experimental group quickly formed an association between lever pressing and food reward, and maintained lever pressing throughout the duration of the session. The Control group pressed significantly less than the Experimental group, usually for a brief duration at the beginning of the session. Immunohistochemical analysis indicates induction of Fos expression in medial prefrontal cortex and nucleus accumbens—two regions critical for the acquisition of goal-directed learning and motivated behavior. In future experiments, we will use *c-fos-GFP* transgenic rats in which strong neuronal activation activates the *c-fos* promoter and drives expression of GFP. Whole cell brain slice electrophysiology will then be used to assess functional alterations in behaviorally activated GFP-labeled neuronal ensembles.

Title: Specific impairments of brain activations in individuals with trait anhedonia: A preliminary study

Authors: *R. C. CHAN[1], Z. LI[1], W.-Z. XIE[2], C. YAN[3]
[1]Key Lab. of Mental Hlth., Inst. of Psychology, Chinese Acad. of Scienc, Beijing, China; [2]Univ. of California, Riverside, Riverside, CA; [3]East China Normal Univ., Shanghai, China

Abstract: Objectives: Anticipatory and consummatory dissociation of hedonic experience may manifest as trait anhedonia in healthy and clinical populations. Most studies on trait anhedonia used monetary-based incentive delay paradigms and very few studies have focused on affect- or social-based stimuli. It is still unclear if the underlying neural mechanisms of the monetary-based and affect-based incentive delay paradigms really dissociate from each other. We aimed to examine the similarities and differences between the Affect Incentive Delayed (AID) and the Monetary Incentive Delay (MID) imaging paradigms on brain activation. Method: We administered the AID and the MID tasks to 28 healthy participants (age=18.88+1.81). A cue signaling the type of forthcoming feedback (reward or punishment) was displayed to the participants, followed by a target-hit task with corresponding reward or punishment. All participants were scanned with a 3-Tesla scanner (Siemens 3T-Trio A Tim, Erlangen, Germany). All the participants were also administered the Chapman Social Anhedonia Scale, the Chapman Physical Anhedonia Scale, and the Temporal Experience of Pleasure Scale, and were subsequently clustered into an anhedonic group (n = 8) and a non-anhedonic group (n = 20) according to these scales scores. Results: In the anticipatory phase of the MID, the left substantia nigra, the right caudate body, the right insula, the right medial frontal gyrus, the right parahippocampal gyrus, and the left insula were activated to the positive cue, while the left substantia nigra and bilateral thalami were activated to the negative cue. In the consummatory phase of the MID, the right medial frontal gyrus, the left anterior cingulate cortex, the right

insula and the right precuneus were activated when gaining monetary points, while none of activation was found when losing monetary points. In the consummatory phase of the AID, the right inferior frontal gyrus, the right anterior cingulate cortex and bilateral superior frontal gyrus were activated to the positive pictures, while the right superior temporal gyrus, bilateral medial frontal gyrus and bilateral inferior frontal gyrus were activated to the negative incentives. In the subgroup analyses, the anhedonic group exhibited significant hypoactivation than the non-anhedonic group in the left pulvinar, the left claustrum and the left insula to the positive cue during anticipation of AID. Conclusions: The present study demonstrates that both the AID and the MID tasks have unique and similar activation patterns. Our findings also suggest that the AID task is more sensitive to detect anhedonia in people with trait anhedonia.

Title: Improving how we measure motivation by dissociating goal directed responding from arousal induced responding with a novel progressive hold down task

Authors: *M. BAILEY[1], G. JENSEN[2], K. TAYLOR[4], C. MEZIAS[4], C. WILLIAMSON[3], V. MAGALONG[4], R. SILVER[2,4], E. SIMPSON[5], P. BALSAM[4,3,5]

Abstract: Motivated behavior consists of a goal directed and arousal component. Commonly used measures of motivation such as the progressive ratio schedule (PR) do not dissociate these two processes. For example, amphetamine is known to increase responding in a PR as well as to induce hyperactivity and arousal. We directly address this challenge by developing a novel behavioral assay known as the progressive hold down (PHD) which can in conjunction with a PR schedule dissociate goal directed persistence and arousal. We use methamphetamine (meth) treatment in both the PR and the PHD to show how separating behavior into these two

components of motivated behavior more precisely informs our understanding of how alterations in motivation affect responding. Adult male C57Bl/6 mice received operant lever press training. Mice were then trained to hold the lever in the depressed position to earn reward. We next tested mice on the PHD task, in which each reward required a progressively longer hold of the lever. In this PHD, mice press for longer durations until reaching a breaking point, which ranged from 54 seconds to 235 seconds between subjects. The PHD task is sensitive to motivation manipulations as mice had significantly higher breakpoints when hungry compared to sated mice. Moreover, behavioral output is increased when the reward magnitude is increased. Meth was injected IP at 1.0 mg/kg 20 minutes before behavioral sessions and mice were tested in either the standard PR or the PHD tasks. In the PR, treatment with meth lead to an increased number of lever presses, longer sessions, and more earned reinforcers - all suggesting that goal directed motivation was increased. However, on the PHD task, meth did not alter the breakpoint but did impair the efficiency of responding because of bursts of brief duration responses. Taken together these data indicate that meth acts to increases hyperactivity or arousal rather than enhanced goal directed motivation. Our novel assay allows behavior to be measured in a way which dissociates goal directed motivation from arousal and hyperactivity. This gives us a new tool for dissecting the impact of pharmacological and genetic manipulations on different specific aspects of motivation.

Ciências Médicas, Univ. Nova de Lisboa, Lisbon, Portugal; [4]Dept. of Psychiatry and Mental Hlth., Ctr. Hospitalar de Lisboa Ocidental, Lisboa, Portugal, Lisbon, Portugal

Abstract: Hypocretinergic (HCRT) neurons, with cell bodies located in the Lateral and Dorsomedial Hypothalamus (LH and DMH), project to the main monoaminergic nuclei in the brain, including the ventral tegmental area (VTA). Through these connections, hypocretinergic neurons closely interact with systems that modulate emotion, the sleep/wake cycle, energy homeostasis and reward. Previous research has shown that animals will self stimulate electrodes implanted in the LH, and that intrinsic LH neurons are necessary for this process. Given the well known relationship between VTA dopaminergic neurons and reward seeking behavior we hypothesized that stimulation of LH HCRT neurons is reinforcing and induces self stimulation. To address this hypothesis we used mice with cre-dependent expression of channel rhodopsin (ChR2) in HCRT neurons, and tested if these mice would engage in self-stimulation of these neurons. ChR2 was delivered to the LH of Cre-HCRT mice using an adeno-associated virus, and optic fibers were implanted above the injection site in order to allow for light-mediated stimulation of HCRT cell bodies. After recovering from surgery these mice were trained in an operant box containing two levers - an active lever that controlled delivery of light pulses through the optic fiber and inactive lever that had no such effect. Dependent on specific stimulation conditions, including the cell infection rate and the laser power, male mice acquired the operant task, with high press rates on the active lever, in order to modulate the activity of HCRT neurons. These results suggest that hypocretin neurons are part of a circuitry that is involved in motivation, and that stimulation of hypocretinergic neurons has reinforcing properties, probably relevant for reward-seeking behavior.

Title: The enhancement of cue-induced motivation in obesity-prone vs. resistant rats is accompanied by sensitization to cocaine and increased CP-AMPA receptor expression in the NAc

Authors: C. W. NOBILE[1], P. B. GOFORTH[1], J. T. CORTHELL[1], M. J. F. ROBINSON[1,2], K. C. BERRIDGE[3], *C. R. FERRARIO[4]

Abstract: While the decision to eat is shaped strongly by hunger, satiety, and energy demand, it is also greatly influenced by environmental cues associated with food (food-cues). For example, in humans exposure to food-cues, like a blinking donuts sign, can increase ratings of desire to eat, and the amount of food consumed (Fedoroff et al., 1997, Soussignan et al., 2012). Similarly, in rodents food-cues can elicit approach, reinforce operant responding, and increase food consumption (Kelley et al., 2005; Holland and Petrovich, 2005; Cardinal et al., 2002; Balleine, 2005). Obesity-prone people are more susceptible to these motivational effects of food-cues, and food-cues activate the striatum more strongly in obese vs. non-obese people (Rothemund et al., 2007; Stoeckel et al., 2008). This differential activation may be driven in part by alterations in AMPA receptor (AMPAR) expression as AMPARs provide the main source of excitation to the striatum, play a role in behavioral responses to food-cues, and are increased after exposure to sugar (Crombag et al., 2008; Peng et al., 2011; Tukey et al., 2013). We recently found that rats that are susceptible to diet-induced obesity show enhanced attraction to and motivation for food-cues compared to non-obese rodents fed the same diet. Here, we determined whether mesolimbic function differs in obesity-prone vs. resistant rats prior to and/or after exposure to the junk-food diet. In addition, alterations in striatal AMPAR expression and function were also evaluated. We found that both obese and obesity-prone rats showed a sensitized locomotor response to cocaine compared to non-obese and obesity-resistant rats, consistent with enhanced reactivity of mesolimbic systems. In outbred obese rats, sensitization was seen after "junk-food" diet was removed and rats were given ad lib access to standard lab chow only for 2 weeks, whereas sensitization was evident in selectively bred obesity prone vs. resistant rats without any diet manipulation. In addition, prolonged exposure to a “junk-food” diet followed by a return to standard lab chow for two weeks was associated with a selective increase in surface GluA1 protein expression only in obese rats. This selective increase in GluA1 in obese rats in the absence of changes in GluA2 may be indicative of calcium-permeable AMPARs (CP-AMPAR), which play a role cue-induced drug craving (Loweth et al., 2013; Wolf and Ferrario, 2010). These results are being confirmed by whole-cell patch clamp recordings and will be discussed in light of the potential contribution of enhanced glutamatergic transmission and sensitization of incentive-motivation to obesity.

Title: Activation of ventral pallidum versus lateral preoptic area: double dissociation by threat discounting and locomotion

Authors: ***D. S. ZAHM**, H. S. STEVENSON, Z. M. SCHWARTZ, K. P. PARSLEY
Pharmacol. and Physiological Sci., St. Louis Univ. Sch. of Med., Saint Louis, MO

Abstract: We have been interested in brain substrates that may subserve an adaptive balance between threat tolerance and reward acquisition. In an earlier study (Soc Neurosci Abst 393.16, 2013), we evaluated the hypothesis that threat tolerance varies directly in relation to locomotor activation elicited by disinhibition of the lateral preoptic area (LPO). That study exploited the innate aversion of rats to bright illumination and their reluctance to enter open spaces (thigmotaxis). We observed that unfasted rats readily entered the field centers of dimly illuminated activity monitors to acquire sweet chocolate pellets (TestDiet, Richmond, IN, cat. #1811256, 45 mg), but almost never took pellets in monitors fitted with overhead spotlights (GE 90W 120V 1260 lumens) aimed at the field centers. However, the willingness of rats to consume pellets in spotlighting was marginally, but significantly, increased by stimulating locomotion with LPO infusions of bicuculline (bic), a GABA A receptor antagonist. In the present study, the experiment was repeated with the infusions targeted to the ventral pallidum (VP), which activate locomotion less vigorously than the LPO infusions (Brain Struct Funct 219:511-26, 2014). In contrast to the LPO study, in which the increase in threat tolerance observed following LPO activation was slight, rats receiving bic infusions into the VP essentially disregarded the presumed threat of spotlighting, acquiring as many sweet pellets in the spotlit as in the dimly lit control condition. In contrast, the numbers of pellets ingested in dim lighting by rats receiving VP bic infusions were no greater than the numbers ingested by the vehicle-infused controls, and, insofar as neither the bic-infused rats nor the vehicle-infused controls routinely consumed all of the 20 pellets allotted per session, pellet consumption elicited by VP bic may reflect other than a

compulsive feeding response. Also, consistent with previous results cited above, VP bic infusions done in the present study increased locomotion slightly or not at all. Thus, the present data complete a double dissociation of bic infusions into the LPO and VP. LPO infusions increase locomotion robustly (3-8 fold) and pellet taking in the spotlight modestly. Infusions into the VP increase locomotion not at all or modestly (less than 2 fold), but greatly enhance pellet-taking in the spotlight. Some tolerance of threat in the pursuit of reward is essential to the survival of organisms, but a tendency to discount threat becomes maladaptive. Liberal threat discounting by humans contributes to faulty decisions and adverse or injurious consequences. The VP may contribute to overriding threat.

Title: Lesions of the paraventricular nucleus of the thalamus differentially affect the acquisition and expression of Pavlovian-conditioned responses

Authors: *J. HAIGHT[1,2,4], K. M. FRASER[3], B. N. KUHN[2], H. AKIL[4], S. B. FLAGEL[1,4,2]
[1]Psychiatry, [2]Neurosci. Grad. Program, [3]Undergraduate Program in Neurosci., Univ. of Michigan, Ann Arbor, MI; [4]Mol. and Behavioral Neurosci. Inst., Ann Arbor, MI

Abstract: In recent years, evidence has emerged suggesting a role for the paraventricular nucleus of the thalamus (PVT) in the processing of reward-associated cues. However, the specific role of the PVT in these processes has yet to be elucidated since much of the previous work is confounded by the fact that Pavlovian-conditioned reward cues can act as both predictive and incentive stimuli. Using an animal model that captures individual variation in response to discrete reward-associated cues, we have been able to parse the incentive from the predictive

properties of reward cues. When rats are exposed to a Pavlovian conditioning paradigm, wherein a discrete cue predicts food reward, some rats, termed sign-trackers (STs), attribute incentive salience to the cue. Other rats, termed goal-trackers (GTs), treat the cue as a predictor. Here we investigated the role of the PVT in the expression and acquisition of these conditioned responses (CRs). First, outbred Sprague-Dawley rats were trained in a Pavlovian-conditioning task. After sign- and goal-tracking CRs were acquired, ibotenic acid was used to lesion the anterior and posterior PVT. Following recovery, rats resumed Pavlovian training and the expression of their CRs was measured. Lesions of the PVT after rats had learned their respective CRs affected GTs, but not STs. When compared to sham-operated controls, PVT lesions attenuated the expression of a goal-tracking response, and increased a sign-tracking response selectively in GTs. To determine whether PVT lesions affected the incentive motivational properties of the lever-cue, rats were subsequently tested in a conditioned reinforcement paradigm. PVT lesions did not affect responding for lever-cue presentation in STs, but increased responding in GTs. In a separate experiment, we assessed the effects of PVT lesions on the acquisition of sign- and goal-tracking CRs. This was accomplished using selectively bred rats lines in which it is known a priori whether these rats will acquire a sign- or goal-tracking CR. PVT lesions were performed prior to training and following recovery rats underwent 12 sessions of Pavlovian conditioning. Sign-tracking rats with PVT lesions showed an exaggerated sign-tracking response, compared to sham-operated controls. In addition, PVT lesions attenuated the development of a goal-tracking response in rats with an inherent tendency to goal-track. Together, these data suggest that the PVT is critically involved in both the acquisition and expression of sign- and goal-tracking behaviors, and that this structure plays a critical role in the attribution of incentive motivational properties to reward cues.

Title: Local injection of oxytocin into the primate amygdala enhances prosocial motivation

Authors: *S. W. CHANG[1,2], K. TODA[2,3], A. V. UTEVSKY[2], M. L. PLATT[2]
[1]Dept. of Psychology, Yale Univ., New Haven, CT; [2]Duke Inst. for Brain Sci., Duke Univ., Durham, NC; [3]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: The primate amygdala (AMYG) is thought to be critical for mediating social behavior. Single-unit recording studies in AMYG have found motivational signals (Paton et al., 2006) as well as signals relevant to social information, such as identity and facial expression (Gothard et al., 2007). However, the contributions of AMYG to motivations during social interactions (social motivation) remain unknown. We previously showed that when there is no cost to actor monkeys in a social reward-allocation task, the activity of AMYG neurons tracks the reward values associated with each decision similarly across rewards delivered to oneself, another individual, or both, and that these signals predict how prosocial or antisocial actor monkeys are across trials (Chang and Platt, 2013, SfN abstract). These results suggest that AMYG neurons encode the value of rewards received by others with respect to the value of rewards experienced by oneself. The neuropeptide oxytocin (OT) is thought to modulate social motivation and saliency by acting on multiple brain regions. Previous studies in humans and rodents have implicated AMYG to be one of these core sites of OT action. Furthermore, OT-induced changes in BOLD activity in AMYG seem to be critical in individuals with autism. Together, these observations suggest that OT may influence social behavior via modulation of activity in AMYG. To test this idea, we probed the impact of local injections of OT into the AMYG on social decisions in male rhesus macaques. On alternating sessions (separated by at least one day), we locally injected OT (5µg/µl in 2µl saline) or vehicle (saline, 2µl) into the AMYG sites where we recorded social reward-related activity, while the actor chose between rewarding himself and both himself and the recipient as well as when he chose between rewarding the recipient and no one (Chang et al., 2011, 2012, 2013). As a control, we injected OT or vehicle into the dorsolateral prefrontal cortex (dlPFC), an area that has not been implicated in OT regulation of social function. OT injections in AMYG, relative to vehicle, increased the frequency of prosocial choices. OT injections in AMYG also modulated gaze directed at the recipient following all decisions, relative to vehicle. Changes in social gaze varied between individual monkeys. By contrast, these injections did not affect choice reaction times. Finally, OT injections in dlPFC did not influence any of these behaviors. Our results demonstrate that locally enhancing OT levels in AMYG enhances the motivation to make prosocial decisions.

Title: Motivation for palatable food in an animal model of diet-induced obesity

Authors: *F. CORTÉS SALAZAR[1], J. O. SUÁREZ-ORTÍZ[1], D. DÍAZ-URBINA[1], V. E. LÓPEZ-ALONSO[1], J. M. MANCILLA-DÍAZ[1], N. TORRES-TORRES[2], R. E. ESCARTÍN-PÉREZ[1]
[1]Neurobiología de la Alimentación, Univ. Nacional Autónoma de México, Facultad De Estudios Superiores Iztacala, Mexico; [2]Fisiologia de la Nutricion, Inst. Nacional de Ciencias Médicas y Nutricion Salvador Zubiran, Ciudad de Mexico, Mexico

Abstract: Obesity is a global health problem associated with diseases that significantly increase mortality rates. Despite obesity and overweight have multifactorial causes, recurrent over-consumption of energy dense foods is frequently present in these conditions. These diets are commonly highly palatable and activate the brain reward circuit, promoting over-consumption of food. The finding that children and adults are more motivated to work for food than non-overweight peers suggests that the processing of the rewarding properties of food might be related to obesity induced by diet, however it is not clear if differences in motivation to eat among obese and non-obese is a cause or a consequence of over-consumption of food. Accordingly, the present study was aimed to evaluate in an animal model of obesity (diet-induced obesity, DiO) if the chronic (6 months) exposure to a high-fat diet induced changes in motivation to eat palatable food using a progressive ratio (PR) schedule of reinforcement and to determine if the initial motivation to eat predicts the final weight gain in rats exposed to the high-fat diet. Male Sprague Dawley rats (weighting 100-150 g at the beginning of the experiment) were feed with a high-fat diet (45% of energy from fat, n=24) or the control diet (similar flavor, 10% of energy from fat, n=12) for 6 months. Motivation for palatable food (chocolate flavored sugar pellets) was measured at three different points of time, at the beginning of the protocol (after 2-3 weeks), after 3 months, and after 6 months of exposure to the high-fat diet (independent groups of rats). We measured biochemical markers in palsma (Leptin, cholesterol, triglycerides, and insulin), weight gain (g), and the fat mass/body weight ratio to validate the

obesity model. By measuring break points under a PR schedule of reinforcement we assessed motivation for palatable food (rats were trained with fixed ratio 1 and 5 schedules before the PR schedule). We found that animals exposed to the high-fat diet gained significantly more body weight after 4 months of the protocol. Additionally, we found that the biochemical markers of obesity (high levels of Leptin, cholesterol, triglycerides, and insulin in plasma) were higher than controls after 4 months of high-fat diet consumption. According to the behavioral tests, break points of rats exposed to the high-fat diet were significantly higher than controls only in the first period of evaluation and the initial break points did not predict the body weight gain. Our results suggest that differences in motivation to eat palatable food are not directly associated to the development obesity.

Title: The effect of glucocorticoid receptor antagonism on sign-tracking behavior

Authors: S. SEWANI[1,2], K. H. LONG[1,2], T. SHAPIRO[1,2], H. AKIL[1], *S. B. FLAGEL[1,2]
[1]Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, ANN ARBOR, MI; [2]Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Cues in the environment can guide our everyday behavior leading us towards valuable resources. However, cues can also acquire the ability to guide behavior in maladaptive ways. For example, cues that have previously been associated with drug-taking behavior can instigate drug-seeking behavior and relapse. Reward cues gain inordinate control over behavior when they are attributed with incentive motivational value (i.e. incentive salience), but this only occurs for

some individuals. Using a Pavlovian conditioning paradigm, it has been shown that some rats, termed sign-trackers, approach and engage a discrete reward-associated cue, whereas other rats, goal-trackers, approach the location of reward delivery upon presentation of the cue. Thus, the cue attains incentive motivational value for sign-trackers and not goal-trackers. It has previously been shown that sign-trackers exhibit a greater increase in corticosterone in response to repeated pairings of a cue and reward in a Pavlovian conditioning paradigm. Here we examined the effects of systemic glucocorticoid receptor (GR) antagonism on the propensity to attribute incentive salience to a discrete cue associated with a food reward. We used selectively bred rats that differ in their predisposition towards sign- or goal-tracking behavior in order to examine the effects of GR antagonism on the acquisition of these conditioned responses. Rats were injected with the GR antagonist mifepristone (40mg/kg, i.p.) prior to Pavlovian autoshaping sessions, and their propensity to approach and contact the reward associated cue or the location of reward delivery was measured. There was no effect of mifepristone administration on the first day of Pavlovian training; however, sign-tracking behavior was attenuated across sessions in mifepristone-treated rats with an inherent tendency towards this behavior. These rats were less likely to contact the reward-associated cue, and when they did contact it they did so with less vigor and at a slower rate compared to their vehicle-treated counterparts. Goal-tracking behavior was not affected by mifepristone in these rats. Interestingly, when taken off of the drug after 9 days of training, the rats that were previously treated with mifepristone continued to exhibit attenuated sign-tracking behavior relative to vehicle-treated control rats. Thus, GR antagonism appears to block the development of a sign-tracking response in rats with an inherent tendency to exhibit this behavior. These findings demonstrate a role for glucocorticoids in the attribution of incentive motivational value to discrete reward-related cues.

Title: Selective optogenetic stimulation of d1 'direct' or d2 'indirect' neurons of nucleus accumbens versus lateral septum

Authors: *S. L. COLE, M. J. F. ROBINSON, K. C. BERRIDGE
Univ. of Michigan, Ann Arbor, MI

Abstract: The nucleus accumbens (NAc) shell and lateral septum are two brain regions that are similar in neuron types and anatomical projection patterns, and are both implicated in motivation and reward. The NAc has two main output projections: a "direct" pathway to the brainstem, comprised of neurons bearing D1 dopamine receptors that projects directly to ventral tegmentum, and an "indirect" pathway containing D2 neurons, which projects first through the ventral pallidum and hypothalamus before going to midbrain regions. The lateral septum is also comprised of both D1 and D2 containing neurons, and has connectivity patterns similar to NAc medial shell . Here, we optogenetically stimulated selectively either D1 containing neurons or D2 containing neurons in NAc shell versus lateral septum as anatomical structures,using Cre mice differentially expressing channelrhodopsin (ChR2) in either D1 or D2 neuron types. We compared stimulation effects on 2 tasks: 1) an 'internal reward' self-stimulation task in which mice directly earned ChR2 laser stimulation by touching a metal empty spout and 2) an 'external sensory reward' task in which laser stimulation modulated an external food reward: mice could choose to earn either a sucrose pellet reward that was paired with laser stimulation or an alternative equally good sucrose reward without laser stimulation. Results showed that for the 'internal reward' task, NAc D1 stimulation or NAc D2 stimulation were each sufficient to support laser self-administration. However, mice never showed self-stimulation in lateral septum regions. By contrast, for the external reward task, laser stimulation of lateral septum D1 neurons (but not D2 neurons)enhanced the preference for the laser-paired sucrose reward and intensified its pursuit at the expense of the alternative sucrose-without-laser reward. However, laser stimulation of NAc shell did not enhance the external sucrose reward (neither D1 or D2). These results show differences between reward functions of neuronal populations in NAc shell and lateral septum, as well as implicating a somewhat surprising self-administration reward role for D2 neurons in NAc and potentially its indirect pathway.

Title: Representation of past negative outcome and subsequent behavioral shift in the primate lateral habenula and anterior cingulate cortex

Authors: *T. KAWAI[1,2,3,5], H. YAMADA[3,4], N. SATO[2], M. TAKADA[1], M. MATSUMOTO[3,4]
[1]Div. of Systems Neurosci., Primate Res. Institute, Kyoto Univ., Inuyama, Japan; [2]Grad. Sch. of Humanities, Kwansei Gakuin Univ., Nishinomiya, Japan; [3]Grad. Sch. of Comprehensive Human Sci., [4]Fac. of Med., Univ. of Tsukuba, Tsukuba, Japan; [5]JSPS Res. Fellow, Tokyo, Japan

Abstract: Neurons in the lateral habenula (LHb) and anterior cingulate cortex (ACC) are excited by negative experiences. However, little is known about how their signals contribute to subsequent choice behavior. To address this issue, we recorded single-unit activity from the LHb and ACC in monkeys performing a reversal learning task. While the monkey was gazing a fixation point, two saccadic targets were presented on both the left and the right sides of the point. The monkey was required to choose one of the targets with a saccade. Choosing one target was followed by reward with 50% probability, whereas choosing the other was followed by no-reward. The reward-position contingency was fixed within a block of 20 to 40 trials, and then reversed without any instruction. The monkey learned to choose the rewarded direction by trial-and-error, and changed the choice to the alternative if the choice was repeatedly followed by no-reward. Thus, the monkey decided to "stay" the current choice or "shift" to the alternative in the next trial through the experience of several past outcomes. We recorded the activity of 62 LHb neurons and 359 ACC neurons in two monkeys. Ninety-two percent (57/62) of the LHb neurons and 35% (125/359) of the ACC neurons were more strongly activated by no-reward outcome than by reward outcome. To examine how these no-reward responsive neurons contribute to subsequent choice behavior, we conducted a multiple linear regression analysis of their activity. We found that the no-reward response of ACC neurons reflected several past outcomes, and that this response further represented whether the monkey stay the current choice or shift to the alternative in the next trial. Notably, these two responses were observed in different ACC neurons. On the other hand, the response of LHb neurons mainly reflected the no-reward outcome in the current trial. The response latency was significantly shorter in LHb than in ACC neurons (LHb, 207.3ms ± 18.1ms; ACC, 580.2ms ± 38.1ms; Wilcoxon rank-sum test, $P < 0.01$). Our findings suggest that the ACC links past negative experience to subsequent adaptive choice, whereas the LHb may be involved in this process by signaling the current negative outcome via reciprocal connections between the two areas.

Title: Impact of binge eating upon learning and performance of a sucrose discrimination task

Authors: *E. G. FONSECA DE LA CRUZ[1,2], M. VILLAVICENCIO[3], R. GUTIERREZ[3]
[1]Pharmacol., Ctr. De Investigación Y Estudios Superiores, Mexico, Mexico; [2]Inst. de Fisiología Celular, Mexico City, Mexico; [3]Pharmacol., Ctr. de Investigación y Estudios Avanzados del I.P.N, Mexico, Mexico

Abstract: Binge eating disorder (BED) is characterized by the rapid ingestion of palatable food in a brief period of time. In rodents, sucrose intermittent access produces behavioral responses similar to those observed in BED followed by neurochemical changes that affects brain reward system. However, BED impact over gustatory system remains elusive. It is not known whether BED can produce a long-term modulation over perceptual and/or oromotor abilities of rats to detect and identify sucrose and whether these changes contributes to BED maintenance. We explored the effect that BED over sucrose discrimination. During 28 days three groups of rats were assigned to one of three conditions: 1) Intermittent (INT/BINGE) 2h sucrose access, 2) Ad Libitum (AdL), 24h sucrose access, 3) Chow (CH) 2h sucrose access on day 1 and 28. All rats had 12h chow access in the dark phase. During the 2h sucrose access, INT/binge group significantly consumed 15 and 21 ml more sucrose than AdL and CH group, respectively. At day 29, sucrose access was suspended for all groups, subjects were water deprived for 22h and discrimination training began. Rats were trained to emit 2-4 dry licks in a central spout to receive a drop of water (washout) followed by 2-4 dry licks to randomly receive a single 15µl drop of a discriminative taste cue: 3% or 10% sucrose concentration. Subsequently, subjects required to stop licking and emit differential responses (left or right) according to the taste cue received. Correct responses were reinforced by three 15µl water drops. Additional Licks (AL's) after cue provides the reaction time needed to detect the sucrose drop. During the first training week,

before learning occurs, licking pattern among groups was significantly different. AL's evoked by taste cues was concentration-dependent and was significantly lesser only for the INT/BINGE group relative to AdL and CH group, indicating that BED rats can better halt the consummatory reflex evoked by a drop of sucrose, which might allow these animals to overconsume sucrose in a short period of time. Similarly, Body Movement Time (BMT, time elapsed between the last lick in the central spout and go to collect the reward in the lateral spout) was shorter for INT/BINGE than for AdL and CH groups. In sum, these data suggest that BED increases the motivation to collect a reward, by reducing the BMT and improving the fine-grain top-down control of oromotor responses. Learning and performance changes in sucrose discrimination will be evaluated; as well as BED effect over neuronal activity of the insular and orbitofrontal gustatory cortices during task.

Title: Optogenetic stimulation of ventral tegmental area dopamine cells facilitates operant shock avoidance behavior

Authors: *J. M. WENZEL, E. B. OLESON, V. C. CHIOMA, W. N. GOVE, A. RAGANATH, L. N. SMITH, J. F. CHEER

Abstract: The role of the mesolimbic dopamine system in positive reinforcement processes has been well documented. Utilizing a signaled operant footshock avoidance procedure our laboratory has previously shown that the mesolimbic system is also involved in negative reinforcement learning. Indeed, dopamine transients within the nucleus accumbens at the

presentation of a warning signal preceding footshock delivery were shown to predict successful shock avoidance, revealing a positive correlation between phasic mesolimbic dopamine transmission and shock avoidance. In order to assess a causal relationship between phasic dopamine transmission and avoidance behavior, the current study employed optogenetic techniques in a transgenic rat model. Briefly, rats expressing Cre-recombinase driven by the tyrosine hydroxylase promoter (TH::$Cre^{+/-}$ rats) received bilateral transfection with a Cre-inducible channelrhodopsin-2 (ChR2-EYFP) virus into the ventral tegmental area (VTA) as well as implantation of chronic bilateral optical fibers aimed at the VTA. Following recovery, animals learned a signaled operant shock avoidance task wherein illumination of cue light served as a warning signal which was presented 2s before the onset of footshock (0.6mA over 0.5ms, occurring at 2s intervals). Execution of a single lever press during this initial 2s interval resulted in the avoidance of footshock, whereas a lever press made after the initiation of shock delivery resulted in escape from footshock. Animals were trained on this task until they reached a stable level of avoidance behavior with successful avoidance on >50% trials for three consecutive days. Animals then underwent three test sessions that were identical to training sessions except that prior to each test animals' optical fiber implants were connected to a 473nm wavelength laser via sheathed fibers allowing for the delivery of optical stimulation to the VTA. Each test session consisted of a no-stimulation 30-min baseline session followed by a 30-min stimulation session during which the presentation of each warning signal coincided with VTA stimulation (20Hz, 10 pulses, 5ms duration). In congruence with our previous work, optical stimulation of VTA dopamine cells resulted in a significant increase in operant shock avoidance, illustrating a causal role for phasic mesolimbic dopamine activation in avoidance behavior. Importantly, similar stimulation-dependent enhancement of shock avoidance behavior was not observed in genotype (TH::$Cre^{-/-}$) and virus (EYFP) control groups that underwent identical training and test conditions.

Title: Motivational deficits and reduced cortico-striatal communication in Huntington's Disease transgenic rat model

Authors: *E. A. COLE[1], I. GILDISH[1], R. CACHOPE[2], J. F. CHEER[1]
[1]Anat. & Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]CHDI Fndn., Los Angeles, CA

Abstract: Huntington's Disease (HD) is a neurodegenerative disorder that occurs as a result of a >37 polyglutamine (CAG) repeat expansion within the huntingtin gene (htt). Initial progression of HD is characterized by cognitive and emotional impairments including depression, anxiety and decreased motivation, followed by motor deficits such as a lack of coordination and the development of chorea. Neural degeneration affects primarily the indirect pathway of the basal ganglia as well as the cortex. Prior to significant striatal degeneration, compromised cortico-striatal communication is thought to occur, however how this correlates with motivational deficits is still unclear. In order to characterize this, a behavioral test to assess motivation was carried out in combination with extracellular electrophysiological recordings from the prefrontal cortex (PFC) and the nucleus accumbens (NAc) in freely-moving animals. 3, 6, 9, and 12 month-old BACHD TG5 rats (a transgenic animal model of HD that carries a full length human mhtt gene with 97 CAG repeats) were surgically implanted with multielectrode microarrays. Rats performed a food-motivated progressive ratio lever-pressing task while local field potentials (LFPs) and single neuron firing were recorded simultaneously. Significantly lower breakpoints were observed in TG5 rats across all age groups indicating a decrease in motivation that is characteristic of the disease. Analysis of LFPs showed an overall decrease in oscillatory accumbal gamma power as well as reduced PFC-NAc gamma rhythm coherence. Analysis of single-units revealed alterations in the percentage of encoding inhibitory neurons in the NAc in TG5 rats compared to WT rats. The impairment in cortico-striatal communication present in TG5 rats may underlie pathological changes in behavior, specifically motivational deficits found in these rats.

Title: Psychometric assessment of brain stimulation reward discriminability

Authors: *M. S. MCMURRAY, J. A. SAUREZ, J. D. ROITMAN
Psychology, Univ. of Illinois At Chicago, Chicago, IL

Abstract: Intracranial self-stimulation (ICSS), in which rats perform motivated behaviors to earn electrical stimulation delivered to various regions of the brain, has been widely used to investigate reward neurocircuitry. Its primary implementation has been to construct a rate-frequency (R-F) curve, which describes the animals' rate of responding across a range of frequencies. The parameters that describe R-F curves are sensitive to chemicals that alter reward processing, such as drugs of abuse or peptides of hunger and satiety. Recently, brain stimulation reward (BSR) has become increasingly used as a replacement for food reward in cognitive tasks due to its stability over time, lack of food restriction, high temporal specificity, and lack of sensory cues. In many such tasks, animals choose between different frequencies of BSR; however, the discriminability of BSR frequencies and their relationship to R-F curve parameters has not been fully characterized. To parametrically determine the discriminability of BSR frequencies, we first trained rats to lever press for 100Hz stimulation to the medial forebrain bundle, followed by standard R-F curve estimation. Once stable, pairs of frequencies from each animal's R-F curve were compared in a choice task, in which presses on one lever resulted in 0.5s delivery of the higher BSR frequency, and presses on the other resulted in the lower BSR frequency. The frequencies compared varied randomly from session-to-session and included the animal's minimally reinforcing frequency (Theta), as well as 25%, 50%, 75%, 100% and 125% of the maximally reinforcing frequency. Discriminability, as indicated by subject preference, was assessed for both the absolute and ratio differences between the two frequency values. We found that regardless of ratio, frequency differences lower than 7Hz did not support a clear preference, suggesting that animals cannot effectively discriminate BSR stimulations that differ in less than 7Hz. Additionally, there was a strong correlation between an animal's discriminability threshold and both the slope and Theta of their R-F curve. These results have implications for the design of cognitive tasks relying on BSR, and suggest that numerous aspects of an animal's R-F curve may determine the reinforcing value of BSR.

Title: Resolving the interface between glucose homeostasis and reward

Authors: *T. L. DAHLE-MORVILLE[1], M. KERAMATI[2], B. GUTKIN[3], H. R. SIEBNER[1], O. J. HULME[1]
[1]714, DRCMR, Hvidovre, Denmark; [2]Gatsby Computat. Unit, Univ. Col. London, London, United Kingdom; [3]Group for Neural Theory, ENS, Paris, France

Abstract: Given the narrow range of physiological states compatible with survival, coupling reward maximisation to homeostatic optimisation places fundamental constraints on adaptive behaviour. Although there is converging behavioural evidence that homeostatic errors systematically amplify reward-values associated with minimising those errors, the neuroanatomical and computational basis of this homeostatic-reinforcement interface remains unresolved. Whilst acquiring high-resolution fMRI data, glucose-deprived subjects engaged in a simple probabilistic foraging task in which they chose between monetary and glucose prospects. We modelled the subjects' choice behavior as a function of blood-glucose and gut hormones using a Homeostatic Reinforcement Learning (HRL) framework, in which glucosensory states map onto putative drive states, and where rewards, defined as drive-reductions are learnt, and maximised using model-based RL-algorithms. We found that the homeostatic errors induced by glucose deprivation systematically modulated glucose-foraging behavior; that systemic-glucose correlated with slow-drift signal in the hypothalamus; and that homeostatic error systematically scaled the neurometric encoding of a diversity of reward variables.

Title: Nucleus Accumbens shell neurons monitor tastant consumption independent of their palatability

Authors: *M. A. VILLAVICENCIO CAMARILLO[1], I. O. PEREZ[2], S. S. SIMON[3], R. GUTIERREZ[1]
[1]Pharmacol., Ctr. De Investigación Y Estudios Avanzados, Mexico, Mexico; [2]Facultad de Estudios Superiores Izatacala, Carrera de Cirujano Dentista, Univ. Nacional Autónoma de México, Tlalnepantla, Mexico; [3]Neurobio., Duke Univ. Med. Ctr., Durham, NC

Abstract: Gustatory stimuli such as quinine or sucrose innately evoke either aversive or palatable responses such as gaping or licking (in rodents). It has been reported that neurons in the rat Nucleus Accumbens (NAc) shell selectively respond to quinine or sucrose by increasing or decreasing their firing rate (Roitman et al. Neuron, 45(4): 587-597, 2005). However, this behavioral task does not separate taste palatability from oromotor responses. The question then arises as to whether such NAc responses arise from differences in palatability and/or oromotor responses. To test this hypothesis, we recorded activity of 232 neurons from NAc shell of rats performing a palatability-detection Licking Reaction Task (LRT) (Perez et al. AJP-Regulatory, 305(3): 252-70, 2013). In this task during each trial, rats were required to lick an empty spout (dry licks) 3 to 5 times at the central port of a behavioral box before randomly receiving a 10-µl drop of a cue [water, quinine hydrochloride (QHCl), NaCl or sucrose] which served as tastants (with different palatability's) and as a signal to stop licking. Licks elicited after release of the stop signal [additional licks (ALs)] were measured. If ALs were ≤ 40 a reward of 10-µl drop of water was available in each of the two lateral spouts. We found that few neurons preferentially responded to one or more tastants (NaCl (0.4%), sucrose, (2.6%) water (4.3%) and QHCl (1.7%)). In contrast, oromotor licking responses per se evoked significantly greater neuronal modulations in that 32% of neurons were inhibited and 7% activated ~1.5 s before and during licking an empty spout. In addition, most neurons maintained the same neuronal modulation (either inhibition or activation) even after the release of the tastant stop signal. Neuronal activity then returned to baseline activity but not until ~ 0.5 s after licking was terminated. These results indicate that NAc neurons better reflect oromotor responses rather than encoding hedonic value. To support this hypothesis, we used the ensemble activity of NAc neurons and a PSTH-based classification algorithm to predict the tastant the rats received in each trial. Accordingly, the algorithm failed to predict which tastant rats received, but performance significantly improved when the algorithm classified trials as a function of short vs. long ALs, regardless of which of tastants delivered. Importantly, the ensemble of neurons accurately predicted QHCl vs. sucrose trials, since they evoked short vs. long ALs respectively, and not because NAc neurons

responded to differences on taste palatability. In summary, our data indicate that NAc neurons monitor consumption independent of tastant palatability.

Title: Selectively bred HAD-1 rats exhibit a unique emotional phenotype predictive of excessive alcohol intake

Authors: *N. THAKORE[1], J. M. RENO[2], E. KUSEY[3], A. GONZALEZ[4], T. SCHALLERT[2], R. A. GONZALES[5], C. L. DUVAUCHELLE[6]
[1]Col. of Pharm., Austin, TX; [2]Behavioral Neurosci., [3]Psychology, [4]Col. of Natural Sci., [5]Col. of Pharm., [6]Univ. of Texas at Austin, Austin, TX

Abstract: Emotionality is a well-established motivator of excessive ethanol drinking in humans. Until now, no animal studies have reported emotional response during voluntary excessive ethanol drinking. Selectively bred High Alcohol Drinking (HAD-1) rats exhibit high voluntary alcohol intake, and are proposed to be an animal model for alcoholism. It is unknown what motivational factors drive initial drinking in HAD-1 rats. To examine this, ultrasonic vocalizations (USVs), which are considered to be an accepted index of emotional status, were recorded from HAD-1 rats across 8 weeks of 7-hr "drinking-in-the-dark" (DID) sessions. Findings revealed that both alcohol-naïve and alcohol-experienced HAD-1 rats emit unprovoked 22-28 kHz USVs during DID sessions. Such spontaneous, unprovoked 22-28 kHz USVs are not commonly seen in the average lab rat. In fact, typical rat strains require mildly aversive stimuli (e.g., airpuffs) and alcohol dependency before emitting this type of call. Further analysis showed that alcohol experience enhances 22-28 kHz USVs produced by HAD-1 rats. Alternatively, frequency-modulated 50-55 kHz USVs were constant and equal across weeks in both groups, and do not appear to be affected by alcohol experience. A correlational analysis revealed a significant linear relationship between ethanol intake and 22-28 kHz, but not 50-55 kHz FM

calls. The results suggest that emotional phenotypes exhibiting spontaneous 22-28 kHz USVs and low levels of 50-55 kHz FM USVs may be predictive of vulnerability to excessive alcohol intake. Furthermore, the data indicate that increased 22-28 kHz USVs are directly linked to increased alcohol drinking. Taken together, these findings suggest that unprovoked 22-28 kHz USVs sensitized to ethanol in HAD-1 rats may convey an aspect of emotional response that was not previously associated with this call type.

Abstract: Deficits in memory and attention play an important role in schizophrenia and other neurological diseases. Cannabinoids have received increased attention as activation of CB1 receptors produce similar cognitive impairments to those associated with schizophrenia. Importantly, blocking CB1 receptors facilitates working memory. This effect is reversed by administration of rivastigmine (a cholinesterase inhibitor), suggesting an interaction between cannabinoid and cholinergic systems. The mechanism through which CB1 receptors interact with cholinergic interneurons to modulate memory, attention, and ultimately behavior remains unknown. To investigate this question, we generated mice lacking CB1 receptors on cholinergic terminals. We first hypothesized that this specific deletion would increase acetylcholine release leading to enhanced performance on cognitive tasks. Specifically, we concentrated on the dorsal

lateral striatum for its role in reward-directed locomotor behaviors and on the medium septum for its connection to the hippocampus. Using a combination of radioactive in-situ hybridization and immunohistochemistry, we initially verified that CB1 receptors co-localize with cholinergic terminals in both anatomical regions. Next, we observed that knockout animals express normal cholinergic populations, but these did not co-localize with CB1 receptors. To evaluate changes in working-memory, we used a delay-non-match-to-sample task and found that mice lacking CB1 receptors in cholinergic terminals had better retention at intermediate to long delays compared to wild-type animals. Next, we assessed motivational processes with a progressive ratio paradigm and found that knockout animals have higher breakpoints for palatable foods compared to control animals. Cholinergic neurons have also been implicated in the place conditioning properties of cocaine; therefore, we determined whether this comprised a CB1 receptor-dependent component. However, we did not observe differences in cocaine conditioned place preference in mutant animals compared to controls. These findings suggest that CB1 receptors on cholinergic terminals facilitate acquisition of information and its processing depending on the unconditioned characteristics of the reinforcer.

Title: Evaluation of behavioral differences between rats selectively bred for low and high voluntary running

Authors: *D. K. MILLER[1], J. D. BROWN[2], A. I. FILIPI[2], R. K. WILDING[2], F. W. BOOTH[3]
[1]Psychological Sci., [2]Med. Pharmacol. and Physiol., [3]Biomed. Sci., Univ. of Missouri, COLUMBIA, MO

Abstract: Physical activity is known to promote acquired and adaptive improvements in mental health, while low levels of physical activity are associated with poor mental health outcomes. For this study, we posed the question: does genetic inheritance of low or high physical activity

motivation cause the inheritance of negative or mental health outcomes, respectively? Our approach to answering this question was to measure how selectively breeding for low (LVR) and high (HVR) voluntary running behavior affected performance in behavioral tests classically used to determine anxiety-like behavior (i.e. elevated plus maze), depressive-like behavior (i.e. forced swim test), and nociception (i.e. thermal and mechanical stimulus sensitivity). We used young (post-natal day 30-40), male and female Wistar rats generated from 10th and 11th generation LVR and HVR lines as well as wild type (WT) Wistar rats in order to provide a comparison to non-selected rats of the same strain. One group of rats was measured for inherent performance in the elevated plus maze followed 72 hours later by forced swim testing, while a separate group of rats was used to determine inherent sensitivity to thermal and mechanical stimuli. Our results demonstrate that selectively breeding for low and high voluntary running behavior does affect inherited performance in all tests. Specifically, HVR rats are more likely to venture into novel, open spaces compared to LVR rats as measured by the elevated plus maze; HVR rats exhibit more immobile behavior than WT rats in the forced swim test; and LVR rats are less sensitive to thermal stimulation than WT and HVR rats. We conclude that LVR and HVR rats are a valuable voluntary, physical activity model for examining interactions between physical activity genetics/behavior, mental health, and nociception.

Title: Cholinergic regulation of depression like-behavior: Role of VTA nicotinic and muscarinic receptors

Authors: *E. J. NUNES, R. J. WICKHAM, N. A. ADDY
Psychiatry, Yale Univ., New Haven, CT

Abstract: The ventral tegmental area (VTA) has been implicated in numerous psychiatric disorders such as schizophrenia, bipolar disorder, and depression. Moreover, dopamine (DA) neurons in the VTA have recently been demonstrated to regulate depression-like behaviors on various animal models of depression including the tail suspension task, sucrose preference test, and social defeat stress. VTA DA neurons display two *in vivo* patterns of firing, low frequency tonic firing and high frequency phasic firing. We and others have shown that VTA nicotinic and muscarinic acetylcholine receptors (AChRs) regulate DA burst activity and downstream phasic DA release in the nucleus accumbens (NAc). While phasic DA activity has been demonstrated to play a causal role in depression like-behavior, the role of VTA AChRs on these behaviors are unknown. For that reason, we sought to determine the role of VTA cholinergic manipulations on depression-like behavior. The current studies investigated the behavioral effects of increasing VTA cholinergic tone and VTA AChR blockade during the forced swim test (FST), an animal model of depression. Intra-VTA infusion of the acetylcholinesterase inhibitor physostigmine (PHYSO) (1 or 2 μg/side) increased time spent immobile in the FST. This depression-like behavioral effect was similar to that of systemic administration of PHYSO (0.125mg/kg IP) but in contrast to what we observed with PHYSO infusion into the NAc (1 or 2 μg/side), which decreased immobility time in the FST. In addition, the same doses of PHYSO used in the FST experiments produced no significant effect on locomotor activity. Blockade of VTA cholinergic receptors with either the nicotinic AChR antagonist mecamylamine(MEC, 3 or 30 μg/side) or the muscarinic AChR antagonist scopolamine (SCOP, 2.4 or 24 μg/side) decreased time spent immobile. Next, either MEC or SCOP was co-administered with PHYSO to test whether cholinergic blockade can reverse the effects of intra-VTA PHYSO on the FST. Co-administration with AChR antagonists reversed the pro-depressive effects of intra-VTA PHYSO. Taken together, these results demonstrate that increased cholinergic tone in VTA produces a pro-depressive effect on the FST that can be reversed by cholinergic receptor blockade. Future studies should examine the effects of cholinergic manipulations in VTA on other behavioral models of depression.

Title: Serotonergic neurons signal reward and punishment on multiple timescales

Authors: *J. Y. COHEN[1], M. W. AMOROSO[2], N. UCHIDA[2]
[1]Neurosci., Johns Hopkins Univ., Baltimore, MD; [2]Mol. and Cell. Biol., Harvard Univ., Cambridge, MA

Abstract: Serotonin's function in the brain is unclear. One challenge in testing the numerous hypotheses about serotonin's function has been observing the activity of identified serotonergic neurons in animals engaged in behavioral tasks. We recorded the activity of dorsal raphe neurons while mice experienced a task in which rewards and punishments varied across blocks of trials. We "tagged" serotonergic neurons with the light-sensitive protein channelrhodopsin-2 and identified them based on their responses to light. We found three main features of serotonergic neuron activity: (1) a large fraction of serotonergic neurons modulated their tonic firing rates over the course of minutes during reward versus punishment blocks; (2) most were phasically excited by punishments; and (3) a subset was phasically excited by reward-predicting cues. By contrast, dopaminergic neurons did not show firing rate changes across blocks of trials. These results suggest that serotonergic neurons signal information about reward and punishment on multiple timescales.

Title: Role of histamine in the ventral tegmental area during a motivation dependent, and resistance to extinction tasks

Authors: *M. A. TORO, R. FALCON, J. L. VALDES
Lab. de Neurociencias, Programa De Fisiologia Y Biofisica, Fac. Med., Santiago, Chile

Abstract: Goal directed behaviors are determined by probabilistic learning and motivational aspect of the process associated to them. The mesolimbic dopaminergic pathway has been deemed as the most relevant neuromodulatory system involved in the operation of these processes, by controlling the motivational state of the subject, and learning the probabilistic relationship between actions and rewards. However the interaction of the dopaminergic system with other components necessary for goal directed behavior of the ascending arousal system, such as the histaminergic system, are still poorly understood. In this work, we studied the effects of bilateral injections of histamine or saline vehicle in the Ventral Tegmental Area (VTA) of rats, previous to: i) a progressive ratio task, were the animal (n=5, adult male Sprague-Dawley rats) must press a lever in a geometrically increasing way to get rewards, to measure motivation; and ii) a resistance to extinction task (n=5, adult male Sprague-Dawley rats), consisting on a training session were rewards are given at different probabilities (25,50,75, and 100%), and then no more lever presses are rewarded, to evaluate the resistance to extinction. The animals injected with histamine into VTA, compared to saline vehicle injections, showed a significant decrease in the motivation to get rewards in the progressive ratio and a diminished capacity to extinguish non rewarded behaviors, during the probabilistic rewards paradigm,. These results are in agreement with *in vitro* studies which suggest that the histamine may have an indirect inhibitory effect over the dopaminergic system, helping to unravel the interaction between this neuromodulatory system during goal directed behaviors.

Title: Selective ablation of mu opioid receptor expressing gaba neurons in the rostromedial tegmental nucleus promotes ethanol intake

Authors: ***R. FU**, X. CHEN, W. ZUO, J. LI, J.-H. YE
Dept. of Anesthesiology,njms,Rutgers Univ., NEWARK, NJ

Abstract: BACKGROUND AND PURPOSE The cellular mechanisms underlying the aversive effect of ethanol that limits its intake are not well understood, although recent evidence has linked aversion with synaptic inhibition of dopamine neurons in the ventral tegmental area. Emerging evidence indicates that the rostromedial tegmental nucleus (RMTg), a newly defined midbrain structure exerts a major GABAergic inhibitory control over midbrain dopamine neurons and encodes aversive stimuli. The RMTg contains mostly GABAergic neurons and with dense μ-opioid receptor (MOR) immunoreactivity. However, the role of RMTg in the regulation of ethanol intake has not been well investigated. EXPERIMENTAL APPROACH We compared voluntary ethanol intake and locomotion in rats with intra-RMTg infusion of dermorphin-saporin or blank saporin. Dermorphin-saporin is a neurotoxin, which could selectively lesion MOR-expressing neurons. We measured ethanol intake in rats given intermittent access to ethanol (20% vol/vol) using a two bottle choice paradigm. We euthanized the rats, dissected their brains and analyzed the glutamic acid decarboxylase67 (GAD67) and MOR protein expression and immunoreactivity immediately following the behavioral test. KEY RESULTS In rats that received intra-RMTg injection of dermorphin-saporin, we observed a robust increase in the intake of and the preference to ethanol, and in the locomotor activity; but a significantly reduced GAD67 and MOR protein expression, as well as a massive loss of neurons with GAD67 and MOR immunoreactivity within the RMTg. We observed no such changes in rats that received injection of blank saporin or saline. Together, These findings indicate that MOR-expressing GABA neurons in the RMTg play a crucial role in the regulation of ethanol consumption, implicating the dysfunction of these neurons likely play a critical role in the pathogenesis of alcoholism, and that these neurons should represent an appropriate target for the development of therapeutic strategies against alcohol use disorders.

Title: Sex differences in the depressive-like effects of kappa opioid receptor activation do not depend on circulating gonadal hormones in rats

Authors: D. J. PUTTICK, S. E. RUSSELL, D. N. POTTER, *E. H. CHARTOFF
Psychiatry, Harvard Med. Sch., BELMONT, MA

Abstract: The neuropeptide dynorphin activates kappa opioid receptors (KORs) in neural stress circuits to produce depressive-like states. There are pronounced sex differences in behavioral responses to stress. For example, females are more sensitive to the aversive effects of drugs of abuse and stress-induced relapse. Using intracranial self-stimulation (ICSS), we previously found that gonadally intact female rats are less sensitive than males to the depressive-like effects of the KOR agonist U-50,488_regardless of estrous cycle stage. U50,488 induced sex-dependent elevations in c-Fos expression in the paraventricular nucleus of the hypothalamus (PVN) and the bed nucleus of the stria terminalis (BNST), two stress-responsive regions that express corticotropin releasing factor (CRF). We hypothesized that the effects of KOR activation on reward depend on interactions between circulating gonadal hormones and CRF. To examine the activational effects of gonadal hormones on aversive responses to U50,488, we gonadectomized male and female rats that had previously been trained in ICSS. After five weeks, during which plasma sex hormones decreased (measured with ELISA), baseline ICSS responding was similar across groups (male and female, gonadectomized and sham). Rats were treated with U50,488 (0.0, 2.5, 5.0, and 10.0 mg/kg, IP) and stimulation thresholds compared. No significant differences to U50,488-induced increases in ICSS thresholds were detected between sham and gonadectomized rats. These data suggest that sex differences in KOR-mediated depressive-like states are not due to circulating gonadal hormones. Using quantitative real-time RT-PCR, we found higher basal levels of prodynorphin mRNA in the female PVN, BNST, and amygdala, and lower KOR mRNA in the BNST. Finally, levels of CRF receptor 1 (CrfR1) mRNA were lower in the amygdala and BNST of intact female compared to male rats. These findings raise the possibility that elevated dynorphin tone in females occludes the effects of KOR agonists, and that KOR-mediated activation of CRF systems is blunted in females due to decreased CrfR1. This underscores the importance of understanding KOR function in both sexes such that pharmacotherapeutics targeting mood disorders can be rationally designed.

Title: Estrogen suppresses negative vocalizations in female rats during methamphetamine withdrawal

Authors: *J. R. BROWNING, J. A. MONG
Dept. Pharmacol., Univ. of Maryland Med. Ctr., Baltimore, MD

Abstract: Withdrawal is a debilitating negative state brought on by drug cessation that is characterized by depression, anxiety, and many negative physical side effects. Avoidance of withdrawal symptoms drives addicts to continue drug use or relapse to drug use despite the many negative consequences. Thus discovery of future treatments aimed at lowering the symptoms of withdrawal are crucial to large-scale recovery. Women rate higher on depression scales during drug withdrawal than men. More importantly, negative mood correlates with drug craving in women and the induction of negative mood in a laboratory setting leads to drug craving in women but not men. Taken together, these studies show that women may be at an increased risk for negative mood during drug withdrawal and that this negative mood may put women at a greater risk for craving and possibly relapse. Women show higher levels of drug craving during the late luteal phase, when both estrogen and progesterone levels decrease. In animal models, female rats show higher levels of cue-primed reinstatement during the estrous phase, again following a decrease in estrogen and progesterone. This leads to the possibility that estrogen and/or progesterone might be protective against negative mood during drug withdrawal in females. Examination of ultrasonic vocalizations (USVs) is a useful tool for studying emotional states in rats. Studies using an air-puff device as a negative stimulus have shown that rats undergoing withdrawal from stimulants show a greater number of the vocalization type indicative of negative affect (22 kHz USVs) than rats given saline. In the present study we sought to examine estrogen's effects on air-puff induced 22 kHz USVs during methamphetamine withdrawal in female rats. Animals were implanted with either oil or estradiol containing capsules. All animals were habituated to the test chamber for 15 minutes the day prior to testing.

On the test day, animals were given a 15mg/kg injection of methamphetamine or saline. Six hours following the injection each animal was put in the testing chamber and given one air-puff every 30 sec for 9 min. Following the air-puff procedure, the animals' vocalizations were recorded for an additional 5 min. We found that oil-implanted animals undergoing methamphetamine withdrawal emitted significantly more 22 kHz USVs than their estrogen-implanted counterparts. There was no difference in the number of 22 kHz USVs emitted between estrogen- and oil-implanted females given a saline injection. This preliminary study provides evidence for estrogen's suppression of negative affect during drug withdrawal.

Title: Doublecortin-positive cells in male adolescent mice brain after repeated social defeat

Authors: *L. S. RESENDE[1,2], L. ALVES-DOS-SANTOS[1,2], J. F. S. CARILLO[1], A. S. ALVES[3], L. R. G. BRITTO[3], S. CHIAVEGATTO[1,2]
[1]Pharmacol. Biomed. Sci. Inst., Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Natl. Inst. for Develop. Psychiatry (INCT-CNPQ), Univ. of Sao Paulo Med. Sch., Sao Paulo, Brazil; [3]Physiol. Biomed. Sci. Inst., Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: The early years of life constitute a sensitive period during which chronic stress may compromise the neurodevelopment. Stress has been shown to inhibit cell proliferation and, ultimately, neurogenesis in the hippocampus. Worldwide, 20-30% of adolescents are regularly involved in school bullying and the adverse experience of being bullied induces a variety of potential psychological and somatic sequelae. Here, we used social defeat, a valuable animal model for bullying in humans, to evaluate the impact of social stress in adolescent mice on anxiety, social avoidance and neurogenesis. C57BL/6 male mice aged 30 days were subjected to

daily bouts of social defeat for 10 days in a 5-min session. Encounters were performed in the home cage of a CD-1 male aggressor, and after the physical interaction the defeated mouse was left isolated for 24h in an adjacent compartment separated from the aggressor by a perforated acrylic partition. Control mice were exposed to the same situation without the physical interaction. Anxiety-like behavior and social avoidance were analyzed by the elevated plus maze test (EPM) and social approach-avoidance test, respectively. Twenty-four hours after the last test, animals were anesthetized, perfused, and brains sectioned for doublecortin (DCX) immunolabeling. Defeated adolescent mice showed social avoidance by a reduction in interaction time ($p<0.05$) and higher latency to perform the first interaction with a target mouse ($p<0.05$), but no difference in anxiety-like behaviors in the EPM when compared to controls ($p>0.05$). High levels of DCX immunoreactive cells were found in the olfactory bulb, piriform cortex, hippocampal dentate gyrus (DG) and the subventricular zone. Quantification of DCX+ cells (pixels/mm^2) in the ventral or dorsal DG did not show difference between groups ($p>0.05$). Interestingly, the positive correlation of DCX+ cells between dorsal and ventral DG in the control group ($R^2= 0.99$; $p<0.05$) was not found in the adolescent defeated mice ($R^2= 0.07$; $p>0.05$). We are now analyzing additional areas. Our results in male adolescent mice confirm the social aversion after repeated social defeat and are indicating some perturbation in the neurogenesis of particular brain areas. Ongoing studies are being conducted to further explore these findings.

Title: Association between vitamin D levels and depression-like behaviour in mice

Authors: ***T. H. BURNE**, J. MCGRATH, C. SIMPSON
Queensland Brain Inst., Brisbane, Australia

Abstract: Purpose Adult vitamin D deficiency is common in up to one third of the adult population and has been associated with cognitive decline and depression in some, but not all, studies. Here we examined the effect of manipulating vitamin D levels on cognitive and depression-like behaviours in an adult mouse model. Methods Adult male BALB/c mice were fed a diet that was either deficient (0 IU), insufficient (100 IU), replete (1,500 IU) or contained excess (15,000 IU) vitamin D for at least 12 weeks. Serum vitamin D levels were confirmed at the end of the experiment. Separate groups of mice were tested in either operant chambers using the 5 choice serial reaction time task or on a behavioural test battery which included the forced swim test. Results There was a significant effect of vitamin D levels on the time taken to reach criteria for the 5CSRTT but once acquired there was no effect of diet on performance.There was a significant effect of dietary vitamin D levels on both the time spent immobile and total distance moved during the forced swim test. There was a significant difference between diets in terms of time spent immobile ($F_{3,26} = 12.5$, $p < 0.001$), with the insufficient group spending significantly more time ($p = 0.01$), and the elevated group spending significantly less time ($p = 0.02$) immobile than mice on the replete diet. There was also a significant effect of diet on total distance moved during the trial ($F_{3,26} = 23.3$, $p < 0.001$), the elevated vitamin D group moved a significantly greater distance than the other 3 dietary groups ($p < 0.001$). Conclusions Adult vitamin D dietary intake was not associated with any gross behavioural or cognitive abnormalities, however there were specific and prominent changes in the forced swim test and in the acquisition of the 5CSRTT. These data support a role for vitamin D levels in depression-like behaviour. There is epidemiological research linking low vitamin D levels with brain-related outcomes and we have previously shown that adult vitamin D deficiency is associated with altered brain function and behaviour (Groves et al., 2013). The findings open up a new frontier in understanding the role of vitamin D in brain health. If these changes generalize to humans, then this could have important public health implications.

Title: The effects of prenatal immune activation and infantile repeated maternal separation stress on maternal behavior

Authors: *S. CHOU, C. DAVIS, M. LI
Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Maternal care encompasses a complex group of behaviors that require the coordination of various functions, including motivational and affective regulations. It has previously been shown that a wide array of hormonal and socioenvironmental factors can disrupt maternal care and induce abnormal postpartum affective behaviors such as depression and anxiety. However, current paradigms focus largely on stress triggers applied to adult pregnant or postpartum dams, including hormone simulated pregnancy, daily postpartum corticosterone treatment, chronic gestational psychosocial stress, and repeated pup separation. We have previously shown that female postpartum dams subjected to 3 hours daily repeated pup separation on postpartum (PPD) days 6-9 display acoustic startle reflex (ASR) deficits during the early postpartum period, and that male rat offspring subjected to the double insult of prenatal immune activation and repeated maternal separation during early infancy displays abnormal cognitive behaviors and sensitivities to psychoactive drugs in adulthood. Thus, it is likely that early developmental stress in female rats increases the risk of abnormal postpartum behavior in adulthood as well. The current study investigates the long term consequence of this combination of early neurodevelopmental and infantile psychosocial stress on postpartum behavior of adult female rats. Female offspring of pregnant dams exposed to polyinosinic:polycytidilic acid (PolyI:C, 4.0 mg/kg, intravenous on gestational day [G] 13 and 6.0 mg/kg on G15) were separated for 3 hours daily between postnatal days (PND) 2-14. They were then mated on PND77 and assessed for maternal behaviors - including pup licking, nursing, retrieval, nest building - as well as prepulse inhibition (PPI) on postpartum days (PPD) 2-11. Postpartum females were also assessed for depressive symptoms in forced swim tests (FST), as well as attentional and anxiety behaviors using PPI, acoustic startle response (ASR), and fear potentiated startle response (FPS). Differential behavioral effects are discussed.

Title: Δ9-Tetrahydrocannabinol withdrawal alters affective-like behaviors in mice

Authors: *S. G. KINSEY, K. M. GABELLA, M. S. JONES, S. R. NASS
Psychology, West Virginia Univ., Morgantown, WV

Abstract: Chronic Cannabis users develop tolerance and are susceptible to withdrawal. Reflecting the increased incidence of these phenomena, the DSM-V includes Cannabis Use Disorder and Cannabis Withdrawal Syndrome, the primary symptoms of which are increased cravings, anxiety, and depressed mood. Current rodent models of cannabinoid withdrawal quantify somatic withdrawal symptoms, including of paw tremors and head twitches. One limitation of these models is that they do not measure changes in emotionality or arousal, such as anxiety-like and depressive-like behaviors, that are key withdrawal symptoms in humans. The goal of the present study was to test the hypothesis that withdrawal from Δ9-tetrahydrocannabinol (THC), the main psychoactive component of Cannabis, alters behaviors related to emotionality in mice. Naïve male C57BL/6J mice were administered vehicle or THC (10 or 50mg/kg, s.c.) for 6 days, and then withdrawal was precipitated by acute administration of the CB1 cannabinoid receptor antagonist, rimonabant (SR141716A) (3 mg/kg, i.p.). The Tail Suspension and Marble Burying tests were performed to quantify depressive-like and anxiety-like behaviors, respectively. Mice subjected to precipitated THC withdrawal exhibited a significant increase in struggling time in the Tail Suspension Test ($t(18) = 9.2$, $p<0.01$), and a significant decrease in marble burying ($t(19) = 6.1$, $p<0.01$) with no concomitant alteration in locomotor activity. These data indicate that standard models of mouse emotionality and motivation may be useful tools for investigating cannabinoid withdrawal in rodents.

Title: Cotinine reduced depressive-like behavior and enhanced VEGF in mice after forced swim stress

Authors: *A. GRIZZELL[1,3], M. MULLINS[3], A. IARKOV[3], S. PATEL[3], R. ZEITLIN[3], A. ROHANI[3], L. CHARRY[3], V. ECHEVERRIA MORAN[3,2,4]
[1]Psychiatry and Behavioral Neurosciences, [2]Dept. of Mol. Med., Univ. of South Florida, Tampa, FL; [3]Bay Pines VA Healthcare system, Bay Pines, FL; [4]Univ. Autonoma de Chile, Providencia, Santiago, Chile

Abstract: Depressed individuals smoke tobacco more prevalently than the general population and, in doing so, report a reduction of symptoms, suggesting that a component of tobacco smoke may be alleviating impairment associated with this debilitating disease. Cotinine, a tobacco-derived compound and predominant metabolite of nicotine, may be one such component. Cotinine is nootropic and has a demonstrated positive safety profile in humans. Like other antidepressants,cotinine stimulates the protein kinase B/glycogen synthase kinase 3 (Akt/GSK3 beta) pathway and may therefore exert antidepressant effects through a mechanism involving hippocampal neurogenesis. Over a series of experiments, we investigated the effect of cotinine on depressivelike behavior induced by forced swim (FS) stress in adult, male C57BL/6J mice. Daily oral cotinine (5 mg/kg) administered throughout the stress-exposure period consistently reduced depressive-like behavior induced by acute or repetitive forced swim stress. Furthermore, this effect was seen whether treatment began prior to or at the onset of stress-exposure. Real-time polymerase chain reaction (RT-PCR) data indicate that stress induced but cotinine normalized changes in six neurogenesis factors. Cotinine also enhanced the expression of the v-erb-b2 erythroblastic leukemia viral oncogene homolog 2 (Erbb2) and the vascular endothelial growth factor (VEGF) genes in the hippocampi of mice subjected to repetitive FS stress. Altogether, the results suggest that cotinine may be an effective antidepressant positively influencing mood through a mechanism involving the preservation of cellular homeostasis via the enhancement of genetic expression of neurogenesis factors.

Title: Pituitary adenylate cyclase-activating polypeptide (PACAP) disrupts motivation, attention, and social interaction

Authors: *R. J. DONAHUE, A. VENKATARAMAN, A. VAN'T VEER, C. J. WEBBER, E. G. MELONI, D. A. PIZZAGALLI, W. A. CARLEZON, Jr.
Dept. of Psychiatry, Harvard Med. School, McLean Hosp., Belmont, MA

Abstract: Exposure to severe or prolonged stress can cause psychiatric illnesses including anxiety and depressive disorders. The mechanisms by which stress induces these illnesses are not fully understood. Recent work has shown that PACAP (pituitary adenylate cyclase-activating polypeptide) is released in the brain in response to stress and produces anxiety-related behaviors. For example, PACAP treatment in rats causes persistent anxiogenic responses as reflected by increases in acoustic startle. It is well established that stress can also disrupt cognition, motivation, and social interaction. The present studies were designed to investigate how PACAP (0.25-1.0 µg, administered intracerebroventricularly [ICV]) affects behaviors that reflect these core features of mood disorders in adult Male Sprague-Dawley rats. First, we confirmed that PACAP induces anhedonia (reduced ability to experience reward) in the intracranial self-stimulation (ICSS) test. Rats implanted with an ICV cannula and an ICSS electrode were trained in the rate-frequency variant of the ICSS procedure. When reward thresholds were stable (60% correct responses and <20% omissions on 3 consecutive days). Following ICV cannula implantation and re-stabilization of performance, rats were infused with PACAP and tested in 5CSRTT 1 hr later. Finally, we examined if PACAP alters social interaction and social withdrawal. One week after ICV cannula implantation, rats were infused with PACAP and placed in a 60 x 60 x 40 cm Plexiglas chamber with a weight-matched partner rat 1 hr later. Social behavior was videotaped for 10 min and scored by an observer blinded to treatment condition. PACAP produced dose-dependent disruptions in motivation, attention, and social interaction as reflected by increases in reward thresholds in ICSS, disruptions in 5CSRTT metrics (e.g. decreases in correct responses, increases in omission errors, and decreases in post-error performance), and decreases in social interaction behaviors. Interestingly, unlike previously reported effects on acoustic startle, the effects of PACAP on these behaviors were not long-lasting. A better understanding of the impact and persistence of PACAP effects on behavior may facilitate the development of improved treatments for stress-related illnesses.

Title: Lidocaine infusions in the centromedial amygdala reduce successive negative contrast, without affecting anticipatory negative contrast

Authors: *K. KAWASAKI[1], A. C. GLUECK[2], I. ANNICCHIARICO[2], M. R. PAPIN[2]
[1]Hoshi Univ., Shinagawa / Tokyo, Japan; [2]Dept. of Psychology, Texas Christian Univ., Fort Worth, TX

Abstract: The amygdala plays a key role in negative emotions, including frustration induced by reward devaluations. Massive corticomedial amygdala lesions have been shown to eliminate the consummatory successive negative contrast (cSNC) effect, without apparently affecting the consummatory anticipatory negative contrast (cANC) effect in rats. In cSNC, rats given daily access to 32% sucrose consume less 4% sucrose than rats always exposed to 4% sucrose. In cANC, rats consume less 4% sucrose when each session is followed by access to 32% sucrose rather than by 4% sucrose. Pharmacological manipulations suggest that cSNC induces a negative emotion, whereas cANC induces reward anticipation. To test the hypothesis that the amygdala is involved in the emotional modulation, but not in anticipatory processes, we sought to produce reversible amygdala lesions at specific times during training. Animals were implanted with cannulae and then trained in cSNC followed by cANC. A Sucrose (32-to-4 vs. 4-to-4) x Infusion (lidocaine vs. PBS) x Session analysis of downshift behavior in the cSNC situation yielded a significant triple interaction [$F(4,120)=4.398$, $p=0.001$]. Pairwise LSD comparisons derived from the main analysis indicated that transient amygdala inactivation before the first 32-to-4% sucrose downshift reduced cSNC relative to 4-to-4% sucrose controls ($p=0.120$), and attenuated consummatory suppression relative to a 32-to-4% sucrose group treated with the PBS vehicle ($p=0.028$). The cSNC effect was present in vehicle-treated groups ($p=0.000$). Unlike in the cSNC situation, transient amygdala inactivation did not affect cANC, which occurred unchanged in groups treated with lidocaine, PBS, or nothing [Infusion x Contrast interaction: $F(2,48)=1.998$, $p=0.147$]. These results are consistent with the hypothesis that output from the amygdala is required for the emotional modulation of consummatory behavior after reward devaluations, but not for anticipating the occurrence of the same sucrose solutions presented in a sequential manner. The fact that amygdala inactivation had its effects on the very first exposure to the 32-

to-4% sucrose downshift suggests this was a nonassociative effect (i.e., emotional), rather than a consequence of memory disruption.

Title: Partial excitotoxic lesions of the rostromedial tegmentum (RMTg) diminish the inhibitory effects of lateral habenula stimulation on midbrain dopamine neurons *in vivo* and reduce the incidence of learned helplessness in rats

Authors: *P. D. SHEPARD[1], P. L. BROWN[2], H. PALACOROLLA[1], D. BRADY[1], K. RIEGGER[1], C. MAYO[1], M. KLIMA[1], G. I. ELMER[1]
[1]Dept. of Psychiatry/MPRC, [2]Program in Neurosci., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Neurons in the lateral habenula (LHb) are transiently activated by aversive events ranging from noxious stimuli to the loss of an anticipated reward and have been implicated in aversive learning. More sustained increases in LHb activity have been linked to major depressive disorder in humans and the appearance of a depressed phenotype in animals. Functional changes associated with tonic and phasic activation of the LHb are often attributed to a corresponding inhibition of midbrain dopamine and/or serotonin neurons. A growing body of evidence suggests that activation of GABAergic neurons in the rostromedial tegmentum (RMTg), a region that receives dense projections from the LHb and projects strongly to midbrain monoaminergic nuclei, underlies the physiological and behavioral effects attributed to activation of the LHb. In an effort to test this premise, the effects of axon sparing lesions of the RMTg were assessed on i) LHb-induced inhibition of substantia nigra (SN) dopamine (DA) cell activity *in vivo* and ii) the expression of learned helplessness. All experiments were conducted in adult, male, Sprague-Dawley rats. A single midline injection of quinolinic acid (0.4 M in 166 nl of artificial cerebrospinal fluid, aCSF) significantly decreased the number of NeuN positive profiles in the

RMTg compared to rats receiving an equal volume of aCSF (VEH: 1649 ± 87, n=4; QUIN: 457 ± 55, n=21; $t(23) = -8.9$, $p < 0.001$). Two weeks following injection of QUIN or VEH, rats were anesthetized with chloral hydrate and single unit recordings were taken from spontaneously active DA neurons in the SN. Consistent with previous reports, the majority of DA-containing neurons (28/30; 93%) in VEH-treated rats were transiently inhibited by single pulse stimulation of the LHb. By contrast, DA neurons in QUIN-treated rats were less likely to be inhibited by LHb stimulation (16/24, 67%) and those cells that remained responsive were inhibited for a shorter duration (49 ± 17 ms) than VEH-treated rats (108 ± 12 ms). A separate group of experiments was conducted to assess the effects of RMTg lesions on the development of learned helplessness. VEH- (n = 18) and QUIN-treated (n = 26) rats were evaluated in a two day procedure comprised of 120 trials of unpredictable, inescapable footshock followed one day later by 30 trials of signaled, escapable shock. As a group, QUIN-treated rats showed significantly fewer escape failures (7.0 ± 1.5) than VEH-treated rats (13.7 ± 2.7; $p < 0.05$). These results suggest that the RMTg is required for the expression of learned helplessness and support the notion that this structure is an important component of a pathway mediating the aversive properties of LHb activation.

Title: Superior collicular neurons reveal preferential responses to snakes in primates

Authors: *Q. V. LE, J. MATSUMOTO, Q. V. LE, E. HORI, T. ONO, H. NISHIJO
Syst. Emotional Sci., Univ., Toyama, Japan

Abstract: Snakes are suggested to be predators of early primates. Under evolutional selection pressure by snakes, specific subcortical and cortical areas have evolved to detect threat relevant stimuli, especially snakes in primates (Isbell, 2006). Consistent with the theory, we recently reported that monkey pulvinar neurons responded stronger and faster to snakes than other stimuli (Le et al., 2013). The superior colliculus (SC), which receives inputs from the retina and projects directly to the pulvinar, is one of these areas and plays a crucial role in alerting mechanisms in

mammals, especially primates. However, responses of SC neurons to snakes remain unknown in primates. In the present study, we recorded monkey SC neuronal responses to photos of snakes, monkey faces, monkey hands and simple geometrical figures. The monkeys were required to discriminate these 4 categories of the visual stimuli in a delayed non-matching to sample (DMNS) task. Of 983 neurons recorded, 356 neurons were visual responsive. Of these neurons, 43 neurons had their receptive fields at the center of the visual fields, and were located in the antero-lateral part of the SC. Although there were no significant differences in response magnitudes to the 4 categories of the stimuli, they responded faster to the snake images and ratio of snake-best neurons was larger than those of other categories. Multidimentional scaling (MDS) analysis showed that snakes were separated from the other stimuli as early as the first 25 ms period after stimulus onset. These results provide new evidence of SC involvement in rapid snake detection.

Title: The role of prelimbic inputs to the rostromedial tegmental nucleus in aversive behavior

Authors: *E. J. BURNETT[1], D. H. LENCH[2], T. C. JHOU[2], L. J. CHANDLER[2]
[1]Ctr. for Drug and Alcohol Programs, [2]Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Activity in the rostromedial tegmental nucleus (RMTg) is associated with aversive behavior measured in various assays including conditioned fear, elevated plus maze, and tasks measuring passive avoidance. Activity in the prelimbic cortex (PrL) has also been implicated in the expression of many of these same behaviors. Importantly, the PrL sends a remarkably dense projection to the RMTg, but the contribution of this particular pathway to signaling the aversive properties of environmental stimuli has yet to be elucidated. To investigate the role of the PrL-RMTg pathway in aversive signaling, we first measured the effect of optogenetic stimulation of this pathway in a real-time conditioned place task. Rats were bilaterally stereotaxically injected with AAV expressing channelrhodopsin in the PrL cortex and implanted with bilateral optic fibers in the RMTg. Six weeks following surgery, rats were tested in an unbiased two-compartment apparatus where one compartment was paired with the delivery of 10 mW of 473 nm blue light at 60 Hz and the other compartment was associated with no light delivery. Rats spent significantly less time in the light-paired compartment than the unpaired compartment ($p \leq 0.001$) indicative of real-time place aversion in response to stimulation of PrL terminals in the RMTg. In a follow up experiment, we examined cFos induction in RMTg-projecting PrL neurons following the presentation of a cue predictive of footshock. Rats were unilaterally stereotaxically injected with the retrograde tracer cholera toxin B (CtB) into the RMTg. One week following surgery, rats underwent fear conditioning to associate a tone with the delivery of a 0.5 mA footshock. Control rats were exposed to the same number of tone and shock presentations but in a randomized, unpaired manner. Rats were sacrificed 90 min following presentation of the tone alone and brains were processed for cFos and CtB visualization using standard immunohistochemical methods. In control animals, who did not associate the presentation of the tone with a shock, exhibited no cFos expression in RMTg-projecting PrL neurons. In contrast, re-exposure to the tone in conditioned rats resulted in a modest but significant enhancement of cFos expression in PrL neurons co-labeled with CtB ($p \leq 0.05$). Together, these data suggest that RMTg-projecting PrL neurons are involved in modulating the behavioral response to aversive stimuli.

Title: Substantia nigra pars reticulata guides gaze to reward-associated objects and punishment-associated objects

Authors: *A. GHAZIZADEH, O. HIKOSAKA
LSR NIH, Bethesda, MD

Abstract: Visual objects that have been repeatedly associated with reward (good objects) attract gaze even in the absence of immediate reward. Recent studies from our lab showed that the basal ganglia play a crucial role in this process through the inhibitory connection from the substantia nigra reticulata (SNr) to the superior colliculus (Hikosaka et al, Ann Rev NS 2014). SNr neurons are inhibited by 'good' objects, thereby disinhibiting SC neurons (Yasuda et al, 2012). However, there may be other reasons why a visual object attracts gaze; one of them may be punishment. Here we asked two questions: 1) Do punishment-associated objects attract gaze?; 2) If so, do the basal ganglia also contribute to the punishment-induced gaze bias? Two male rhesus monkeys (Macaca mulatta) participated in this study. They experienced many visual objects (n=24 fractals) , each of which was consistently associated with juice ('good'), airpuff ('punish'), or no outcome ('neutral'). On most trials (75%) two objects were presented from different categories (good, punish or neutral) and the monkey chose one by making a saccade to it. On the other trials (25%) one object was presented, which was followed by the associated outcome regardless of the animal's action. To answer question #1, we presented 4 randomly chosen objects and let the monkey look at them freely (free viewing). Neither juice nor airpuff was presented in free viewing. The monkey's gaze was attracted more strongly to 'punish' objects compared to 'neutral' objects (i.e., more frequent saccades to and within the object, longer duration of gaze on the object), although gaze bias was strongest to 'good' objects. To answer question #2, we recorded activity of single SNr neurons and presented these objects sequentially while the monkey kept fixating. Most SNr neurons were inhibited by both 'good' objects and 'punish' objects, and excited by 'neutral' objects. These results suggest that the basal ganglia facilitate gaze orienting to both 'good' and 'punish' objects - a behavior that might reflect 'motivational salience' (Matsumoto & Hikosaka, 2009).

Title: Differential regulation of negative emotion by areas 25 and 32 of the marmoset ventromedial prefrontal cortex

Authors: *C. U. WALLIS[1,2], A. C. ROBERTS[1,2], H. F. CLARKE[1,2]
[1]Physiology, Develop. and Neurosci., Cambridge, Cambridge, United Kingdom; [2]Behavioural and Clin. Neurosci. Inst., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: There is strong evidence that the human ventromedial prefrontal cortex (vmPFC) is important for emotion regulation. Abnormal vmPFC activity is consistently associated with disorders of negative emotion (anxiety and depression), and its reversal is associated with successful treatment. A functional subdivision regarding the role of the vmPFC in emotion regulation has been suggested, with the subgenual region, focused on area 25, associated with negative affect, and a perigenual region, including area 32ac, associated with positive affect (Myers-Schulz & Koenigs, 2012). Most experimental studies on the role of the vmPFC in negative emotion have been carried out on fear conditioning and extinction in rats. Yet findings regarding the role of infralimbic and prelimbic regions in emotion regulation do not translate to areas 25 and 32, respectively, of the human vmPFC (their putative structural homologues (Vogt et al., 2013). To bridge the gap between rodents and humans, this study investigates the functions of areas 25 and 32 in the marmoset (Callithrix jacchus); a new world primate with a highly developed PFC; cytoarchitectonically similar to that of humans. Implanted cannulae were targeted at areas 25 and 32 of the marmoset vmPFC, to enable temporary pharmacological inactivation by infusion of muscimol and baclofen (GABAA and GABAB receptor agonists) or a vehicle control. The effects of these manipulations on both cardiovascular and behavioural indices of emotion were assessed under (i) an affectively neutral condition and (ii) during an aversive Pavlovian discriminative conditioning paradigm. In the neutral condition, inactivation of area 25 vs. 32 produced contrasting effects. Compared to vehicle, inactivation of area 25 reduced both vigilant scanning behaviour and cardiovascular activity (heart-rate, blood pressure, and sympathetic activity). Inactivation of area 32 increased vigilant scanning behaviour, blood pressure and sympathetic activity. Whilst inactivation of both areas 25 and 32 disrupted discriminative, conditioned behavioural and heart rate responses, initial results suggest this discriminative loss is due to reduction and facilitation of emotional reactivity respectively. The results suggest that inactivation of areas 25 and 32 of the marmoset vmPFC differentially effect behavioural and cardiovascular indices of emotion, with inactivation of area 25 reducing, and inactivation of area 32 increasing, negative emotional reactivity. This supports the proposed vmPFC functional sub-division regarding emotion regulation in humans (Myers-Schulz & Koenigs, 2012).

Title: Emotion regulation preference in anger: A combined behavioral- resting state fMRI approach

Authors: J. ROEBBIG[1], D. KUMRAL[1], A. SCHAEFER[1], M. GAEBLER[1], M. ERBEY[3], J. REINELT[1], L. SCHAARE[1], A. REITER[2], A. BABAYAN[1], *A. VILLRINGER[1]
[1]Dept. of Neurol., [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [3]Max Planck Inst. for Human Development, LIFE, Berlin, Germany

Abstract: Successful emotion regulation (ER) of anger is vital for psychological and cardiovascular health (Suls, 2013). Most studies addressing ER, with the most adaptive ER strategy known as cognitive reappraisal (Ochsner et al. 2012), conceptualized it as a stable personality trait, while recent findings suggest that an emotional state's intensity also determines how it is regulated (Sheppes et al., 2011). Here we addressed ER preference in anger on the behavioral level, comparing the predictive value of trait reappraisal and anger intensity. Furthermore, we investigated whether trait reappraisal is represented in resting state-functional connectivity (rs-fc), the intrinsic synchronization of functionally coupled networks, a method that can serve as a measure of personality (Fulwiler et al., 2012). In 23 healthy participants (11 males; age: 23.8±2.86 years), we acquired 15 min of rs-scans in addition to their emotion regulation- (ERQ) and anger disposition (STAXI). On the following day, we asked participants to remember two anger autobiographical memories of varying intensity and to choose either reappraisal or distraction to regulate. For rs-fMRI data analysis we defined the left and right amygdala as seed regions and investigated their whole-brain rs-fc, including trait reappraisal, trait anger, and gender as covariates. Thresholds were $p < .01$ on the voxel- and cluster level (FDR corrected). Our behavioral results indicate that trait reappraisal is a stronger predictor for ER choice (Wald-$\chi^2(1) = 7.22$, $p = .007$) than emotional intensity (Wald-$\chi^2(1) = 3.71$, $p = .054$). Correlation analysis of rs-fMRI data and trait reappraisal (see Figure 1) revealed a positive association between the connectivity of amygdalae and bilateral insula and an anticorrelation of the right amygdala and areas of the mPFC, which overlap with previous fMRI findings on ER

(e.g., Ochsner et al., 2012) and anger regulation (Fulweiler et al., 2012). We show that trait reappraisal is associated with individual differences in rs-fc and influences ER preference in autobiographical anger regulation.

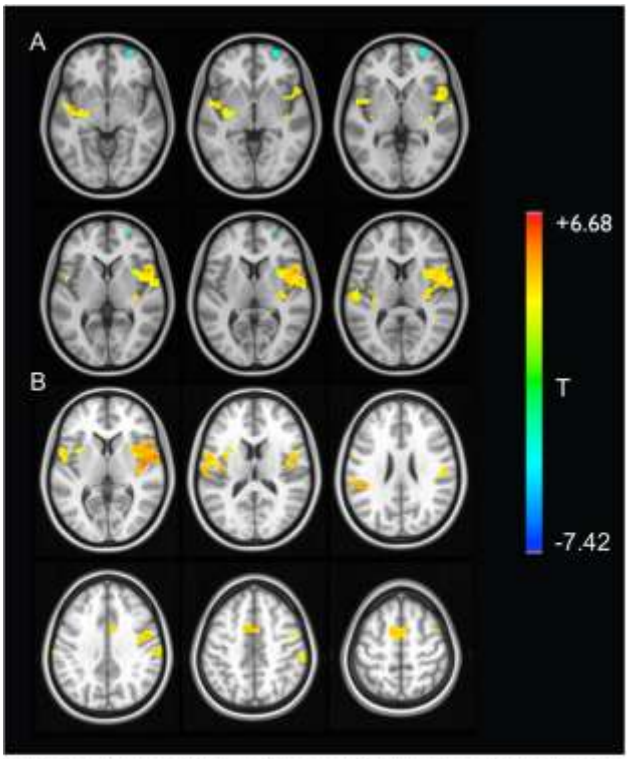

Figure 1. Association between trait reappraisal and rs-fc from the unilateral amygdalae (x = ±24, y = 0, z = -16). The analysis revealed a positive association (warm colors) between trait reappraisal and the positive coupling of right amygdala (Figure 1A) with right insula (x = 51, y = 12, z = 6; 4239 mm³; T = 3.77), left insula (x = -39, y = -15, z = 12; 1584 mm³; T = 3.25), as well as an inverse coupling (or anticorrelation; cold colors) with right medial orbitofrontal gyrus (30, 48, -12; 567 mm³; T = -2.92) and left middle frontal Gyrus (x = -30, y = 24, z = 36; 468 mm³; T = -4.09). The correlation of trait reappraisal and the rs-fc between left Amygdala (Figure 1B) revealed a positive association with the right insula (x = 45, y = -6, z = 9; 3735 mm³; T = 3.79), left insula (x = -42, y = -6, z = -9; 3375 mm³; T = 3.22) and the bilateral medial frontal gyrus (x = -9, y = 6, z = 45; 1890 mm³; T = 4.15).

Title: Cholinergic modulation of emotion and memory in humans: a pharmacological fMRI study

Authors: *Y. NISHIO[1], N. ABE[3], Y. SHIGEMUNE[4], S. MUGIKURA[2], T. FUJII[5], E. MORI[1]
[1]Dept. of Behavioral Neurol. and Cognitive Neurosci., [2]Dept. of Diagnos. Radiology, Tohoku Univ., Sendai, Japan; [3]Kokoro Res. Ctr., [4]Dept. of Cognitive and Behavioral Sci., Kyoto Univ., Kyoto, Japan; [5]Tohoku Fukushi Univ., Sendai, Japan

Abstract: We utilized pharmacological functional magnetic resonance imaging to explore the impact of cholinergic blockade on emotion and cognition. Subjects underwent emotion rating and two-week-delayed recognition memory test for emotionally-negative and emotionally-neutral pictures under trihexyphenidyl, a selective M1 receptor antagonist, and under placebo. Emotion rating was unaffected by drug, whereas emotional memory bias was significantly reduced by trihexyphenidyl. BOLD responses in the prefrontal, insular and visual cortices were unmodulated by cholinergic manipulation, whereas ventral striatal and amygdalar responses were significantly reduced by trihexyphenidyl. These results suggest that subcortical cholinergic system mediates unoconscious emotional modulation of cognition.

Title: The invisible variable: Sleepiness and suicidality in a large national college health survey

Authors: A. TARTER, *J. R. PRICHARD
Dept Psychol, Univ. St. Thomas, SAINT PAUL, MN

Abstract: Introduction Insomnia is both comorbid for and a consequence of depression. Longitudinal studies in adults with PTSD and population studies with school aged children have demonstrated that sleep problems are also independent predictors of suicidal thoughts and attempts. More research is needed to evaluate the interactions between poor sleep and suicidality

in emerging adults, a vulnerable population who is at high risk for both mood disorders and profoundly disturbed sleep. Our study evaluated the relationships between sleep difficulties and self-harm behaviors and suicidal thoughts in a large national sample of college students. Methods Data from the Spring 2009 American College Health Association National College Health Assessment-II were analyzed for trends in daytime sleepiness, suicidality (self-harm behaviors, suicidal thoughts, and suicide attempts in the last year) among undergraduate students (n = 72,966) with diagnosed insomnia, with probable undiagnosed insomnia, and without major sleep initiation and maintenance problems. Results Five percent of the total population had been diagnosed with or treated for insomnia within the last year. Of these students, 71.3% had a comorbid anxiety disorder and 62.2% had a comorbid depression diagnosis. Students with diagnosed insomnia were at elevated risk for self-harm behaviors [O.R. 3.02, C.I. 2.74-3.34], suicidal ideation [O.R. 3.28, C.I. 2.99-3.60] and suicide attempts within the last year [O.R. 5.89, C.I. 5.01-6.02]. Another 8.3% of the population had probable undiagnosed insomnia (defined here as sleep initiation and maintenance problems >1.5 s.d. from the mean; trouble falling asleep approximately 6 days/week and awakening too early 4 days/week.) These students were also at elevated risk for self harm behaviors, suidicidal ideation and suicide attempts [O.R. > 2.7, for all cases]. Conclusion College health professionals can provide more effective and targeted interventions for students by understanding the elevated risk factors for self-harm, suicidal ideation, and suicidal attempts in those with insomnia.

Title: Participant expectations of the Healthy Body Healthy Mind exercise program for youth with major depressive disorder

Authors: *R. CALLISTER[1], A. GILES[2], Y. NASSTASIA[3], A. BAKER[3], S. HALPIN[4], B. KELLY[3]

[2]Sch. of Biomed. Sci. and Pharm., [3]Sch. of Med. and Publ. Hlth., [4]Sch. of Psychology, [1]Univ. of Newcastle, Callaghan, Australia

Abstract: Although regular exercise may benefit young people with major depressive disorder (MDD), engaging them and attaining adherence during an exercise program are substantial challenges. Expectations may influence the success of such interventions including adherence. The aim of this analysis is to examine mental health characteristics, exercise self-efficacy and outcome expectations, as well as relationships among these variables prior to randomisation in the Healthy Body Healthy Mind (HBHM) trial of the efficacy of an exercise intervention for youth with MDD. Methods: Eligible participants were youth aged 15-25 years. Participants completed online questionnaires (satisfaction with life, self-esteem, exercise self-efficacy, exercise and HBHM program expectations), then the paper-based Beck Depression Inventory (BDI-II) and Beck Anxiety Inventory (BAI) and underwent a structured diagnostic interview (SCID) with a clinical psychologist to determine whether they met criteria for current MDD (according to DSM-IV). Relationships between variables were investigated with Spearman's correlation coefficients. Results: Data from eligible participants with MDD (n=39, Female=33, mean age 21 y, range 16-25 y) were examined. Median (interquartile range (IQR]) BDI of 31(IQR 18) was classified as severe; BAI of 17 (IQR 20) was moderate; satisfaction with life (13, IQR 5; maximum 35) was very low; self-esteem (2; IQR 2; maximum 5) was low; and self-efficacy for exercise (120; IQR 61; maximum 220) indicated moderate confidence they could exercise three times a week for the next three months. Expectations that they would obtain benefits from exercise on depression, anxiety, stress, sleep, etc, were high (29; IQR 5; maximum 35) and expectations of likely benefit from the HBHM program were high (22; IQR 5; maximum 27), however the extent of improvements expected was only 50% (IQR 20%). Significant correlations ($p<0.05$) were found between BDI and BAI ($r=0.79$), self-esteem ($r=-0.53$) and satisfaction with life ($r=-0.40$) but not with outcome expectations ($r<0.25$). Self-esteem and exercise self-efficacy were both correlated with satisfaction with life ($r=0.33$ and $r=-0.38$, respectively). Discussion: Participants in this trial have moderate-severe MDD, moderate anxiety, low self-esteem and very poor satisfaction with life. Those who volunteered for this exercise-training program expect to benefit in a number of ways including reducing their depression and anxiety symptoms as well as reducing stress and improving sleep quality and energy levels but the extent of improvement expected is modest. Title: Recalling the positive past dampens the physiological response to acute stress

Authors: *M. SPEER, H. MANGLANI, E. S. KIM, M. R. DELGADO
Psychology Dept., Rutgers Univ., Newark, NJ

Abstract: Recalling happy memories from the past can elicit positive feelings and enhance an individual's wellbeing (Young et al., 2013). Thus, one potential adaptive function in reminiscing about the positive past may be the ability to cope with stressors in daily life. The goal of this study was to examine whether positive emotion evoked by recalling the positive past can blunt the effects of a negative affective state (i.e., acute stress). That is, can such memories dampen the hypothalamic-pituitary-adrenal (HPA) axis stress response (i.e., cortisol levels)? To test this, 96 healthy participants described and gave subjective emotion ratings for specific episodic memories of positive (e.g., family vacation) and neutral (e.g., commuting to work) content. Three days later, they were either exposed to an acute stressor (i.e., socially evaluative cold pressor task) or performed a non-stressful control task. Afterwards, they were asked to retrieve a subset of the same episodic memories triggered by visual word cues (e.g., family vacation). The memories were of only positive valence or only neutral valence, creating 4 experimental groups (stress-positive, stress-neutral, control-positive, control-neutral). To measure changes in cortisol levels over time, salivary cortisol samples were collected at baseline (before stress or control task), peak (after recalling autobiographical memories, 20 min), and recovery (50 min). As expected, participants who recalled positive memories rated their memories with greater positive affect and stronger emotional intensity than participants who recalled neutral memories. In support of the idea that internally generated positive emotion evoked by memory recall can buffer the physiological response to acute stress, we observed a negative correlation between subjective ratings of positive emotion experienced during autobiographical recall and cortisol response. Critically, the stress-positive group showed a sharper decrease in cortisol rise 20 min after stress exposure compared to the stress-neutral group, even though the two groups did not differ in subjective ratings of stress or skin conductance response during acute stress exposure. Interestingly, individuals who experienced greater positive affect during recall were also individuals who reported higher levels of resiliency, highlighting how something naturally-occurring like recalling the past may be a potentially advantageous strategy for buffering negative affect in some individuals. Our findings support the idea that positive autobiographical

memories may serve an adaptive function of regulating emotion and reinforcing positive wellbeing.

Title: Effects of prenatal music on the emotional behavior and neuronal activity in offspring

Authors: *Y. TAKANO[1], S. YANAGITA[2], N. KUBOTA[3], T. MATSUZAWA[1], K. TAKEDA[3]
[1]Dept. of Pharmaceut. Sci., [2]Dept. of Sci. and Technol., [3]Res. Inst. for Sci. and Technol., Tokyo Univ. of Sci., Chiba, Japan

Abstract: Music has overarching influences in human life. Music often attenuates anxiety and improves learning ability, and has been widely used as an additional tool for medical treatment. Recently, effect of prenatal music on offspring is thought to be one of fascinating topics as with that many pregnant women play music for their babies *in utero*. Furthermore, it is believed that music is more effective tool for fetal development since the prenatal period shows high sensitivity to environmental situations. Although some previous studies have shown that the relationship between prenatal music and developmental changes are being revealed, it remained unclear about the neuronal mechanism underlying the effects of prenatal music in offspring. In this study, we investigated the effects of prenatal music on emotional behavior in offspring. We also examined the effects of prenatal music on neuronal activity in brain regions with immunohistochemistry. In order to evaluate continuous neuronal activity, we used a long lasting marker for neuronal activity, FosB. Pregnant Wistar/ST rats were exposed to music environment during the late gestational period while control dams were exposed to a similar decibel ambient noise. Offspring at six weeks old, we measured emotional behavior using open field test (OFT), elevated plus maze (EPM), and forced swimming test (FST). In this results, there were no significant differences in anxiety-like behavior in the OFT and EPM regardless of prenatal music environment. On the other hand, prenatal music environment significantly increased the immobility time of FST in the offspring compared with ambient noise environment. There were no differences in the number of FosB positive cells in several brain regions related in emotional behavior. Additionally, we used an acute marker for neuronal activity, c-Fos, in order to evaluate

neuronal activity for stress response in FST. Prenatal music significantly increased the number of c-Fos positive cells in several brain regions related in emotional behavior compared with ambient noise environment. Therefore, our results indicated that prenatal music influenced depression-like behavior in the offspring but the continuous neuronal activity in several brain regions related depression-like behavior, suggesting that prenatal music might influence other neuronal systems related depression-like behavior.in the brain.

Title: Does the response to negative TV news depend on the level of emotional burnout?

Authors: *S. TUKAIEV[1], I. ZYMA[2], S. SOBISHCHANSKYI[3], Y. HAVRYLETS[4], M. MAKARCHUK[3], V. RIZUN[4], I. SOSIEDKA[2], I. BABYN[2]

Abstract: TV is usually focused on the negative aspects of life, which leads to stress, and, further, to burnout. However, the impact of the initial emotional state of a viewer on the perception of TV news haven't been studied previously. The purpose of this study was to investigate the response to violent TV news depending on the level of burnout. 110 healthy volunteers (18-22 y.o.) participated in the study. The first part of it (53 volunteers) involved 5 75-sec long videos depicting violence, suffering, war, and street accidents. We estimated the spectral power density (SP) and the levels of coherence of all frequencies from 0.2-35 Hz. In the second part (57 volunteers), we used the P300 component with a simple discrimination task in "oddball" paradigm to investigate P300 modulations. The participants were presented a set of 72 negative and 72 neutral frames taken from TV news plots. We used the following tests: Syndrome of emotional burnout (V.Boyko), WAM (Wellbeing, Activity, Mood), and the State Anxiety Inventory by C. Spielberger, Y. Hanin. The data of psychological tests were collected before and after the experiment. Enhancement of state anxiety and worsening of mood after

watching negative TV news were observed only for the participants without the desensitization due to burnout. After watching the negative TV-news plots, we observed adequate semantic associative emotional processes in the group without burnout (increasing alpha-3). Formation of the resistance stage led to the decrease in SP in theta, alpha1, alpha2 and beta1-subbands indicating the "removal" of negative news from the conscious processing and analysis of negative information. The decrease of interhemispheric coherence of low- and high-frequency components of EEG indicates altered reactions and the development of deterioration processes in those beginning to exhibit burnout. The amplitude of P300 showed reduced sensitivity to the affective content of frames, perhaps due to blunting: only those without burnout showed larger amplitudes of P300 after negative images than the neutral ones. Thus, burned-out people demonstrate desensitization toward the emotional content of TV news.

Title: Persistent enhancement of unprovoked 22-28 kHz USVs and decreased 50-55 kHz USV counts after alcohol experience may underlie alcohol avoidance behavior in low-alcohol preferring rats

Authors: *C. L. DUVAUCHELLE[1], N. THAKORE[1], J. RENO[2], E. KUSEY[1], W. T. MADDOX[2], R. GONZALES[1], T. SCHALLERT[2]

[1]Pharmacol. & Toxicology, Univ. of Texas, AUSTIN, TX; [2]Psychology, Univ. of Texas, Austin, TX

Abstract: Emotionality plays an important role in excessive alcohol drinking as well as alcohol avoidance behaviors. In rodents, 22-28 kHz and 50-55 kHz frequency-modulated (FM) USV calls are reliably associated with negative and positive emotional states, respectively. To study the role of emotional status associated with excessive drinking and alcohol avoidance, ultrasonic vocalizations (USVs) were recorded from selectively bred high- and low-alcohol preferring rat lines (P/NP and HAD-1/LAD-1) during 6 wks of daily 4-hr water only access sessions. Prior to USV recordings, animals in each rat line had access to water only (EtOH Naïve) or water and alcohol (EtOH Experienced: 24-hr alcohol access 3 days/wk x 6 wks) while in the home cage. For the EtOH Experienced groups, mean daily 24-hr EtOH intake (g/kg) was comparable between P and HAD-1 rats (P: 7.31 +/- 0.34 SEM; HAD-1: 7.46 +/-0.30 SEM) and NP and LAD-1 rats (NP:2.26 +/-0.3; LAD-1: 3.36 +/-0.58 SEM). Data analyses revealed significant differences across all USV measures (e.g., 22-28 kHz and 50-55 kHz USV counts, mean frequencies and durations) in comparisons between EtOH Naive and EtOH Experienced animals of both bi-directional lines (e.g., HAD-1 vs LAD-1 and P vs NP). Of particular interest are USV data revealing that increased 22-28 kHz and decreased 50-55 kHz USV counts emitted from low-alcohol preferring rats (NPs and LAD-1) endured for weeks after alcohol experience, even though prior alcohol intake was relatively low. Our overall findings suggest that alcohol experience results in persistent, negative emotional status that may underlie alcohol avoidance in rats selectively bred for low alcohol preference.

Title: Changes in effective connectivity between dorsal and ventral prefrontal regions moderate emotion regulation

Authors: *C. MORAWETZ[1], S. BODE[2], J. BAUDEWIG[3], E. KIRILINA[4], H. HEEKEREN[5]
[1]FU Berlin, Berlin, Germany; [2]Melbourne Sch. of Psychological Sci., The Univ. of Melbourne,

Melbourne, Australia; [3]Biomed. Imaging, Dept. of Radiology, Christian-Albrecht Univ. Kiel, Kiel, Germany; [4]Dahlem Inst. for Neuroimaging of Emotion, [5]Dept. of Emotion Psychology and Affective Neurosci., Freie Univ. Berlin, Berlin, Germany

Abstract: Introduction Reappraisal, the cognitive reevaluation of a potentially emotionally arousing event, has been proposed to be based upon top-down appraisal systems within the prefrontal cortex. It still remains unclear, how different prefrontal regions interact to control and regulate emotional responses. We used functional magnetic resonance imaging (fMRI) and dynamic causal modeling (DCM) to characterize the effective connectivity between the inferior frontal gyrus (IFG), dorsolateral PFC (DLPFC), and other reappraisal-related regions during emotion regulation (ER). Methods 23 right-handed subjects (mean age=22.95±3.57 years) performed specific reappraisal strategies (Increase, Decrease) while viewing 60 highly arousing extreme sports film clips and 42 neutral film clips in the scanner (3T, Siemens). The experimental design involved four different conditions: 'Increase' (engage with the depicted situation), 'Decrease' (distance from it), 'Look Neutral' and 'Look Sports' (no reappraisal). We used an event-related design (2s instruction, 8s picture/film clip, 4s "How do you feel?" rating, 4-8s fixation). Based on previous findings, we used 5 ROIs (IFG, DLPFC, SMA, SMG, V1) as sources and systematically constructed a model space, divided into two model families with two different central nodes (family1: DLPFC; family2: IFG). All competing models within one family had the same architecture with six endogenous connections that modeled the forward and backward connections between regions. Within each of the two families the modulatory effects of ER were modeled. Results The DCM results revealed that family1, with DLPFC as central node, represented the best explanation of the data with a total exceedance probability of 0.997. Within family1, the winning model had an exceedance probability of 0.557. The analysis of the intrinsic connection strength of the winning model showed that most endogenous connectivity parameters were significant. One intrinsic connection (IFG to DLPFC) was negative. The analysis of the modulatory effects of ER revealed significant modulations of connectivity from the DLPFC to the IFG and from the IFG to the DLPFC. Reappraisal reduced the effective connectivity between the DLPFC and IFG in both directions. Conclusion The results of our DCM analyses support the hypothesis that ER is mediated by bidirectional changes of connection strength between the IFG and DLPFC. The findings indicate a feedback mechanism between the DLPFC and IFG during ER, in which the selection process of a reappraisal, most likely involving the IFG, modulates the connectivity between IFG and DLPFC.

Title: Impact of frustration on brain activation pattern of subjects with different temperamental traits during a tactile discrimination task

Authors: M. BIERZYNSKA[1,2], M. BIELECKI[2], A. MARCHEWKA[1], W. ZAJKOWSKI[2], P. SOBCZAK[2], W. DEBOWSKA[1], *M. M. KOSSUT[1]
[1]Nencki Inst. Expmtl Biol, Warsaw, Poland; [2]Univ. of Social Sci. and Humanities, Warsaw, Poland

Abstract: Frustration is a complex psychological construct, most clearly defined as an emotional state that occurs when an expected gratification is not fulfilled (Dollard et al, 1939) or an expected goal not attained (Anderson & Bushman, 2002). Laboratory experiments on effects of frustration on cognitive abilities were narrowed to its affective subcomponents, mostly acute stress, a crucial affective component of frustration. To examine effects of frustration on people with different temperamental traits we designed a new stress inducing procedure allowing for comparison of performance on the same task prior to and after the stress induction in an fMRI setting. The effectiveness of the procedure was verified with GSR. The subjects were screened with the Formal Characteristics of Behavior - Temperament Questionnaire by Zawadzki and Strelau (1997), high emotionally reactive (n=15) and low emotionally reactive (n=14) were selected. They were examined with a 3-Tesla MRI scanner (Siemens Magnetom Trio TIM,) equipped with 32-channel phased array head coil. Prior to the scan, they attended two weeks of Braille reading training. To induce frustration, we gave misleading negative feedback information to subjects performing in the scanner sensory tactile discrimination based on a well learnt task of detecting raised dots. fMRI procedure consisted of three parts: two runs of tactile discrimination divided by Frustration Induction Procedure. During the Braille runs subjects were asked to compare two (same-different) simultaneously applied Braille characters. During the Frustration run the subjects were asked to touch a new set of stimuli and discriminate if the signs were symmetrical or unsymmetrical. New stimuli were not previously learne and meaningless. Despite correct responses, negative feedback was entered. We contrasted the second and first Braille run. Second level contrasts from single subjects were entered into paired t-test design placing the task on two levels: after and before stress induction. The results revealed increased activity in superior frontal gyrus, cingulate cortex, thalamus and precuneus during the run following frustration induction, confirming the effectiveness of the proposed stress manipulation and identifying neural substrates of frustration. The results were different in the two

temperamentally different groups. Low emotionally reactive group showed increased activity in the posterior cingulate gyrus, middle temporal gyrus and precuneus. This result suggests that temperamental traits may have significant impact on reactions under frustration.

Title: Differential effects of neuroticism on the entropy of spontaneous brain activity at rest

Authors: ***I. A. CRISTEA**[1], C. GENTILI[2], E. RICCIARDI[2], D. DAVID[1], P. PIETRINI[2]
[1]Clin. Psychology and Psychotherapy, Babes-Bolyai Univ., Cluj-Napoca, Romania; [2]Dept. of Surgical, Med. and Mol. Pathology and Critical Care, Univ. of Pisa, Pisa, Italy

Abstract: Neuroticism is a stable personality trait, characterized by a tendency to experience higher anxiety, depression, and other negative emotions and has been consistently linked to an increased risk for psychopathology. We questioned if neuroticism would modulate resting brain activity. We designed an fMRI study to assess this relationship in regards to the Hurst Exponent (HE), an index of time series predictability. In fMRI time series, HE typically ranges between 0.5 (lowest predictability) to 1 (highest predictability). Methods: Thirty-one healthy volunteers (25 F; mean age±s.d.: 25±3 yrs) were enrolled. All subjects were medication free and did not refer history or presence of any disorder that could affect brain function. A single resting state time series of 512 volumes was acquired for each subject on a 3T Siemens SKYRA (32-channel coil - 16 axial slices; TR/TE 1560/30 ms; matrix 94x94). Subjects were instructed to lie in the scanner with eyes closed. To assess neuroticism we used the Anxiety-Neuroticism factor of the Zuckerman Kuhlman Personality Questionnaire (ZKPQ), a 99-item self-administered scale measuring five independent personality traits. ZKPQ was administered one week prior the scan. We used CAMBA for time and spatial registration and for HE calculation. We used AFNI for Talairach transformation and to compute a multiple regression in which neuroticism was used as a criterion to predict HE. Clusters with a volume > 80 mm3 at a p-value threshold of 0.01 were

considered significant. Results: Neuroticism negatively predicted the HE in the precuneus (PCUN), cingulate cortex (CC), and right inferior frontal gyrus (IFG) (fig. 1). Discussion: Higher neuroticism seems to be associated with increased predictability, time redundancy and most likely rigidity of activity in brain areas involved in emotion regulation (CC; IFG), introspection, rumination and self-referential processes (PCUN). We note these areas showed altered resting state activity in anxiety and mood disorders. Our results offer neurobiological support for the link between neuroticism and psychopathology.

Title: Optimum optical wavelength pair for high-CNR multi-distance NIRS system

Authors: *J.-K. CHOI[1], M. CHOI[2], J. KIM[1], G.-P. HWANG[1], H.-M. BAE[1]
[1]Yuseong-gu, [2]KAIST, Daejeon, Korea, Republic of

Abstract: Near-infrared spectroscopy (NIRS) has been widely used to monitor local changes in cerebral hemodynamics, which are caused by blood oxygenation and deoxygenation due to functional brain activities. Modified Beer-Lambert law (MBLL) is the main governing equation for NIRS, which extracts the concentrations of oxy- and deoxyhemoglobin by using light signals with two wavelengths. The fidelity of the extracted oxy and deoxy hemoglobin can be quantified by using concentration-to-noise ratio (CNR). The CNR is strongly coupled with electrical signal-to-noise ratio (SNR), power contrast in multiple-wavelength measurements, and the propagation

trajectory of the light signal. The light reaching 2~4cm separated photo detectors propagate in a banana shape through the brain channel. Typically the wavelengths are selected to maximize the contrast between two measurements assuming that the electrical signal-to-noise ratio (SNR) is sufficiently large and the incident light penetrates deep into the cerebral cortex. However, the electrical SNR degrades and eventually limits the CNR when the separation between the source and detector pair increases. In the case of limited source and detector separation, only a small fraction of emitted photons reach the cerebral cortex of the brain. Thus the CNR is low despite high electrical SNR. Consequently, the wavelengths should be chosen carefully depending on the separation between source and detector pair under the given incident light power because the sensitivity of the photo detector, the absorption and scattering parameters (μ_a and μ_s) and the differential path-length factor (DPF) of light are dependent on a single parameter, which is the wavelength of the light. In this paper, the optimum wavelength pair for maximum CNR under various circumstances is investigated. Simulated and measured results validate our investigation.

Title: Fine spatiotemporal control of voltage-gated ion channels in neuronal dendrites

Authors: *A. V. FEDORCHAK, R. H. KRAMER
UC Berkeley, Berkeley, CA

Abstract: Voltage-gated ion channels are widely implicated in active dendritic signal propagation and intrinsic excitability. Not much is known about how the precise dendritic distribution of voltage-gated ion channels contributes to dendritic function. Here, we introduce a novel method to control voltage-gated ion channels in acute rat (Sprague-Dawley) brain slices with spatiotemporal resolution comparable to that of neurotransmitter uncaging. To achieve such control we use the small molecule Quarternary-ammonium Azobenzene Quarternary-ammonium (QAQ), which blocks voltage-gated ion channels under 488 nm light, in conjunction with 488 nm laser photoisomerization and 390 nm wide-field photoisomerization. Next, we determine the

dendritic length in which blocking voltage-gated channels significantly dampens signal propagation. We then block voltage-gated ion channels either along the main apical dendrite or at the main apical branch-point, and compare the corresponding effects on signal propagation. This method allows one to investigate voltage-gated ion channels and active dendritic properties in finer detail than has previously been achieved, and this study reveals the extent to which the spatial distribution of voltage-gated ion channels affects active signal propagation.

Title: Centering device for high content imaging of neuronal screens using micro culture platforms

Authors: *K. GORDON[1,2], A. M. TAYLOR[1,2,3]
[1]UNC/NCSU Joint Dept. of Biomed. Engin., [2]Neurosci. Ctr., [3]Carolina Inst. of Developmental Disabilities, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Objective: High-throughput screening (HTS) has been difficult to utilize for primary neurons because they are post mitotic, require high plating densities, and are harvested directly from brain tissue from a finite number of animals. These limitations therefore create tremendous costs for screens with neurons. Whereas traditional screening methods use at least ten thousand neurons per well of standard 384-well plates, here we use 'microraft' culturing platforms to grow and isolate significantly smaller (500-700 cells) populations of neurons and then place them into 384-well plates for screening. This method offers a unique advantage because it decreases the number of cells necessary for screening, but still allows enough culturing density for proper viability. Furthermore the evaporative issues that have plagued small neuron cultures are also avoided because of the larger volume of 384-well plates. These microraft platforms, which are flat 500 um square magnetic polystyrene particles, must be centered in order to utilize automated high content imaging systems in cell based screens. Therefore, the objective of this work is to create a device to achieve the maximum centering efficiency of these microrafts and validate its

use with primary neurons. **Methods:** The magnet array plate was first conceived and modeled in 3D using SolidWorks. Finite element models were then created using COMSOL to analyze the magnetic field, force of attraction, and interaction between neighboring magnets. A test prop was created from poly(dimethylsiloxane) (PDMS) with a 3 x 3 embedded array of magnets, and the final device was fabricated out of a translucent polymer using an automated CNC milling machine. **Results and Conclusions:** The results of this study include finite element analysis, physical centering tests and cell viability measurements using the magnet array plate. The finite element analysis shows trends in the attractive force on the microrafts at various distances from the magnet as well as the field interaction between neighboring magnets. We proved that microrafts can be attracted and centered with no interference from neighboring magnets. The physical centering tests consisted of two different techniques and the mean centering efficiency as well as the overall technique efficiency is reported and compared. Additionally, cell viability assays were performed measuring neuron viability before and after the centering process. The results from these tests conclude that this device displays a remarkable ability to center and secure the microrafts, with no loss in neuron viability, when loaded before or after placement of the multiwell plate over the magnet array plate.

Title: Chronic cranial window with access port allowing repeated cellular manipulations and electrophysiology

Authors: *C. J. ROOME, B. KUHN
Optical Neuroimaging Unit, OIST, Okinawa, Japan

Abstract: Chronic cranial windows have been instrumental in advancing *in vivo* imaging studies, permitting long term high resolution imaging in various brain regions (Holtmaat, A. et al. 2009). Despite their utility, a major limitation remains in the window design: Access to the brain beneath the window for cellular manipulations such as drug delivery or dye loading but also electrophysiology is presently not achievable but indispensable for many projects. To overcome this limitation we have designed a chronic cranial window that allows direct brain

access via glass or quartz pipettes and metal electrodes. This device comprises of a regular cranial window glass with drilled access hole which is sealed with biocompatible silicone before mounting. This chronic cranial window with access port is cheap, easy to manufacture, and can be mounted just as the regular glass coverslip window described by Holtmaat et al., 2009. Multiple injections or recordings can be performed through the silicone seal by beveled or skillfully broken glass or quartz pipettes, patch pipettes, or metal electrodes. Following each retraction of the pipette or electrode, the silicone re-seals and by this maintains the sterile cranial window necessary for long term, high resolution *in vivo* imaging. As an example, we demonstrate how the chronic cranial window with access port can be used to combine *in vivo* imaging with cellular manipulation by repetitively bolus loading calcium sensitive dye (oregon green bapta-1 AM) into cortical layer 2/3 of barrel cortex and recording their spontaneous activity in lightly anaesthetized mice for up to 8 times over a period of 6 weeks. During this period we do not find any signs of infection or change in neuronal activity. However, care has to be taken to avoid blood vessel puncture. As for the regular chronic cranial window, regrowth of bone can hamper the imaging quality and prevent simple access to the brain. As an example for electrophysiology, multiple recordings with metal electrodes can be easily performed through the access port of the window. Additionally, in a terminal experiment, the silicone plug can be removed exposing the dura which allows electrophysiology experiments as in acute preparations. This includes *in vivo* whole-cell patch clamp or sharp recordings. Reference: Holtmaat, A. et al. (2009) Nature protocols 4, 1128 - 1144

Title: Intrinsic connectivity network strength modulated by working memory load: An fNIRS study

Authors: *F. A. FISHBURN[1,2], M. E. NORR[3], A. V. MEDVEDEV[4], C. J. VAIDYA[3,5]
[2]Interdisciplinary Program in Neurosci., [3]Dept. of Psychology, [1]Georgetown Univ., Washington, DC; [4]Ctr. for Functional and Mol. Imaging, Georgetown Univ. Med. Ctr., Washington, DC; [5]Children's Res. Inst., Children's Natl. Med. Ctr., Washington, DC

Abstract: Background: In light of findings showing similar resting-state and task-evoked functional network architecture in fMRI, we examined whether intrinsic connectivity networks (ICNs) identified with fNIRS (functional Near-Infrared Spectroscopy) during the resting-state were sensitive to cognitive load demands. We identified ICNs in the resting state and used regression to examine working memory (WM) load-dependent activation and functional connectivity (FC) of individual networks. **Methods:** Sixteen subjects (6 male) were subjected to a 10-minute resting scan followed by a 6.5-minute letter n-back task with loads of 1-, 2-, and 3-back. Optical data were recorded on a two-wavelength (690 and 830 nm) continuous-wave CW5 imaging system (TechEn, Inc., Milford, MA). The 40 optical channels covered: ventrolateral prefrontal cortex (vlPFC), dorsolateral prefrontal cortex (dlPFC), frontopolar cortex (FP), and parietal cortex (Par). Raw signals were converted to oxygenated hemoglobin concentration. Resting-state signals were then filtered to .009-.09 Hz, downsampled to 2 Hz, and trimmed to the middle 6 minutes. Each channel was then normalized such that its root-mean-square (i.e., quadratic mean) was equal to 1. Data from each subject was concatenated to produce a group timecourse for each channel. Independent component analysis (ICA) was performed using FastICA. The positive and negative portions of each component were separated, doubling the number of components. The task signals were filtered to .009 - 2 Hz and downsampled to 10 Hz. The unmixing matrix from the resting-state ICA was used to project the task data into network space for each subject. The task-related components were then analyzed for WM load-dependent activation using NIRS-SPM. To assess FC, the outer product of the network channel weights was taken to produce an FC matrix for each network. These matrices were used to compute mean within-network correlation for each n-back load. The correlation values were then regressed against load for each network. **Results:** ICA yielded 6 networks: 1) parietal, 2) frontopolar, 3) anterior PFC, 4) vlPFC and frontal pole, 5) lateral PFC, 6) dlPFC, parietal, and frontal pole. Network activation increased with increasing n-back load for IC #5 ($t=2.18$, $p<.05$). FC increased with increasing n-back load for ICs #1 ($t=3.51$, $p<.005$) and #6 ($t=3.08$, $p<.005$). **Conclusions:** These results show that ICNs identified from resting-state fNIRS signals exhibit cognitive-load sensitive activation and FC. Thus, cognitive load effects can be expressed as a modulation of engagement of specific ICNs. Network-level analyses may facilitate probing cognitive phenomena using fNIRS.

Title: Development of a transmembrane fusion protein with tagging peptide for optical sensing of membrane potential during neuronal activity

Authors: *S. LEE[1], Y. BANG[1,2], J. LEE[1], J. JANG[1], Y.-K. SONG[1,2]
[1]Dept. of Transdisciplinary Studies, Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Advanced Inst. of Convergence Technol., Suwon, Korea, Republic of

Abstract: Since the late 1970s when Erwin Neher and Bert Sakmann invented a method called patch clamp, it has been extensively used for studying electrical properties of neurons. The technique has many advantages but also some limitations such as invasiveness, poor spatial resolution, difficulty to target specific population of neurons and inability to study multiple cells simultaneously1. In an attempt to overcome these limitations, several types of genetically encoded voltage indicators(GEVIs) that optically image membrane potential change have been developed since the late 1990s2. Many researchers developed GEVIs so far utilizing one or two fluorescent proteins to report voltage change of neurons and majority of them placed the fluorescent proteins in intracellular side2. So we came up with an idea to place a fluorophore in the outside of a cell to improve ability of a voltage sensor in reporting membrane potential change. To realize the idea, we have been working on to devise a voltage sensor combined with a fusion protein domain3 that connects the intracellular terminus of voltage sensing part to the extracellular side. Also, we have incorporated a tagging peptide4, Avitag, to connect the voltage indicator with an extrinsic fluorophore such as quantum dots or a nanoparticle working as fluorescence quencher. Several gene constructs containing the components above have been designed and prepared. The gene constructs were expressed in HEK293 cells and in cultured

primary neurons. The expression level of the protein based voltage sensors were verified with fluorescence microscopy and western blot analysis. Future plans of this study include toxicity tests such as phototoxicity and effects to membrane capacitance, and verification of photophysical properties using electrophysiology and optical techniques in several cell types such as HEK293 cells, cultured primary neurons, and acute brain slices of mouse. Title: *In vivo* measurement of intracellular Chloride and pH during neuronal development by means of 2-photon spectroscopy

Authors: S. SULIS SATO[1], P. ARTONI[1], A. I. IDILLI[2], S. LANDI[3], S. LUIN[1], R. PARRA[1], J. SZCZURKOWSKA[4], F. TROVATO[1], D. AROSIO[2], F. BELTRAM[1], L. CANCEDDA[4], *G. RATTO[3]

Abstract: The regulation of the intracellular concentration of Chloride ($[Cl^-]_i$) is an important modulator of inhibitory neurotransmission in the brain. In adult neurons, the Cl^- Nerst equilibrium is close to the resting membrane potential, and GABAergic activity through

ionotropic Cl^--permeable $GABA_A$ receptors plays its inhibitory role by inducing inward chloride fluxes that hyperpolarize the membrane potential. In the immature brain, where GABA is the predominant neurotransmitter, GABA behaves as a depolarizing and mostly excitatory neurotransmitter. By increasing network excitability and promoting the maintenance of spontaneous activity, GABA in early development exerts a key role in the maturation of neuronal networks. $[Cl^-]_i$ is regulated by the expression of two cotransporters, NKCC1 and KCC2, which move Cl^- in opposite directions. Interestingly, their expression is strongly regulated during development: NKCC1 is highly expressed in the pre and neonatal life, whereas KCC2 is mostly expressed in the adult; this should cause a shift in $[Cl^-]_i$ between neonatal and adult brains. Although several studies in slice and cell cultures have suggested that Cl^- is depolarizing in the perinatal period in immature neurons, the *in vivo* absolute measurement of the $[Cl^-]_i$ shift is still missing. Here, we have devised a method for absolute measurement of $[Cl^-]_i$ (and pH) *in vivo* in rodents by using a modified genetically-encoded sensor (ClopHensor). This sensor is formed by the fusion between a pH and Cl^- sensitive GFP (E^2GFP) and an insensitive RFP (LSS-mKate). First, we characterized the 2-photon spectral properties of the sensor, showing that increasing $[Cl^-]_i$ causes a decrease of the green/red fluorescence. A shift in pH causes a strong alteration of the 2-photon excitation spectrum of E^2GFP. Then, the sensor was targeted to the visual or somatosensory cortex by means of *in utero* electroporation at E15.5 (mouse) or E17.5 (rat). We demonstrated the integrity and stoichiometry of the sensor by *in situ* fluorescence correlation spectroscopy and by measuring trafficking across the nuclear membrane. We found that brain tissue has a sizable wavelength-dependent effect on scattering and extinction of excitation and emission and we devised a method to compensate for these effects. Finally, we determined that $[Cl^-]_i$ is very high until P8 (50.6±21.5 mM) and then strongly decreases (12.9±8.2 mM) after P18 suggesting a switch of GABAergic transmission from depolarizing to hyperpolarizing *in vivo*. Surprisingly, we have also found a shift in pH during development from more acidic values at P8 (median 6.85) to more basic values at P18 (median 7.2).

Title: Genetically encoded voltage sensors for optical monitoring of rapid neuronal activity

Authors: *F. ST-PIERRE[1], Y. YANG[1], X. DING[2], J. D. MARSHALL[1], Y. GONG[1], M. J. SCHNITZER[1], M. Z. LIN[1]

Abstract: The ability to monitor electrical activity in genetically-defined populations of individual neurons would empower the functional dissection of the brain. In particular, being able to follow rapid trains of action potentials (APs) would help understand how neuronal networks encode and process information as patterns of electrical activity. To enable optical detection of neuronal activity, we recently developed a novel genetically encoded voltage indicator (GEVI) called Accelerated Sensor of Action Potentials 1 (ASAP1) [St-Pierre et al., Nature Neuroscience (2014)]. While ASAP1 enables optical detection of single and trains of APs *in vitro* and *in vivo*, we sought to improve its response amplitude and brightness to facilitate detection of smaller voltage transients. We also wanted to increase ASAP1 kinetics to further improve its accuracy in representing the underlying voltage transients. From our rational screening approach, we obtained new ASAP variants with improved performance. Our work also highlights how key amino acids within ASAP can tune the its fluorescence response, presumably by affecting the voltage-dependent movement of ASAP's voltage sensitive domain.

Title: New optical CNiFERs to detect neuropeptides

Authors: J. ZHANG[1], A. MULLER[2], L. MELLANDER[2], E. LACIN[1], D. KLEINFELD[2], M. FERNANDO[1], *P. A. SLESINGER[1]
[1]Mount Sinai, Friedman Brain Inst., New York, NY; [2]UCSD, La Jolla, CA

Abstract: Neuropeptides are essential participants in the regulation of neural activity and the control of vascular tone. Although neuropeptides are widely expressed, the mechanisms, dynamics and consequences of neuropeptide release *in vivo* remain largely unexplored, largely due to a lack of analytical approaches for neuropeptide detection We are developing new biophotonic tools to monitor the release of neuropeptides in real-time in awake animals. We have previously created a cell-based neurotransmitter fluorescent engineered reporter (CNiFER) for detecting acetylcholine (Nguyen, Schroeder et al. 2010, *Nature Neuroscience* 13:127). CNiFERs are HEK293 cells engineered to express a specific G-protein coupled receptor and a genetically encoded FRET-based Ca2+ sensor, TN-XXL. Activation of GPCRs that couple to endogenous Gq G-proteins trigger an increase in cytosolic [Ca2+] through the PLC/IP3 pathway, leading to an increase in FRET. Here, we report on the development of CNiFERs for detecting three neuropeptides; orexin, somatostatin and vasoactive intestinal peptide (VIP). For the orexin CNiFER, we used the OX1 and OX2 receptors, which both respond to orexin A and B peptides. The OX1 receptor couples to Gq while the OX2 receptor couples to Gi G-proteins. The OX2 CNiFER therefore required creating a HEK293 cell expressing a G protein chimera Gqi5, which enables the OX2 to stimulate the Gq pathway. The same approach was used for the somatostatin CNiFER, where we used the Gi G-protein coupled receptor SST2. For the VIP CNiFER, we used VPAC2, which couples to Gs G-proteins and hence required coexpression of the chimeric Gqs5 G-protein. We have created CNiFER clones for OX1 and OX2, which have EC50's of ~5 nM and ~35 nM respectively, which are comparable to the EC50s for native OX1/2 receptors in the brain (10-50 nM). The somatostatin CNiFER has an EC50 of ~475 nM and the VIP CNiFER has an EC50 of ~10 nM. Importantly, each neuropeptide CNiFER line has little or no non-specific response to a panel of other neuromodulators. These new CNiFERs provide a unique means to measure neuropeptide release *in vivo*, which in addition can be combined with complementary imaging techniques, such as genetically encoded Ca2+ indicators.

Title: Transcriptomic analysis of CLARITY-processed tissues

Authors: *J. H. CHO[1], E. MURRAY[1], X. ADICONIS[2], J. LEVIN[2], K. CHUNG[1]
[1]MIT, Cambridge, MA; [2]Broad Inst., Cambridge, MA

Abstract: Understanding the molecular basis of the pathological changes in the diseased brain is vital for developing improved therapeutics. Various technologies have been developed to deduce and quantify transcriptomic details from distinct population of cells. However, the destructive nature of existing methods makes it difficult to correlate these molecular signatures to many crucial properties (e.g. connectivity, morphology, activity). Here, we will present a novel technique capable of selectively cataloging desired transcripts from subpopulation of cells with known functional, spatial, connectomic, and morphological details. This technique exploits the imaging capability and the biomolecule-retention efficiency of CLARITY-treated brains to synthesize and capture cDNA *in situ*. First, we will evenly disperse reverse-transcriptases throughout the CLARITY-processed brain and synthesize cDNA *in situ*. Next, target cells will be optically identified and precisely heat-treated to release the bound cDNA. Freed cDNA molecules will be then extracted by electrophoresis through the porous CLARITY-treated brain into an anodic gel-loaded capillary. The gels in the capillary captures cDNA molecules as they migrate through. Once the capture is complete, the gels are melted and released from the capillary, and the cDNA bound to the gels will be then eluted and analyzed using RNA-Seq. This approach may enable gene profiling of distinct population of cells with known connectivity, morphology, and molecular properties in human brain tissues as the method does not require any genetic manipulation *in vivo*.

Title: Rapid and quantitative phenotyping of intact biological systems

Authors: *S.-Y. KIM[1], E. MURRAY[1], J. H. CHO[2], N. BAKH[2], K. OHN[2], K. CHUNG[1]
[1]Inst. of Med. Engin. and Sci., [2]Dept. of Chem. Engin., MIT, Cambridge, MA

Abstract: For decades, sectioning-based two-dimensional molecular phenotyping techniques have been extensively used for investigation of tissue samples across biology and medicine. These techniques ensure that molecular targets in ultrathin tissue slices experience relatively similar reaction conditions (e.g. probe concentration and reaction time) to achieve complete and uniform labeling of given samples. However, three-dimensional information is lost unless a sophisticated and laborious 3D reconstruction is employed. CLARITY has succeeded in proving that an intact brain could be labeled, but penetration was poor because passive diffusion of molecular probes in the dense nanoporous mesh was slow (Chung et al., Nature 2013). Even near the surface, labeling was highly non-uniform due to large variations in probe concentration and in the probe-target interaction time across the superficial layers. Moreover, labeling of the crucial inner structures remained incomplete even after months. These critical limitations of the current techniques have prevented us from obtaining system-wide quantitative molecular information from large scale intact tissues. Here we introduce a new technology (termed eTANGO) that addresses these challenges by integrating two novel concepts: stochastic electrotransport and dynamic affinity shift. The penetration problem is solved by stochastic electrotransport, which selectively and rapidly drives only charged molecules (e.g. antibodies and RNA probes) without disrupting surrounding charged matrix (e.g. brain). Furthermore, probe-target binding affinities are dynamically modulated to synchronize reaction times brain-wide. Integration of these two concepts enables all the endogenous molecular targets in billions of cells to experience the same reaction condition (time and concentration). This yields complete and uniform staining of the

intact brain within hours. We applied eTANGO to immunostain various cellular, molecular and structural markers and further demonstrate quantitative molecular phenotyping over a large volume. The unique strength of eTANGO_complete homogeneous immunostaining_also opens the possibility of high-throughput brain-wide proteomic profiling at single cell resolution. Together with CLARITY, we anticipate eTANGO to facilitate integrated understanding of large-scale intact biological systems.

Title: Enhanced infrared peripheral nerve stimulation using local heating of gold nanorods

Authors: K. EOM[1], *S. JUN[2,3], S. HWANG[4], Y. LEE[4], K. BYUN[5], S. KIM[1]
[1]Dept. of Electrical and Computer Engin., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Electronics, [3]Dept. of Brain and Cognitive Sci., [4]Dept. of Electronics Engin., Ewha Womans

Univ., Seoul, Korea, Republic of; [5]Dept. of Biomed. Engin., Kyung Hee Univ., Yongin, Korea, Republic of

Abstract: Infrared neural stimulation (INS) is gaining increasing attention due to the large penetration depth, the contact-free and the electrical artifact-free stimulation as well as no genetic modification. However, the conventional INS suffers from tissue damage due to the high dosage of laser exposure and the poor light confinement. Hence, a safe and effective INS technique is required. Here, we propose an enhanced INS method using localized surface plasmon resonance (LSPR) of gold nanorods. To verify the photothermal effect of plasmonic gold nanorods on neural stimulation, *in vivo* experiments were performed with sciatic nerves of Sprague-Dawely rats. Pulsed infrared laser (wavelength: 980 nm, duration: 1 msec) was irradiated on to the sciatic nerves after injecting gold nanorods. From a location of 50 mm away from the optical stimulation site, compound nerve action potentials (CNAPs) were extracellularly recorded. The evoked CNAPs were compared when the optical stimulations were applied in the presence and the absence of the gold nanorods. When stimulating the nerve with gold nanorods, 0.159 J/cm2 was the stimulation threshold, while 0.480 J/cm2 was obtained in the absence of gold nanorods. Moreover, the responsivity of CNAP was more than five times higher in the presence of the gold nanorods. It is likely that the heat generated from the LSPR phenomena could effectively accelerate the depolarization of the neuronal cells with a lower optical power. In summary, we successfully showed the remote and safe activation of neural tissue via the LSPR effect of gold nanorods with the increased neural responsivity and the lower threshold level.

Title: Single-molecule patch-clamp fret microscopy studies of nmda receptor dynamics in living cells

Authors: *H. LU, D. K. SASMAL
Dept. of Chem., Bowling Green State Univ., Bowling Green, OH

Abstract: Stochastic and inhomogeneous conformational changes regulate the function and dynamics of ion channels that are crucial for cell functions, neuronal signaling, and brain functions.We have developed a new combined approaches of using single ion channel patch-clamp electrical recording and single-molecule fluorescence imaging for probing ion channel conformational changes simultaneously with the electrical single channel recording. By combining real-time single-molecule fluorescence imaging measurements with real-time single-channel electric current measurements in artificail lipid bilayers and in living cell membranes, we were able to probe single ion-channel-protein conformational changes simultaneously, and thus providing an understanding the dynamics and mechanism of ion-channel proteins at the molecular level.(1-4) We will focus our discussion on the new development and results of real-time imaging of the dynamics of gramicidin, colicin, and NMDA receptor ion channels in lipid bilayers and living cells. Our results shed light on new perspectives of the intrinsic interplay of lipid membrane dynamics, solvation dynamics, and the ion channel functions. Reference: 1.Suneth P. Rajapaksha, Xuefei Wang, H. Title: Development of wearable monitoring system for acquisition of physiological information from diverse portions of the whole body using near infrared lights (NIRS)

Authors: *H. EDA[1], R. SHIMOKITA[2], T. YAMAUCHI[2], N. KAZETANI[2], H. WADA[2], T. SAWADA[2], K. UJIIE[2], K. SOETA[3], Y. OHTAKI[3], M. SAKURAI[3], M. HIRAYAMA[3], S. IJUIN[3]
[1]Grad. school of GPI, Hamamatsu, Japan; [2]Genial Light. co.,LTD, Hamamatsu, Japan; [3]ALPS ELECTRIC CO., LTD, Tokyo, Japan

Abstract: Near infrared spectroscopy (NIRS) calculates hemoglobin parameters, such as change in oxygenated hemoglobin and deoxygenated hemoglobin (deoxyHb), using the near infrared lights around the wavelength of 800 nm. We developed portable NIRS (Eda et al., SfN2007). Other compact NIRSs were reported after that. Since the portable system can measure a brain with a free posture and can evaluate a brain also outside a laboratory, it sustains the possibility of the new application of the brain measurement technique. However, some reports seem to be not brain activation but a skin blood flow, because the skin blood flow of a forehead is changed by a posture. Some reports are also showing deoxyHb increases, this is contradictory to the blood oxygenation level dependent (BOLD) theory of fMRI. The BOLD theory is founded on the decreasing of the deoxyHb. The purpose of this research is to examine the technique of measuring brain activation correctly with the free posture measurement system. It is hard to demonstrate that the data mainly reflects the brain activation. One of the proving methods is to measure parts of whole body other than a brain. We developed the wearable system, which can measure each part of the whole body. One probe of the system has two light sources and one detector. Two light sources are near-infrared LEDs of two wavelengths. Now optical measurement is used for not only NIRS (2 or more lights, near infrared, some include visible) but the pulse oximeter (2 LEDs, one is visible and the other is near infrared), the plethysmography (1 LED, visible), etc. A pulse rate can be calculated as a periodic change of hemoglobin, and it is strongly influenced of autonomic nerves and of a motion of the whole body. This system was induced into a higher sampling rate than conventional NIRS, so that a pulse waveform could be exposed. Several pieces of the whole body, such as both hands, the head, and a breast, were evaluated using this system. The analog output of a pulse waveform measured by this system and that by the pulse oximeter (Nihon Kohden Corp., Japan) were compared. We put the probe on the fingertip, the wrist, the forehead, the temple, the cheek, the top of the head, the back of the head, and the neck, the heel of a leg, and several places of the left breast. The pulse waveform has been measured, respectively. Measurement of various parts showed that pulse waveforms differed, respectively. The pulse waveform of the fingertip measured by this system and that by the pulse oximeter were in agreement. This wearable system enables it to acquire physiological information and to discuss about the reliability of the brain activation data in a free posture.

Title: Fruit fly functional imaging

Authors: *S. AIMON[1], T. KATSUKI[1], L. GROSENICK[2], M. BROXTON[2], K. DEISSEROTH[2], R. J. GREENSPAN[1]
[1]Kavli Inst. For Brain and Mind UCSD, La Jolla, CA; [2]Departments of Computer Sci. and Bioengineering, Stanford Univ., Stanford, CA

Abstract: We seek to understand neuronal dynamics at the level of a complete network. For this purpose we use light field microscopy to observe neuronal activity in the whole brain of behaving flies. A calcium sensor -GCamp6- or voltage sensor -Arclight- are expressed, either pan-neuronally, or in subsets of neurons broadly distributed in the brain (including dopamine, octopamine, NPF, and FruM neurons). We then observe the whole brain's fluorescence through light field microscopy, and record at 100Hz with a high-speed CMOS camera. We are currently exploring the response of the network in various situations: while the fly is behaving freely (typically walking or grooming) and in response to a range of stimuli (including an air puff, an odor, a flash of light, sound...). We have also developed a paradigm to induce panic-like and relief-like behaviors while recording brain activity. 3D stacks are then reconstructed from the light field images using wave optics to model point spread functions, before applying 3D-deconvolution. We then use techniques taken from fMRI data analysis (including seed-based correlation and independent component analysis) to extract the activity of some single neurons, brain regions, and networks. This study is a first step towards outlining brain-wide functional networks for either spontaneous or event related activity in *Drosophila*.

Title: Multichromic optical interrogation of neural systems using caged compounds

Authors: *J. M. AMATRUDO, J. P. OLSON, H. K. AGARWAL, G. C. R. ELLIS-DAVIES
Neurosci., Mount Sinai Sch. of Med., New York, NY

Abstract: Caged compounds have been widely used by neurophysiologists to study many aspects of cellular signaling in glia and neurons. Most of these studies have been conducted with near-UV light in the 330-410 nm range. Recently, two-photon (2P) excitation at about twice this wavelength range has proved very useful for the optical interrogation of visually designated spine heads, principally because two-photon uncaging can be fine scaled in terms of space, time and amplitude so as to mimic quantal release. We show that recently developed caging chromophores (RuBi and DEAC450) that are photolyzed with blue light (ca. 430-480 nm range) can be combined with traditional nitroaromatic caged compounds (e.g. MNI and CDNI) to enable two-color optical probing of neuronal function. For example, one-photon uncaging of RuBi-GABA (10 uM) with a 473-nm laser is facile, and can block action potentials evoked by 2P uncaging of CDNI-Glu (1 mM) at 720 nm. The success of these two-color experiments rests upon both the optical transparency of CDNI at 473 nm and the low concentration of RuBi required for effective GABA uncaging with blue light. The power used to uncage glutamate at 720 nm evoked no response from RuBi due to this low concentration (RuBi has 70% activity at 720nm compared its maximum at 800nm). We also show that 2P uncaging of DEAC450-Glu (0.4 mM) and CDNI-GABA (1 mM) at 900 and 720 nm, respectively, can be used to fire and block action potentials. Since 2P uncaging required that the DEAC450 cage was applied at 40x higher concentration than that required for blue light, the success of this experiment rests on the significant 2P absorption minimum of this cage at 720 nm (60-fold lower than 900 nm). Note, CDNI is optically transparent at 900 nm. To date almost no 2-color actuation experiments have been published, largely because all previous long wavelength chromophores are effectively excited at short wavelengths. Our experiments illustrate that our recently developed

chromophore (DEAC450) has taken uncaging out of the "monochrome era" in which it existed since 1978, so as to enable multichromic interrogation of neuronal function with single synapse precision. Since the uncaging technique has been applied to the widest possible array of molecules (natural products such neurotransmitters, peptides, DNA, enzymes, miRNA, calcium and cAMP, and non-natural products such as fluorophores, drugs and antibodies), we believe that bimodal, wavelength-selective examination of many cellular processes is now possible.

Title: Imaging medial prefrontal and entorhinal cortex at cellular resolution in behaving mice using chronically implanted microprisms

Authors: *R. J. LOW, Y. GU, D. W. TANK
Princeton Univ., Princeton, NJ

Abstract: *In vivo* two-photon microscopy provides the foundation for an increasingly powerful array of techniques for measuring the structure and function of neural circuits. However, its use in deep brain tissue is limited by scattering, absorption, and out of plane fluorescence excitation[1]. Several approaches have been developed for deep imaging, but challenging tissue properties and geometry continue to prevent optical access to a key set of brain regions: those located along the walls of deep fissures. These regions include widely studied structures such as medial prefrontal and medial entorhinal cortex (mPFC and MEC), which are of central importance to learning, memory, and decision making. We present a general method for *in vivo* two-photon imaging of brain regions situated within fissures. Our approach involves inserting a right angle microprism into the fissure, which bends the optical path within the brain by 90 degrees and provides optical access to the fissure wall with subcellular resolution. We designed an implantable microprism

assembly for long-term, chronic imaging, and characterized its optical properties. We also developed novel surgical procedures for implantation amidst the unique anatomical features that surround fissures, including overlying venous sinuses (superior sagittal, transverse), associated vasculature (e.g. bridging and emissary veins), and dural folds and attachments. Our approach allows imaging during head-fixed behavior, such as navigation and decision making tasks in virtual reality. We demonstrate fissure imaging in mPFC and MEC, which lie within the longitudinal and transverse fissures, respectively (between cerebral hemispheres, and between the cortex and cerebellum). We imaged mPFC and MEC in head fixed mice running on a spherical treadmill, and performed chronic recordings over multiple weeks. We recorded structural images using fluorescent marker proteins, and measured network activity at cellular resolution using the GCaMP family of genetically encoded calcium indicators. By providing optical access to fissures, our approach opens up these regions for study at cellular resolution in behaving animals using a rapidly expanding palette of optical tools for perturbing and measuring network structure and function. Title: Optimizing CLARITY for the analysis of brain wide activity mapping

Authors: ***J. R. EPP**[1], Y. NIIBORI[2], H.-L. L. HSIANG[2], K. DEISSEROTH[3], S. A. JOSSELYN[2], P. W. FRANKLAND[2]
[1]Program in Neurosciences and Mental Hlth., Hosp. For Sick Children, Toronto, ON, Canada; [2]Hosptial For Sick Children, Toronto, ON, Canada; [3]Stanford Univ., Palo Alto, CA

Abstract: Understanding the coordinated activity of neural circuits throughout the entire brain is a central goal in neurobiology. Such a goal requires techniques that allow for high throughput imaging of whole brains at cellular resolution. A recently described technique known as CLARITY can be used to produce structurally intact yet optically transparent tissue that can be

labeled and imaged without the need for sectioning. The CLARITY technique involves replacement of opaque lipids with a hydrogel matrix. By exchanging the membrane lipids with a clear hydrogel matrix, CLARITY transforms the opaque and impermeable brain into a transparent and porous structure. The hydrogel matrix maintains the structure and localization of proteins but is permeable such that immuno-labeling or *in situ* hybridization of intact rodent brains is possible. CLARITY is capable of generating incredibly detailed tissue for 3D analysis but the success of this procedure is dependent on a large number of factors such as, temperature, hydrogel composition, and polymerization conditions. Here we have investigated the effects of systematically varying these factors in order to provide an optimized and highly replicable procedure. This protocol is suitable for high throughput imaging with confocal and single plane illumination microscopy. In combination with cellular activity markers and an analytical approach for producing functional connectomes, CLARITY offers a strong approach for whole brain activity mapping in the mouse brain.

Title: Imaging action potentials and subthreshold depolarizations in single trials with single cell resolution using the FRET based hybrid voltage sensor hVOS

Authors: *N. GHITANI, P. BAYGUINOV, Y. MA, M. B. JACKSON
Univ. of Wisconsin, Madison, WI

Abstract: Genetically-encoded voltage sensors provide researchers with optical tools for imaging electrical activity in targeted populations of neurons. This approach has the potential to reveal the dynamic activity of neuronal circuits, and enable researchers to elucidate the complex mechanisms by which the nervous system processes information. The hybrid Voltage Sensor (hVOS) technique employs Förster resonance energy transfer between a fluorescent protein and small charged molecule to generate optical signals arising from voltage-induced changes in

donor-acceptor distance. We expressed hVOS in sparse subsets of layer 2/3 neurons of the mouse somatosensory cortex by in-utero electroporation. Electrical stimulation of cortical slices from these animals evoked fluorescence changes in single cells in single trials. We also recorded hVOS signals in single trials with single cell resolution in brain slices from the hippocampus and entorhinal cortex of a transgenic mouse line expressing this probe in sparse neuronal populations. These fluorescence signals tracked subthreshold depolarizations and action potentials with excellent temporal fidelity as confirmed by simultaneous whole cell patch clamp and fluorescence recordings. Action potentials triggered by current injection via the patch pipette in the entorhinal cortex produced a mean fluorescence response of 2.37 ± 0.38% and a signal to noise ratio of 11.32 ± 1.79. Signals were distinguished in as many as 9 different cells within one field of view, as well as in dendrites and cell bodies from the same neuron. The sequence of activation of cells provided insight into the propagation of electrical activity through the slice circuitry. Thus, hVOS provides a tool for studying a variety of forms of electrical signaling and circuit activity in genetically targeted cells in intact tissue. Supported by NIH grant R21 NS078301.

Title: Evaluating conduction and action potential broadening with an axonally targeted genetically-encoded voltage sensor

Authors: *Y. MA[1,2], M. B. JACKSON[2]
[1]Physiol. Grad. Training Program, [2]Univ. of Wisconsin-Madison, Madison, WI

Abstract: Axonal conduction plays important roles in the transmission and processing of information throughout the nervous system, but the small size of axons often makes direct electrical recording of their voltage changes very difficult. We have addressed this problem by utilizing a genetically-encoded optical hybrid Voltage Sensor (hVOS), that preferentially targets axonal membranes. hVOS combines a fluorescent protein (FP) probe with a small negatively

charged molecule, dipicrylamine (DPA). DPA moves when membrane potential changes, to alter the donor-acceptor distance and generate a fluorescence change as the result of a change in Förster resonance energy transfer. The probe hVOS 2.0 was created from cerulean FP, tagged at the C-terminus with a truncated h-ras motif and at the N-terminus with a GAP-43 motif. Since GAP-43 is an axonal protein hVOS 2.0 preferentially targets axons when expressed under the control of thy-1 promoter in transgenic mice. Hippocampal slices from hVOS 2.0 transgenic mice show highly concentrated labeling in the stratum lucidum, due to dense probe expression in mossy fiber axons from granule cells. Strong labeling is also seen in the inner molecular layer of the dentate gyrus, due to probe expression in the axons of hilar mossy cells. hVOS imaging in these regions provides signals predominantly reflecting these axons, and because DPA crosses the membrane in less than 0.5 msec, hVOS signals can track action potentials with high temporal fidelity. Imaging experiments in mossy fibers revealed rapid action potentials which propagated with a conduction velocity of 0.23 ± 0.02 m/s. Furthermore, action potentials broadened during repetitive firing, with spike half-width increasing by up to 40% during high frequency stimulation (25 Hz). Spikes broadened somewhat less at lower frequencies. Frequency-dependent spike broadening in axons from hilar mossy cells was also detected in the inner molecular layer of the dentate gyrus. Conduction velocity of these axons was 0.18 ± 0.04 m/s. Thus, hVOS imaging with this axonally targeted probe provides evidence of activity-dependent action potential broadening in the axons of two distinct classes of neurons. Voltage imaging with hVOS 2.0 offers an opportunity to investigate action potential conduction and broadening in very fine axons that are inaccessible to electrical recording techniques. Genetically targeted hVOS 2.0 can be used to investigate signals in the axons of specific neuron subtypes. Supported by NIH grant R21 NS078301.

Title: Surface modification of micro electrode array with gold nanorods for photo-thermal stimulation of cultured neuronal networks

Authors: S. YOO[1], J. PARK[2], *Y. NAM[1]
[1]Bio and Brain Engin., [2]KAIST, Daejeon, Korea, Republic of

Abstract: Nanotechnology for controlling the molecular or cellular events in biological study has a significant impact, which is continuously extended to clinical purposes. However, design of the nanotechnologies to exploit the nerve system is still in early stage. Previously, we reported that photothermal stimulation using membrane bound gold nanorods (GNRs) can modulate electrical activity of neurons. Based on our finding, we hypothesized that nerve device that was integrated with GNR array could be a noble platform for modulation of neural network activity. Here, we developed a neural-interfacing nanoplatform by integrating GNR array with a multielectrode array (MEA). This nanoplatform provides bifunctional modality to electrically excite or optically inhibit the neural activity, which would be a useful tool for studying the dynamics of neural network. Gold nanorods were synthesized using seed-mediated method, and surface of the GNRs were coated with amine terminated poly ethylene glycol (PEG). Then, PEGylated GNRs were directly assembled on plasma treated MEA surfaces. Change of surface temperature and impedance of electrode were analyzed before and after GNR deposition. E18 rat hippocampal neurons were plated on the nanoplatform and early development and long-term survival rate were investigated. Near infrared (NIR, 785nm) laser was irradiated with 0~21mW/mm2 power density to matured neural networks, and change of spike rate was recorded. Concentration of the GNR on MEA surfaces was determined by changing the incubation time with GNRs. The number of deposited GNRs was increased by increasing the incubation time, but overlapping of the GNRs was not observed in our fabrication method. GNR array showed heat conversion of NIR laser, and its temperature was controllable depending on laser power density. Integrated MEA with GNR array did not show significant toxicity for long-term survival as well as early development. In contrast, surface photothermal stimulation (sPS) onto the nanoplatform showed significant changes on neural activity. Spontaneous activity of neurons was completely inhibited by 6mW/mm2 power density or gradually suppressed by increasing the sPS power up to 21mW/mm2. Our results indicated that GNR array integrated MEA system can provide a nontoxic and simple platform for studying the neural network and it has a great potential in implantable electrode applications.

Title: Imaging neural spiking in brain tissue using FRET-opsin protein voltage sensors

Authors: *Y. GONG, M. WAGNER, J. LI, M. J. SCHNITZER
Stanford Univ., Stanford, CA

Abstract: Genetically encoded fluorescence voltage sensors offer the possibility of directly visualizing neural spiking dynamics in cells targeted by their genetic class or connectivity. Sensors of this class have generally suffered performance-limiting tradeoffs between modest brightness, sluggish kinetics, and limited signaling dynamic range in response to action potentials. Here we describe sensors that use fluorescence resonance energy transfer (FRET) to combine the rapid and substantial voltage-sensitivity of the rhodopsin voltage-sensing domain derived from L. Maculans with the brightness of engineered protein fluorophores. These FRET-opsin sensors significantly improve upon the spike detection fidelity offered by the genetically encoded voltage sensor, Arclight, by offering approximately four-fold faster kinetics and four-fold higher brightness. Using FRET-opsin sensors we imaged neural spiking and sub-threshold membrane voltage dynamics in cultured neurons and in pyramidal cells within neocortical tissue slices. In live mice, rates and optical waveforms of cerebellar Purkinje neurons' dendritic voltage transients matched expectations for these cells' dendritic spikes.

Title: Analyzing morphology-dependent neuronal function using laser dendrotomy

Authors: ***V. DARIA**[1,2], M. GO[2], A. COLIBABA[3], S. REDMAN[2], S. REDMAN[2], H. BACHOR[4], C. STRICKER[2,3]
[2]John Curtin Sch. of Med. Res., [3]ANU Med. Sch., [4]Res. Sch. of Physics and Engin., [1]The Australian Natl. Univ., Canberra, Australia

Abstract: Objective: Dendrotomy can experimentally modify the neuron's dendritic structure and can be used to verify morphology-dependent neuronal firing. Several techniques have been used to sever processes from neurons in brain slices but these are invasive and may incur collateral damage to the cell and the surrounding tissue. Here, we report the use of a focused femtosecond pulsed laser as an ultra-sharp scalpel to cut dendrites and analyze the neuron's firing properties. The nonlinear nature of the multi-photon light - tissue interaction localizes dendrotomy to a diffraction-limited focal volume with minimal damage to surrounding tissue. We use a custom-built two-photon laser-scanning microscope to image as well as prune the dendritic tree of layer II/III, layer V and CA1 pyramidal neurons and assess how this affects firing. Methods and Results: We imaged neurons filled with 100 μM of Alexa-488 via a patch-pipette in 300 μm thick slices of somatosensory cortex and hippocampus from 15-19 day-old rats using 12-22 mW of 800 nm laser light. Dendrotomy sites were chosen from such images and performed with 100 ms pulses of 30-150 mW either at 720 or 800 nm. The holding current was monitored and firing patterns before and after dendrotomy were compared. Success of a cut was verified by generating EPSPs via 2P uncaging of MNI-glutamate at identified spines proximal and distal to the cut and via biocytin staining post hoc. Dendrotomy was characterized by a sudden increase in holding current regardless of the location of the cut in the dendritic tree after which it returned close to the initial value within 20 min. Successful dendrotomy was verified histologically in biocytin stainings proximal to the point of cut and by functionally checking that proximal uncaging responses remained but distal ones disappeared. Small-scale dendrotomy of 3rd- or 4th order dendritic segments did not change neuronal firing rate significantly. However, large-scale dendrotomy of 1st- and 2nd-order segments resulted in an increase in firing rate for the same current injected. Conclusion: We have demonstrated the use of laser surgery to dynamically prune the dendritic arbor of a neuron. This approach can be used to experimentally investigate the relationship between dendritic structure and neuronal function.

Title: Measuring voltage in dendrites and dendritic spines using quantitative all-optical electrophysiology

Authors: *S. L. FARHI[1], E. N. WEINSTEIN[1], A. E. COHEN[1,2]
[1]Harvard Univ., Cambridge, MA; [2]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: The dendrites of hippocampal pyramidal neurons perform computations by filtering and integrating voltage responses from multiple synaptic inputs. Dendritic integration has been investigated by dual dendritic patch clamp recordings, but these do not give the full spatial structure of the membrane voltage, and are difficult to perform on structures with small radii. Few direct measurements have been reported of the voltage responses of distal dendrites or dendritic spines. Further, the degree to which spines serve as electrical compartments remains uncertain. Voltage-sensitive dye recordings suffer from phototoxicity and require intracellular injection of the dye, which is slow and technically demanding. To study voltage in small dendrites and spines, we developed a system for quantitative and spatially resolved all-optical electrophysiology. The system consists of QuasAr2, a fast and sensitive genetically encoded voltage sensor, and CheRiff, a highly sensitive and spectrally orthogonal channelrhodopsin actuator. We applied this system to dissociated rat hippocampal excitatory neurons and made quantitative measurements of membrane voltage in dendrites and spines following activation with CheRiff or in response to synaptic activation with caged glutamate.

Title: Imaging Fast Calcium Currents: a pilot study of native T-type Ca2+ channels in CA1 hippocampal pyramidal neurons

Authors: *M. CANEPARI[1], N. JAAFARI[2]
[1]Grenoble Inst. of Neurosci., Grenoble Cedex 9, France; [2]Grenoble Inst. of Neurosci., Inserm, Grenoble, France

Abstract: The measurement of fast cellular Ca2+ currents is routinely achieved using the patch clamp technique in voltage-clamp mode. This experimental approach, however, is not applicable to the study of local native Ca2+ channels during physiological changes of membrane potential in complex cells since the voltage clamp configuration constrains the membrane potential to a given value. Here, we report how Ca2+ currents from individual cells can be measured beyond the limitations of voltage-clamp using fast Ca2+ imaging with low-affinity indicators. Individual CA1 hippocampal pyramidal neuron of the mouse were filled with 1 mM of the low-affinity indicator Oregon Green 488 BAPTA-5N and fluorescence from the apical dendrite was acquired at 20,000 frames/s. The Ca2+ current was obtained by conversion of the fractional change of fluorescence into Ca2+ influx and by its differentiation. The optical measurement of the Ca2+ current was correlated with the membrane potential simultaneously measured with a voltage-sensitive dye to investigate the activation of Ca2+ channels along the apical dendrite of the neuron during the back-propagation of an action potential. By using this innovative approach, we analyzed the voltage-dependence of high- and low-voltage gated Ca2+ channels. In particular, we measured the Ca2+ current component mediated by T-type channels by using pharmacological agents and we investigated the mechanisms of recovery from inactivation of these channels. We found that T-type Ca2+ channels are inactivated when the initial membrane potential is -60 mV and that recovery from inactivation occurs if the initial membrane potential is -80 mV. When the cell is firing 2-4 action potentials at high frequency (>50 Hz), a T-type channel component independent of the initial membrane potential is observed after the first spike. Using our novel approach we investigated the mechanisms underlying this form of activity-dependent recovery from inactivation of T-type Ca2+ channel. In conclusion, the

method of imaging fast Ca2+ currents presented here is expected to become a reference approach to investigate Ca2+ channels in their native physiological environment.

Title: Development of an integrated platform for standardized, high-throughput *in vivo* functional imaging

Authors: ***T. M. KEENAN**, K. ROLL, J. PERKINS, E. MOUNT, M. GARRETT, C. WHITE, N. ORLOVA, S. DE VRIES, C. FARRELL, C. LAU, L. NG, S. OLSEN, D. RIZZUTO, C. SLAUGHTERBECK, W. WAKEMAN, J. WATERS, D. WILLIAMS, C. REID, A. JONES, J. PHILLIPS, A. BERNARD
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Information processing in the mammalian brain is achieved in large part via the physical connectivity between relevant processing centers, and the encoding and routing of information carried on those connections. Understanding how the brain receives, sorts, and interprets information to engender higher order function requires: 1) a fundamental ability to identify areas of enhanced neural activity due to changes in behavioral state, and 2) the ability to assess single cell responses within those areas. The Allen Institute is interested in a variety of questions relating to brain function and information processing and accordingly has developed a novel platform for functional imaging of mouse cortex. The platform utilizes highly-standardized procedures, controls, and analytical tools to identify functionally-defined processing centers using reflectance-based intrinsic signal imaging (ISI)and subsequently quantifies single neuron responses using 2-photon optical physiology. All experimental and tracking data is stored within an integrated and searchable database that will ultimately be developed into a publicly-available resource.

Title: Two-photon optogenetic control of cAMP dynamics in dendritic spines for studying synaptic plasticity

Authors: *T. LUYBEN[1,2], M. KHAN[1], K. OKAMOTO[1,2]
[1]SLRI, Samuel Lunenfeld Res. Inst., Toronto, ON, Canada; [2]Mol. Genet., The Univ. of Toronto, Toronto, ON, Canada

Abstract: Understanding how synaptic structure and function are modulated by neural activity is essential for elucidating the mechanisms of learning and memory. Here we study the role of cyclic adenosine monophosphate (cAMP) in the structural plasticity of dendritic spines by developing two-photon optogenetic and live imaging techniques in cultured hippocampal slices. cAMP is a ubiquitous second messenger involved in synaptic plasticity, such as the late phase of long-term potentiation (L-LTP). However, its precise dynamics and role in dendritic spines remains elusive. Dendritic spines are thought to change their shape and properties through a process called structural plasticity. Structural plasticity occurs during synaptic activities such as LTP and long-term depression (LTD). Since cAMP is involved in LTP, we hypothesize that postsynaptic cAMP may therefore play a role in structural plasticity as well. To understand how cAMP regulates structural plasticity, at first we visualized cAMP dynamics during synaptic plasticity in living neurons by preparing genetically-encoded cAMP sensors utilizing Förster resonance energy transfer (FRET) and two-photon microscopy. We fused the cAMP binding domain of Epac1 (exchange protein directly activated by cAMP) with CFP (Cyan Fluorescence

Protein) and YFP (Yellow Fluorescence Protein) to make a cAMP FRET sensor, resulting in a probe with a high sensitivity to cAMP *in vitro* (EC50 = 1.68 μM). Time-lapse imaging of two-photon FRET in living neurons showed a transient increase in cAMP after tetanic stimulation (L-LTP induction) but did not detect a change in cAMP levels after caged-glutamate uncaging (early LTP induction). In order to examine the effect of cAMP on structural plasticity, we have established a two-photon optogenetic approach to non-invasively manipulate cAMP levels by light, using a combination of two-photon microscopy and photoactivatable adenylyl cyclase (PAC). These tools were biolistically transfected into CA1 pyramidal neurons and confirmed to not interfere with the induction of structural plasticity in dendritic spines by caged-glutamate uncaging. We found that light-dependent postsynaptic PAC activation enhanced dendritic spine enlargement during the plasticity after LTP induction by caged-glutamate uncaging. This may suggest a role for postsynaptic cAMP in the maintenance of the dendritic spine structure reorganization during structural plasticity. Thus, two-photon optogenetic approach provides a powerful tool to elucidate intracellular signaling mechanisms, such as synaptic plasticity, in living neurons.

Title: Scanless two-photon fluorescence imaging in the intact mouse brain

Authors: S. BOVETTI[1], C. MORETTI[1], M. DAL MASCHIO[1], S. ZUCCA[1], P. BONIFAZI[2], *T. FELLIN[1]
[1]Inst. Italiano di Tecnologia, Genova, Italy; [2]Sch. of Physics and Astronomy, Tel Aviv University, Israel

Abstract: Two-photon laser scanning fluorescence microscopy allows imaging the activity of extended cellular networks at high spatial resolution within largely scattering tissue, such as the brain. However, scanning microscopy is intrinsically limited in its time resolution by the sequential illumination scheme. Indeed, in both raster and random-access modalities, acquisition speed decreases as the number of imaged points increases. Here, we present a scanless, two-photon microscope for fast fluorescence imaging in the intact mouse brain *in vivo* based on structured light illumination by phase modulation. The microscope is based on a liquid crystal spatial light modulator (SLM), which is placed in a plane optically conjugated to the objective back-focal plane, and a galvanometric mirror-based laser scanhead. Emitted fluorescence is collected either in non-descanned mode by photomultiplier tubes or with a fast camera. In the scanless configuration, we report fluorescence calcium measurements from multiple layer II/III principal neurons in anesthetized mice at high acquisition frequency while maintaining subcellular spatial resolution and sufficient signal-to-noise ratio. Importantly, in the scanless approach, acquisition speed is independent on the dimensions of the imaged region. By monitoring the activity of neuronal populations on a fast time scale, this technique will help to elucidate the cellular mechanisms underlying information processing within brain networks.

Title: Gabaergic transmission and its long-term potentiation revealed by voltage sensitive dye imaging at mesoscale level

Authors: *M. COLAVITA[1,2,3], C. LEMERCIER[1,2], G. TERRAL[1,2], F. DRAGO[3], G. MARSICANO[1,2], F. MASSA[1,2]
[1]INSERM U862, Bordeaux, France; [2]Univ. de Bordeaux, Bordeaux, France; [3]Dept. di Biomedicina Clinica e Molecolare, Univ. degli Studi di Catania, Catania, Italy

Abstract: In cortical regions GABAergic interneurons form a heterogeneous population of cells with their intricate arborisations of dendrites and axons spreading along wide areas. This network of interneurons is critical in providing a temporal framework for principal cells activity thus regulating cortical computations. Considering the crucial role of GABAergic interneurons in the CNS and their large spatial extent, new tools to monitor their transmission in wide areas would permit us a better understanding of interneuronal networks functioning. For this aim we used Voltage Sensitive Dye Imaging (VSDI) and we took advantage of its possibility to record coincident changes in membrane potential at mesoscale level (i.e. at the level of local populations of neurons) with very high temporal resolution (milliseconds). Using acute hippocampal slices from adult mice we found that after the blockade of ionotropic glutamatergic transmission we were able to record evoked homosynaptic GABAA-mediated signal along the different layers of the CA1 region. This VSDI signal was abolished by the GABAA receptor antagonist Picrotoxin and it was increased by the benzodiazepine Chlordiazepoxide. Moreover, it could be modulated in amplitude proportionally to the applied stimulation intensity. Finally, we found that brief application of the selective group I metabotropic glutamate receptor (mGluR) agonist (S)-3,5-Dihydroxyphenylglycine (DHPG; for 10 minutes) induced a persistent enhancement of GABAergic VSDI-mediated signal lasting at least 80 minutes after washout. These results indicate that VSDI allows studying GABAergic transmission and plasticity in the hippocampus at a large spatial scale. In addition, we highlight a novel long-term potentiation specifically at GABAergic synapses. Title: High throughput optical imaging of the CLARITY-processed tissue

Authors: *H. CHOI, K. CHUNG
MIT, Cambridge, MA

Abstract: Understanding brain function and dysfunction requires integrative knowledge of the brain's architecture−how neuronal connectivity and molecular machinery orchestrate mental function. Recent advent of tissue processing technologies, such as CLARITY and other optical clearing methods, open the possibility of investigating anatomical and molecular architecture of intact brain without laborious mechanical sectioning and reconstruction. Conventional confocal and two photon microscopies, however, significantly limits their utility due to the slow scanning nature of the imaging methods. Here, we introduce a temporally focused line scanning two photon microscope which can provide a resolution equivalent to point scanning two photon microscopy while the image acquisition rate is limited only by the readout speed of the sCMOS camera. Further increase in depth resolution is achieved by using a rolling shutter of the sCMOS as a dynamic confocal pinhole. This new imaging system may be particularly useful for human brain mapping because the unique optical configuration and open design of the sample chamber permits samples with any shape and size (e.g. whole coronal block of the human brain, rat brain, monkey brain, and other organs) can be readily imaged. The imaging depth will be limited by the working distance of the objective, but when combined with sectioning by vibrating blade microtome, this imaging modality may even enable imaging of whole mounted primate/rat brains in an automated manner.

Title: Scalable CLARITY

Authors: *E. MURRAY[1,2], N. BAKH[3], J. H. CHO[3], S.-Y. KIM[2], K. OHN[3], K. CHUNG[1,2,3]
[1]Picower Inst. for Learning and Memory, [2]Inst. for Med. Engin. and Sci., [3]Chem. Engin., MIT, Cambridge, MA

Abstract: The recent development of the CLARITY technique has opened the doors for structural and molecular interrogation of large, intact blocks of tissues. However, there are many issues with the technique in its original form: lengthy processing time, expensive reagents, hard-to-reproduce procedures, accumulation of "black gunk" on tissue surfaces, and fundamental limitations in the size of clearable samples. Applying principles from chemical engineering, we have re-visited each stage of the CLARITY procedure in order to improve the technique as a whole, making it scalable to larger brains and more available to a wider base of users. We have (1) optimized the conditions of fixation to maximize retention of structural and molecular information, (2) increased the reproducibility of the de-gassing and tissue-hydrogel hybridization procedure through development of a customized apparatus, (3) developed a novel stochastic electrotransport device to improve the reliability and overall speed of the tissue-clearing step while decreasing the cost by ten-fold, and (4) developed a replacement immersion medium for FocusClear that can be made at a small fraction of the cost. This next generation CLARITY technique is scalable to larger samples, such as whole rat brain or large blocks of human/non-human primate tissues.

Title: Development of a portable optical system for *in vivo* deep-brain neuronal imaging

Authors: *B. OZBAY[1], J. T. LOSACCO[2], E. A. GIBSON[1], D. RESTREPO[3]
[1]Bioengineering, Univ. of Colorado Denver, Aurora, CO; [2]Neurosci. Program, [3]Cell & Developmental Biol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Many chronic diseases of the central nervous system, such as epilepsy and depression, are thought to have important cellular and sub-cellular dynamics that may be probed to understand disease progression and to identify possible therapeutic targets. Furthermore, continuous *in vivo* monitoring of neuron activity in the brain can be used to provide feedback to better tune therapies. Currently, *in vivo* monitoring of deep-brain neurons is accomplished primarily by electrophysiological methods, such as intracranial deep-brain electrodes. While these methods can allow for single unit action potential recordings, they lack cell-type specificity, sub-cellular spatial resolution, and are limited to recordings from small populations of neurons. In this work, we utilized innovations in genetically encoded optical sensors combined with custom-designed optical tools to be used as an *in vivo* deep-brain neuronal imaging system with high spatial resolution, large imaging volume, and cell-type specificity. We have designed a portable fiber-coupled miniature imaging system that can be coupled to most commercial inverted laser scanning microscopes. The distal optics are 2 mm in diameter and can be implanted to acutely record from deep-brain regions. Lateral imaging is accomplished by the use of a high-density fiber-bundle that can achieve a resolution of ~2 μm and a lateral field of view of ~200 μm. The system is designed for multiphoton microscopy, which can be used to obtain large imaging volumes to capture extensive neuronal processes and populations. The optical system was tested *in vivo* to image neuronal GFP expressing oligodendrocyte cell bodies in an anesthetized mouse olfactory bulb. The distal optics were also implanted in anesthetized mice for acute deep-brain recording sessions. Furthermore, the recently developed genetically-encoded calcium sensor, GCaMP6s, was expressed in piriform cortex pyramidal neurons via viral delivery into mice with Ntsr1-driven Cre expression with the purpose of performing functional high resolution deep-brain imaging in an anesthetized mouse. Further development of this system offers the promise of a new type of functional imaging in an awake behaving animal allowing for the observation of morphological and physiological changes over time which will clarify both normal and pathological network dynamics.

Title: Rapid *in situ* three dimensional gene profiling

Authors: *N. BAKH[1], K. CHUNG[1,2,3]
[1]Chem. Engin., [2]Inst. for Med. Engin. and Sci. (IMES), [3]Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Elucidating spatial heterogeneity and complexity in gene expression is crucial for understanding brain function and dysfunction. *In situ* hybridization is an essential tool that enables imaging of mRNA expression in a morphological context. Its power, however, has been limited to small-scale samples due to the opaque and impermeable nature of biological tissues. The advent of the CLARITY technique to render intact tissue transparent and permeable to molecules, while preserving structural and molecular information, opens the possibility of obtaining 3D transcription information from a large-scale intact tissue using fluorescent *in situ* hybridization (FISH). However, the slow nature of passive diffusion significantly limits the penetration depth of the probes and the throughput of this method. To overcome this limitation, we developed an electrophoretically assisted FISH technique to boost transport of highly charged oligonucleotide probes for rapid labeling and mapping of mRNAs in CLARITY-processed tissues. In addition, we developed a new immersion medium that preserves RNA integrity during the imaging step to enable consecutive rounds of FISH on the same tissue. After imaging, fluorescent dyes are optically inactivated to allow iterative staining and imaging cycles. We envision that this high-throughput *in situ* gene profiling technique will greatly help us navigate the transcriptional landscape of the brain in health and disease.

Title: A comparative study of the two-photon performances of GCaMPs and GECOs

Authors: *B. PODOR[1], Y. ZHAO[2], J. WU[2], Y.-L. HU[1], M. OHKURA[3], J. NAKAI[3], R. CAMPBELL[2], R. CROLL[1], A. FINE[1]
[1]Dalhousie Univ., Halifax, NS, Canada; [2]Chem., Univ. of Alberta, Edmonton, AB, Canada; [3]Brain Sci. Inst., Saitama Univ., Saitama City, Japan

Abstract: Genetically encoded calcium indicators (GECI) are increasingly being used to monitor neuronal activity. With appropriate targeting strategies they permit non-invasive imaging of activity of neuronal networks, individual cells, or even subcellular compartments. Development of the first GECI, GCaMP (Nakai *et al*., 2001), has been followed by substantial progress in both the variety and utility of these indicators; new GECIs have been reported with increased sensitivity (ΔF/F, the fractional change in fluorescence upon Ca^{2+} binding), and in a range of colours ("GECOs", Zhao et al., 2011). However, newly developed sensors have mainly been characterized *in vitro* or in model cells, and their performance may be significantly different in particular neurons under experimental conditions. We therefore compared the ability of members of the GCaMP and GECO families to report proximal dendritic calcium transients imaged by two-photon laser scanning microscopy. Specifically, these were: GCaMP-3; GCaMP-7; Green-GECO1.0, 1.1, 1.2 (G-GECO); Blue-GECO (B-GECO); Red-GECO (R-GECO); Rex-1A-GECO; Rex-1B-GECO; Carmine-GECO (CAR-GECO); Orange-GECO (O-GECO); and Yellow-GECO (Y-GECO-1s). After first determining the optimal 2P excitation wavelength for each indicator, we evoked and recorded increasing numbers of action potentials in CA1 pyramidal cells in hippocampal slice cultures by intracellular current injection and monitored the achieved ΔF/F values by 2P microscopy. By far the most sensitive indicator for reporting single action potentials was GCaMP-7. Kinetics of all tested indicators proved too slow to resolve individual action potentials beyond 10 Hz, but GECO1.2, Rex-1A and Y-GECO-1s exhibited a linear relationship between number of evoked action potentials (APs) and fractional change in fluorescence up to at least 8 APs @ 100Hz.

Title: Genetically targeted, cell-type specific optical recording of membrane voltage dynamics in freely moving mice

Authors: *J. D. MARSHALL[1], P. JONES[2], Y. GONG[2], J. LI[2], F. ST-PIERRE[2], M. LIN[2], M. SCHNITZER[2]
[1]Stanford Univ., Menlo Park, CA; [2]Stanford Univ., Palo Alto, CA

Abstract: Electrical field recordings of aggregate neural activity such as electroencephalogram (EEG) and local field potential (LFP) recordings are widely used research and clinical tools for observing evoked potentials, distinguishing brain states such as sleep or wakefulness, detecting oscillatory electrophysiological rhythms, and tracking coherent activity across brain areas. However, field recordings are generally difficult to interpret from a mechanistic standpoint and often reflect the combined action of multiple electrophysiological mechanisms and cell types. Here we describe an optical measurement technique that, like LFP or EEG recordings, reports on the collective activation of neural populations, but unlike these methods does so in manner that is selective for a genetically specified class of neurons. To accomplish this, we combined newly developed genetically encoded optical voltage sensors [St-Pierre *et al.*, *Nature Neuroscience* (2014); Gong *et al*., *Nature Communications* (2014)] and a multi-color fiber-optic recording apparatus, which together enabled a fast optical readout of neuronal membrane potential dynamics in specific neuron types of freely behaving mice. Using this approach, we recorded oscillatory and evoked optical transients in neocortical pyramidal cells, neocortical interneurons, and in D1- and D2-dopamine receptor expressing medium spiny neurons of the striatum. The high sensitivity of our measurement approach enabled the use of sufficiently weak illumination to permit extended recordings (>1 hour/day) with minimal photobleaching. Comparisons of recordings acquired during spatial exploration versus during sleep revealed an enhancement of

delta oscillations during sleep that occurred more sparsely in time than those seen in EEG recordings. This difference between the optical and EEG measurements may reflect a superior spatial resolution for the optical approach. In optical recordings of D1- and D2-receptor expressing medium spiny neurons, we found that haloperidol-evoked high-voltage spindles were phase-locked to the cortical EEG with indistinguishable phase offsets for the two cell types. This suggests these prominent cortico-striatal oscillations are synchronized between the direct and indirect pathways of the basal ganglia. Overall, our methodology provides a versatile new approach to examine aggregated neural activity in a cell-type specific manner.

Title: A high-throughput technology for fixation optimization and antibody screening of CLARITY-processed tissue

Authors: *A. C. HOUSTON[1,2,3,6], E. MURRAY[1,3,4], J. CHO[1,4,5], K. CHUNG[1,3,4,5]
[2]Brain and Cognitive Sci., [3]Picower Inst. for Learning and Memory, [4]Inst. for Med. Engin. and Sci., [5]Chem. Engin., [1]MIT, Cambridge, MA; [6]F.M Kirby Neurobio. Ctr., Children's Hosp. Boston, Boston, MA

Abstract: CLARITY is a technology that renders intact biological tissue optically transparent and chemically accessible while maintaining structural and molecular information. Molecular phenotyping techniques (e.g. immunohistochemistry) can be employed to probe biochemical components (e.g. protein, DNA, RNA, small molecules) that are fixed and tethered to a

polyacrylamide hydrogel. The introduction of the hydrogel tethering, however, alters the biochemical environment within the tissue from that found within standard fixation protocols. Therefore, optimization of fixation conditions (i.e. paraformaldehyde, glutaraldehyde, acrylamide, bis-acrylamide concentrations) and immunolabel screens are critical to ensuring the validity of molecular phenotyping of a CLARITY-processed tissue. It is notable that fixation optimization and antibody screening are labor and resource intensive when CLARITY-processing a whole tissue. Thus, a high-throughput method of processing small tissue samples is needed. Here, we describe a novel method for rapid CLARITY processing and immunolabeling of thin sections. This technology platform utilizes a pressure drop to generate convective flow through the sample to rapidly deliver molecules while a membrane support is used to stabilize tissue sections. Large numbers of samples can be processed in parallel on a significantly smaller time scale allowing efficient testing of fixation conditions and screening of antibodies. By utilizing this methodology we are able to rapidly clear small tissue sections from a wide variety of host species (e.g. mouse, rat, monkey, human) and screen hundreds of antibodies under various fixation and staining conditions. Importantly, we have found the incorporation of glutaraldehyde fixation to maximize structural stability and better preserve small-molecules, such as neurotransmitters and neuropeptides, for immunolabeling. This novel high-throughput technique will extend the utility of CLARITY by greatly reducing the resources and time required in optimizing conditions for biochemically probing CLARITY-processed tissue.

Title: Programmable wireless LED stimulator for chronic stimulation of optogenetic molecules in freely moving mice

Authors: *M. HASHIMOTO[1], T. MIYATA[1], H. HIRASE[2]
[1]Dept. Cell Biol., Nagoya Univ. Med., Nagoya, Japan; [2]Lab. for Neuro-Glia Circuitry, RIKEN Brain Sci. Inst., Wako, Japan

Abstract: The cloning and subsequent bioengineering of light-driven channels (e.g., channelrhodopsins) or pumps (e.g., halorhodopsin and archaerhodopsins) has opened a new avenue in the field of optogenetics. Optogenetics is a powerful method in neuroscience because these opsins can be expressed in specific subsets of neurons by genetic manipulation, allowing dynamic modulation of the discharge of these cells by light. In animal experiments, the effectiveness of brain manipulation is ultimately assessed by an animal's behavior. Because most rodent behavioral experiments assume free movement of the animals, a light delivery method that does not compromise their movement is desired. We produced a miniaturized, multicode, multiband, and programmable light-emitting diode (LED) stimulator for wireless control of optogenetic experiments. The LED stimulator is capable of driving three independent LEDs upon reception of an infrared (IR) signal generated by a custom-made IR transmitter. Individual LED photopulse patterns are assigned to different codes of the IR signals (up to 256 codes). The photopulse patterns can be programmed in the on-board microcontroller by specifying the parameters of duration (>1 ms), frequency (<500 Hz), and pulse width (>1 ms). The IR signals were modulated at multiple carrier frequencies to establish multiband IR transmission. Using these devices, we could remotely control the moving direction of a Thy1-ChR2-YFP transgenic mouse by transcranially illuminating the corresponding hemisphere of the primary motor cortex. The photopulses (frequency, 10 Hz; duration, 50 ms; interval, 2 s) presented to the right and left motor cortex changed the moving direction of a freely moving Thy1-ChR2-YFP mouse the left and right, respectively (Fig. A). IR transmitter and LED stimulator will be particularly useful in experiments where free movement or patterned concurrent stimulation is desired.

Title: A large bi-directional interface for optogenetic stimulation and recording in non-human primates

Authors: *A. YAZDAN-SHAHMORAD[1], T. HANSOS[1], C. DIAZ-BOTIA[1,3], P. LEDOCHOWITSCH[3], V. KHARAZIA[2], M. MAHARABIZ[3], P. N. SABES[1]
[1]Physiol., [2]Univ. of California San Francisco, San Francisco, CA; [3]Univ. of California Berekley, Berekley, CA

Abstract: Optogenetics offers the promise of manipulating large-scale neural circuits with both high temporal and spatial precision. While optogenetics has been used successfully in non-human primates (NHPs), reliable techniques have not yet been reported for large-scale, bi-directional study of neural circuits in NHP. Here we describe such a large-scale interface that combines optogenetics with high-density micro-electrocorticography (μECoG). To obtain expression across large areas of cortex, we infused AAV5-CamKIIa-C1V1-EYFP viral vector using a novel infusion technique based on convection-enhanced delivery in primary somatosensory (S1) and motor (M1) cortices. Following viral injection, a soft, transparent artificial dura (AD) was implanted to cover the injection sites. It provided an optical window to monitor the spread of viral expression using epifluorescent imaging and a platform for targeted, non-invasive optical stimulation. Based on this imaging, we estimated high levels of expression across at least 110 mm2 of cortex spanning S1 and M1. In order to record large-scale activity across this region, we incorporated a 192-channel μECoG array spanning 96 mm2 into the AD for simultaneous electrophysiological recording during optical stimulation. Our array was designed to include 300 μm diameter perforations to enable unattenuated optical access and was implanted to cover the opsin-expressing areas in M1 and S1. We implanted the μECoG both acutely (within one session) and chronically (for the span of several weeks). In both cases, we observed reliable light evoked neural responses in M1 and S1. The temporal and spatial

distribution of activity near the stimulation site varied with the stimulation parameters. Spatio-temporal analysis of the activity across the array showed reliable evoked activity not only close to the stimulation site but also in neighboring areas. For example, stimulating a particular location in S1, we were able to record reliable activity in an area of M1 at a distance of about 2 mm from the site of stimulation. These results show the feasibility of implementing a large bi-directional interface using optogentics, AD and μECoG array technologies in NHPs. This interface is a powerful tool to study circuits and connectivity across extended cortical areas, improve the specificity of neuromodulation and provide real-time dynamic titration of stimulation on the basis of the brain state.

Abstract: Most optogenetics studies in nonhuman primates currently require inserting an optical fiber on a daily basis. The cortical damage caused by this process makes chronic multichannel stimulation undesirable or unfeasible. Unlike in rodents, primate anatomy prohibits the use of any cannulas or LED probes that are fixed to the skull. Tiny, injectable light sources have been fabricated by other groups (i.e. Kim et al., Nature 2013). While these devices have been successful in rodents, we wanted to develop an implant optimized for a primate study spanning 6 to 12 months, and allowing for the arbitrary configuration of light sources as the experiment requires. We wire bonded commercially available bare-die Cree blue LEDs (220x270x50 μm, 460nm wavelength) onto a glass wafer (100 μm thickness) and diced them to get individual devices. We used conductive epoxy to attach 75 μm wire to the devices. We then dip coated the devices to provide strength and a watertight encapsulation. Recent results show that our aramid

nanofiber (ANF)/epoxy film provides superior metal adhesion performance and better neural cell biocompatibility than the more commonly used parylene-C (in preparation). 1 g of purchased Kevlar® thread was dissolved in 100 ml of DMSO with 4 g of KOH for a week to prepare a 10 mg/ml ANF dispersion. Each device was dipped into ANF nanofiber dispersion first, and then rinsed with water to remove the excess DMSO. Then, the device was dipped into 3% epoxy resin in acetone and dried in the oven at 80 degrees Celsius. Repeating this process for six dip cycles results in a pinhole-free film that is 3 μm thick. We have demonstrated implantation of the device into rat cortex using a standard stereotax micromanipulator, with no bleeding. We are now in the process of testing the devices for hermeticity and effectiveness of stimulation. In previous experiments we have stimulated with a laser (Omicron Laserage) of a comparable wavelength (473nm) with a power of 6mW out of a 200um optical fiber (Doric Lenses). During application of 50 Hz stimulation (2ms pulse width) in motor cortex (AP 1.7, ML 2.5, DV 1.0mm), we observed robust increases in locomotion and neural activity. We will take these results as baseline for comparisons with the new LED device. These LEDs are ideal for use in primates for several reasons. They can be implanted individually in any configuration, such as surrounding any electrode array, or laid on the surface of cortex. The wires can run along the surface of the brain and emerge through the bone as a bundle, reducing strain and making the surgical close easier. Finally, they are fabricated relatively simply, using commercially available materials.

Title: Effect of spectrally-shaped light stimulation on Channelrhodopsin-2 currents and spike response in cortical neurons

Authors: *K. PAUL, H. TU, E. D. ARK, Y. ZHAO, S. A. BOPPART
Beckman Inst., Univ. Illinois, Urbana-Champaign, URBANA, IL

Abstract: Optogenetics has traditionally been regarded as the integration of genetic targeting/manipulation with optical stimulation. Since the initial demonstrations of neural control using the ChR2, genetic manipulation has given rise to a number of variants with different properties that either improve upon those of ChR2 or are geared towards a specific desirable response. However the possibility of controlling neuronal output by modifying the optical properties of the light stimulus has so far been neglected. Given the known state changes accompanied by varying wavelength absorbances in the ChR2 photocycle, we hypothesized that independent control of phase and amplitude at different wavelengths of pulse shaped light would alter the neuronal output properties. In this study, we have investigated the effects of this "tailored" light stimulus on ChR2 expressing excitatory pyramidal neurons in neocortical slice tissue. For our investigations, we used a light pulse shaping system (FemtoJock, BiophotonicsSolutions, Inc.) for precisely controlling the spectral and temporal properties of femtosecond pulsed light from a laser source. A Ytterbium laser source (High-Q) was used to generate ~250 fs pulses at a center wavelength of 1040 nm. Pulses were coupled into a photonic crystal fiber to spectrally broaden the light, and then sent to an optical grating to spectrally separate the light wavelengths. The light was then passed through a spatial light modulator (SLM) which enabled us to independently control the phase and amplitude of the spectrally and spatially separated light at known wavelengths. A second grating then recombined the shaped light, which was then passed through the microscope objective for ChR2 excitation in slice tissue. Whole-cell patch-clamp recordings were obtained from pyramidal neurons from slices obtained from the prefrontal and somatosensory neocortex of mice (P12-45). We measured light evoked ChR2 currents in the voltage clamp configuration and in the presence of TTX (0.5 μM). For each neuron, we obtained current responses from 3 light sources: full field continuous wave (CW) light from an LED light source (470 nm), direct 2-photon laser excitation (1040 nm) and tailored 2-photon laser excitation via pulse shaping. For the "tailored light", various configurations of phase and amplitude were independently varied and the corresponding output was recorded. We measured peak and steady state current response, "ON" and "OFF" time constants as well as the recovery time between successive pulses. In the current clamp mode, we independently varied the light amplitude or phase at known wavelengths in order to observe alterations in spike responses.

Title: Optically-integrated multiwell microelectrode arrays for high-throughput drug discovery and disease modeling with optogenetics

Authors: I. P. CLEMENTS[1], D. C. MILLARD[1], A. M. NICOLINI[1], *M. BROCK[2,1], A. J. PREYER[1], J. D. ROSS[1]

Abstract: *In vitro* microelectrode arrays (MEAs) provide extraordinary insight into neuronal network interactions because they can actively monitor and manipulate electrical activity at both the single neuron and tissue level. Recently-developed multiwell MEA systems enable high-throughput experimentation with significantly reduced experimental time and cost. For example, 768 microelectrodes can be distributed among 48 or 96 distinct culture wells on a single microplate for highly parallel experiments. Although MEA recording electrodes can also be used to deliver electrical stimuli, optogenetic stimulation provides several advantages, including spatially uniform stimulus delivery, minimal stimulus artifacts, the ability to suppress activity, and cell-specific targeting through directed expression of light-gated ion channels. This precise control of excitation level enables *in vitro* modeling and modulation of electrical phenotypes for diseases such as epilepsy, autism, and Parkinson's disease. Here we describe the development of an LED array based optical stimulation device, specialized for integration into a multiwell MEA system. This device features independently controllable light delivery within each MEA culture well, and incorporates algorithms for automation and closed-loop control, which are essential in high well count experiments.Using both rodent primary neurons and human induced pluripotent stem cell (hiPSC) derived neurons, we demonstrated multiwell light-based excitation through expression of Channelrhodopsin-2 (ChR2) and suppression of activity through expression of Archaerhodopsin (ArchT). The system's multiwell architecture enabled rapid parallel screening of the effects of various ion channel and receptor modulators on light-evoked activity. These findings demonstrate the potential of optically-integrated multiwell MEA systems to enable high-throughput drug screening and phenotypic modeling of neurological diseases.

Title: Multi-focal photostimulations with light emitting diodes on a multi-channel electrocorticographic array in non-human primates

Authors: *M. KOMATSU[1], E. SUGANO[2], H. TOMITA[2], N. FUJII[1]
[1]Lab. Adaptive Intelligence, RIKEN Brain Sci. Inst., Saitama, Japan; [2]Dept. of Chem. and Bioengineering, Iwate Univ., Iwate, Japan

Abstract: Optogenetics has potential applications in the study of epilepsy and neuroprostheses, as well as neural circuit dynamics. However, to achieve translation to clinical usages, optogenetic interfaces capable of chronic multisite stimulations and recordings with minimal brain trauma are required. In this study, we developed a multi-channel electrocorticography (ECoG) incorporates light emitting diode (LED) chips to perform simultaneously electrophysiological recordings and light delivery in non-human primates. This technique enables chronic optical stimulation and simultaneous monitoring of neural response at the adjacent area and the distant area of the stimulation site. A device consists of 24 ECoG electrodes and 12 blue-light LED chips. We performed chronic implantations of the devices in two macaque monkeys, which are virally transduced with channelrhodopsin-2. One of the devices was implanted in subdural frontal motor areas of a monkey and another was in subdural primary sensorimotor areas of another monkey. With one of the monkeys, we examined progress of ECoG responses over 5 months after the viral injection. The ECoG responses occurred a week after the injection at some stimulation sites, and six weeks after at all stimulation sites. Furthermore, we applied photostimuli in different locations and various intensity to the cortical surface of the monkeys. Optical stimulations evoked spatially localized ECoG potentials, and the amplitude of the ECoG responses increased with light intensity. For simultaneously applied multisite stimuli, ECoG responses were spatially separated. These results demonstrate that our device is an effective application of optogenetics.

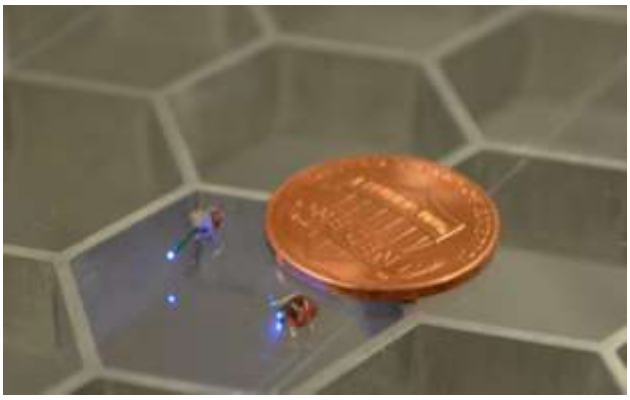
Title: Fully internal wireless optogenetics for truly untethered stimulation

Authors: *A. J. YEH, K. L. MONTGOMERY, J. S. HO, V. TSAO, E. A. FERENCZI, S. M. IYER, L. GROSENICK, Y. TANABE, K. DEISSEROTH, S. L. DELP, A. S. Y. POON
Stanford Univ., Stanford, CA



Abstract: Current techniques for untethered optogenetic stimulation require fiber optic cables or bulky head-mounted prostheses. We have demonstrated a system for optogenetic stimulation in which the entire stimulator - energy harvesting component, electronics, and light source - is less than 0.008 cm^3 in volume, weighs 20 mg, and is fully implanted within a mouse. A new form of wireless powering, in which a microwave resonant cavity is placed underneath an animal's home cage, powers the device. Evanescent waves at the surface of the resonator electromagnetically couple to high dielectric tissue, inducing energy transfer to the device through tissue. Autofocusing of electromagnetic energy to a moving mouse over an area 20cm in diameter is provided through the physical structure of the microwave resonant cavity; therefore, no electronic tracking is required. This approach has been applied to both the central and peripheral nervous system. We have successfully applied this fully internal system for truly untethered optogenetic stimulation of the motor cortex of Thy1-ChR2-YFP transgenic mice. Furthermore, we have implanted the stimulator directly at the sciatic nerve to study the pain response of AAV6-ChR2 injected mice. The system described here can be further applied to study social behavior of mice since there are little to no alteration to the appearance of mice.

Title: An implantable optogenetics device based on CMOS integrated circuit technology for a freely moving animal

Authors: *M. HARUTA, S. NAKAJIMA, N. KAMIYAMA, H. TAKEHARA, H. TAKEHARA, T. NODA, K. SASAGAWA, T. TOKUDA, J. OHTA

Abstract: In optogenetics study, it is important to measure and control brain activities in a freely moving animal. However, conventional imaging systems is not suitable for such condition, because invasiveness and size of these devices do not meet freely moving experiments of a small

animal. In this study, we develop a small implantable optogenetics device. This device has two functions which are brain functional image sensor and optical stimulation system (Fig. 1). For the device, we designed a custom sensor using CMOS integrated circuit technology. This enables to integrate multi functions in the device and reduce the size and weight of the device [1]. In our previous work, we developed a neural interface device for optogenetics [2]. Our novel device is developed for implanting into animal's head. A CMOS chip which is integrated with a CMOS image sensor and electrical circuits for LED light-stimulation is bonded on a flexible polyimide substrate. A LED array is integrated on the CMOS chip. The LED array has 10 × 8 blue LEDs (λ= 469 nm). This wavelength is excitation wavelength of Channelrhodopsin-2 in the neuron [3]. This device has a very compact shape with the dimension of 3.0 mm × 3.5 mm in a sensor head. We demonstrated optical stimulation with the device for adult transgenic mice expressing Channelrhodopsin-2. We placed the device directly on the brain surface. In this experiment, we performed neural recording using single-unit recording at the same point as the optical stimulation. We have successfully evoked neural activities by using the device. In the future work, we will measure intrinsic signals with a red light source (λ= 630 nm) and perform an interactive communication with the implantable device. At this wavelength, intrinsic signals arise from oxyhemoglobin in the brain. It is expected that this greatly contributes to understanding brain functions in animal behavior. [1]M. Title: Silicon multi electrode-optrode arrays for optogenetics *in vitro* and *in vivo*

Authors: ***L. HOFFMAN**[1,2], A. ANDREI[1], R. PUERS[1,2], G. GIELEN[1,2], D. BRAEKEN[1]
[1]Imec, Leuven, Belgium; [2]ESAT, KULeuven, Leuven, Belgium

Abstract: The technologies developed for optogenetics are important new tools to study neuronal circuits in the brain. With these fast developing tools, also other technological advances, such as devices to monitor electrical activity in the brain, are driven towards improved capabilities. To serve the fast growing and diverse field of optogenetics, ideally, these devices should incorporate multiple, independent optical outputs of different wavelengths and combine these optical outputs with electrical recording in the same plane. Tools that incorporate this set of advantages would ensure an increase in the degrees of freedom of the experimental design aiding the progress in neuroscientific research. This work presents a collection of novel electrode-optrode arrays for *in vivo* and *in vitro* optogenetic applications. In order to fabricate these tools we have integrated state-of-the-art titanium nitride electrode fabrication with silicon nitride waveguide technology. Both technologies are part of imec's CMOS compatible technology portfolio for neuronal biosensors and telecommunications and are highly reproducible, reliable and scalable. In all the presented tools, these waveguides are used to channel light of two different wavelengths (470 nm and 590 nm) into the optrode array site. The light from external sources (light emitting diodes or lasers) is coupled into these waveguides and subsequently out-coupled orthogonally at the array site by means of optical grating couplers. The *in vitro* device is composed of an array of 8 by 8 titanium nitride electrodes and 8 by 8 optrodes. Each electrode has a corresponding optrode close to it in order to register the response of optically stimulated cells. The optical outputs are approximately 6 by 20 µm thereby capable of single cell stimulation; the electrodes have a diameter of 30 µm. Both arrays have a pitch of 100 by 100 µm. For *in vivo* applications, several devices were designed. Some comprise only of optrodes and others have optrodes and electrodes. The optical-only devices are 60 µm wide and the electro-optical 100 µm. All of them contain 24 electrodes and/or 12 optical outputs (6 of each color). Additionally, the electrodes are 15 by 15 µm, while the optical outputs have the same size as their *in vitro* counterpart. For each type of probe there are three different lengths: 3, 5 and 10 µm with electrode/optrode pitches of 400, 100 and 100 µm respectively. Each option is available with thicknesses of 50 and 30 µm. Finally, the optical outputs were tested using a miniature laser diode (470 nm). The smallest optical power density measured on the grating out-couplers was 70 mW/mm², which is more than sufficient to activate opsins.

Title: Virtual reality environment for patching and imaging in brain slices

Authors: *J. V. HIBBARD, M. A. NAVARRO, L. S. MILESCU
Biol. Sci., Univ. of Missouri, Columbia, MO

Abstract: We are developing a program that constructs a 3D representation of a virtual workspace that visualizes the brain slice and the perfusion chamber, the patch-clamp and other recording electrodes, and the imaging objectives. The user can control the operation and 3D positioning of the instruments relative to the sample, with real-time visual feedback. Specific cells can be bookmarked and linked to optical and electrical recordings, and the 3D workspace can be saved for later viewing and data analysis. We are using this software platform to explore cellular and network interactions in the respiratory pacemaker, with an experimental rig based on a Scientifica two-photon microscope and motorized positioners. This unified interface provides a more streamlined approach for combining electrophysiology, structural and functional imaging, and optogenetics experiments.

Title: Spatiotemporally-controlled optogenetic activation of developing ferret visual cortex

Authors: *J. OSIK[1], A. ROY[1], N. J. RITTER[1], J. R. HURVITZ WOLFF[1], J. MILLER[2], Y. WANG[1], J. FISER[3], S. D. VAN HOOSER[1]
[1]Biol., Brandeis Univ., Waltham, MA; [2]MIT, Cambridge, MA; [3]Central European Univ., Budapest, Hungary

Abstract: Realizing the full potential of optogenetic techniques will require concurrent development of light delivery technologies that improve spatial and temporal control of neuronal stimulation to facilitate increasingly informative electrophysiology recordings. Excitation (or inhibition) by light-activation of channelrhodopsin (ChR) and its many variants has quickly emerged as a preferred methodology in the neurosciences by reason of the cellular specificity achievable through conditional genetic expression. However, despite the variety of cell types targetable through the use of promoter-driven constructs, the spatial distribution of cells of any given classification can still be quite homogeneous, a fact that complicates the targeting of neural circuits that exhibit a very specific structure-function relationship, as in the circuits underlying functional maps. In studying the emergence of cortical maps *in vivo* where response variations are closely tied to spatial locations on the order of a few hundred microns in width, new light delivery techniques are needed to improve on the dispersive, on/off light control of implanted fiber optics that are commonly used to drive ChR stimulation. Two specific advances would enhance the utility of optogenetic stimulation in such applications: 1.) use of a controllable light source capable of projecting both stationary and dynamic light patterns; and 2.) improved spatial and temporal resolution while sustaining power sufficient to drive ChR activation at depth in the intact living brain. We have developed an optogenetic stimulator based on epi-illumination microscope design and equipped with a high numerical aperture objective to stimulate and collect images through the same optical axis. The stimulator is coupled to an LCD-MLA projector light source to produce high-resolution spatiotemporally varying patterns in a very confined area. We evaluate the performance of this stimulator with respect to power, optical resolution and the quality of spatial and temporal control of single and multi-unit responses at a multichannel NeuroNexus electrode. We further assay the stimulator's suitability for experimental paradigms calling for fine sequential control of horizontal cortical connections *in vivo*. Preliminary results indicate that retinotopically-constrained horizontal activation through

ChR-mediated surface training in ferret V1 is sufficient to drive asymmetry in the orientation-tuning response to drifting gratings.

Title: neuroPG: Open source software for optical pattern generation, experimentation, and data analysis

Authors: *D. MURPHY[1], B. W. AVANTS[2], J. A. DAPELLO[4], J. T. ROBINSON[2,3]
[1]Physics and Astronomy, [2]Electrical and Computer Engin., [3]Bioengineering Dept., Rice Univ., Houston, TX; [4]Hampshire Col., Amherst, MA

Abstract: Patterned illumination using a digital micromirror device (DMD) is a powerful tool for optogenetics. Compared to a scanning laser, DMDs allow for simultaneous illumination of any number of regions up to the number of pixels in the DMD. Furthermore, the intensity of illumination can be easily adjusted by modulating the light source or the DMD. Altogether, DMD illumination combined with optogenetics provides a powerful tool to investigate neural circuit behavior by allowing scientists to manipulate the complex spatiotemporal patterns of neural activity. To fully utilize DMD illumination with optogenetics, specialized software is necessary to coordinate optical stimulation patterns with the acquisition of electrophysiological and fluorescence data. To meet this need we have developed neuroPG, an open-source software package combining pattern generation and DMD control, sample visualization, and data acquisition in one application. Built on a MATLAB platform, neuroPG is also capable of post-processing, analysis, and visualization of data. The neuroPG platform greatly improves the speed and accuracy of optogenetic experiments using DMD stimulation. It enables experiments such as mapping neural responses, tracing circuit connectivity, and investigating synaptic integration. It also facilitates the task of data analysis, saving researchers a great deal of time and effort. By changing microscope objectives, it is possible to greatly increase the available field of view and allow simultaneous stimulation of tens or hundreds of neurons. Even at this scale, neuroPG

allows researchers to conduct complex experiments within the limited time window of patched cell viability.

Title: A turn-key system for optogenetic light delivery and simultaneous electrophysiological recording

Authors: *D. A. JOHNSON[1], S. GABBERT[1], H. P. HARMON[1], E. NAYLOR[1], D. A. JOHNSON[1], P. G. HAYDON[2], R. DOYLE[2], D. J. HINES[2], P. A. PETILLO[1]
[1]Pinnacle Technol, Inc., LAWRENCE, KS; [2]Neurosci., Tufts Univ. Sch. of Med., Boston, MA

Abstract: Optogenetics harnesses a combination of genetic and optical methods to directly control neuronal events in specific cells of the central nervous system. These methods can be used to provide an unprecedented understanding of neuronal activity. Numerous commercial sources for optogenetic components exist, but turn-key systems that combine optogenetics with other neurophysiological measurement modalities do not. We successfully combined an optogenetic light delivery system and electrophysiological recording into a single turn-key, modular system designed for use with rodents. The system is capable of delivering a select wavelength of light to a specific brain region while simultaneously recording electrical signals. All synchronization between the electrophysiological, mechanical and visual inputs, and optical and stimulus outputs are controlled via a master timing, digital input/output platform as well as sophisticated software timing techniques. The optogenetics light source and coupling fiber is implemented on a standardized platform that can be easily, and accurately, implanted using existing stereotaxic techniques. Since the light source is at the head, fiber optic commutators are not required. The approach will be compatible with wireless implementations in the future. Cultured astrocytomas transfected with YFP-ChR2 were used to verify that sufficient power was delivered to the fiber optic tip to trigger relevant opsin responses. A two-photon fluorescence

microscope was used to monitor and image a light-evoked response, with RHOD 2/AM used as the fluorescent reporter of Ca^{2+} activity. For measurement of evoked Ca^{2+}, cells were incubated with RHOD 2/AM for 30 min prior to imaging. Baseline cell images were acquired and the cells were then exposed to brief pulses of light (up to 2 seconds in duration) at 470 nm from the device. The speed and duration of the evoked Ca^{2+} was dependent upon the light power and pulse length, demonstrating that the tunable system is suitable for deployment in live animals.**SUPPORT:** This research was supported by NIH grant # 1R43 AG046030.

Title: A transparent ZnO optoelectrode array for probing neural circuits through spatiotemporally controlled light delivery and simultaneous multisite electrophysiology

Authors: ***J. LEE**[1], I. OZDEN[1], Y.-K. SONG[2], A. NURMIKKO[1]
[1]Sch. of Engin., Brown Univ., Providence, RI; [2]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Within the last decade, optogenetics has established itself as a powerful technique to study brain function. However, its applicability to a rich variety of neuroscience problems can be enhanced by further development of optoelectronic devices. For example, it has been rarely utilized in studies requiring simultaneous multi-site modulation and recording of neural activity. Earlier, we introduced a transparent micro-optoelectrode array (MOA), which would allow

simultaneous intracortical multisite light-delivery and electrophysiological recordings with high temporal resolution. The MOA was made from a single crystal of the transparent semiconductor zinc oxide (ZnO), in geometry and physical dimensions mimicking that of a silicon Blackrock/Utah array. For initial rodent studies, it consisted of 4×4 transparent electrodes, "optoelectrodes". Due to high transparency, neural activity could be easily recorded without light induced artifacts even at the sites of light delivery. We report here the utilization of the MOA in a transgenic (Thy1-ChR2) mouse model to characterize the effects of light power and spatiotemporal delivery on neural population activity and behavior. To perform light delivery through the MOA, the MOA was inserted acutely into either motor or barrel cortex, and broadband neural activity was recorded in response to light delivered through one or more optoelectrodes by scanning laser beam. At very low light power levels (~1 μW, 473 nm), modulated neural activity was observed, but only at the optoelectrodes from which light was delivered. This very low power regime was quite useful for precise spatiotemporally controlled stimulation of underlying neural circuitry. As an example, we reproduced barrel cortical activity in response to whisker stimulation by patterned optical stimulation which has not been practically possible with other means. As optical power began to increase closer to more typical excitation levels in the literature (up to 1 mW), modulated activity began to spread over the 4×4 array due to network connectivity (and some additional light diffusion). In our "medium power regime" (several 10 μW), we could deduce network connectivity and connection strength by response latency and firing rate analysis. At higher power levels (several 100 μW), we could observe behavioral responses in both awake and anesthetized animals which helped us to map the motor cortex functionally below the array. Ongoing work is focusing on the use of the ZnO MOAs to study the motor cortical neural dynamics in response to rodent behavior, while also characterizing and improving device features, in preparation for chronic implant and larger size arrays.

Title: A system for neural circuit mapping at single cell resolution using two-photon excitation of soma-targeted channelrhodopsin

Authors: *C. A. BAKER[1], A. PARRA-MARTIN[2], M. M. BOLTON[1]
[1]Disorders of Neural Circuit Function, [2]Functional Architecture of Cerebral Cortex, Max Planck Florida Inst., Jupiter, FL

Abstract: Psychiatric disorders are being increasingly linked to dysfunctions in molecules involved in the development or maintenance of functional neural circuit connectivity. Delineating the effects of disease-associated genetic changes on the fine structure of neuronal networks will be crucial to understanding these disorders and for the development of therapeutics. Optogenetics using channelrhodopsin (ChR2) and selective targeting of genetically-defined cell types has revolutionized the study of long range projections at moderate resolution, but conventional optical stimulation paradigms likely excite cells above and below the cell of interest and thus limit their use in mapping neural circuits at single-cell resolution. Two-photon microscopy can stimulate a diffraction-limited volume deep within tissue, but may not simultaneously excite enough ChR2 molecules to depolarize a neuron to action potential threshold. We utilize recent developments in temporal focusing of two-photon excitation to generate a disk-like field of excitation in acute brain slices, simultaneously exciting multiple ChR2 molecules in a single focal plane off-target activation of cells above or below the neuron of interest. Moreover, we have further reduced the potential for off-target effects by spatially restricting ChR2 expression to the neuronal soma and proximal dendrites. Under these conditions we elicit action potentials only when stimulating the soma of ChR2-expressing cells; the lack of responses to stimulating fibers of passage or at axially displaced locations highlights the utility of the technique for fine mapping. These protocols can also be combined with optical calcium or voltage indicators to verify the stimulation effects and examine the responses of neurons throughout the network. We apply these techniques to examine local circuit connectivity in the neocortex of mice harboring mutations associated with autism in humans.

Title: Tuning optical characteristics of Channelrhodopsin-2 by conjugating plasmonic nanoparticles

Authors: *Y. BANG[1,2], S. LEE[1], Y. KIM[1,2], A.-H. LEE[1], Y.-K. SONG[1,2]
[1]Dept. of Transdisciplinary Studies, Program in Nano Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Advanced Inst. of Convergence Technol., Suwon, Korea, Republic of

Abstract: Channelrhodopsin-2(ChR2) is one of the major light-gated ion channels which can depolarize neurons with an optimal action spectra at 473nm wavelength. Even in this precise cell-type specific photo-stimulation technique, it generally requires a high power laser or a high brightness LED as an optical excitation source, due to relatively small optical density of ChR2 [1,2]. Moreover, in intact brain, blue light tends to scatter more than red light and have limited penetration depth issues [3]. Thus, in current optogenetic fields, many researchers have focused on genetic approaches to develop ChR variants with various optimal action spectra ranging from 450nm to 630nm, and to acquire faster kinetics and more efficient membrane trafficking [3]. These conventional genetic methods have succeeded but it takes lots time and resources for finding the right genetic mutations and optimizing their expressions in mammalian neurons. With consideration of effective nanotechnology approaches rather than genetic approaches, we applied AviTag bio-conjugation method in order to induce Localized Surface Plasmonic Resonance (LSPR) effect through metallic plasmonic nanoparticles near ChR2 channels. Especially, silver nanoparticle has stronger LSPR peaks than any other metallic nanoparticles, ranging from 400nm to 500nm, depending on their sizes. It also enables inducing enhancement of light intensity [4]. The DNA sequence for 15 amino acids representing AviTag was cloned to Synapsin1-hChR2-EYFP lentiviral plasmids, allowing the expression of AviTag at the N-terminal of ChR2 for conjugating biotinylated plasmonic nanoparticles. In order to confirm the tagging strategy of AviTag in primary rat hippocampal neuron, biotin conjugated 655nm Qdots were used to visually localize N-terminal side of ChR2 channel through fluorescence and electron microscopy imaging. In addition, application of biotinylated silver nanoparticles and its optical/kinetic analysis were conducted. Thus, by conjugating different sizes of silver nanoparticles to ChR2, we could tune its optical characteristics and also increase its photosensitivity, which could enable photo-modulation of neurons with much less optical power and various wavelength of light. Title: Multiscale computational tools for optogenetics

Authors: ***K. NIKOLIC**[1], S. JARVIS[2], S. SCHULTZ[2]
[1]Electrical & Electronic Engin., [2]Bioengineering, Imperial Col. London, London, United Kingdom

Abstract: Optogenetics is rapidly becoming a key technology for neuroscience and deconstruction of brain circuits, and new applications are rapidly emerging throughout biology. At the same time new variants of opsins are being synthesized. There are several families of opsins, each of which has unique temporal and spectral properties. There is a substantial effort to characterize opsins for each cell population, and a continual drive to improve their efficacy. While the effect of an opsin can be quantified at the level of individual cells (e.g. neurons), it currently remains practically impossible to experimentally test each opsin for each cell type or biological system of interest. This significantly limits the effectiveness of optogenetics as a biological tool. Hence we propose a set of computational tools for optogenetics. Firstly, we developed a tool for characterizing opsins, allowing us to link from the underlying biophysical photocycle that defines kinetic model of opsins (molecular-complex scale) - tool 1. This level is significant to obtain a functional understanding of each opsin and hence guide not only opsin choice for a given system, but potentially also guide opsin development. From the biophysical model, the corresponding state-model representations (of ChR2 and NpHR, a few more opsins to follow) have been included into ion-channel representation in NEURON (tool 2). This tool allows the inclusion of opsins within single-compartment and multi-compartment representations of single neurons. Finally, we implement opsins within “point neurons”, such as Leaky Integrate

and Fire (LIF), for inclusion in network level simulations - tool 3. We demonstrate the tools on the example of ChR2 and NpHR-expressing neocortical layer 5b pyramidal cells. We first identify a six-state functional model for ChR2 and a three-state model for NpHR and then implement it in NEURON. Then we present results for typical illumination strategies, back-propagation of action potentials, threshold dynamics, etc. We demonstrate how the gain and threshold of the transfer characteristics of a transfected neuron (input: current, output: spikes) can be modulated by selectively targeting whole cell, or apical and basal dendrites. This approach will allow the inclusion of realistic models of optogenetics in existing simulations, allowing the use of virtual opsins to identify the correct experimental opsin choice. Together, these tools will improve the use of optogenetics as an effective and refined tool, enabling its potential to transform the biological sciences.

Title: Characterizing EEG artifacts with matching pursuit time-frequency decomposition

Authors: *K. W. WHITAKER, V. LAWHERN, P. J. FRANASZCZUK
Translational Neurosci. Br., U.S. Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: Electroencephalography has the potential to be adapted and utilized outside of the lab, but this will require new computational approaches to understanding the data. Matching pursuit is a data-driven approach to signal analysis and decomposition that is not dependent on expert judgment and expertise. A dictionary of Gabor functions (atoms) in time -frequency space was used to characterize EEG data with specific categories of common movement-based artifacts. The data was acquired with three different EEG acquisition systems worn by the same five subjects who performed a predefined set of movements after an auditory cue. All of the EEG acquisition systems have been used in real world environments such as shopping centers, office buildings and parks. Extremely minimal preprocessing, down selection of channels and data filtration, was performed on the data. The parameters of the atoms in the decomposition were found to be specific to categories of movement artifacts. These atoms are characterized by a set of five parameters (phase, modulus, frequency, time and octave (scale)). Only frequency, time

and modulus were necessary and sufficient to discriminate between different categories of artifacts. This analysis of EEG artifacts revealed useful information for providing context to interpret and understand real world brain activity. In addition to enabling the development of novel classification schemes for movement artifacts, this experiment supports EEG acquisition technology with minimal data pre-processing prior to analysis.

Title: Real time algorithms for sharp-wave ripple detection

Authors: *A. SETHI, C. KEMERE
Rice Univ., Houston, TX

Abstract: Neural activity during sharp wave ripples (SWR), short bursts of co-ordinated oscillatory activity in the CA1 region of the rodent hippocampus, is believed to be responsible for a variety of memory functions from consolidation to recall. Detection of these events using real time methods, has thus far relied on simple heuristic thresholds. This investigation tests and improves the current methods for detection of SWR events in neural recordings. We propose novel methods and profile current methods, in time and frequency domain, to reduce latency in ripple detection. Proposed algorithms are tested on simulated data. The findings show that simple real-time algorithms can improve upon existing power thresholding methods and can detect ripple activity with latencies in the range of 10-20 ms with acceptable false positive rates.

Title: Automatic eye-movement artifact removal using short fast fourier transform and nonnegative matrix factorization

Authors: *H. TSUBAKIDA[1], T. SHIRATORI[1], A. ISHIYAMA[1], Y. ONO[2]
[1]Sch. of Advanced Sci. and Engin., Waseda Univ. c/O Prof. Tsushi Ishiyama, Shinjukuku, Japan; [2]Meiji Univ., Kanagawa, Japan

Abstract: This paper introduces a novel method to automatically remove electro-oculogram (EOG) artifact using short Fast Fourier Transform (sFFT) and nonnegative matrix factorization (NMF). This method requires at least single channel Electroencephalogram (EEG) and concurrently measured EOG. First, sFFT is separately applied to EEG and EOG data to construct nonnegative matrix data Xeye and Xch, respectively, which correspond to the time-frequency distribution of the respective signals. We set the frequency band for extraction from 1 to 22Hz, the frequency band that is frequently used in EEG analysis. Second, NMF decomposed Xeye into two matrices, basis matrix Aeye and coefficient matrix Seye. Third, NMF further decomposed Xch into A = [Aeye Ach] and S = [Seye Sch], under the constraint that A and S should include Aeye and Seye as subspaces. Forth, reconstruct nonnegative matrix data X'ch by multiplying Ach and Sch. Finally, inverse sFFT was applied to reconstruct noise-removed EEG signal. We tested the feasibility of this method using EEG signals measured from eight healthy young volunteers. Participants kept rest for a period of 3 s when a cue appeared on a computer screen while EEG and EOG signals were recorded. The cue appeared 20 times per one session. EEG signals were recorded from 15 electrodes placed on the scalp of a subject and EOG was from electrode placed near the left eye, sampled at 125Hz. Our method removed EOG artifact more effectively than the conventional NMF-related method using only Aeye or Seye as a constraint for generating Ach and/or Sch. Our method removed the EOG artifact as effectively as independent component analysis (ICA), which has been reported to be an efficient signal processing to remove EOG artifact from EEG. Our method is superior to ICA in the sense that it can remove EOG artifact without any subjective criteria and hyper-parameters which ICA requires. Figure1 shows raw EEG data measured from a representative subject and the results of noise removal using our method, conventional method, and ICA. These results demonstrate the effectiveness of our new method.

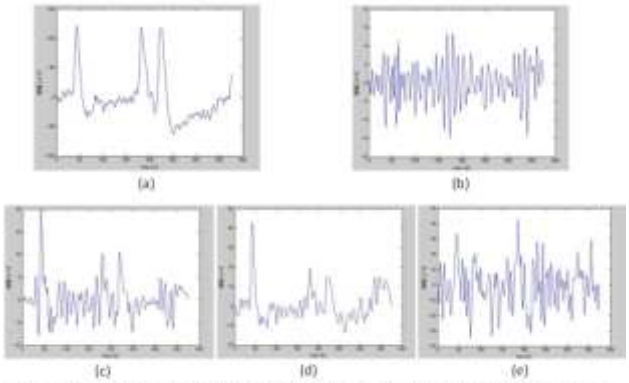

Fig.1 (a) raw EEG data (b) the result of noise removal using our method (c) the result of noise removal using conventional NMF-related method under the constraint that ***A*** should include ***Aeye*** as subspace (d) the result of noise removal using conventional NMF-related method under the constraint that ***S*** should include ***Seye*** as subspace (e) the result of noise removal using ICA

Title: Spatiotemporal adaptive filter for cleaning MR artifacts in simultaneous EEG-fMRI recordings

Authors: *A. M. GORDON[1], A. GONZALEZ-BARBOSA[2], J. M. ALES[1], A. M. NORCIA[1], A. D. WAGNER[1,3]

[3]Neurosciences Program, Stanford Univ., Stanford, CA

Abstract: Simultaneous recording of electroencephalographic (EEG) and functional MRI (fMRI) data can provide spatiotemporal precision not achievable by using either technique individually. One limitation of simultaneous EEG/fMRI recordings is that the EEG signal is contaminated with MR-related artifacts. There are two main noise sources added to the EEG signal: 1) gradient-based artifacts related to MR data acquisition, and 2) biophysical artifacts

amplified by the large B0 field in the MR environment. While there has been an increase in the number of studies in which EEG and fMRI data are acquired simultaneously, how to optimally remove these artifacts remains unresolved for task-related designs. Here, we propose a new technique that uses spatial and temporal analysis to adaptively extract artifacts from the EEG signal. This technique finds the optimal basis (via Singular Value Decomposition) that loads on the spatial (channels) and temporal (time-points locked to artifact onset) data matrix. Additionally, this filter uses information--the MR slice ID and heart rate (monitored through a photoplethysmogram)--to better fit the data. To quantify performance, we examined the signal-to-noise ratio (SNR) of task-related measures, including visually evoked potentials (VEPs) and motor response evoked potentials (MEPs), across subjects and recording sessions (N=95). After gradient artifact removal, we found a significant increase in SNR for VEPs and MEPs compared to the most commonly used technique in the literature (FASTR, Niazy 2005). Subsequent BCG cleaning yielded further improvements on SNR for VEPs but not MEPs. This work provides a novel artifact removal technique that outperforms the current standard in task-related measurements of artifact removal performance.

Title: Statistics: Minimal effort but maximum profit!

Authors: *H. THIJS[1], R. MEESEN[2], K. CUYPERS[2]
[1]I-Biostat, Diepenbeek, Belgium; [2]REVAL, Hasselt Univ., Hasselt, Belgium

Abstract: In what follows a more detailed description is provided about how the investment of time in such collaboration of clinical researchers within the field of brain research with a statistician contributed in optimizing the results of the experiments. More precisely, as described in CUYPERS et al (2013), applying anodal tDCS in humans has shown to influence CS excitability. Within this experiment anodal tDCS and sham tDCS were both applied to the primary motor cortex for 20 min and TMS was used to measure the influence on CS excitability. In a first statistical approach the area under the recruitment curves were compared for both

anodal tDCS and sham tDCS showing a significantly increase after application of anodal tDCS while after application of sham tDCS no increase was detected. In contrast, a second statistical analysis used a sigmoidal curve-analysis which indicated a higher level of CS output after anodal tDCS. The key aspect of this second approach is the use of a mathematical model to describe the individual curves in much more detail. While the area under the curve may not be able to discriminate between two patients this second approach has a much better discriminative power. Finally, both results lead to the same conclusion that anodal tDCS caused an increase in CS output and might can therefore be used to facilitate motor recovery in MS patients, but from the second approach more insights with respect to the behavior of the CS output could be derived. In conclusion simple methods should be used where possible but the drive for the correct analysis is equally important. In the end it are the Multiple Sclerosis patients who might benefit most from the combination of an excellent experiment with a correct statistical analysis. **Reference:** CUYPERS K., LEENUS D., VAN WIJMEERSCH B., THIJS H., LEVIN O., SWINNEN S. and MEESEN R. Title: Fractal analysis of spontaneous activity in single neurons

Authors: L. H. FAVELA[1], C. A. COEY[2], *E. R. GRIFF[3], M. J. RICHARDSON[2]
[1]Philosophy and Psychology, [2]Psychology, Univ. of Cincinnati, Cincinnati, OH; [3]Univ. Cincinnati, Cincinnati, OH

Abstract: The spontaneous activity of single neurons was analyzed via fractal methods. Time-series data in the form of interspike intervals (ISIs) from single-unit recordings were obtained from reliably identified mitral cells recorded *in vivo* from the main olfactory bulb of freely breathing anesthetized rats (Nica, Matter, & Griff, 2010). The anesthetic plane was adjusted such that a toe pinch desynchronized the EEG without causing limb withdrawal. These data were originally analyzed via standard linear statistics in order to compare mean spike rates. That analysis suggested different subclasses of mitral cells. Results from other previous experiments compared the spontaneous activity of mitral and tufted cells (Stakic, Suchanek, Ziegler, & Griff, 2011). A goal of the current research was to further examine the different subclasses of mitral cells by utilizing nonlinear methods to distinguish subclasses based on the dynamical structure of their spontaneous activity. Detrended fluctuation analysis (DFA), a type of nonlinear, fractal analysis was utilized to examine the ISIs from 29 single unit mitral cell recordings (Nica et al., 2010). The spontaneous activity of these cells was recorded for an average of 540 s (range 100-1243 s). DFA identifies the structure in the fluctuations in a measurement variable over time by assessing the scaling relation between the size and time scale of variation in behavior. The Hurst exponent (H) is a measure of fractal scaling (Ihlen, 2012). Results of the DFA suggested two subclasses of mitral cells, referred to here as A and B. There was no significant difference in the fractal scaling of cell groups A and B at shorter timescale fluctuations, with cells in both groups exhibiting dynamical structure near random variation ($H \approx 0.5$). There was a significant difference between the groups at longer timescales, with group B exhibiting variation near $H \approx 1.0$, whereas group A did not. The results of our DFA analysis highlight the power of nonlinear methods to capture the dynamical structure of neural behavior. This approach is being extended to multifractal techniques and to a comparison between mitral and tufted cell spontaneous activity.

Title: Automatic white matter bundle dissection in ad and pd - results from adni and ppmi

Authors: *M. DESCOTEAUX[1,2], J.-C. HOUDE[1,2], J.-R. BÉLANGER[2], P.-M. JODOIN[1,2], F. MORENCY[2]
[1]Computer Sci., Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Imeka, Sherbrooke, QC, Canada

Abstract: Introduction: This work presents a technique to automatically dissect the white matter bundles of the human brain from non-invasive diffusion Magnetic Resonance Imaging (MRI) fiber tracking datasets from the ADNI (Alzheimer's Disease NeuroImage Initiative) and PPMI (Parkinson's Progression Markers Iniative) public databases. Methods: We performed fiber tractography using Dipy (www.dipy.org) on the ADNI and PPMI databases from available subjects with diffusion tensor imaging (DTI) datasets. Using anatomical *FreeSurfer* labels from T1-weighted images of each subject, we can automatically and robustly extract 27 major white matter bundles (corticospinal tract, arcuate fasciculus, cingulum, amongst many others). The white matter query language tool is used to define specific queries for the ADNI and PPMI databases, where careful exclusion and inclusion definitions are defined to obtain white bundles free of spurious tracts. Finally, the mean and standard deviation fractional anisotropy (FA), diffusivities (axial, radial, mean), and apparent fiber density diffusion metrics are computed along each bundle. Results: All 27 bundles are successfully extracted from more than 90% of the subjects in the ADNI and PPMI databases. A quality assurance procedure was run to identify the white matter bundles with spurious tracts. The majority of bundles are robustly dissected. This dissection is done in the native space of every subject and thus avoids having to register to a template space. Mean and standard deviation of the diffusion metrics show large variations across populations and more statistical analysis needs to be done. Conclusions: We used a novel white matter query language to dissect detailed white matter bundles using state-of-the-art tractography. This novel analysis could permit automatic construction of brain atlases on dedicated populations, automatic delineation of eloquent structures of the brain and most importantly the detection of abnormalities in white matter bundles, which we are confident could improve the diagnostics Alzheimer's and Parkinson's disease.

Title: Introducing Multiple Kernel Learning for automatic selection of features in intracranial EEG

Authors: *J. V. SCHROUFF[1,2], M. ÖZKER[3], M. DASTJERDI[1], B. FOSTER[1,2], V. RANGARAJAN[1,2], J. MOURÃO-MIRANDA[4], C. PHILLIPS[5], J. PARVIZI[1,2]
[1]Lab. of Behavioral and Cognitive Neurosci., [2]Stanford Human Intracranial Cognitive Electrophysiology Program (SHICEP), Stanford Univ., Palo Alto, CA; [3]Hlth. Sci. Ctr., Univ. of Texas, Houston, TX; [4]Dept. of Computer Sci., Univ. Col. London, London, United Kingdom; [5]Cyclotron Res. Ctr., Univ. of Liège, Liège, Belgium

Abstract: Introduction Machine learning models have been successfully applied to neuroimaging data to make predictions about behavioral/cognitive states of interest based on the pattern of activation or anatomy over a set of features. While these multivariate methods have greatly helped the neuroimaging community, their application to electrophysiological data has been scarce, particularly for invasive techniques (e.g., electrocorticography, ECoG). In the present work, we propose a novel approach to decode electrophysiological recordings based on multiple kernel learning (MKL). This technique combines the signal from different channels and/or frequency bands hierarchically. In addition, the considered algorithm is sparse, which eases model interpretation. We illustrate the success of this approach using our own previously published ECoG data. Material and Methods The dataset used in this work comprises ECoG recordings from 3 subjects implanted with grid and strip electrodes for clinical treatment of refractory epilepsy. The patients performed an experimentally controlled task involving numerical and autobiographical episodic memory conditions. The ECoG signal used for further classification was the instantaneous power in 6 frequency bands (δ:1-4Hz, θ: 4-8Hz, α: 8-12Hz, β: 15-25Hz, low-γ: 30-55Hz, high-γ a.k.a. high frequency broadband, HFB: 70-110Hz). For classification, we used the simple MKL algorithm, which linearly combines multiple models defined by kernels. From each kernel (here channel and/or frequency band), a multivariate model was built, distinguishing between the two task conditions. The MKL algorithm then linearly combines the different models obtained by computing a weight for each kernel. The algorithm considered in this work is sparse, i.e. some of those weights will be perfectly null and the corresponding channel and/or frequency band will hence not contribute to the model. Results For each subject, considering each channel in the HFB range led to high classification accuracies (S1: 96.9%, S2: 75.8%, S3: 85.8%). This result was expected in view of the previous univariate analyses performed on this dataset (Dastjerdi et al, Nature Communications 2013). Furthermore, the channels most contributing to the obtained model were the same as previously reported in the aforementioned study. However, considering the different frequency bands as different kernels led to higher classification accuracies for all subjects (S1: 96.9%, S2: 77.4%, S3: 90.2%). This result shows that, although the HFB was always selected in the final model, other bands were also contributing to the classification (S1: HFB and low- γ, S2: β, HFB, α, δ, θ, S3: HFB, α, δ).

Abstract: Advancements in diffusion weighted imaging methods enable novel approaches to quantify individual differences in structural connectivity, providing a means to understand how much variability in structure can account for functional and behavioral processes. However, in order to understand structural differences between individuals or structural changes within an individual, an understanding of the reproducibility of the measurement is essential. We obtained diffusion spectrum imaging (DSI) scans for 14 subjects at 6 month intervals to examine the reproducibility of diffusion-based metrics at three different levels of analysis: voxel-based, tractography-based, and network-based analyses. The primary white matter fiber tract directions within each voxel were reconstructed in MNI-space using q-space diffeomorphic reconstruction (QSDR). QSDR yields an orientation distribution function (ODF) at each voxel, giving the magnitude and direction of anisotropy of multiple independent fiber tracts in a standardized space across subjects. Voxel-based analyses of quantitative anisotropy (QA) showed that white-matter regions were variable across subjects and yet highly reproducible within subjects. Across the brain, we found varied reproducibility in the ODF, where some areas were more sensitive to distortions. Whole-brain tractography was then used to examine reproducibility of estimated structural connectivity across voxels. The length, counts, and overall directions of fibers were reproducible across time, though individual tracts showed variable levels of reproducibility. This variability in the tracts was confirmed in the network-based analyses where we found substantial individual variability in the degree of reproducibility. Networks for each individual scan were created using tract counts between region parcellations from a T1-weighted scan. Region-

specific statistics including betweenness and degree distribution showed highly variable reproducibility across subjects, suggesting that network measures may be less stable in the presence of noise and compounded errors in pre-processing. Overall, we find that DSI can reliably capture individual variability in white matter pathways, with high within-subject reproducibility at relatively short (e.g., 6 month) time frames. Our findings guide expectations for how well diffusion imaging can detect longitudinal changes in white matter integrity.

Title: Most informative graph theory metrics for unsupervised classification of cognitive states

Authors: L. C. BUCHANAN, *J. GONZALEZ CASTILLO, C. W. HOY, D. A. HANDWERKER, P. A. BANDETTINI
SFIM/LBC/NIMH/NIH, Bethesda, MD

Abstract: Background: Previous studies [1,2] have shown how whole-brain functional connectivity can differentiate cognitive states. One remaining challenge is to compress the large dimensionality of the connectome's feature space to ease computational hurdles and uncover drivers of distinct mental states while maintaining classification power. Here, we evaluate if graph theory network metrics can dramatically reduce the dimensionality of the data without negatively affecting classification accuracy. We also rank graph theory metrics by their ability to discriminate cognitive states. Finally, we find a subset of metrics that convey the most cognitively relevant information about the network structure of the brain. Methods: We collected 25mins of fMRI data (TR=1.5s, voxel size=8mm3, 7T) on 22 subjects as they perform and transition between 4 tasks: rest, math, 2-back, and visual attention. Each task was performed for 3mins during 2 different blocks within the scan. After pre-processing, time-series for 150 ROIs from the Craddock Atlas [3] were extracted and segmented into 90s non-overlapping windows aligned with task blocks. For each window, we computed 20 graph theory metrics using the Brain Connectivity Toolbox [4]. Some metrics were computed at the whole brain level, while others were computed for each ROI. Metrics were then sorted based on how well they discriminate between tasks. Finally, vectors with an increasing number of metrics entered a k-

means clustering algorithm (k=4). Agreement between k-means results and the window groupings according to task was quantified using the Adjusted Rand Index (ARI) [5]. Results: (1) The discriminative values of the evaluated set of metrics varied substantially across metrics. (2) Locally computed metrics (i.e., per ROI) are more informative than global metrics in discriminating cognitive states. (3) Optimal combinations of metrics produced moderate accuracy when classifying windows according to task (ARI = 0.71 +/- 0.20). These accuracy levels are lower than those obtained with classification algorithms based on whole-brain connectivity matrices for the same set of ROIs and tasks [2]. Conclusions: We show how only a subset of graph theory metrics conveys relevant information about functional brain reorganization when performing different tasks. Optimally combining these metrics helped us achieve moderate classification accuracy when attempting to discriminate between cognitive states established by the task paradigm. Title: Extracellular recordings of human dorsal root ganglion cells using the *in vitro* chip-based human investigational platform (ichip)

Authors: *S. H. FELIX, M. W. MCNERNEY, H. A. ENRIGHT, E. V. MUKERJEE, N. O. FISCHER, J. J. OSBURN, A. S. CHANG, S. E. BAKER, F. QIAN, J. V. CANDY, K. S. KULP, E. K. WHEELER, S. S. PANNU
Lawrence Livermore Natl. Lab., Livermore, CA

Abstract: The envisioned *In Vitro* Chip-Based Human Investigational Platform (iCHIP) system will integrate multiple representative cell types with the objective of dramatically reducing the time needed to develop countermeasures against toxic agents and bring new therapies to market.

We have demonstrated that the iCHIP can sustain human neural cultures for over 29 days *in vitro*. Electrophysiological recordings from a multielectrode array (MEA) provide information about cell health and responses to different agents. To extract useful information from the MEA, it is important to understand the significance of synchronous signals that are detected on multiple channels. We have analyzed various scenarios of synchronous spiking in order to distinguish between duplicated spikes and local propagation in the human neural culture. The MEA consisted of a four by four array of electroplated platinum electrodes, 20µm in diameter with a pitch of 250µm. Human primary dorsal root ganglion (DRG) cells were obtained from Anabios, Inc. Various chemical challenges and rinses were introduced into the cell culture using an automated FloPro fluidic handling system while monitoring electrophysiological recordings. Statistical signal processing algorithms were used to detect spikes that exhibit a relatively low signal to noise ratio. We analyzed the occurrence of correlated spiking on multiple channels. Some of the spikes are duplicated indicating strong electrical coupling between the electrodes. Other instances exhibit shifted waveforms between channels, indicating that the MEA had resolved local propagation among the DRG cells. Additional studies to be presented will include fluorescent changes with an intracellular Ca^{2+} indicator dye (Fluo8). The results provide insight on spatial and temporal resolution of the iCHIP MEA, coupling of the cells to the electrodes, and the morphology of the human DRG culture. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52- 07NA27344. Document #LLNL-ABS-654038

Title: Assessing signal quality of a dry EEG system across multiple signal domains common in EEG research

Authors: *W. HAIRSTON, G. A. APKER
Translational Neurosci. Br., US Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: As neuroscientists challenge the boundaries of the conventional laboratory, there has been an increased demand for easy-application "dry", high-density, mobile EEG systems. However, the research community has been reluctant to adopt newly developed systems over concerns regarding their signal quality relative to the standard gel (wet) electrode technologies. This skepticism in part is due to a lack of in-depth demonstration of viability across the compendium of classically studied EEG signals. Here we present a method for standardized validation of any EEG-system for laboratory quality recording of brain signals and demonstrate its application to a 32-channel dry EEG system with the goal of providing a quantitative assessment of its signal reproduction quality. In our method, a multi-section waveform is generated with 1 & 2 Hz triangle waves, known oscillatory signals spanning 0.1-200 Hz, as well as pre-recorded EEG signals recorded in the laboratory during typical experimental conditions (VEP, eyes open/closed, movement/artifact generation) laboratory grade gold standard. These signals are passed into a 'phantom head' device on which an EEG system is mounted and the signal is repeated several times to assess the long term reliability of the recordings. The recordings of the known signal are compared between the test system and a laboratory grade system (also driven by signals from the phantom) for each section of input signal using typical EEG analysis techniques (i.e. signal correlation, RMS comparison, spectral analysis, ERP amplitude, etc). Simple correlation analysis between laboratory standard and input signal in each phase of the signal were generally high (average R2 of 0.63, maximum of 0.96) with the exception of extremely low frequencies (< 1 Hz). We found similarly strong correlation of the test system's performance with both the laboratory standard system and the input signal itself in nearly all phases of the recording (average R2 of 0.62 and 0.58, respectively, with a maximum of 0.96 for both). Further, these relationships did not significantly change over the course of several hours of recording with the dry-system, a known limitation of gel-based systems. We did observe a significant delta-band deviation of the test system signal, presumably due to differences in embedded filter characteristics. While these results suggests that signal reproduction quality of the test system performs comparably to the laboratory standard in most cases, additional tests using human subjects will be needed to ensure performance robust to human elements (e.g. hair penetration, varied head sizes, sweating, etc).

Title: An approach to studying neural signals underlying acute and chronic Stress in the real-world

Authors: T. DOTY[1], *B. KELLIHAN[2], J. CANADY[2], G. APKER[1], W. HAIRSTON[1], K. MCDOWELL[1]
[1]Human Res. and Engin. Directorate, Army Res. Lab., Aberdeen, MD; [2]DCS Corp., Alexandria, VA

Abstract: Stress has a significant societal and health impact. Of particular importance is how acute stress events affect chronic stress levels. Previous research has revealed that stress in the real world has a much larger effect on the body than stress induced in laboratory settings, but previous studies of real-world stress have been limited to the study of physiology and self report. Due to technological limitations, researchers have been unable to study the neural signature of real-world stress. Additionally, no research to date has studied the interaction of acute and chronic stress in the real-world. Therefore, we have developed a novel, real-world neuroimaging system, called the Multi-Aspect Real-world Integrated Neuroimaging (MARIN) system, optimized to study physiological phenomena in the real-world and particularly suited to the study of acute and chronic stress. This system integrates neurological data from a gel-free, wireless EEG device with physiological data from wireless cardiac and skin conductance sensors, as well as self-reports of activity and stress. Coordination of the system is managed through an Android handheld mobile device. The system provides the capability for users to indicate an acute stressful event has occurred by pressing an alert button on the mobile device. Users may also add additional information about the event, e.g. if the event happened five minutes beforehand. This capability allows for acute stress information to be time locked to the physiological and neurological data streams for post hoc processing. Additionally, several times per day the system prompts the user to perform a baseline eyes open rest task , which includes stress and mood inventories. The exact time of these inventories and baseline periods is recorded on the mobile device for post hoc processing. The level of chronic stress associated with those baseline periods is assessed via self-report, which allows for an investigation of the neural and physiological signals associated with varying levels of chronic stress. In addition, the interplay between neural and physiological signals associated with acute and chronic stress can be studied in the same user when they wear this system over multiple days in their daily life. We believe our system is an important step in demonstrating that neuroimaging can be transitioned from the laboratory into the real world and while the system is optimized for the study of stress, the advances of this approach can be applied to study other naturally occurring psychological phenomena.

Title: Fully-Bayesian inference of time-varying synaptic weights from neural spike trains

Authors: *S. LINDERMAN[1], C. STOCK[2], R. ADAMS[1]
[1]Sch. of Engin. and Applied Sci., [2]Harvard Univ., Cambridge, MA

Abstract: Learning and memory in the brain are implemented by complex, time-varying changes in neural circuitry. Recent innovations in neural recording technology offer unprecedented views into the brain, and motivate the development of novel statistical tools to formulate and test hypotheses about synaptic dynamics. Here we present a fully Bayesian method of discovering time-varying synaptic weights from spike train data. We build upon the generalized linear model (GLM), a widely applied model for functional interactions underlying neural spike trains. We exploit the particle MCMC algorithm to infer unobserved synaptic weight trajectories. Though our approach can handle arbitrary plasticity models, for the purposes of this abstract we focus on the well-known spike timing dependent plasticity rule (STDP). We produced synthetic data of a two-neuron system undergoing STDP (Fig. 1). Given only the spike trains and the STDP learning rule, our particle MCMC inference algorithm is able to infer an accurate posterior distribution over the hidden weight trajectories (Fig 2). For comparison, we show how a traditional GLM with static weights would compromise by either ignoring the connection and increasing the background firing rate, or by taking an average of the weight trajectory. Our probabilistic framework lays the foundation for application to biological recordings, Bayesian model comparison of learning rules, and nonparametric inference of the learning rule itself.

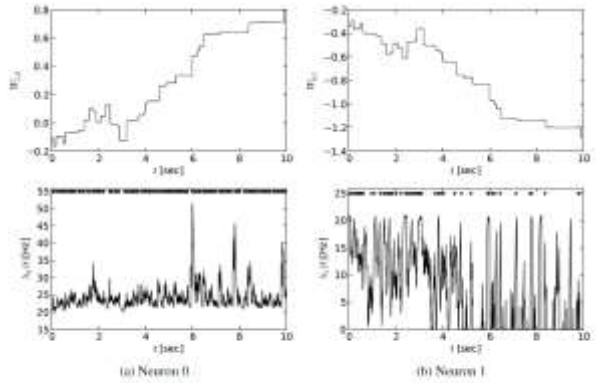

Figure 1: Example of simulated spike trains from a GLM with two recurrently connected neurons undergoing spike-timing dependent synaptic plasticity. The top row shows the evolution of the synaptic weight for neuron 1 to 0 (left) and 0 to 1 (right). The bottom row shows the induced firing rates (black line) and the spikes (black dots). The excitatory connection from 1 to 0 strengthens over time, causing increases in neuron 0's firing rate. Simultaneously, the inhibitory synapse from neuron 0 to 1 strengthens and suppresses firing of neuron 1.

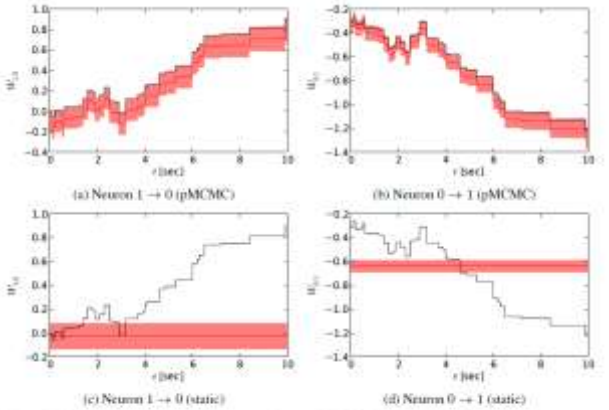

Figure 3: Inferred synaptic weight trajectory using particle MCMC with the STDP learning rule (top row). For comparison, we show the inferred weights using MCMC and a static weight model (bottom row). Both inference algorithms observe only the spike trains shown in Figure 1. Black line: true weight trajectory. Red line: mean of inferred weight trajectory. Red shaded area denotes one standard deviation about the mean.

Title: MELD: Mixed effects for large datasets

Authors: *D. M. NIELSON[1], P. B. SEDERBERG[2]
[1]Physical Med. and Rehab, [2]Psychology, The Ohio State Univ., Columbus, OH

Abstract: Technical advances are providing ever increasing amounts of data and analysis techniques have not kept pace. Large datasets, where the features far outnumber observations, are difficult to analyze because the sheer number of statistical comparisons reduces power and increases processing time. In EEG and fMRI, current statistical methods rely on the randomness of noise in time and space to circumvent multiple comparisons problems. In doing so, you lose the ability to detect tightly focussed but significant signals. Our mixed effects for large datasets (MELD) method combines the power of linear mixed effects regression (LMER) with approaches inspired by partial least squares for maximizing variance in the dimensions of interest. MELD is much faster than an element wise LMER analysis, and on simulated data MELD is more sensitive at lower subject numbers and smaller signal extents than standard

techniques, such as GLMs. When evaluated on publicly available EEG and FMRI datasets, MELD produces comparable results to standard analytical techniques.

Title: Conserved spatiotemporal motifs during evoked reverberation in cultured neuronal networks

Authors: *W. WU[1,2], L. QI[1], Y. LI[3], P.-M. LAU[1], G.-Q. BI[1,2]
[1]Sch. of Life Sci., Anhui, China; [2]Hefei Natl. Lab. for Physical Sci. at the Microscale, USTC, Hefei, China; [3]Shenyang Inst. of Automation, CAS, Shenyang, China

Abstract: Persistent reverberatory activity in brain circuits has been proposed to serve as a neural substrate underlying working memory and motor planning. Previously, we have reported reverberatory activities in small networks of cultured neurons (Lau and Bi, PNAS 2005). To further study the spatiotemporal dynamics of such collective neuronal activity, we grew hippocampal neurons on multi-electrode arrays (MEAs) and evoked network reverberation via electrical stimuli from single electrode. Based on the distance metric in high-dimentional feature space, we developed a new method to find conservd motifs of network activity with precise spatiotemporal patterns and to estimate statistical significance of their occurrences in a non-parametric way. After calibrating on various simulated data sets, we demonstrate that the method is reliable and robust for detecting precise neuronal firing sequences in different conditions. Using this method, we analyzed experimental data sets of network reverberation from the MEA recordings. In networks exhibiting evoked reverberation, the activity following each stimulus of a specific input site often contained a dominating motif with precision of a few milliseconds that repeated many times throughout the whole reverberation period. Interestingly, reverberation evoked at different input sites in the same network contained motifs of distinct patterns, although

sometimes they could share overlapping subpopulations of neurons in the network that might have formed a core circuit. These results demonstrate that activity motifs with precise spatiotemporal patterns could be maintained within a neuronal network during reverberation, and could potentially serve as a precise and efficient way of information coding.

Abstract: “How does it work?” Basic neuroscience is largely concerned with establishing causal links between biological phenomena or processes in the nervous system. Accordingly, top-tier biomedical journals such as Nature Neuroscience are increasingly demanding mechanistic details connecting experimental intervention and outcome. Providing these will require avoiding inferences from ‘ecological’ analyses - those based on aggregate measures - which are at present, highly prevalent, according to our systematic review of the neuroscience literature. We use simulated data to define and demonstrate ‘ecological fallacy’ within the context of basic neurosciences sciences, and propose a simple solution to avoid this common error.

Neurosci., Göttingen, Germany; [6]ChaLearn, Berkeley, CA; [7]Inst. for Systems Neuroscience, Univ. Aix-Marseille, Marseille, France

Abstract: We have organized a crowdsourcing challenge to reverse engineer the structure of neuronal networks from patterns of activity recorded with calcium fluorescence imaging. Unraveling the connectivity of neuronal circuits involving hundredths to tenths of thousands of neurons or more is an important step in neuroscience applications, relevant for the investigation of animal and human cognition and learning, as well as for the understanding of brain function and dysfunction. However, a direct assay of such a large number of synaptic connections is still unfeasible, and probably unpractical. Even connectomics methods based on axonal tracing are time consuming and often applicable only post-mortem. This challenge proposes to approach the problem from a different angle, by reconstructing an approximation as precise as possible to the structural connectivity of a large neuronal circuit algorithmically inferring it from the simultaneous observation of the neuronal activity of thousands of neurons, which can be achieved via state-of-the-art calcium fluorescence imaging. To stimulate the development of novel connectivity-from-activity inference algorithms by providing at a same time a way to benchmark and compare their efficiency, we resorted to competition-driven crowdsourcing. We generated simulated calcium fluorescence traces from simulated neuronal cultures of different topologies and with a realistic bursting dynamics, accounting even for artefacts such as light scattering. Participants to the challenge were ranked based on the achieved performance in reconstructing selected competition instances, with know ground-truth structural connectivity. Many of the top participants made then available their code for extensive post-challenge

validations and verifications. This allowed us to gather a rich suite of highly diverse algorithms, all with a performance significantly advancing current state of the art, thanks to a genuine knowledge transfer between usually segregated research communities. A review article, written collectively with a "crowdpublishing" approach phylosophically coherent with the challenge, will comment on challenge results and act as a reference for the use of publicly released codes.

Title: Neural networks with combination of individual and template-based input information improves attenuation correction in quantitative PET/MR hybrid scanner settings

Authors: E. ROTA KOPS[1], *H. HAUTZEL[2], A. SANTOS RIBEIRO[3], G. ANTOCH[4], H. HERZOG[1], H.-W. MÜLLER[2], N. J. SHAH[1]
[1]Inst. of Neurosci. and Medicine-4, Res. Ctr. Jülich, Jülich, Germany; [2]Res. Ctr. Juelich & Univ. of Duesseldorf, Juelich, Germany; [3]Fac. of Sci., Univ. of Lisbon, Lisbon, Portugal; [4]Dept. of Diagnos. and Interventional Radiology, Heinrich-Heine-University Düsseldorf, Med. Fac., Düsseldorf, Germany

Abstract: Aim: PET imaging for quantitative brain receptor modeling is inevitably depending on adequate attenuation correction of the raw emission data. With the introduction of hybrid PET/MR scanners attenuation data as previously derived from rotating radioactive transmission rods or CT scans is no longer available. Therefore, one approach is the use of a transmission or CT-based attenuation coefficient (AC) template. However, the use of standard AC maps is limited with regards to anatomical variability between subjects. An alternative for acquiring AC-maps with increased individual precision is the inclusion of anatomical MRI data for segmentation of skull, soft tissue and air. In this study a feed forward neural network (FFNN) algorithm for calculating AC maps is presented which uses individual MRI data and an AC template either without (FFNN1) or with (FFNN2) adding information from one corresponding individual CT scan during the training step. FFNN1 yields maps with predefined ACs for each segmented tissue while continuous AC maps are obtained by FFNN2. Methods: Up to now,

MRI, FDG PET and CT data were acquired in 13 subjects. FFNN1 used ultrashort echo time (UTE) MRI together with template-based AC maps as input data for the training (n=1) and the classification step (n=12). For training FFNN2 the network weights of FFNN1 were optimized by guiding the network's output with the corresponding CT-based AC map (n=1), leading to continuous AC maps in the classification step (n=12). The FFNN1/2 results were compared with the CT-based ones (reference standard). All classification results were evaluated by using dice coefficients D. After reconstruction of the FDG PET emission data with the AC maps derived either from FFNN1/2 or CT, the influence of the FFNNs' results was assessed in volumes of interest (AAL-atlas in MNI space). Finally, relative differences (RD) were calculated. Results: The resulting Ds showed similar values for FFNN1 and FFNN2 in whole-head bone regions (D1=0.71, D2=0.73) and in skull regions only (D1=0.79, D2=0.81). In contrast, FFNN1 demonstrated a less accurate quantification of the corresponding PET signal as compared to FFNN2 (mean RD of all ALL VOIs: FFNN1 4.6%, FFNN2 3.9%). Conclusions: Our preliminary results indicate that neural networks combining individual data from UTE MRI with general template-based information improve quantitative analyses in PET/MR hybrid scanner settings. This approach is capable for optimizing brain receptor modeling and quantification in paradigms with cognitive tasks or neuro-/psychopharmacological challenges which sought to measure cerebral blood flow by fMRI and changes in neurotransmission by PET in parallel.

Title: Improving fMRI data test-retest reliability using independent component analysis (ICA) denoising technique

Authors: *Y. TONG[1], K. E. HEALY[1], L. H. STERNBERG[1], E. XIAO[2], Y. XU[3], S. DAS[1], K. F. BERMAN[1], D. R. WEINBERGER[2], V. S. MATTAY[2]
[1]NIH/NIMH, Bethesda, MD; [2]The Lieber Inst. for Brain Develop., Baltimore, MD; [3]NIH/NIDCD, Bethesda, MD

Abstract: Studies have shown that fMRI time series data can be decomposed into maximally independent components (ICs) that either reflect stimulus-induced or spontaneous brain activity, or reflect scanner-related noise, head movement and physiological artifacts. Identifying and removing noise-related ICs from an individual subject's time series could potentially improve the signal to noise ratio of fMRI data. In this study, we examine whether a ICA-based noise removal method can improve the test-retest reliablity as measured by individual subject's intraclass correlation (ICC) between two fMRI sessions obtained under similar conditions. Three BOLD fMRI tasks were used to test the effectiveness of the denosing technique: 1) a modified Flanker task (Sambataro, 2013) with 36 subjects (11 male); 2) an affective face matching task (FMT; Hariri, 2002) with 36 subjects (10 male); 3) a picture encoding and retrieval task (PEAR; Hariri, 2003) with 34 subjects (9 male). Healthy subjects (age = 18 - 48 yrs old) underwent BOLD fMRI on the same GE 3T MRI scanner, while they performed these tasks under similar conditions on two separate occassions. Images were preprocessed in SPM8. A pre-selected contrast image was generated per subject per session for each task: the response inhibition contrast map for the Flanker task; the face matching contrast map for the FMT task; and the neutral picture encoding contrast map for the PEAR task. Denoising of the fMRI time series data was performed using an ICA approach. Using the GIFT toolbox, each task related fMRI time series was decomposed into 60 ICs. The systematic classification of artifactual and neuronal activity related ICs was based on their degree of spatial clustering, location of major positively weighted clusters and neighborhood connectedness between positively and negatively weighted clusters (Xu, submitted). The noise components identified through an automated procedure were subtracted from the original dataset. To assess the effect of denoising on test-retest reliability, a whole brain voxel-wise ICC was computed between each subject's contrast maps for each task from the two sessions (Kristo, 2014). We also compared the temporal signal-to-noise ratio (TSNR) between the denoised and non-denoised data. As expected, the ICA denoising method significantly improved within-subject whole brain ICC values for these tasks (Flanker: $p < 0.03$; FMT: $p < 0.005$; PEAR: $p < 0.01$). The TSNR values were also greatly improved in the denoised data ($p < 0.000$ for all tasks). These results indicate that the ICA noise removal approach can be a useful tool to improve the test-retest reliability of fMRI data.
